Table of Contents

Paper 1: A Comparison of Metaheuristic Methods for the Vehicle Routing Problem

Authors: Manal El Jaouhari, Ghita Bencheikh, Ghizlane Bencheikh

PAGES 1 – 7

Paper 2: A Confidence-Aware Multi-Layer Framework for Drone Forensic Inference Using Heterogeneous Digital Evidence Sources and Flight Logs Analysis

Authors: Nidhiba Parmar, Naveen Kumar Chaudhary

PAGES 8 – 18

Paper 3: Real-Time Data-Driven Decision Support in Retail: A Hybrid GraphSAGE+XGBoost Model for Predicting Reorder Behavior and Unraveling Consumer Communities

Authors: Balayet Hossain, Md Deluar Hossen, Md Nuruzzaman Pranto, Belal Hossain, Sabrina Shamim Moushi, Nusrat Ameri, Khandakar Rabbi Ahmed

PAGES 19 – 25

Paper 4: Evaluating the Efficiency of LLM-Generated Software in Resisting Malicious Attacks

Authors: Dominic Niceforo, Haydar Cukurtepe

PAGES 26 – 34

Paper 5: Beyond the Interface: AI Integration Through Input Stream Mediation and Intelligent Output Simulation

Authors: Divij H. Patel

PAGES 35 – 47

Paper 6: Deep Learning Models: A General Methodology

Authors: Alberto Nogales, Ana M. Maitín, Álvaro J. García-Tejedor

PAGES 48 – 55

Paper 7: A Constraint-Driven Conversational Architecture for Staged Task Interaction Using Large Language Models

Authors: Joseph Benjamin Ilagan, Jose Ramon Ilagan

PAGES 56 – 63

Paper 8: Measurement of Dataset Quality and Computational Quality of Graph Neural Networks on Analog Integrated Circuit Recognition System

Authors: Arif Abdul Mannan, Koichi Tanno

PAGES 64 – 73

Paper 9: LayCoder: UI Layout Completion with an Encoder-Only Transformer and Layout Tokenizer

Authors: Iskandar Salama, Luiz Henrique Mormille, Masayasu Atsumi

PAGES 74 – 87

Paper 10: Reducing Interference in Human–Robot Collaboration: A Distance-Based Policy for Disassembly Collaborative Task

Authors: Wendy Cahya Kurniawan, Wen Liang Yeoh, Osamu Fukuda

PAGES 88 – 94

Paper 11: Understanding Authentication and Authorization: A Comparative Analysis of Role-Based Access Control (RBAC), Attribute-Based Access Control (ABAC), and Relationship-Based Access Control (ReBAC) Authorization Models

Authors: Madhuri Margam

PAGES 95 – 99

Paper 12: Construction of an International Trade Financial Risk Assessment and Prediction Model Based on Big Data Analysis

Authors: Zeyu Liu

PAGES 100 – 112

Paper 13: Attention and Representation Learning in Byte-Level Digital Forensics: A Survey of Methods, Challenges, and Applications

Authors: Teena Mary, Sreeja CS

PAGES 113 – 124

Paper 14: Estimation of Landslide Hazard Zones Using Deep Learning Based on Diverse Geospatial Data

Authors: Kohei Arai, Kengo Oiwane, Hiroshi Okumura

PAGES 125 – 134

Paper 15: A Hybrid Framework Integrating GNN-LSTM-CNN to Map the Impact of MSME User Behavior on Digital Transformation

Authors: Jani Kusanti, Erni Widiastuti, Bintara Sura Priambada, Ramadhian Agus Triono Sudalyo, Masdava Aviv Masyayissa, Rizki Adhi Pratama

PAGES 135 – 140

Paper 16: A Computer Vision–Based Method for Determining the Vaccine Injection Position in Pangasius Fingerlings

Authors: Nguyen Phuc Truong, Luong Vinh Quoc Danh, Nguyen Chanh Nghiem

PAGES 141 – 150

Paper 17: Exposure-Based Media Mix Modeling Using Machine Learning and Genetic Algorithms

Authors: Thejan Dulara, Indra Mahakalanda, Prasanga Jayathunga

PAGES 151 – 160

Paper 18: An Ensemble Learning Framework with Metaheuristic Optimization for Credit Card Fraud Detection

Authors: Agung Nugroho, Muhtajuddin Danny, Ismasari Nawangsih

PAGES 161 – 167

Paper 19: A Lossless Medical Image Compression Framework Using Logic Minimization

Authors: Swathi Pai M, Jacob Augustine, Pamela Vinitha Eric

PAGES 168 – 178

Paper 20: An Empirical Evaluation of Multivariate Temporal Convolutional Networks with Global Market Indicators for Forecasting the Indonesian LQ45 Index

Authors: Yohanes Marakub, Muhammad Zarlis

PAGES 179 – 190

Paper 21: Integrating ABM and GIS for Flood Evacuation Planning: A Systematic Review and Future Direction

Authors: Kabir Musa Ibrahim, Abubakar Ahmad, Noor Akma Abu Bakar,
Mazlina Abdul Majid, Azamuddin Rahman

PAGES 191 – 203

Paper 22: A Novel Lightweight Explainable Multilayer Adaptive RNN-Based Intrusion Detection Framework

Authors: Nidhi Srivastav, Rajiv Singh

PAGES 204 – 214

Paper 23: Empirical Validation of Learnability Factors in Web-Based AR: Insights from the LEMARK–Hafsa Model Grounded in Kolb's Experiential Learning Theory

Authors: Sayera Hafsa, Mazlina Abdul Majid, Shafiq Ur Rehman

PAGES 215 – 224

Paper 24: Automating Computation Independent Model Elicitation in MDA using Task-Oriented Dialogue with In-Context Learning

Authors: Mohamed EL Ayadi, Yassine Rhazali, Mohammed Lahmer

PAGES 225 – 231

Paper 25: Mapping Research on Artificial Intelligence in Customer Experience: A Bibliometric Analysis

Authors: Firdaws Hayoun, Brahim Ouabouch, Youssef Aatif, Taoufiq Yahyaoui, Fatima Zahra El Arbaoui

PAGES 232 – 239

Paper 26: AI-Driven Robotic Waste Sorting for Techno-Economic Assessment in Urban Indonesia

Authors: Ida Nurhaida, Mohammad Nasucha, Hari Nugraha

PAGES 240 – 249

Paper 27: A Unified Benchmarking Framework for Offline Handwritten Signature Verification Using Deep Learning Architectures

Authors: Eissa Alreshidi

PAGES 250 – 264

Paper 28: Deep Learning Based Detection of Prostate Cancer in MRI Using Biopsy-Confirmed Ground Truth

Authors: Samana Jafri, Gajanan Birajdar

PAGES 265 – 272

Paper 29: A Composite Approach Extracting Software Quality Attributes Assessing Operational Profiles

Authors: Sudhakar Kambhampati, G Vamsi Krishna

PAGES 273 – 283

Paper 30: Robust Medical Image Reconstruction Using a Self-Evolving Encoder–Decoder and Adaptive Convolutional Power Scaling

Authors: Dhanusha P B, J. Bennilo Fernandes, A. Muthukumar, A. Lakshmi

PAGES 284 – 292

Paper 31: Cybersecurity Awareness Among Undergraduate Students in Saudi Arabia: A Quantitative Study

Authors: Turky A. Saderaldin, Ali Abuabid

PAGES 293 – 298

Paper 32: An Analytical Study of Data Augmentation Across Audio Representations for Infant Cry Classification

Authors: Meriyem Ghanjaoui, Abdelaziz Daaif, Abdelmajid Bousselham, Sajid Rahim,
Ahmed Bouatmane, Mohamed Elyoussfi

PAGES 299 – 304

Paper 33: Hybrid BERT–BiLSTM Architecture for Enhanced Cyber Threat Intelligence Classification

Authors: Syarif Hidayatulloh, Salman Topiq, Ifani Hariyanti, Dwi Sandini

PAGES 305 – 315

Paper 34: An Offline Estimation Method for Hip and Knee Joint Angles of Lower Limbs Based on Quaternion and DTW Time Alignment

Authors: Yuling Zhang, Yuejian Hua, Shengli Luo, Xiaolong Shu, Hongyan Tang, Hongliu Yu

PAGES 316 – 323

Paper 35: Radiomics Feature Profiling of Brodmann Regions in Structural MRI: A Machine Learning Study of Intensive Verbal Memorisation (Huffaz vs Controls)

Authors: Mohd Zulfaezal Che Azemin, Iqbal Jamaludin, Abdul Halim Sapuan, Mohd Izzuddin Mohd Tamrin

PAGES 324 – 330

Paper 36: Cognitive Assistance for Prosopagnosia Patients Using Landmark-Based Identity and Emotion Recognition

Authors: Bhavana Nagaraj, Rajanna Muniswamy

PAGES 331 – 340

Paper 37: Comparative Analysis of Neural Network Architectures for Classifying Depressive Content in Social Networks

Authors: Yntymak Abdrazakh, Rita Ismailova, Nurseit Zhunissov, Arypzhan Aben,
Anuarbek Amanov, Aigerim Baimakhanova

PAGES 341 – 351

Paper 38: Attention-Based Capsule Network with Vision Transformer for Underwater Hyperspectral Image Classification

Authors: Thiyagarajan B, Thenmozhi M

PAGES 352 – 365

Paper 39: Effectiveness of Capsule Networks in Detecting Deepfakes Instead of Traditional CNNs

Authors: M. C. Weerawardana, T. G. I. Fernando

PAGES 366 – 374

Paper 40: Machine-Learning–Assisted Probabilistic Wind Assessment at Sechura, Peru

Authors: Ubaldo Yancachajlla Tito, Celso Antonio Sanga Quiroz, Edilberto Velarde Coaquira, Germán Belizario Quispe

PAGES 375 – 383

Paper 41: Ziraai SSI: A Blockchain-Based Self-Sovereign Identity Model for Agricultural Supply Chains

Authors: Tariq Alar, Gnana Bharathy, Usha Batra, Mukesh Prasad

PAGES 384 – 393

Paper 42: Rubric-Relational Discourse Modeling with Counterfactual Explainability for Multi-Trait Automated Essay Scoring

Authors: N. Sreedevi, M. Madhusudhan Rao, Sridevi Dasam, Roopa Traisa, Jasgurpreet Singh Chohan, V. Saranya, Ahmed I. Taloba

PAGES 394 – 407

Paper 43: Face Sketch Recognition: Ethnic Groups Classification and Recognition Via a VGG16 Model Approach

Authors: Khalid OUNACHAD, Mohamed EL GHMARY

PAGES 408 – 419

Paper 44: Integrating Japanese Festival Traditions into Computational Thinking: A Culturally Responsive Approach to Micro:Bit-based Physical Computing

Authors: Daiki Sugiyama, M. Fahim Ferdous Khan, Ken Sakamura

PAGES 420 – 427

Paper 45: Machine Learning-Based Effort Prediction and Early Risk Detection in Software Development Projects: A Case Study

Authors: Andreea-Elena Catana, Adriana Florescu

PAGES 428 – 439

Paper 46: Self-Supervised and Explainable Transformer-Based Architectures for Robust End-to-End Speech and Language Understanding

Authors: Mahfuzul Huda

PAGES 440 – 446

Paper 47: Secure Ultra-Low Latency Data Paths: A Hybrid Architecture for High Speed Networking under Adversarial Conditions

Authors: Abdulbasid Banga

PAGES 447 – 456

Paper 48: Hybrid Deep Learning for Academic Achievement Prediction Using Spatio-Temporal and Behavioral Data in Higher Education

Authors: Asim Seedahmed Ali Osman

PAGES 457 – 470

Paper 49: Farm and Learn: An Offline Mobile Learning System Integrating AR, AI, and Game-Based Learning for Agricultural Education Among Children

Authors: Pubuditha De Silva, Chamodya Prabodhani, Daminda Herath

PAGES 471 – 480

Paper 50: An Enhanced Approach for Workmen's Compensation Insurance Fraud Detection Based on Fuzzy Rule-Based System

Authors: Reham M. Essa

PAGES 481 – 493

Paper 51: Design of a Vision Transformer-Based Architecture for Automatic Facial Emotion Monitoring in Workplace Environments

Authors: Renzo Sebastian Gonzalez Caceres, Jeramel Melissa Avila Saldaña, Patricia Gissela Pereyra Salvador

PAGES 494 – 501

Paper 52: Integrating Acoustic and Image Data Features for Melon Ripeness Classification Using Convolutional Neural Network

Authors: Endang Purnama Giri, Agus Buono, Karlisa Priandana, Dwi Guntoro

PAGES 502 – 511

Paper 53: Comparative Analysis of Machine Learning Based Algorithms for Predicting Injury Severity in Road Accidents

Authors: Soumaya AMRI, Mohammed AL ACHHAB, Mohamed LAZAAR

PAGES 512 – 523

Paper 54: Machine Learning and Deep Learning for Detecting Fake News in a Low-Resource Language

Authors: Elton Tata, Jaumin Ajdarim, Nuhi Besimi

PAGES 524 – 531

Paper 55: AMCS: Adaptive Multi-Controller SDN Security with Stateful Traffic Intelligence for Fast and Accurate Multi-Vector Attack Detection

Authors: Ameer El-Sayed, Mohamed Nosseir Hemdan, Noha Abdelkarim, Ehab Rushdy, Hanaa M. Hamza

PAGES 532 – 546

Paper 56: Wavelet-Based Dual-Domain Phase Alignment for Predicting Stock Index Trends from Investor Sentiment Cycles

Authors: Monika Gorkhe, Diksha Tripathi, Pravin D Sawant, Elangovan Muniyandy, Veera Ankalu Vuyyuru, Pratik Gite, Raman Kumar

PAGES 547 – 557

Paper 57: Machine Learning-Based Autism Spectrum Disorder Classification Using an Enhanced Convolutional Neural Network Algorithm

Authors: P. Yugander, M. Jagannath

PAGES 558 – 565

Paper 58: Privacy-Preserving Federated Learning for Multi-Institutional Lung Cancer Severity Detection

Authors: Ch. Srividya, K. Ramasubramanian, Myneni.Madhu Bala

A Comparison of Metaheuristic Methods for the Vehicle Routing Problem

Manal El Jaouhari[1], Ghita Bencheikh[2], Ghizlane Bencheikh[3]
Moulay Ismaïl University of Meknes, Morocco[1, 3]
LINEACT, Cesi Engineering School, Assat, France[2]

***Abstract*—The Capacitated Vehicle Routing Problem (CVRP) is a fundamental NP-hard combinatorial optimization problem with important applications in logistics and distribution systems. Although numerous advanced approaches have been proposed in recent years, systematic benchmarking of classical metaheuristic algorithms under a unified experimental framework remains limited. This study evaluates the performance and trade-offs of four well-known metaheuristics: Hill Climbing (HC), Ant Colony Optimization (ACO), Particle Swarm Optimization (PSO), and Genetic Algorithms (GA). All methods are implemented within the same computational environment and assessed on benchmark CVRP instances, using the CPLEX exact solver as a reference for global optimality. The results indicate that ACO achieves the smallest optimality gaps and often approaches optimal solutions, at the cost of higher computational effort. PSO strikes a favorable balance between solution quality and runtime across the tested instances, whereas HC delivers very fast solutions but degrades as problem complexity increases. GA exhibits higher variability and less competitive performance under the selected parameter settings. Overall, this comparative analysis highlights the strengths and limitations of classical metaheuristics and establishes a reproducible baseline for future research, including hybrid and learning-assisted approaches for scalable vehicle routing optimization.**

Keywords*—*Metaheuristics; Ant Colony Optimization; Hill Climbing; Genetic Algorithm; Particle Swarm Optimization; exact algorithm; Capacitated Vehicle Routing Problem

I. Introduction

The Vehicle Routing Problem (VRP), first introduced by Dantzig and Ramser [3], is one of the most important problems in combinatorial optimization and has many applications in logistics and transportation. One of its best-known variants is the Capacitated Vehicle Routing Problem (CVRP). In this problem, a fleet of vehicles with limited capacity must deliver goods to a set of customers, and the objective is to minimize the total travel cost.

The CVRP is an NP-hard problem, meaning that it becomes very difficult to solve exactly when the number of customers increases. Exact optimization methods [14], [16] can find optimal solutions, but their computational cost grows quickly, which limits their use to small problem instances. For this reason, heuristic and metaheuristic algorithms are widely used to obtain good-quality solutions in a reasonable time, especially for medium- and large-scale CVRP instances.

Over the years, many classical metaheuristics have been applied to solve the CVRP, such as Genetic Algorithms (GA) [7], [8], Ant Colony Optimization (ACO) [4], [5], Particle Swarm Optimization (PSO) [9], [15], and Hill Climbing (HC). In addition, modern state-of-the-art VRP solvers often rely on more advanced strategies, including Adaptive Large Neighborhood Search (ALNS), Variable Neighborhood Search (VNS), Tabu Search, and hybrid metaheuristics that combine different optimization mechanisms to improve performance on large-scale instances [10], [11], [17], [18], [19].

More recently, learning-assisted methods, such as reinforcement learning approaches, have also gained attention as promising directions for solving routing problems. These developments further highlight the importance of establishing reliable baselines through systematic benchmarking of classical metaheuristics [2], [6].

Despite the large number of studies in this area, direct comparisons of classical metaheuristics under the same experimental conditions remain limited. Many works focus on improving a single algorithm or use different benchmarks and implementations, which makes it difficult to clearly understand the relative strengths and weaknesses of these approaches [1], [21].

The main objective of this study is to provide a structured comparison of four widely used metaheuristic algorithms (HC, ACO, PSO, and GA) for solving the CVRP. All algorithms are implemented within the same experimental framework and tested on identical problem instances. Their performance is evaluated in terms of solution quality and computational time, using optimal solutions obtained with CPLEX as reference.

This study is structured as follows: Section II reviews related work on metaheuristics for CVRP. Section III presents the mathematical formulation of the problem. Section IV describes the four metaheuristic algorithms evaluated in this study. Section V discusses the experimental results, and Section VI concludes the study and suggests directions for future research.

II. Related Work

The CVRP has been widely studied using constructive heuristics, local search methods, population-based metaheuristics, and hybrid matheuristic frameworks. Although significant progress has been achieved, systematic benchmarking of classical metaheuristics under unified experimental conditions remains relatively limited. As a result, their comparative strengths and weaknesses are not always clearly established.

Avdoshin and Beresneva [1] provide one of the few comparative studies based on a common framework, focusing on constructive heuristics [25] such as nearest neighbor, savings, sweep, and insertion methods. Tiwari and Sharma [21] further investigate local search and Tabu Search strategies for last-mile delivery, comparing neighborhood structures under controlled settings. While informative, these works mainly address local search-based approaches and do not cover broader metaheuristic families. Tan and Yeh [20] note that many recent VRP studies rely on different or newly generated datasets, which makes it difficult to compare algorithms under a unified standard. They emphasize the need for publicly available benchmark datasets to improve comparability across studies.

In recent years, research has increasingly shifted toward advanced and state-of-the-art methods. Variable Neighborhood Search (VNS) and its extensions have been successfully applied to several VRP variants with capacity and time constraints [11], [19], [24]. Adaptive Large Neighborhood Search (ALNS) has also emerged as one of the most effective frameworks for large-scale routing problems, with important contributions on operator design and adaptive mechanisms [17],[18],[23]. In parallel, hybrid matheuristics combining metaheuristics with exact optimization components have achieved highly competitive results for the CVRP and related routing problems [13],[14],[16].

Despite these advances, existing studies often rely on different benchmarks, problem variants, or experimental protocols, which makes direct comparison across algorithms difficult. In particular, a controlled evaluation of classical metaheuristics such as Hill Climbing, Ant Colony Optimization, Particle Swarm Optimization, and Genetic Algorithms under identical conditions is still missing.

To address this gap, we implement HC, ACO, PSO, and GA within a single unified experimental framework and benchmark their performance against exact optimal solutions obtained via CPLEX. By providing a reproducible baseline, this work supports future research on hybrid, adaptive, VNS-based, and learning-assisted approaches for scalable vehicle routing optimization.

III. Mathematical Formulation

- Notation

N : Set of nodes, including the depot and customers.

K : Number of vehicles.

d_{ij} : Euclidean distance between node i and node j.

q_j : Demand of customer j.

C : Vehicle capacity.

x_{ijk} : Binary decision variable that equals 1 if vehicle k travels from node i to node j, and 0 otherwise.

u_{ik} : Continuous variable representing the load of vehicle k when leaving node i.

- Objective Function

The objective is to minimize the total distance traveled by all vehicles:

$$Min \ \sum_{k=1}^{K} \sum_{i \in N} \sum_{j \in N} d_{ij} x_{ijk} \quad (1)$$

- Constraints

Capacity Constraints: Ensure that the total demand served by each vehicle does not exceed its capacity:

$$\sum_{j \in N} q_j \sum_{i \in N} x_{ijk} \leq C \ / \ k \in \{1, .., \mathrm{K}\} \quad (2)$$

Visit Constraints: Each customer must be visited exactly once by one vehicle:

$$\sum_{k=1}^{K} \sum_{i \in N} x_{ijk} = 1 \ / \ \forall j \in N \quad (3)$$

Flow Conservation Constraints: Ensure that if a vehicle arrives at a node, it must leave that node:

$$\sum_{j \in N} x_{ijk} = \sum_{j \in N} x_{jik} \ / \ \forall i \in N, \forall k \in \{1, .., \mathrm{K}\} \quad (4)$$

Depot Constraints: Each vehicle must start and end at the depot:

$$\sum_{j \in N} x_{0jk} = 1 \ / \ \forall k \in \{1, .., \mathrm{K}\} \quad (5)$$

$$\sum_{j \in N} x_{j0k} = 1 \ / \ \forall k \in \{1, .., \mathrm{K}\} \quad (6)$$

Subtour Elimination (MTZ Constraints): To prevent subtours (cycles that do not include the depot), we adopt the classical Miller–Tucker–Zemlin (MTZ) formulation [12]:

$$u_{jk} \geq u_{ik} + \ q_j - C \, . \left(1 - x_{ijk}\right) \ / \ \forall i \in N, \forall j \in N \backslash \{0\}, \mathrm{i} \neq \mathrm{j}, \forall k \in \{1, .., \mathrm{K}\} \quad (7)$$

The load variables are bounded as follows:

$$q_j \leq u_{ik} \leq \ C \ / \ \forall i \in N \ , \forall k \in K \quad (8)$$

These constraints eliminate subtours by ensuring that the vehicle load increases consistently along each route, thereby forcing all visited customers to be connected to the depot.

IV. Metaheuristic Algorithms

Metaheuristic algorithms are generally classified into two categories: single solution-based algorithms and population-based algorithms [1]. In this study, we include algorithms from both categories: HC as a single solution-based metaheuristic, and ACO, PSO, and GA as population-based metaheuristics. These methods are selected as representative classical approaches, providing a reproducible baseline for comparing solution quality and computational efficiency on the Capacitated Vehicle Routing Problem (CVRP) [22]. In the following subsections, we briefly describe each algorithm and its adaptation to the CVRP.

A. Hill Climbing

Hill Climbing is a local search optimization algorithm that starts from an initial solution and iteratively improves it by moving to a neighboring solution with a better objective value. At each step, the algorithm selects the best available improvement in the local neighborhood and continues the search until no further improvement is possible. The process stops when a local optimum is reached.

The application of HC to the CVRP is summarized in Algorithm 1:

Algorithm 1: HC Algorithm applied to the CVRP

x_0 : Initial solution
x : Current solution
x^* : Best solution
$x \leftarrow x_0$
$x^* \leftarrow x_0$
While *True* do
  $x \leftarrow \underset{x_i \text{ neighbor of } x}{\text{argmin}} f(x_i)$
  if ($f(x) < f(x^*)$) then
    $x^* \leftarrow x$
  else
    Break
  End
End

Solutions are represented as permutations of customer indices, with vehicle routes separated by depot markers. The neighborhood operator generates new solutions through 2-opt exchanges within routes and relocation moves between routes, ensuring feasibility by checking capacity constraints before accepting modifications.

B. Ant Colony Optimization

Ant Colony Optimization (ACO) is a metaheuristic inspired by the behavior of ants in nature. Artificial ants construct their solutions by selecting components based on two values: the pheromone trails $(\tau_{ij})_{i,j\in N}$ and heuristic information $(\eta_{ij})_{i,j\in N}$, in the CVRP case, it's the inverse of the distance between customers. The pheromone trails are updated over time to reinforce good solutions and reduce the influence of poor ones.

The application of ACO to the CVRP is summarized by Algorithm 2:

Algorithm 2: ACO Algorithm applied to the CVRP

Initialize the pheromone trail by a small value : $\tau_{ij} \leftarrow \tau_0$
For (a Maximal number of iterations) do
  For (each ant k) do
    Initialize the current vehicle v by 1 : $v \leftarrow 1$
    Initialize the vehicle's route by depot 0
    While (The set of unserved clients is not empty) do
      Select a client j according to :

$$P_{ij} = \frac{\eta_{ij}^{\alpha}.\tau_{ij}^{\beta}}{\sum_l \eta_{il}^{\alpha}.\tau_{il}^{\beta}}$$

      If (vehicle capacity is not exeed) then
        Insert j into the route
      else
        return to depot and $v \leftarrow v + 1$
      End
      Remove j from the unserved clients set
    End
  End
  Calculate the Best Solution
  Update the pheromone
End
End

Each ant constructs a solution by sequentially selecting customers using the probabilistic transition rule. Feasibility is maintained by tracking cumulative vehicle load and returning to the depot when adding the next customer would violate capacity constraints.

C. Genetic Algorithm

Genetic Algorithms (GA) are population-based metaheuristics inspired by Darwin's theory of evolution. A set of solutions (population) evolves over a given number of iterations by applying genetic operators such as selection, crossover, and mutation. The quality of a solution (individual), called fitness, depends on the objective function of this solution. At each iteration, several individuals are selected according to their fitness in order to create new ones by applying two operators: Crossover and Mutation. At the end of the iteration, a phase of replacement is applied to select the individuals that pass to the next iteration. Algorithm 3 presents the application of GA to the CVRP.

Algorithm 3: GA applied to the CVRP

Generate the initial population
For (a maximal number of iterations) do
  Evaluate individuals
  Select a subset of individuals for crossover
  Apply crossover operator to selected individuals taken two by two.
  Select a subset of individuals for mutation
  Apply mutation operator to selected individuals.
  Replace the current population by the new one
  Calculate the best solution
End

Individuals are encoded as permutations of customers. The crossover operator preserves relative customer order from parents, while mutation randomly swaps two customers. Infeasible solutions are repaired by redistributing customers among vehicles to satisfy capacity constraints.

D. Particle Swarm Optimization

Particle Swarm Optimization (PSO) is a population-based metaheuristic inspired by the collective behavior of social organisms such as bird flocks or fish schools. In PSO, each particle represents a candidate solution and moves through the search space by updating its position based on its own best

solution and the best solution found by the swarm. The application of PSO to the CVRP is presented in Algorithm 4.

Algorithm 4: PSO applied to the CVRP

```
Initialize particles with random positions and velocities
Calculate the best solution x*
For (a maximal number of iterations) do
    For (each particle p) do
        If (f(p) < f(x*)) then
            x* ← p
        End
    p ← Update personal best position
    End
    For (each particle i)
        Update velocity for particle i
        Update position for particle i
    End
End
```

Particle positions are represented as priority-based encodings, where real-valued priorities determine customer visit order. Positions are decoded into feasible routes using a greedy insertion procedure that respects vehicle capacity constraints.

The detailed parameter settings for each algorithm, including population size, iteration limits, and coefficients, are reported in Section V. All algorithms are executed multiple times to account for stochastic behavior, and results are averaged over these runs to ensure statistical reliability.

V. Experiment Results

To evaluate the performance of the four metaheuristic algorithms, we implemented them in Python and applied them to randomly generated CVRP instances. The number of clients in each instance varies from 5 to 15, while the number of vehicles ranges from 2 to 5. Exact solutions for these instances were obtained using the CPLEX solver in Python, providing a reference for solution quality.

The CVRP instances used in this study are deliberately small (5–15 customers) so that they can be directly compared with exact optimal solutions obtained using CPLEX. This creates a controlled testing environment where the solution quality of each metaheuristic can be evaluated in a reliable way. Although these instances are not representative of large real-world logistics problems, they provide a useful baseline for understanding and comparing the behavior of classical metaheuristic algorithms before considering larger instances in future work.

All computations were performed on a laptop with an Intel® Core™ i5-8300H processor (2.30 GHz) and 8 GB of RAM. Each metaheuristic was executed multiple times to account for its stochastic nature, and the results reported are averaged over these runs. Detailed parameter settings for each algorithm are presented in the following subsection.

A. Parameter Settings of Metaheuristic Algorithms

The parameter values for all four metaheuristic algorithms (HC, ACO, PSO, and GA) were chosen based on preliminary tests on a small set of instances. Table I shows the settings used for all methods.

TABLE I. Parameter Settings for Metaheuristic Algorithms

Algorithm	Parameter	Value
HC	Number of iterations	1000
ACO	Number of ants	100
	Pheromone importance (α)	1
	Heuristic importance (β)	3
	Pheromone deposit factor	70
GA	Population size	150
	Number of generations	500
	Mutation rate	0.1
PSO	Number of particles	50
	Number of iterations	200
	Inertia weight (w)	0.4
	Cognitive coefficient (c_1)	1.5
	Social coefficient (c_2)	1.7

B. Computational Results

Table II presents the computational results obtained for the CVRP using the four metaheuristic algorithms and compares them with the exact optimal solutions provided by the CPLEX solver.

For each problem instance, the table reports the optimal value found by CPLEX as well as the results obtained by each metaheuristic method. The "Optimal Value" column corresponds to the exact solution returned by CPLEX, while the "CPU" column indicates the computational time (in seconds) required to obtain this solution. Table II shows computational results.

Since metaheuristic algorithms are stochastic, each experiment was repeated 10 independent times for every instance. For each algorithm, the solution value reported corresponds to the best result obtained over these 10 executions.

For the metaheuristic algorithms, three performance indicators are presented:

- BD (Best Distance): the best solution value obtained over the 10 runs.
- GAP (%): the relative difference between BD and the optimal solution provided by CPLEX. It is computed as follows:

$$GAP = \frac{BD - Optimal\ value}{Optimal\ value} \times 100 \quad (8)$$

- CPU: the execution time required by each algorithm.

The problem instances are grouped according to their size and the number of vehicles considered in each case.

TABLE II. COMPUTATIONAL RESULTS

According to these results, we note that for small instances with 5 customers, all metaheuristics reached the optimal solution. With small differences in execution time, HC achieves the solution almost instantly, while ACO and PSO require more computational time. This indicates that for very small problem sizes, simple local search methods are highly efficient.

For instances with 10 customers, we observe differences between the algorithms in terms of solution value and computational time. ACO consistently provides high-quality solutions, often reaching the optimal solution or maintaining a very small gap. However, this accuracy comes at the cost of higher computational times compared to HC and PSO. Hill Climbing remains extremely fast, but its solution quality degrades as the problem becomes more complex, with gaps reaching up to 44% in some instances. Genetic Algorithm (GA) shows moderate performance, producing acceptable solutions but with relatively long execution times. PSO generally achieves a good compromise between solution quality and computational efficiency, maintaining low gaps in most cases while keeping execution times reasonable.

When the problem size increases to 15 customers, the differences between the algorithms become clearer. ACO continues to provide the most accurate solutions, often reaching the optimal value or showing very small gaps. However, its execution time increases significantly. HC remains the fastest algorithm, but its solution quality decreases with very large gaps that can exceed 80%, which limits its use for larger instances. GA shows weak performance in both solution quality and execution time, with large gaps and slow convergence. PSO exhibits more stable behavior, achieving better solutions than HC and GA while keeping reasonable execution times, although it does not always reach the optimal solution.

To better visualize the differences between the metaheuristics in terms of CPU time, Fig. 1 presents the execution time required by each algorithm for all instances.

As discussed previously, we observe that the Genetic Algorithm is the most time-consuming metaheuristic, requiring significantly more CPU time than the other methods. While Hill Climbing (HC) is the fastest algorithm, obtaining solutions almost instantly. ACO needs moderate computational times, generally higher than HC and PSO but lower than GA. PSO demonstrates a balanced performance, maintaining reasonable execution times across all instances.

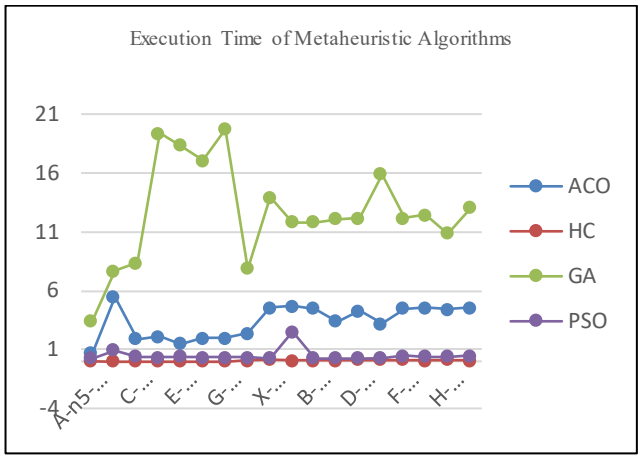

Fig. 1. Execution time of metaheuristic algorithms.

Fig. 2 presents the performance gaps of the four metaheuristic algorithms relative to the optimal solutions obtained by CPLEX.

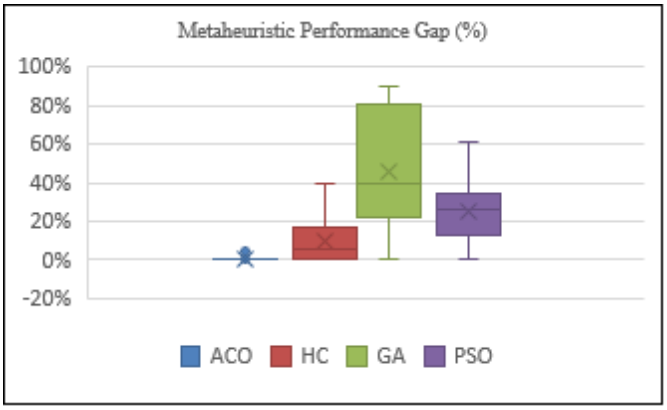

Fig. 2. Metaheuristic performance gap (%).

As shown in Fig. 2, ACO consistently achieves the smallest gaps, with median values near zero and little variation across all instances, confirming its high solution quality. HC performs well on small instances with very low gaps, but its gaps increase and become more variable as the problem size grows, showing that it is less effective for larger instances. GA has large gaps and wide variation, indicating inconsistent performance and slower convergence. PSO achieves moderate gaps with relatively stable performance, offering a good balance between solution quality and reliability.

VI. Conclusion and Future Directions

This study evaluated the performance of four metaheuristics (ACO, PSO, HC, and GA) for solving the CVRP using randomly generated instances. The algorithms were implemented under a unified framework and benchmarked against optimal solutions obtained via CPLEX.

The results reveal distinct performance trade-offs among the methods, consistent with the "no free lunch" theorem: no single metaheuristic dominates across all problem characteristics. ACO consistently achieved the highest solution quality, frequently matching or closely approximating optimal values, though at the cost of substantially longer computation times. PSO demonstrated the most balanced performance, maintaining reasonable solution quality while keeping execution times low, making it well-suited for time-sensitive applications. HC excelled in computational efficiency, generating solutions almost instantaneously, but exhibited significant performance degradation as problem complexity increased, with optimality gaps exceeding 80% on the largest instances tested. GA showed the weakest overall performance in our experiments, requiring the longest execution times while producing solutions with large and inconsistent optimality gaps. This latter result warrants further investigation, as it may reflect parameter sensitivity or implementation-specific issues rather than fundamental algorithmic limitations.

The current study has important limitations. Our analysis focused on small-scale instances (5-15 customers) to enable rigorous validation against exact solutions. Additionally, the relatively poor GA performance diverges from typical findings in the literature and requires further examination.

Future research will proceed along two complementary directions. First, we will extend this comparative analysis to larger problem instances (50-200 customers) and incorporate additional modern metaheuristics, including ALNS, VNS, and ILS, to better understand algorithmic scalability and behavior under more challenging conditions. Second, given the complementary strengths observed across methods, we will investigate hybrid and adaptive approaches. Specifically, we plan to develop a multi-agent framework that dynamically selects or combines these metaheuristics based on problem characteristics. This approach aims to leverage the solution quality of ACO, the efficiency of PSO, and the speed of HC within an integrated system that adapts to instance-specific features, potentially offering more robust performance across diverse CVRP scenarios.

A Confidence-Aware Multi-Layer Framework for Drone Forensic Inference Using Heterogeneous Digital Evidence Sources and Flight Logs Analysis

Nidhiba Parmar, Naveen Kumar Chaudhary
School of Cyber Security and Digital Forensics, National Forensic Sciences University, Gandhinagar, India

***Abstract*—The increasing use of unmanned aerial vehicles (UAVs) in criminal and adversarial contexts has created new challenges for digital forensic investigations. Current UAV forensic research primarily emphasizes artefact extraction and platform-dependent analysis, while insufficient attention has been given to uncertainty modelling and confidence quantification in forensic inference. This study addresses this methodological gap by proposing a confidence-aware multi-layer UAV forensic framework designed to support legally defensible forensic conclusions. The framework integrates chip-off memory acquisition, logical flight log analysis, companion mobile device artefact examination, and wireless trace correlation within a unified analytical architecture. Physics-based flight trajectory reconstruction and cross-device temporal alignment algorithms enhance reproducibility and platform independence. To reflect varying levels of evidentiary reliability, a structured evidence-weighting approach is introduced alongside a novel Forensic Confidence Index (FCI) that quantifies evidentiary support without implying absolute certainty. Validation using a Yuneec Typhoon Q500 4K dataset demonstrates feasible trajectory reconstruction, temporal correlation, and confidence-constrained attribution under realistic investigative conditions. By explicitly incorporating uncertainty modeling and confidence articulation into UAV forensic workflows, the proposed framework improves scientific rigor, transparency, and legal defensibility while providing a scalable foundation for future cyber-physical forensic investigations.**

Keywords*—*UAV forensics; drone investigations; forensic inference; confidence quantification; flight log analysis; digital forensic framework

I. Introduction

The operational footprint of unmanned aerial vehicles (UAVs) has expanded beyond recreational and commercial domains into increasingly adversarial and criminal contexts, including illicit surveillance, cross-border smuggling, critical-infrastructure reconnaissance, and targeted cyber-physical intrusions [1]. The proliferation of UAV use has concomitantly increased the importance of drones from artefacts to a primary vector of evidentiary importance in digital forensics investigations [2]. However, contemporary UAV forensic methodology is largely data-centric (focusing more on extracting information from data than on forensic inference), which limits its probative and explanatory value in high-stakes investigative and judicial settings [3], [4], [5].

Recent UAV forensic studies between 2023 and 2025 have shown significant progress in terms of systematic cataloguing of the artefact locations, demystifying proprietary flight logs, and retrieving multimedia and telemetry information from widely used drone platforms, especially the DJI and, to a lesser extent, Yuneec and Parrot ecosystems [6], [7], [8]. However, these contributions are less than comprehensive in this regard; they outline the data that can be obtained from such types of evidence, but not the degree of confidence with which such data can be used to support forensic attribution, a point in time, or the association with an operator. Consequently, many essential forensic issues related to evidentiary reliability, cross-source consistency, and the propagation of uncertainty are often left implicit or unanswered. A critical, unanswered problem in modern UAV forensics is the absence of formal mechanisms for quantifying evidentiary confidence when analyzing diverse, heterogeneous sources, including chip-off memory, removable storage, companion mobile devices, and wireless communication traces.

Specifically, this study makes the following contributions:

- Proposes a unified multi-layer UAV forensic architecture integrating physical, logical, companion-device, and wireless evidence sources.
- Introduces formal algorithms for flight path reconstruction and cross-device temporal alignment.
- Develops uncertainty-aware evidence weighting model grounded in forensic reliability principles.
- Defines a novel Forensic Confidence Index (FCI) to quantify attribution strength.
- Validates the framework through a Yuneec Typhoon Q500 4K case study while ensuring device-agnostic generalizability.

Although UAV forensic research has advanced in artefact extraction and platform-specific analysis, there remains a lack of structured frameworks for confidence-based forensic inference across heterogeneous evidence sources. Existing approaches rarely incorporate uncertainty modelling or reliability weighting, which limits the scientific rigor and legal defensibility of forensic conclusions. This study addresses this gap by proposing a confidence-aware multi-layer UAV forensic framework integrating diverse evidence sources with explicit confidence quantification.

The remainder of this study is organized as follows: Section II reviews related work and identifies key

methodological gaps in UAV forensic research. Section III presents the theoretical foundation underlying confidence-aware forensic inference. Section IV describes the proposed multi-layer UAV forensic framework and methodological approach. Section V details the associated analytical models and algorithms. Section VI presents the case study validation using the Yuneec Typhoon Q500 4K dataset. Section VII discusses comparative and theoretical implications of the findings. Section VIII addresses generalization, admissibility, and practical deployment considerations. Section IX outlines study limitations and future research directions, and finally, Section X concludes the study.

II. Related Work and Gap Synthesis

The rapid proliferation of unmanned aerial vehicles (UAVs) across civilian, commercial, and adversarial domains has significantly increased the importance of UAV digital forensic investigations. Recent research has focused on artefact extraction, flight log interpretation, and forensic framework development; however, methodological maturity in forensic inference, particularly regarding uncertainty quantification and confidence modeling, remains limited.

Recent UAV forensic studies emphasize systematic artefact acquisition and device-specific forensic analysis. For example, recent forensic investigations of modern DJI drones have demonstrated the feasibility of extracting telemetry logs, encryption structures, and internal storage artefacts through structured parsing frameworks [9]. Similarly, controller-level forensic analysis has shown that remote controller data can reveal pilot identity, pairing timestamps, and operational locations, thereby expanding evidentiary scope beyond onboard storage [10].

Several contemporary studies have proposed broader forensic frameworks. A conceptual digital forensic investigation model for UAVs was introduced to guide the identification, preservation, analysis, and documentation of drone evidence [11]. Likewise, recent survey research has categorized UAV forensic artefacts, tools, and frameworks while identifying unresolved research themes such as evidence standardization and reproducibility [12]. These studies highlight the growing recognition of UAV forensics as a specialized domain but also indicate persistent methodological fragmentation.

Emerging research between 2024 and 2025 has increasingly focused on integrating diverse forensic data sources. Case studies involving DJI Mini and Phantom drones demonstrate that correlating internal storage, controller data, and flight telemetry can improve event reconstruction accuracy [13], [14]. Additionally, recent investigations into live and static digital evidence traceability have emphasized challenges related to data integrity, repeatability, and evidentiary admissibility [15]. These challenges are particularly critical when forensic findings are presented in legal contexts.

Innovative methodological approaches are also emerging. Digital twin technology has recently been explored for drone accident reconstruction, enabling simulation-based validation of forensic hypotheses and improved investigative accuracy [16]. Metamodeling approaches have likewise been proposed to standardize UAV forensic investigation processes across heterogeneous platforms [17]. Furthermore, recent cybersecurity-oriented forensic frameworks advocate real-time anomaly detection and automated evidence preservation mechanisms for UAV ecosystems [18].

Recent literature also highlights operational and legal challenges. Law-enforcement-focused research indicates that drone forensic investigations face difficulties related to proprietary software, encryption, anti-forensic techniques, and privacy concerns [19]. Similarly, studies on tool-based forensic analysis emphasize the need for standardized methodologies to improve evidentiary reliability and legal defensibility [20].

Another significant development is the exploration of multi-source data correlation. Studies involving industrial and security applications demonstrate that combining flight logs, SD card data, and mobile application artefacts can support attribution and event reconstruction [21]. Transformer-based approaches have also been proposed to link mobile devices with UAV activity, indicating increasing interest in AI-assisted forensic correlation [22].

Despite these advancements, several limitations persist. First, most existing studies focus on artefact extraction rather than forensic inference. Second, uncertainty modeling and confidence quantification are rarely explicitly addressed. Third, cross-layer evidence fusion is typically informal and lacks structured reliability weighting. Finally, empirical validation often relies on single case studies or platform-specific datasets, limiting generalizability.

Therefore, a critical methodological gap exists in UAV forensic research: the absence of a confidence-aware, multi-layer forensic inference framework capable of integrating heterogeneous evidence sources while explicitly modeling uncertainty. Addressing this gap is essential for improving the scientific rigor, transparency, and legal defensibility of UAV forensic investigations.

The present study addresses these limitations by proposing a structured multi-layer UAV forensic framework incorporating physics-based trajectory reconstruction, cross-device temporal alignment, explicit evidence reliability weighting, and a novel Forensic Confidence Index (FCI). This approach moves beyond artefact extraction toward confidence-aware forensic inference suitable for investigative and judicial applications.

A. Methodological and Theoretical Weaknesses

Despite substantial progress in UAV forensic artefact extraction and analytical tool development, several methodological limitations remain. First, uncertainty associated with UAV forensic data is rarely formally modelled, even though sensor noise, timestamp drift, synchronization errors, and partial data loss are inherent characteristics of cyber-physical evidence. Second, structured evidence fusion frameworks capable of systematically integrating heterogeneous sources with differing reliability profiles remain limited. Third, there is no widely accepted mechanism for expressing the strength of forensic attribution as a measurable confidence level, despite increasing emphasis on confidence reporting in forensic admissibility discussions.

These limitations constrain the evolution of UAV forensics from a primarily technical data extraction activity toward a mature forensic science discipline grounded in transparent inference and defensible interpretation. To further illustrate these methodological gaps, Table I presents a comparative analysis of recent UAV forensic studies, highlighting the limited treatment of uncertainty modelling, confidence quantification, and multi-layer evidence integration.

TABLE I. COMPARATIVE ANALYSIS OF UAV FORENSIC LITERATURE (2020–2025)

Author & Year	Study Focus / Platform	Evidence Sources	Methods / Approach	Uncertainty Treatment	Confidence Quantification	Key Limitations
(Zhao et al., 2024) [9]	DJI Mavic 2 Pro forensic analysis	Drone telemetry logs, mobile artefacts	Artefact extraction, structured log parsing	Not explicitly addressed	No	Platform-specific focus
(Lee et al., 2023) [10]	DJI remote controller forensic analysis	Controller logs, pairing data	Controller artefact examination	Limited discussion	No	Limited multi-source integration

(Nieszporek et al., 2026)[22]	AI-based UAV forensic identification	Mobile–UAV telemetry	Transformer-based modelling	Partial discussion	No	Emerging research stage
This Work	Multi-layer UAV forensic framework	Chip-off memory + Flight logs + Mobile artefacts + Wireless traces	Physics-based reconstruction + Temporal alignment + Evidence fusion	Explicit reliability weighting	Yes (Forensic Confidence Index)	Single case validation (future expansion planned)

III. Theoretical Foundation of UAV Forensic Inference

When treated as a purely procedural matter, digital forensic science may degenerate into a repertoire of extraction methods that lack explanatory or even inferential coherence. This danger is especially urgent in UAV research, as heterogeneous information sources, unstable storage devices, and distributed control systems make it harder to apply conventional concepts of evidence persistence and attribution. A conceptually grounded framework is therefore necessary to advance UAV forensics to the next level of technical analysis in forensic science before the court.

This is based on the Exchange Principle of Locard, but redefined for the digital and cyber-physical spaces. In UAV flights, each flight triggers cross-turning tracks across several layers: memory registers embedded in the flight, removable storage, accompanying mobile devices, and wireless communication channels. These exchanges are neither homogeneous nor equally persistent; they fluctuate, varying in volatility, granularity, and resistance to manipulation. To achieve principled evidence integration, it is essential to identify and institutionalize this asymmetric exchange of trace [23].

It should also be noted that forensic reliability and forensic certainty should be critically distinguished. The reliability is the subject of trustworthiness of some artefact under specified circumstances of acquisition, whereas the certainty suggests an unconditional conjecture that can hardly be justified by digital evidence. Modern forensic science is more often dismissing pronouncements of certainty in favor of probabilistic or confidence-bounded conclusions [24]. An example of this is UAV data, which is susceptible to sensor noise, timestamp drift, packet loss, and partial overwriting.

Therefore, confidence modelling is not a choice in UAV forensics; it is a methodological requirement. Courts and expert review panels are increasingly demanding that investigators not only state what evidence points to, but also the degree of strength the evidence has for a particular inference and the conditions under which it is made. Without direct measures of confidence, UAV forensic determinations are prone to admissibility challenges.

IV. Proposed Multi-Layer UAV Forensic Framework

A. Multi-Layer Evidence Architecture

To put the above theoretical principles into practice, a multi-layer forensic architecture is proposed. The framework clearly captures UAV evidence as a stratified system, with each layer providing different levels of information, reliability properties, and volatility restrictions.

1) Layer 1: Physical Memory (Chip-off)

This layer comprises raw non-volatile memory extracted directly from the UAV's onboard storage via chip-off procedures. It provides the best evidentiary persistence and resistance to post-incident contamination and must be acquired by invasive means and with sophisticated laboratory controls. There is high reliability and low volatility.

2) Layer 2: Logical Logs (Internal/SD Storage)

The second layer comprises flight logs, configuration files, and cached telemetry on internal flash disks or removable SD cards. These artefacts provide valuable, well-organized records of operations, but can be obsolete, overwritten, or formatted by their users. The reliability is moderate to high, depending on the time of acquisition.

3) Layer 3: Companion Device Artefacts

UAV control mobile apps produce high-context data, such as coordinated timestamps, user feedback, and stalled flight data. Although these artefacts are very informative, they are subject to the operating system's abstraction and update cycles, which create interpretive uncertainty.

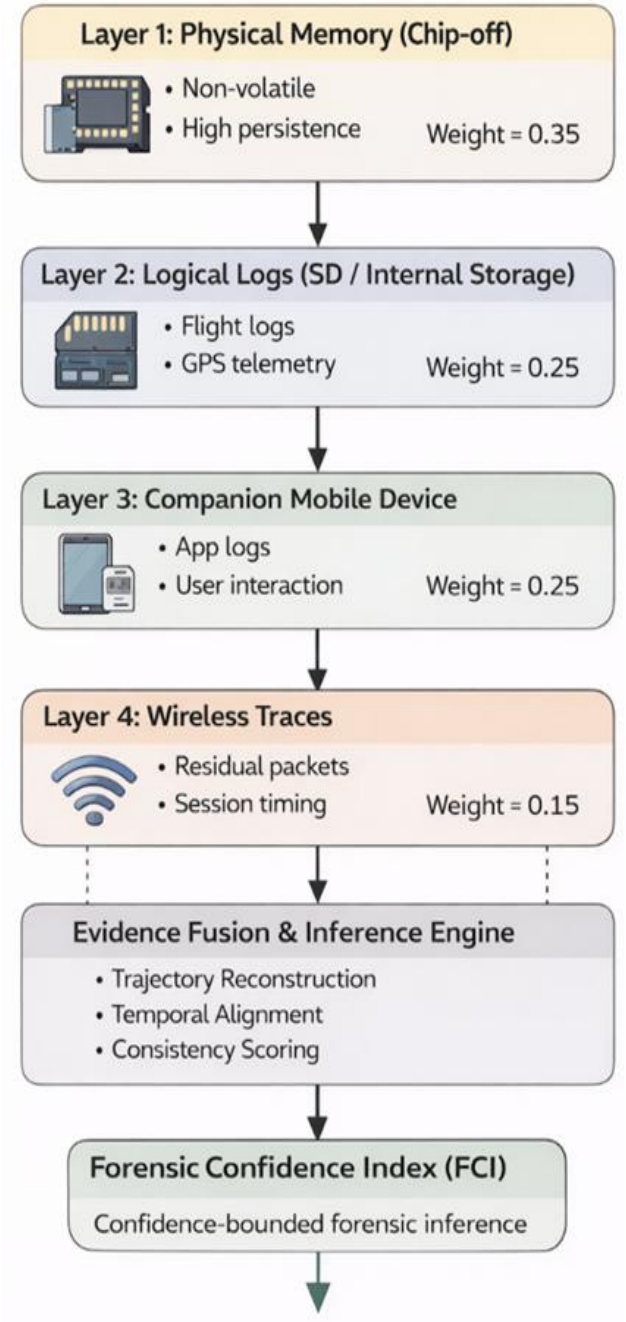

Fig. 1. Multi-layer UAV forensic evidence architecture.

4) Wireless traces: The uppermost layer comprises Wi-Fi, RF, and telemetry transmissions intercepted by access points or monitoring systems. Although partial, these transmissions provide autonomous support for UAV activity and time sequencing. This multi-layered architecture helps provide principled evidence fusion while maintaining source-specific reliability differences.

The general layout of the proposed forensic methodology is shown in Fig. 1, which models UAV evidence as a stratified, reliability-weighted system rather than a flat set of artefacts. The figure shows four forensic layers, each with distinct persistence and trust attributes: physical memory, logical logs, companion device artefacts, and wireless traces. These layers have different persistence and trust properties that are downstream of the inference process.

B. Algorithm 1: Physics-Based Flight Path Reconstruction

Reconstruction of flight paths has been a fundamental inference problem in UAV forensics. This work uses a physics-based, vendor-neutral visualization model rather than vendor-specific tools, ensuring reproducibility and cross-platform applicability.

Given sequential GPS coordinates (ϕi,λi), the geodesic distance between consecutive points is computed using the Haversine formula:

$$d = 2r\arcsin\left(\sqrt{\sin^2\left(\frac{\phi_{i+1}-\phi_i}{2}\right)+\cos(\phi_i)\cos(\phi_{i+1})\sin^2\left(\frac{\lambda_{i+1}-\lambda_i}{2}\right)}\right)$$

where,

- R= Earth radius
- ϕ= latitude
- λ= longitude

Velocity and acceleration are subsequently derived as:

$$v_i = \frac{d_i}{\Delta t_i}$$

$$a_i = \frac{v_{i+1}-v_i}{\Delta t_i}$$

where,

- d_i= distance between consecutive trajectory points
- Δt_i= time interval between successive timestamps
- v_i= velocity at the i-th interval
- a_i= acceleration derived from velocity changes

It is a formulation that allows physically implausible maneuvers to be detected, missing segments to be interpolated, and consistency checking across layers of evidence to be performed. Since the model is not based on proprietary log semantics but on the foundations of basic kinematics, it applies to UAV makers and firmware releases. Algorithm 1 presents the trajectory reconstruction.

Algorithm 1: **Trajectory Reconstruction**

GPS coordinates, timestamps

```
Compute
While (consecutive GPS points exist) do
    For (each consecutive GPS point pair) do
    Update
        Compute velocity using distance and time difference
        Compute acceleration from consecutive velocities
            If (physical plausibility condition satisfied) then
                Search
    End         End
    End
```

C. Algorithm 2: Cross-Device Temporal Alignment

Temporal congruence among heterogeneous devices remains a persistent challenge in UAV forensic investigations, particularly when correlating drone telemetry with artefacts from companion mobile devices. To address this issue, a formal synchronization model is adopted to provide structured and defensible temporal alignment.

For any event i logged on the UAV and event j recorded on the companion device, the temporal discrepancy is defined as:

$$\Delta t_{ij} = | t_i^{\text{drone}} - t_j^{\text{mobile}} |$$

To compensate for clock drift, logging latency, acquisition resolution differences, and communication delays, a synchronization tolerance parameter $\varepsilon$is introduced. Clock drift may arise from hardware timing inaccuracies, firmware offsets, or environmental conditions. Although explicit drift estimation is beyond the scope of the present study, the tolerance parameter accommodates moderate drift effects while maintaining practical forensic applicability. Future work may incorporate formal drift estimation techniques to enhance alignment precision.

False temporal alignment may occur when unrelated events fall within the tolerance window. To reduce this risk, temporal correlation is interpreted alongside contextual evidence such as flight telemetry consistency, operator interactions, and communication traces rather than relying solely on timestamp proximity.

Synchronization uncertainty is inherent in multi-device forensic investigations due to logging latency, sampling resolution, and transmission delays. The proposed tolerance-based alignment model provides a transparent mechanism for acknowledging such uncertainty while preserving

interpretability in forensic reporting. Future work will explore probabilistic synchronization models to improve robustness.

Events are considered temporally consistent when:

$$\Delta t_{ij} \leq \varepsilon$$

where,

- t_i^{drone}= UAV timestamp
- t_j^{mobile}= mobile device timestamp
- ε= synchronization tolerance

This parameterized tolerance model replaces ad hoc time matching with a more defensible alignment strategy, enabling investigators to justify synchronization decisions, quantify temporal uncertainty, and explicitly report assumptions in forensic analysis and expert testimony. Consequently, the framework helps strengthen evidentiary linkage between operator actions, device artefacts, and observed UAV behavior while addressing a methodological gap identified in prior UAV forensic research.

V. Forensic Uncertainty and Confidence Modeling

Conclusions in digital forensics that fail to acknowledge uncertainty implicitly exaggerate the strength of the evidence and, in an adversarial context, compromise their own integrity. The issue is intensified in UAV studies, where evidence is found in heterogeneous subsystems that operate under different time, physical, and operational factors. This means that uncertainty modelling and expressing confidence are not supportive additions but fundamental needs of court-facing UAV forensic science.

A. Evidence Reliability Weighting

The evidence sources in the proposed framework do not receive epistemic equivalence. Instead, each layer gets a reliability weight indicating three forensic dimensions: data persistence, user manipulation, and integrity during acquisition. These weights are not chosen unnecessarily, as they are based on the principles of digital forensic reliability established, known to date [25], and reflect empirical practice that has been reported in the literature of UAV and mobile forensics [26], [27].

The weight of physical chip-off memory is the highest because it is non-volatile and not subject to change after the event, though it is acquired invasively. So logical flight logs, which are stored on internal or removable media, are structured data on operational data but can be deleted or overwritten. Artefacts of companion mobile devices are highly detailed contextual links that are mediated by operating system abstractions and application-layer conversions. Wireless traces, although useful in corroboration, are naturally discontinuous and volatile over time [28].

The explicit weighting of these layers formalizes what is often informal in expert reasoning, thereby enhancing transparency, reproducibility, and defensibility. Extracted evidence sources are not equally forensically reliable due to variability in persistence, manipulation vulnerability, and integrity of acquisition across the ecosystem of UAVs. The weights of reliability that are attributed to each evidentiary layer and applied in this study are captured in a table in the form of Table II.

TABLE II. Evidence Reliability and Weight Assignment

Evidence Layer	Forensic Characteristics	Assigned Weight
Physical memory (chip-off)	Non-volatile, low manipulability, high persistence	0.35
Logical logs (SD/internal)	Structured records, moderate volatility	0.25
Companion mobile device	Context-rich, OS-mediated, moderate uncertainty	0.25
Wireless traces	Volatile, fragmentary, corroborative	0.15

The evidentiary weights are based on forensic reliability factors such as data persistence, susceptibility to manipulation, and acquisition integrity. Physical memory artefacts receive higher weights due to their non-volatile nature, while wireless traces are assigned lower weights because of their volatility.

B. Forensic Confidence Index (FCI) – Novel Contribution

To operationalize uncertainty-sensitive inference, the study proposes a Forensic Confidence Index (FCI), a scalar measure intended to convey the cumulative viability of evidentiary support for a particular forensic statement. The FCI is defined as:

$$\text{FCI} = \sum_{i=1}^{n} w_i C_i$$

where,

- w_i= reliability weight of the i-th evidence layer
- C_i= normalized consistency score (0–1)
- n= number of evidence layers

The proposed Forensic Confidence Index represents a methodological framework rather than a fully statistically validated model. Future studies will focus on empirical calibration using larger UAV forensic datasets.

Where w_i represents the reliability weight of the i -th evidence layer, and $C_i$denotes the normalized consistency score (ranging from 0 to 1) reflecting the internal coherence and cross-layer corroboration of that evidence layer.

The thresholds of the interpretation are established to embrace forensic reporting and expert testimony:

FCI ≥ 0.80: Strong forensic support

0.60 ≤ FCI < 0.80: Moderate support with acknowledged uncertainty

FCI < 0.60: Weak or insufficient support

The FCI threshold values are heuristic and intended to support interpretive guidance rather than absolute probabilistic certainty. Further empirical validation will refine these thresholds.

More importantly, the FCI does not purport to know. Instead, it offers a clear, quantitative expression of confidence that can be scrutinized, challenged, and contextualized - a requirement also emphasized in digital forensic admissibility criteria. An overview of UAV forensic research published in 2020-2025 shows that no similar tool exists to articulate attribution confidence using a combination of evidence types, making this contribution both innovative and needed.

The mathematical calculations behind the Forensic Confidence Index are illustrated in Fig. 2, which shows how heterogeneous evidence inputs are transformed by weighting reliability and scoring consistency, and then aggregated into a single confidence-constrained measure.

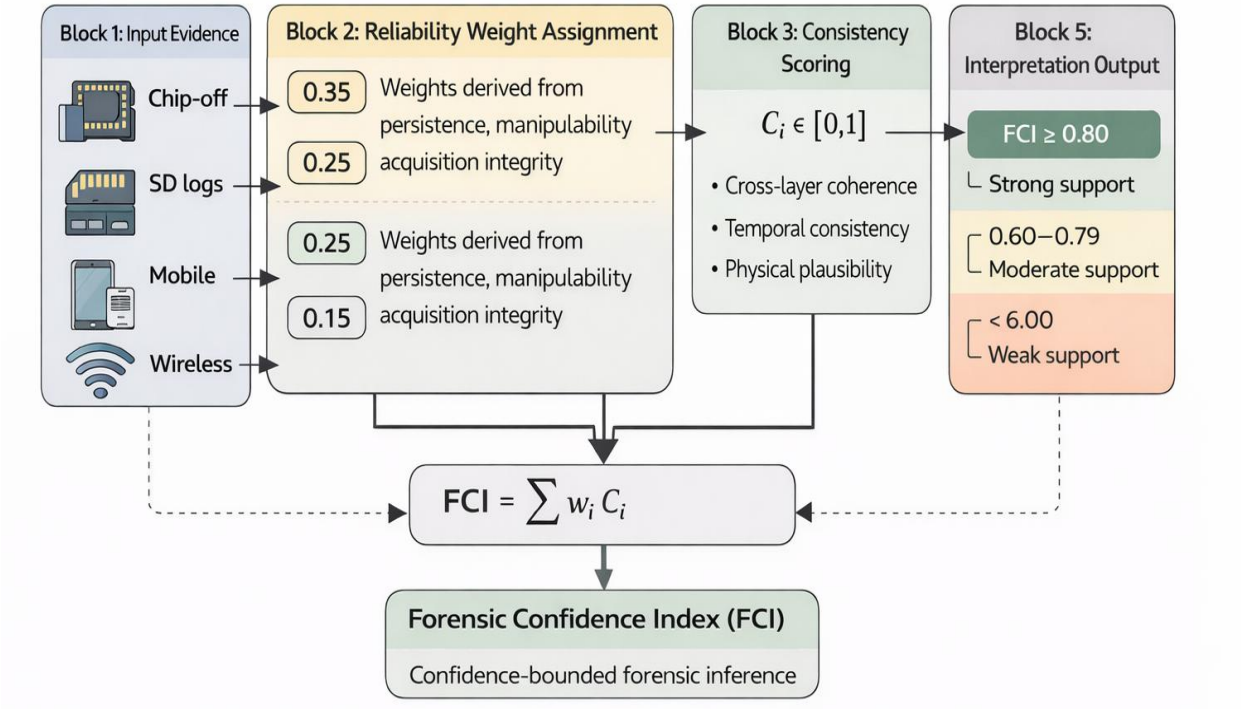

Fig. 2. Forensic Confidence Index computation flow.

VI. Case Study: Yuneec Typhoon Q500 4K (Validation Only)

Forensic science case studies are confirmatory, not creative: they show that a proposed set of concepts can work within real-world constraints. Although the validation focuses on a single UAV platform, this case study serves as a proof-of-concept for the proposed framework under realistic forensic conditions. In emerging forensic domains, initial validation often relies on representative case studies before broader multi-platform evaluation becomes feasible. Accordingly, the Yuneec Typhoon Q500 4K is used as a validation platform for the multi-layer forensic framework, algorithms, and confidence modelling methodology presented earlier.

The inspected UAV was recovered after it was suspected of being used in an unauthorized surveillance operation. The acquisition process was forensically sound, including invasive chip-off acquisition of onboard flash memory, logical acquisition of SD card flight logs, forensic imaging of the companion device, which was also based on Android, and preservation of residual wireless communication artefacts on the local access point. Write-blocked workflows were used for all acquisitions, and the integrity of the evidence was verified through cryptographic hashing of the message.

The artefacts across the four layers of evidence differed in persistence, granularity, and internal coherence. Physical memory provided low-level configuration residues and partial flight buffers that were difficult for the user to erase. Logical logs provided formatted GPS telemetry and timed flight events. Artifacts from companion devices provided application-level sync points and operator touchpoint metadata, whereas wireless traces provided corroborative time anchors at takeoff and landing. More importantly, none of the layers was considered dispositive; the value of the evidence appeared only in the form of systematic composition.

The reconstructed flight path algorithm produced a continuous three-dimensional path within the physical limits of the Q500 platform, and discrepancies between the drone and mobile timestamps were addressed by time-matching within the specified synchronization error. Using the Forensic Confidence Index (FCI), a composite score indicating strong evidentiary support but not absolute confidence was obtained.

The case study focuses on implementing the proposed framework on real forensic artefacts recovered from a Yuneec Typhoon Q500 4K UAV. Table III provides a summary of all recovered artefacts, their provenience, and the confidence measures.

TABLE III. EXTRACTED FORENSIC ARTEFACTS SUMMARY

Source	Artefacts Identified	Count	Confidence Contribution
Chip-off Memory	Configuration remnants, partial buffers	0.35	High
SD card logs	GPS points, timestamps, flight states	0.25	Moderate - High
Companion mobile device	App logs, user actions, sync markers	0.25	Moderate
Wireless traces	Connection timestamps, session IDs	0.15	Low - Moderate

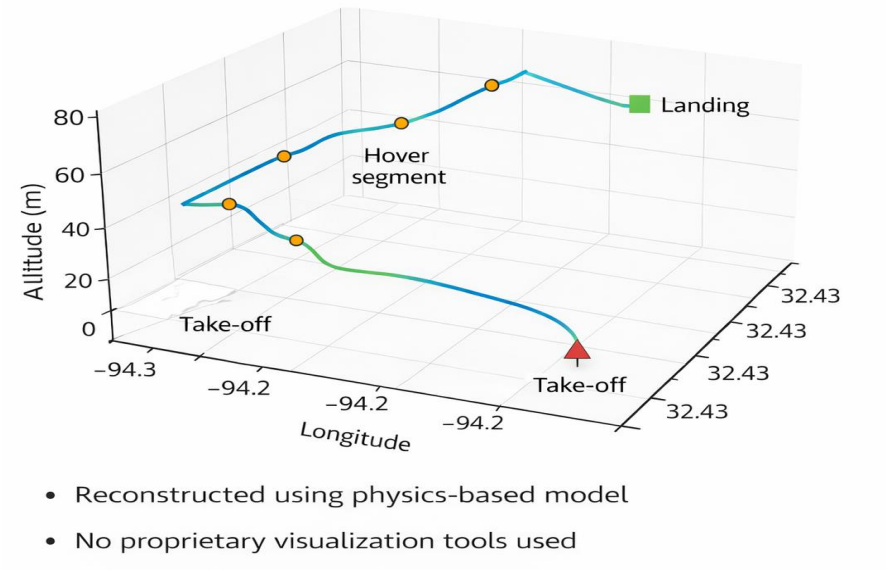

Fig. 3. 3D Flight path reconstruction of yuneec typhoon Q500 4K.

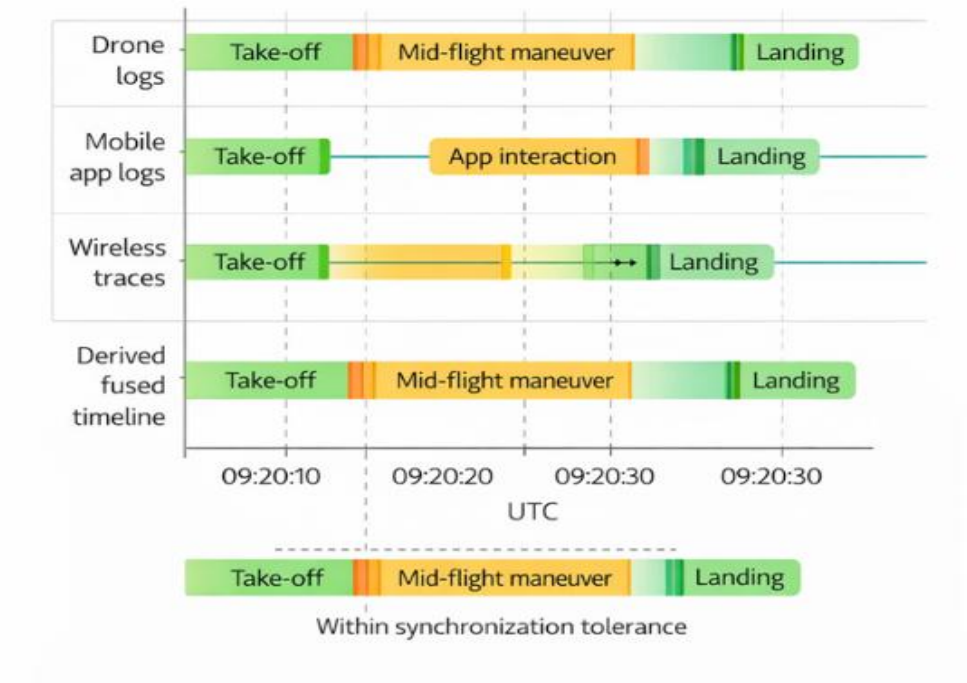

Fig. 4. Cross-device evidence correlation timeline.

The recovered flight path, based on telemetry from the SD card, is plotted in Fig. 3 and shows a physically possible three-dimensional flight path that aligns with the reported take-off, maneuvering, and landing events.

Temporal correspondence between drone logs, mobile application artefacts, and wireless traces is shown in Fig. 4, which presents a coherent timeline extracted within specified synchronization margins.

VII. Discussion: Comparative and Theoretical Implications

The significance of the present study's findings extends beyond artefact retrieval to their implications for the conceptualization, integration, and interpretation of UAV forensic evidence. Compared with previously reported UAV forensic case studies involving DJI and Yuneec platforms, which largely emphasize artefact extraction and platform-specific analysis, the proposed framework explicitly integrates multi-layer evidence fusion, uncertainty modelling, and confidence quantification. This methodological shift enables more transparent forensic inference while maintaining compatibility with established UAV forensic workflows. Earlier studies have demonstrated successful access to forensic artefacts; however, the evidentiary strength often remained implicit and dependent on investigator interpretation rather than structured inference models.

The proposed framework advances UAV forensic investigation along three complementary dimensions. First, physics-based trajectory validation replaces purely descriptive reconstruction, reducing reliance on proprietary visualization tools and improving reproducibility. Second, structured cross-device temporal alignment provides a systematic mechanism for addressing timestamp inconsistencies frequently encountered in forensic investigations and litigation contexts. Third, the explicit incorporation of uncertainty management through reliability weighting and the Forensic Confidence Index (FCI) introduces a quantified representation of evidentiary confidence that has been largely absent from prior UAV forensic literature.

From an interpretive standpoint, the FCI results illustrate how heterogeneous evidence sources contribute differently to overall forensic confidence. More persistent artefacts, such as onboard memory and structured flight logs, typically provide stronger evidentiary stability, whereas volatile wireless traces act primarily as corroborative indicators. This structured integration enhances evidentiary coherence compared with single-source forensic approaches while maintaining transparency regarding uncertainty.

Theoretically, these findings reinforce the applicability of the digital Locard's exchange principle within cyber-physical forensic environments and clarify the distinction between evidentiary certainty and inferential confidence. Rather than asserting deterministic conclusions, the framework promotes calibrated confidence reporting, an approach increasingly recognized as essential for scientific credibility and legal defensibility in forensic science.

More broadly, the framework suggests a transition in UAV forensic practice from artefact-oriented reporting towards inference-oriented reasoning. Such a transition supports improved transparency, reproducibility, and judicial admissibility while aligning UAV forensic methodologies with evolving forensic science standards. Sensitivity considerations indicate that moderate variations in evidentiary weights do not substantially alter overall confidence classification, suggesting preliminary robustness of the framework. Nevertheless, comprehensive quantitative sensitivity analysis and multi-platform empirical validation remain important directions for future work.

VIII. Generalization, Admissibility, and Practical Deployment

To have long-term value, a UAV forensic framework should not be confined to a single platform, while remaining in line with operational and legal limitations. Even though its validation is performed with the Yuneec Typhoon Q500 4K, the proposed framework is deliberately manufacturer-agnostic. The fact that its use of physics-based trajectory reconstruction, abstracted temporal alignment, and evidence-layer weighting is directly applicable to the ecosystems of DJI, Parrot, and Autel UAVs, despite their proprietary log formats or telemetry encodings, is possible [29]. More to the point, the framework is independent of tools. The algorithms are applied to normalized artefact representations rather than vendor-specific parsers, allowing the investigator to combine commercial, open-source, or lab-written tools without modifying the inferential logic. This design option directly reinforces reproducibility and overcomes tool-bias challenges, which are increasingly contentious in forensic admissibility trials.

Legally, the framework corresponds to the principles of reliability used in Daubert-style tests: methods are testable, sources of error are recognized through uncertainty modelling, and inferential steps are transparent and reproducible. Chain-of-custody integrity is maintained by supporting standard forensic acquisition processes and by hash-verified handling of evidence. Conclusions derived from the framework can therefore be expressed as expert opinions with confidence limits, rather than unprovable claims.

IX. Limitations and Future Directions

The strengths notwithstanding, the framework suggested has some limitations. Streaming encrypted telemetry and firmware seals might curtail access to artefacts on newer UAV systems, diminishing the degree of multi-layer evidence integration. Also, the current implementation of wireless trace analysis relies on residual or post-event data; real-time software-defined radio (SDR) capture would improve time resolution but raise logistical and legal issues. The current FCI formulation relies on theoretically grounded weight assignments and requires broader empirical validation across diverse UAV forensic scenarios. Future work will extend validation across multiple UAV platforms, including DJI, Parrot, and Autel ecosystems, to evaluate generalizability and robustness under diverse operational conditions.

To address the problem of time-dependent updating of confidence scores as new evidence is found, future work may generalize the Forensic Confidence Index using probabilistic or Bayesian machine learning models that dynamically update confidence scores as new evidence becomes available. These extensions, though, should be rigorously scrutinized to maintain their interpretability and to remain non-opaque in their explanations before the court.

X. Conclusion

This study advances UAV forensic science by shifting the focus from artefact-centric examination toward confidence-aware forensic inference. A theoretically grounded multi-layer framework was proposed that integrates physics-based trajectory reconstruction, structured cross-device temporal

alignment, and explicit uncertainty modelling. The introduction of the Forensic Confidence Index (FCI) provides a systematic mechanism for expressing evidentiary strength without overstating certainty, thereby supporting transparent and defensible forensic reporting.

The findings demonstrate that multi-layer evidence integration improves evidentiary coherence and interpretability compared with purely descriptive artefact analysis. This approach has practical implications for enhancing transparency, reproducibility, and legal defensibility in UAV forensic investigations while aligning forensic practice with emerging scientific and judicial expectations.

However, validation in the present study is based on a single UAV platform (Yuneec Typhoon Q500 4K), and broader empirical evaluation across diverse UAV ecosystems remains necessary to strengthen generalizability. Despite this limitation, the framework establishes a methodological foundation for structured confidence-aware inference in cyber-physical forensic environments.

Future work will focus on multi-platform empirical validation, refinement of reliability weight assignments, and quantitative sensitivity analysis to further strengthen confidence assessment in UAV forensic investigations.

***Abstract*—The rising demand for real-time, data-driven decision support in retail platforms has underscored the need for intelligent systems capable of modeling both behavioral sequences and product relationships. This study introduces a hybrid architecture for real-time decision support in retailing by coupling graph-based learning with conventional machine learning methods. Based on Instacart 2017 data, it constructs a heterogeneous user-product graph and utilizes GraphSAGE to obtain relational embeddings. This combination of embeddings and domain-specific features is then fed into an XGBoost classifier to predict reorder behavior. Empirical findings show that the proposed GraphSAGE+XGBoost model outperforms conventional baselines, including the sole XGBoost, Multilayer Perceptron (MLP), and Long Short-Term Memory (LSTM) models. In particular, the hybrid model outperformed all baselines across all metrics, achieving a precision of 0.82, a recall of 0.78, an F1-score of 0.76, and a mean Average Precision (mAP) of 0.75. Furthermore, within the co-purchase network, product-level community identification identified significant clusters (such as breakfast staples, health-conscious products, and impulsive snacking) that provided insights into customer demographics and marketing potential. The experimental analysis comparing the proposed GraphSAGE+XGBoost with baseline models, including LSTM, XGBoost, and MLP, demonstrates that the proposed hybrid model outperforms in terms of modeling accuracy, Precision, and generalizability. The system is optimized for real-time inference and can operate in a dynamic commercial landscape, unraveling complex co-purchase behavior and hidden consumer communities.**

***Keywords*—Real-time business intelligence; graph analytics; machine learning; GraphSAGE; XGBoost; retail analytics; recommendation systems; decision support; instacart dataset; hybrid model**

I. Introduction

In the current digital economy, post-hoc analysis and static reporting are no longer the only options available to business intelligence systems [1]. As online platforms and transaction-heavy ecosystems continue to grow rapidly, businesses today require real-time decision-support systems that can extract meaningful insights from continuous streams of client data [2]. In retail and e-commerce settings, in particular, precise, fast, and scalable intelligence solutions are crucial for anticipating customer demands, personalizing recommendations, and optimizing inventory and marketing campaigns [3].

Retail transaction logs, such as those on the Instacart platform, reveal a complex interplay between behavioral, category, and sequential information [4]. Along with what clients buy, these statistics also record when, how often, and in what circumstances. Models that can go beyond conventional feature engineering are needed to utilize such data for predictive purposes.

These models must be able to incorporate both temporal patterns and the structural links between users and items. Existing models commonly used in this domain—such as decision tree ensembles, deep feedforward networks, or sequential architectures like LSTM—tend to address only one aspect of the data. While XGBoost and MLP models excel at handling structured features, they fall short at capturing relational dependencies among entities, such as users who purchase similar items or products that are frequently bought together [5]. Conversely, while LSTM models can model ordered sequences, they often overlook the underlying graph structure of interactions and may struggle when sequences are sparse or highly variable [6].

Furthermore, many real-time systems cannot generalize to unseen products or users, and they offer limited interpretability—both of which are critical in commercial applications. The objective of this study is to bridge the gap between graph-based representation learning and high-performance predictive modelling for real-time business intelligence. Graph-based methods, such as GraphSAGE, can effectively model user-product interactions as nodes and edges in a bipartite graph. At the same time, classifiers like XGBoost remain essential due to their interpretability, scalability, and ability to incorporate domain-specific features. By combining these two strengths—relational learning via graph embeddings

*Corresponding author.

and structured inference via gradient-boosted trees—our proposed model aims to deliver a more accurate and generalizable decision-making system suitable for large-scale retail platforms. This study presents a hybrid framework for real-time reorder prediction using the Instacart 2017 dataset. The main contributions are summarized below:

- We created a heterogeneous graph from transactional data, defining users and products along with temporal and categorical features.
- We presented a hybrid model that combines GraphSAGE embeddings with XGBoost classification, incorporating the strengths of structural learning and boosted decision trees.
- We compared our proposed framework against established baselines, including LSTM, XGBoost, and MLP, demonstrating its superior predictive accuracy and generalization.
- We developed a design optimized for real-time inference, supporting decision support applications in dynamic commercial environments.

II. Literature Review

Recently, the application of Artificial Intelligence (AI) and Machine Learning (ML) in retail analytics and business intelligence has become quite expensive. All of these issues on how these technologies help in decision-making, streamlining operations, and how they can help in the unraveling of latent consumer behaviors have been the subject of numerous studies. This part critically examines advancements over the past few years and the practical applications of AI-based methods in business analytics, co-purchasing modeling, recommendation systems, and customer-behavior prediction across academic and industrial settings. Badmus et al. [7] analyzed the applications of AI and ML in business analytics and their contribution to predictive decision-making, business operations efficiency, and real-time information. SAP case studies showed that AI can boost conversion rates and optimize resource allocation across industries and businesses.

Chintala and Thiyagarajan [8] emphasized that AI-enhanced Business Intelligence (BI) revolutionizes classical business analysis by providing real-time insights, predictive analysis, and automation. They focused on the importance of using technologies such as machine learning and NLP to improve decision-making, streamline processes, and reveal previously inaccessible patterns, backed by real-world experience. Reddy et al. [9] noted that Artificial Intelligence enhances Business Intelligence by improving efficiency, automation, decision-making, and problem-solving. A study conducted by 204 professionals highlights the growing importance of AI for real-time data processing and strategic business development in the context of big data. Niu et al. [10] proposed the ODM-BDA framework, which leverages backtracking and steep optimization methods to enhance business intelligence and decision-making. According to their simulation results, organizations are more effective, better manage risks, and make more accurate data-driven decisions. Hanumanth [11] introduced a bright idea of an intelligent e-shopping system, SmartCart, which allows users to search, in a unified place, across different e-commerce stores and compare them in real-time, providing personalized product suggestions with the support of learning user preferences, to overcome most of the weaknesses of existing online shopping systems. Farheen and Dharani [12] constructed a retail analytics pipeline to reveal association rules and customer online buying trends employing the Apriori algorithm and cloud-based tools. They used their system, augmented with GPT-3.5 Turbo, which reduced error rates and provided useful insights into customer feedback for marketing, bundling, and inventory management.

Meftah, Ounacer, and Azzouazi [13] harmonized network science and AI, incorporating a centrality measure from a co-purchase network into ML models to improve customer purchase prediction. A Random Forest model they developed had an AUC of 0.82, indicating the usefulness of network-based characteristics in retail analytics. Ariannezhad et al. introduced ReCANet, a specialized neural network for next-basket recommendation that explicitly models repeat consumption behavior in grocery.

Ariannezhad et al. [14] introduced ReCANet, a specialized neural network for next-basket recommendation that explicitly models repeat consumption behavior in grocery. Their methodology significantly surpasses state-of-the-art models and demonstrates that repeat items, which comprise only ∼1% of the catalog, account for more than 54% of the recommendation performance. Taken together, the literature explored the ushering effects of AI and ML in retail and e-commerce. These studies offer a reasonable basis for developing innovative, data-driven systems, including leveraging business intelligence and personalization, improving prediction accuracy with network-based features, and modeling repeat consumption.

Nevertheless, though a range of approaches indicate that they are effective in particular operations, like association rule mining, next-basket processing, or user preference (learning), there is still a great chance to clarify these points of view. The study will consequently follow up on these findings by combining graph-based community detection and centrality measures with hybrid machine learning methods to present an efficient approach to constructing recommendations that meet the requirements of retail analytics.

III. Methods and Materials

This section outlines the overall methodology of our study, encompassing the dataset description, preprocessing steps, and the predictive framework adopted. The complete workflow is illustrated in Fig. 1, providing a visual summary of the key components and processes.

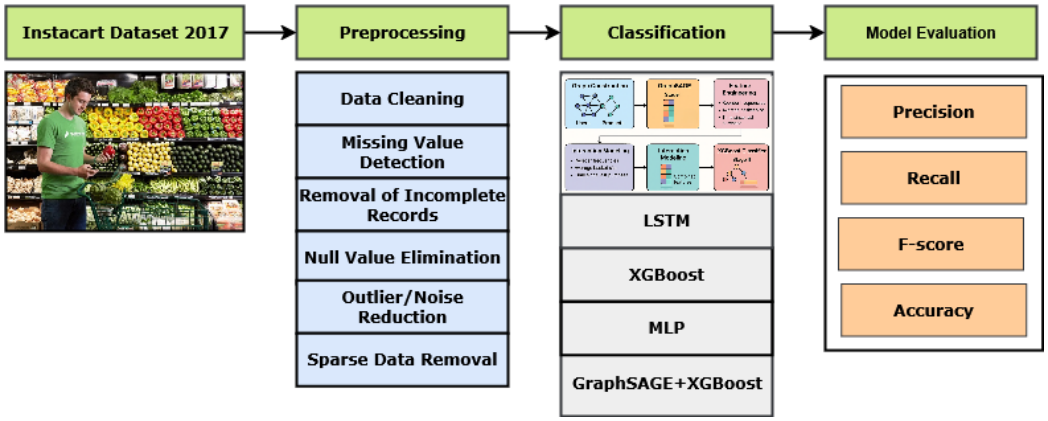

Fig. 1. Overall workflow of the research.

A. Dataset Description

In this work, we utilized the publicly available Instacart Market Basket Analysis 2017 dataset, which provides detailed transactional records from an online grocery delivery platform comprising over 3 million orders placed by more than 200,000 unique users [15]. Each user has between 4 and 100 sequential orders, capturing their longitudinal purchasing behaviour. Each order record includes both the list of purchased products and contextual attributes, such as the day of the week, the hour of the day, and the number of days since the previous order, enabling the modelling of temporal purchasing patterns. Fig. 2 visualizes the number of customers, orders, aisles, and products.

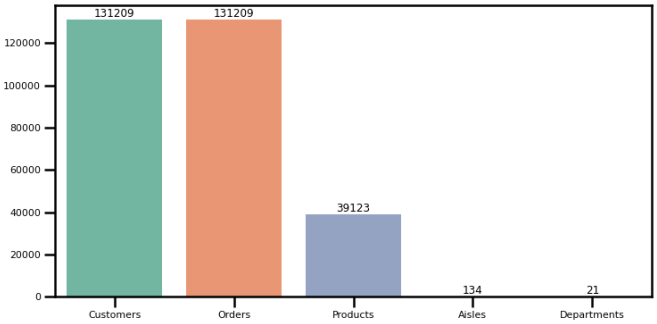

Fig. 2. Structure of the dataset.

The dataset is organized into six structured tables: aisles, departments, products, orders, order_products_prior, and order_products_train. The aisles provide intermediate-level product categories, each with a corresponding aisle identifier, while the departments define higher-level department groupings. The products contain product metadata, including product names, aisle IDs, and department IDs. The order store maintains detailed user order histories, including order identifiers, user identifiers, order sequence numbers, order timing information (day of the week and hour), and the number of days since the previous order was placed. The order products prior and order products train describe the contents of each order, capturing which products were added, the order in which they were added to the cart, and whether the same user reordered the product.

B. Data Preprocessing

Following the first data integration phase, a structured data preprocessing strategy was involved to provide analytical consistency and model readiness. To find missing attribute values and incomplete records, the dataset was thoroughly examined. To maintain the integrity of subsequent studies, these null items were systematically excluded because they accounted for a small portion of the dataset and appeared to be randomly distributed. The dataset's representativeness and statistical balance were preserved, while noise was reduced by removing sparse and uninformative data. As a result, the final dataset was well-structured and free from inconsistencies, making it suitable for robust training of machine learning models and the deployment of graph-based decision support systems in the context of real-time business intelligence. Fig. 3 shows the frequency of days of the week vs. hours of the day.

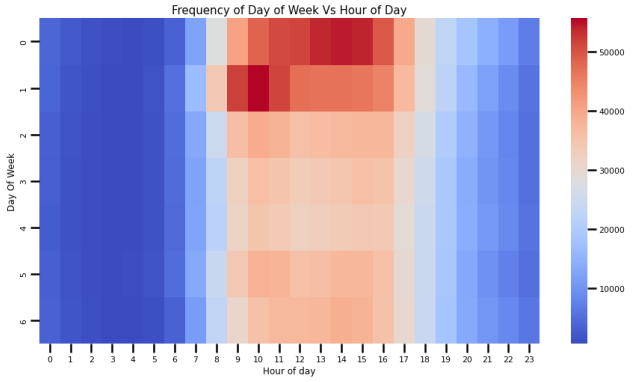

Fig. 3. Frequency of day of week vs hour of day.

C. Baseline Model

Three baseline models were selected for comparison, each representing a distinct modelling approach: sequential, ensemble-based, and feedforward.

1) LSTM: The Long Short-Term Memory (LSTM) model is developed to capture temporal dependencies across ordered user interactions, which possesses information across time steps and generates predictions using the final hidden state [16]:

$$\hat{y} = \sigma(w^T h_T + b) \quad (1)$$

Here, h_T indicates the hidden state at the last time step, and σ is the sigmoid function.

2) XGBoost: XGBoost is a gradient-boosted tree model that creates an ensemble of regression trees in sequence [17], and each tree attempts to minimize the residual error of the previous trees:

$$\hat{y} = \sum_{t=1}^{T} f_t(x) \quad (2)$$

Each function f_t denotes a regression tree, and x is the input feature vector.

3) MLP: The Multilayer Perceptron (MLP) consists of fully connected layers with nonlinear activations, which transform input features through successive linear combinations and nonlinearities [18]:

$$\hat{y} = \sigma(w_T \phi(W_x + b) + b') \quad (3)$$

where ϕ is a ReLU activation involved in the hidden layer output, and σ is a sigmoid function at the output layer.

D. Proposed Model: (GraphSAGE+XGBoost) Model

A hybrid framework designed for effective and timely decision-making in retail analytics, which combines graph-based representation learning with a gradient-boosted classification model to leverage relational patterns in user-product interactions alongside engineered behavioural features. The framework proceeds in two stages, as depicted in Fig. 4:

Stage I: Representation learning on user-product graphs employing GraphSAGE.

Stage II: Prediction through a gradient-boosted decision tree classifier (XGBoost).

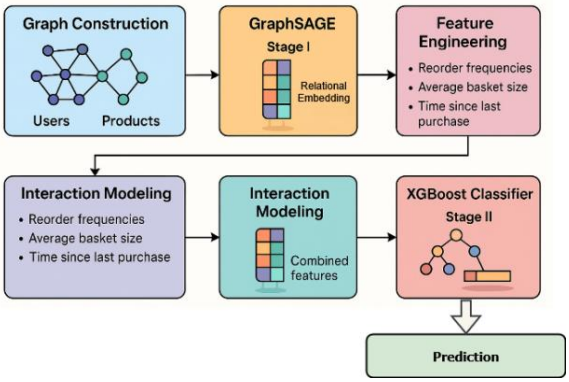

Fig. 4. Architecture of the proposed model.

1) Graph construction: The Instacart transaction data is modeled as a bipartite graph:

$$mathcalG = (\mathcal{V}, \mathcal{E}) \quad (4)$$

where nodes define users $\mathcal{U}$ and products $\mathcal{P}$, so that $\mathcal{V} = \mathcal{U} \cup \mathcal{P}$. An edge $\mathcal{U} \cup \mathcal{P}. \in \mathcal{E}$ exists if user $\mathcal{U}$ purchased product $\mathcal{P}$.

Each node *v* is defined by a feature vector $x_v \in \mathbb{R}^d$ Product nodes encode department and aisle identifiers, reorder frequency, and category popularity. User nodes include metrics such as average basket size, purchase timing, and intervals between orders. This formulation captures both structural relationships and temporal behavior in customer transactions.

2) Representation learning via GraphSAGE: Node embeddings are learned through an inductive aggregation mechanism, where each node updates its representation by integrating its features with those of its neighbors. Formally, for each node *v* at layer *k*:

$$h_v^{(k)} = \sigma(W^{(k)}.AGG^{(k)}\left(\left\{h_v^{(k-1)}\right\} \cup \left\{h_v^{(k-1)} : u \epsilon \mathcal{N}(v)\right\}\right) \quad (5)$$

where, $h_v^{(0)} = x_v$, $AGG^{(k)}$ is the aggregation function (mean aggregator), $W^{(k)}$ is a trainable weight matrix, and σ indicates a nonlinear activation function (ReLU).

The final embedding $z_v = h_v^{(2)}$ is acquired after two such layers, with a hidden dimension of 128.

3) Interaction modeling and feature fusion: To evaluate the potential of a user reordering product p, their embeddings are combined as:

$$z_{(u,p)} = \left[z_u \,||z_p||z_u \Theta z_p\right] \quad (6)$$

where, ‖ signifies concatenation and ⊙ represents elementwise multiplication. This joint vector captures both individual characteristics and interaction effects.

This representation is further enhanced by domain-informed features derived from transaction history, including reorder frequencies, average basket size, time since last purchase, product reorder ratios, and department popularity.

4) Prediction with gradient-boosted trees: The combined feature vector is input to a gradient-boosted decision tree model (XGBoost), which produces an additive sequence of regression trees:

$$\hat{y}_{(u,p)} = \sum_{t=1}^{T} f_t(z_{(u,p)}) \quad (7)$$

with f_t defining individual regression trees. The training objective includes logistic loss connected with regularization to control model complexity:

$$\mathcal{L}^{(t)} = \sum_{i=1}^{n} l\left(y_i, \hat{y}_i^{(t-1)} + f_t(z_{(u,p)})\right) + \Omega(f_t) \quad (8)$$

where,

$$\Omega(f_t) = \Upsilon T + \frac{1}{2}\lambda \sum_j \omega_j^2 \quad (9)$$

Here, ω_j is the score of leaf j in tree f_t. The resulting prediction $\hat{y}_{(u,p)}$ is interpreted as the probability of a reorder event.

IV. Result and Discussion

In this section, a detailed assessment of the chosen GraphSAGE+XGBoost combination model for real-time retail analytics, using the Instacart 2017 data, is presented. This will aim to evaluate how the model can be used to predict user-product reorder behavior by capturing both the time-purchase pattern and the structural relationships in user-product interactions. This section starts with the predictive evaluation of the hybrid model in comparison with three proper baselines: LSTM, MLP, and XGBoost, guided using typical recommendation metrics. Afterwards, we investigate the training and validation behavior of our proposed model to evaluate its learning dynamics and generalization ability. Lastly, the co-purchase surface of products is investigated in this section, using community detection to reveal latent consumer groups and behavioral patterns.

A. Performance Evaluation of Predictive Models

Table I presents a detailed comparison of four predictive models used in next-basket recommendation or co-purchase prediction tasks. The evaluation criteria comprise Precision@10, Recall@10, F1-score, and Mean Average Precision (mAP), all of which are standard evaluation measures in recommendation system evaluation that capture both ranking satisfiability and relevance of prediction. LSTM achieved Precision@10 of 0.76 and a recall@10 of 0.72, indicating moderate performance in predicting the sequential dependencies of purchase behavior. Nevertheless, its F1-score (0.70) and mAP (0.69) indicate that it is not the best at ranking the most relevant items at the top in every case. MLP, a feedforward neural network, scores higher than LSTM with a Precision@10 of 0.77 and a Recall@10 of 0.73, which results in an F1-score of 0.71. XGBoost, which is a gradient-boosted decision tree model, performs better than LSTM and MLP with high scores on all the scoring criteria, and particularly on Precision (0.79) and Recall (0.74), noting the mode of capturing nonlinear association with tabular data, which is one of the additional advantages of the model.

TABLE I. Performance Comparison of Different Models

Model	Precision@10	Recall@10	F1-score	mAP
LSTM	0.76	0.72	0.70	0.69
XGBoost	0.79	0.74	0.72	0.71
MLP	0.77	0.73	0.71	0.70
GraphSAGE+XGBoost (Proposed)	0.82	0.78	0.76	0.75

The GraphSAGE+XGBoost model is the proposed hybrid model that shows the overall performance. Using the graph structure of the purchase network and GraphSAGE embeddings, this model input is fed into the XGBoost classifier. The performance gains are dramatic: Precision@10 of 0.82, Recall@10 of 0.78, F1-score of 0.76, and mAP of 0.75. These measures not only improve the accuracy of recommendations but also enhance the ability to rank products as pertinent. The addition of a strong gradient-boosting classifier to the graph context has significantly improved the comprehensibility of basic user-product associations, yielding much more personalized and meaningful recommendations. To better represent this performance comparison, Fig. 5 provides a clearer view of the benefits of the suggested method.

B. Training and Validation Performance of the Proposed GraphSAGE+XGBoost Model

To determine the learning pattern and generalization ability of the proposed hybrid model (GraphSAGE+XGBoost), training and validation metrics were monitored, with a maximum of 15 training epochs. These are Precision and loss, as depicted in Fig. 6 and Fig. 7, respectively.

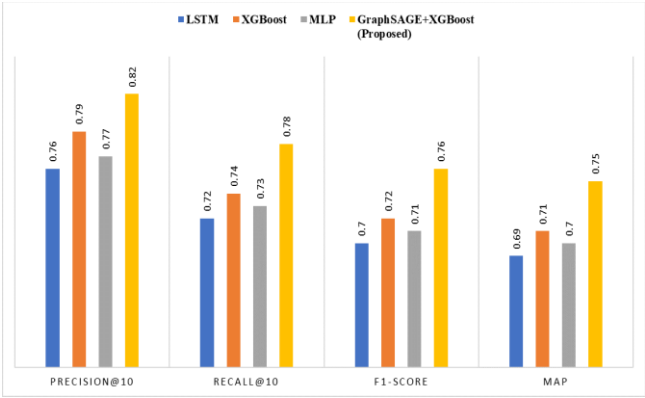

Fig. 5. Visual comparison of different predictive models.

Fig. 6 shows the curves of the training and validation accuracy of the proposed model. The model persistently increases in training and validation accuracy by the last epoch to about 0.89 and 0.84, respectively. That shows it can learn useful features from graph-structured user-product interaction data and achieve excellent classification performance with XGBoost. The monotonically increasing trendline of the validation accuracy suggests good generalization and a low risk of overfitting.

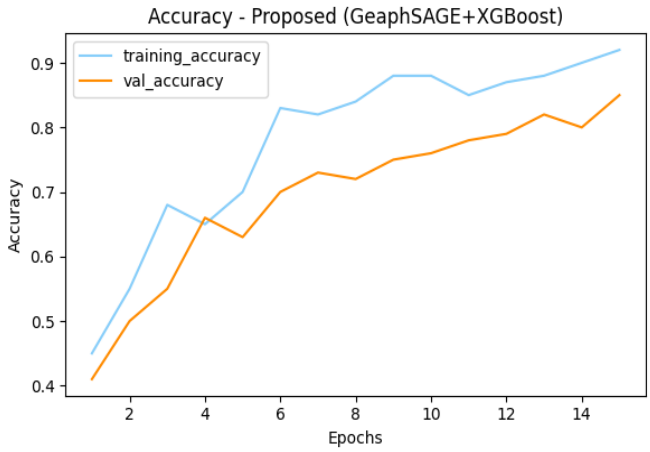

Fig. 6. Training and validation accuracy trends over epochs.

The loss curves during training and verification are set out in Fig. 7. The two loss values drop significantly as the epochs increase, with the training loss tending towards 0.3 and the validation loss towards 0.4. The fact that the curve is declining and the difference between the training and validation losses is minimal further assures the model's stability and appropriateness for recommending tasks that entail intricate interactions.

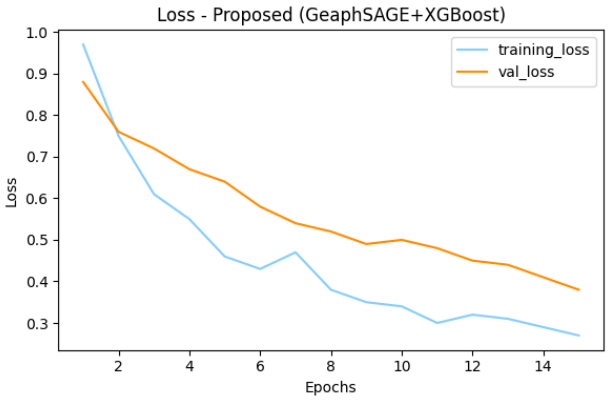

Fig. 7. Training and validation loss trends over epochs.

The effectiveness of the proposed model in revealing meaningful patterns in co-purchase behavior is evidenced by these visualizations, which, in turn, yield better performance than traditional methods.

C. Product Co-Purchase Network with Community Detection and Edge Weights

Fig. 8 illustrates a sample of frequently bought-together grocery items and creates a co-purchasing network based on the sample. The nodes represent products, and the edges indicate co-purchase relationships; the width of an edge indicates the relative frequency of co-purchases. The graph is a good representation of most shopping patterns on online platforms like Instacart. For example, the relationships with high co-purchase rates, like Milk Bread, Milk Eggs, and Banana Yogurt, are not the only ones at a high level; however, such relationships can indicate the possibility of developing repeat consumer behavior.

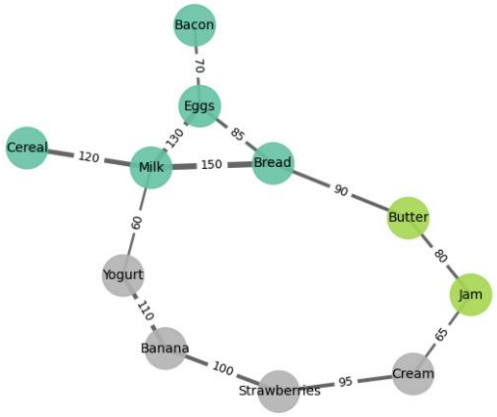

Fig. 8. Product co-purchase network with community detection and edge weights.

The main characteristic of this network is that it automatically partitions products into distinct communities via modularity optimization. The graph has various colors to represent these communities. Remarkably, there is one such community, including Milk, Bread, Eggs, and Butter, which conveys a traditional image of breakfast or a basic grocery basket. The Strawberry, Banana, Yogurt, and cream community correspond to another community that falls into the health-conscious or smoothie-related content basket. The visualization already shows core and peripheral products and indicates that some, such as Milk, are central hubs, connecting several communities.

This would mean that this type of product may become a critical indicator point in the recommendation engines and promotional activities. In addition, it is possible to present edge labels with precise co-purchase frequencies, which provide an even greater opportunity to infer the strength of connections between products. This gives a better view of the structure and behaviors in consumer buying information, which can be helpful in market basket analysis or inventory planning models in online retail platforms, as well as consumer personalization strategies.

D. Expanded Community Analysis in a Diverse Product Network

Fig. 9 extends the discussion of the community detection algorithm's usefulness to a less homogeneous product network. The graph includes not only regular grocery items but also narrower, health-related products like Tofu, Quinoa, and Lentils. The resultant communities are then visualized using a unique color map, and the networks are Spring-embedded to capture both intra- and inter-community associations.

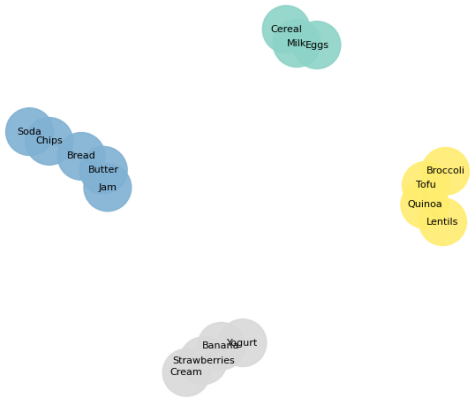

Fig. 9. Community Detection in Product Co-Purchase Network.

This elaborate analysis reveals several interesting clusters. As an example, there is a community with Milk, Eggs, and Cereal, or the essentials of a planetary breakfast. The other cluster comprises Tofu, Quinoa, Broccoli, and Lentils, representing a vegetable- or vegan-oriented consumer group. In the meantime, Chips and Soda have an intimate compact community, which is probably a sign of impulse purchase or a bundle of snacks. The findings illustrate the effectiveness of the community detection method for identifying latent consumer segments based on co-purchasing behavior. The clusters might present distinct shopper profiles, such as health-centered, cost-conscious, or indulgent customers. Recognition of these communities can have important implications for customized marketing, special product packages, and supply chain management. Moreover, the size of nodes and the thickness of edges still provide an intuitive clue as to the importance of the items or the strength of the relation, and the visualization is thus both analytically advantageous and simple to decode.

V. Conclusion

Financial. The research proposed a scalable hybrid model that combines graph representation learning with GraphSAGE

and an XGBoost gradient-boosted model for real-time decision support in retail analytics. The test helped the framework measure both structural and behavioral patterns among consumers by modelling transactional data from the Instacart platform as a bipartite user-product graph. It was noted that the proposed model showed considerable enhancements to the conventional models of LSTM, MLP, and unaligned XGBoost, in predictive accuracy, Precision, Recall, and average mean Precision. Moreover, bigram market structure analysis identified groups of latent consumer segments and frequently occurring co-purchasing activity, yielding a valuable source of actionable insights into how stock should be controlled and how products could be marketed on a one-to-one basis.

Nevertheless, there are still some limitations. To begin with, the current structure uses a static graph that cannot accurately reflect the real-time environment of changing user requirements or products under pre-launch. Second, the model fails to include either textual or image data, which could enhance product representation.

Third, despite the GraphSAGE+XGBoost architecture's effectiveness as an effective middle ground between interpretability and accuracy, it may not be possible to extend it to ultra-large settings with millions of nodes and dynamic edges on some computers due to resource constraints. Also, the analysis was restricted to one data set (Instacart). It cannot be applied to various retail environments or even other application areas. Future directions will focus on overcoming these limitations and extending the framework to support dynamic graph learning and the inclusion of multimodal data, including user reviews and product descriptions. Future work on self-supervised graph pretraining and contrastive learning methods can ultimately help the model achieve high Precision in cold-start conditions. Besides, online learning processes and immediate response chains can be incorporated to maintain readiness to change the market grid. Lastly, during model implementation in live e-commerce systems, it will be practically validated that the model is effective and efficient for decision support.

Disclousure and Conflict of Interest

The author declares that there are no conflicts of interest related to this research. Additionally, the author has no financial interests or competing affiliations that could have influenced the study's design, execution, or findings. This manuscript is the author's original work and has not been previously published or submitted for review to any other journal or conference.

Evaluating the Efficiency of LLM-Generated Software in Resisting Malicious Attacks

Dominic Niceforo, Haydar Cukurtepe
Department of Computing and Information Sciences,
Valparaiso University, Valparaiso, Indiana 46383-7123

***Abstract*—This study introduces a structured framework for evaluating the security of Java applications generated by large language models (LLMs) and presents the results from its implementation across three models: DeepSeek, GPT-4, and Llama 4. The framework integrates Open Web Application Security Project (OWASP)-supported tools, such as SpotBugs with FindSecBugs, OWASP Dependency Check, and OWASP Zed Attack Proxy (ZAP), alongside the NIST Risk Management Framework. These tools and standards were selected for being publicly available, allowing this process to be replicated and extended without proprietary licensing, and for their alignment with widely adopted industry benchmarks. The testing methodology for generated Java applications includes static code analysis, third-party dependency checking, and dynamic attack simulation. Each of the specified tools for this study corresponds to identifying a specific category of critical vulnerabilities. Identified vulnerabilities are then evaluated against NIST risk analysis standards to characterize their threat sources, likelihoods, and impacts, as well as their implications for the overall security risk profile of each application. The effect of prompt design is also explored by comparing a neutral prompt against a security-emphasized prompt incorporating OWASP best practices. Results varied considerably across models: GPT-4 showed noticeable improvements across critical and high-severity vulnerabilities, with 33.3% and 53.8% reductions, respectively. However, Llama 4 and DeepSeek saw an increase in vulnerabilities from the neutral to the secure prompt. Llama 4 had a general increase of 10-15% across critical, high, and medium-severity vulnerabilities, while DeepSeek saw no change in high-severity vulnerabilities and a 40% increase in low-severity vulnerabilities. The framework presented provides a structured process for evaluating LLM-generated code against established software development and security standards, while identifying present limitations and possible directions for future work.**

***Keywords*—Artificial intelligence; cyber security, large language models (LLMs); software security evaluation**

I. Introduction

A core goal in computer security is to reduce software vulnerabilities, both by identifying existing flaws and preventing new ones from emerging. Yet, security problems are still common in software systems. For instance, a report shows that 48% of tested software contains critical, high-risk vulnerabilities [1]. Another report indicates the common vulnerabilities and exposures (CVEs) volume for 2025 is rapidly increasing, with a significant jump from previous years, 16-18% by mid-year. This change is driven by faster reporting and an increased focus on software flaws [2]. Even as advancements in AI offer new ways to aid software development, these security concerns remain, potentially creating new attack vectors in the quality of code generated.

In [3], it is noted that more than 800 million users actively engage with ChatGPT [4] each week, collectively generating over 5.8 billion queries per month. LLMs have been trained to work in a wide variety of domains and have also been integrated into software development environments. The growing use of LLMs for code generation presents both opportunities and significant challenges. As models like GPT-4 [4], DeepSeek [5], and Llama 4 [6] become better trained at generating code, there is a growing interest in handing over parts of the development process to LLMs [7]. These reasons include streamlining coding tasks, enhancing productivity, and reducing development time. While LLMs can speed up the process of writing functional code, this convenience comes with substantial risks to software quality, security, and developer accountability. A growing reliance on these models to handle code generation does not address the challenges, particularly regarding security, which remains largely untested in real-world scenarios. Traditional software development methodologies prioritize secure coding practices, such as threat modeling, code reviews, and penetration testing, to identify and address potential vulnerabilities. In contrast, LLMs face limitations during training, where models lack proper optimization for secure code generation, and during deployment, when LLMs are used for more sensitive tasks without appropriate oversight or validation. As a result, this raises significant concerns about the overall security of LLM-generated solutions. Some studies indicate that the use of LLMs negatively affects code generation. In [8], the authors conducted a controlled experiment with two groups, one of which worked with the help of AI code generators, and the other without their assistance. The authors observed that participants with access to an AI assistant wrote more insecure solutions than those without it. Similarly, Sarkar et al. [9] observed that LLM-supported programming assistants have a negative influence on code development. They also found that inexperienced users often trust code generated by AI tools without much consideration. The survey [10] also highlights the importance of clean and healthy code during LLM training.

Understanding the code-generation capabilities of LLM tools will benefit all relevant groups. This research examines the extent to which the generated code adheres to current security standards and performs under structured vulnerability assessments. Our study integrates established frameworks, such as the OWASP Top 10 [11] and the NIST Risk Management Framework [12], to evaluate Java applications generated by different LLMs. Using tools such as SpotBugs, FindSecBugs, OWASP Dependency Check, and OWASP ZAP, we conduct both static and dynamic testing, as well as third-party dependency analysis. We then analyze, classify, and score

the findings using the NIST framework to produce quantifiable risk assessments.

This research aims to answer multiple key questions about the capabilities of commonly used LLM tools:

- How effective are LLMs in generating code that can resist specific cyberattacks?
- What security benchmarks can accurately evaluate the resilience of this code?
- What attack vectors are these applications most vulnerable to?

This study hypothesizes that secure prompting will influence the security profile of generated applications, with the direction and degree of change expected to vary across the different models, given potential differences in architecture and training.

By exploring these questions, this research establishes a replicable framework for evaluating the security of code generated by LLMs for a structured application. Additionally, it will provide valuable insights into how prompt design can influence more secure code output.

The following sections organize the remainder of this study: Section II provides a brief overview of the background of AI-assisted software development, along with related works, with a special emphasis on performance evaluations and security concerns. Section III expands on how the evaluation process will be implemented within the proposed framework. Section IV presents experimental results, performance comparisons, and discusses the key findings. Lastly, the conclusion in Section V discusses the current limitations of the research, possible future work, and concludes the study.

II. Background and Related Work

This study aims to investigate the efficiency of LLMs in software development, specifically their ability to generate code that withstands commonly known attack types. As AI-powered tools have become increasingly integrated into the general population, their ability to create high-quality code has been the subject of numerous studies.

The survey [10] highlights the powerful capability of LLMs, especially for code generation, when high-quality, clean, and healthy code is used for training. The authors systematically review the use of LLMs in software security. They break down software security into stages and analyze how LLMs can be utilized in each stage. The authors emphasize the powerful potential of LLMs, especially when pretrained with clean data, fine-tuned for specific tasks, and carefully crafted input prompts. A comprehensive survey of LLMs for Software Engineering (SE) is given in [13]. This survey concludes that traditional SE methods, combined with LLMs, play a critical role in enabling reliable and efficient LLM-based SE. The surveys [13], [14] provide AI-assisted development and open technical challenges that highlight their capabilities, limitations, potentials, and security concerns. In [14], the authors reviews how embeddings can be utilized for detecting security vulnerabilities by comparing them to known code patterns. They also suggest that the transformers can be trained to detect security vulnerabilities by learning from labeled data. In [15], the authors provide a survey on the usability of AI tools to assist in software development, with a focus on Copilot and GitHub. The study is based on a survey of a diverse population of developers. The authors observe that developers are motivated to use AI programming assistants; however, 54% are reluctant to do so due to security concerns. In [16], the authors provide a comprehensive survey on LLMs for security. The authors investigate the use of LLMs for identifying possible vulnerabilities in natural language descriptions and source code, as well as generating security-related code, such as patches and exploits. In [17], the authors provide a survey on the security aspects of code generated by LLMs. The authors emphasize the importance of employing robust tools and approaches to enhance code quality.

In [18], the authors provide an analysis of the quality of solutions generated by AI tools, including code writing, testing, reviewing, and documentation. The study is conducted using Claude 3 Opus and GitHub Copilot. The performance of the tools is compared with three security factors: “Provided security configuration from the start”, “Filter out malicious input”, “Up to date on libraries information”, but it does not provide a comprehensive analysis of vulnerabilities. In [19], the authors focus on generating Solidity code with GitHub Copilot. AI-generated code is scanned for vulnerability using a static analysis framework for smart contracts. Despite the advantages of using AI, there are significant challenges, particularly concerning the security, reliability, and quality of the generated code. In [20], [21], the authors focus on developer use of AI tools. In [22], the authors researches the security concerns of developers.

There are many studies evaluating the correctness and usability of the LLM-generated code [23], [24], [25]. The study [26] analyzes developments in AI-supported code generation, focusing on safety, reliability, and code quality. In [27], the authors evaluates the code generated from GitHub Copilot using MITRE vulnerability standards. The authors suggest pairing Copilot with appropriate security-aware tooling during both training and generation to minimize the risk of introducing security vulnerabilities. The study [28] proposes a controlled code generation method (svGen) using LLMs. The authors train the model with secure-accepted code and evaluate the results using a model proposed by [27]. The authors employ this approach to improve the security of LLM-generated code from 59% (for considered cases) to 92%. The evaluation model used in this study needs to be aligned with industry standards and repeatable.

In [29], the authors tested CodeBERT, GPT-3.5, and CodeX for their code generation capabilities and security concerns related to 10 different vulnerabilities, which were selected from common CVEs, Common Weakness Enumerations (CWEs), NIST vulnerabilities, and OWASP’s Top 10 web application security risks. The authors conclude that ChatGPT excels at explaining potential security issues and suggest that all AI models should be integrated with cybersecurity practices. Our study differs from this study in its comprehensive analysis of vulnerabilities, repeatability of implementation framework, modern LLM implementations, and NIST evaluations. Berabi et al. [30] investigate the effectiveness of LLMs for solving code-repair tasks. The authors present a new learning model

that trains LLMs to fix coding errors and vulnerabilities. The authors concluded that improving code quality and security is difficult, as it requires large amounts of high-quality, labeled training data. Another type of risk associated with using AI tools in code generation is highlighted by [31]. The study emphasizes that an attacker can poison the data, infecting AI code generators and leading them to generate code that contains vulnerabilities and security defects. The studies [9], [22] indicate that, although developers have serious security concerns about AI-generated code, AI use will continue to increase for productivity purposes.

Prior studies in this area can be generally categorized into three groups: the first focuses on performing static analysis on LLM-generated code, such as [27] and [19]. The second group examines developer behavior and potential concerns arising from the use of AI tools in practice, such as [9], [22], and [15]. The third group explores the broader capabilities and generation approaches, such as [29] and [28].

The present study differs from all three categories by combining static analysis, third-party dependency checking, and dynamic attack simulation within a single evaluation pipeline and assessing it against the NIST Risk Management Framework. This reflects the multi-faceted nature of real-world security threats, where no single analysis method captures the full risk profile of an application. By integrating the specializations of prior work into a unified framework, this study provides a more complete picture of security vulnerabilities in a given code-generation scenario.

III. Methodology

This section details the implementation of the evaluation process and proposes a framework that integrates software generation, security benchmarking, and attack testing across selected LLMs.

The attack vectors tested in this study are based on the OWASP Top Ten [11], an openly accessible document that outlines the most common and critical security risks faced by web applications. These include:

- Broken Access Control
- Cryptographic Failures
- Injection
- Insecure Design
- Security Misconfiguration
- Vulnerable and Outdated Components
- Identification and Authentication Failures
- Software and Data Integrity Failures
- Security Logging and Monitoring Failures
- Server-Side Request Forgery

The OWASP Top Ten list is globally recognized for providing a thorough, systematic approach to identifying, prioritizing, and classifying vulnerabilities relevant to the type of application generated in this study. We specifically chose this benchmark as our primary reference because of its widespread acceptance in academia and industry [32], [33], [34]. While the OWASP Top Ten is updated regularly to keep pace with new threats and research, using the current version at the time of our study, OWASP Top Ten 2025, ensures our methods are transparent, consistent, and reproducible. By clearly documenting these categories and their integration into our testing, our framework directly aligns with current security standards, making it more credible and applicable. The framework also incorporates the NIST Risk Management Framework to deliver clear, quantifiable assessments of potential security risks.

The proposed framework comprises seven primary components, which form a sequential process for evaluating LLM-generated code from a security perspective, as illustrated in Fig. 1. Details about its implementation and varying components are explained in the following subsections.

A. LLMs and Prompts

LLMs are widely adopted and used intensively for many purposes, including software development assistance [12].

1) LLM selection: In this study, we have selected three distinct large language models: GPT-4, DeepSeek, and Llama 4. Each LLM offers a different perspective on what comprises the evolving landscape of AI. GPT-4 stands as the industry standard, well-known, widely trusted, and high-performing. DeepSeek is a newer model, and its inclusion in this study prompts a different methodological model design. Lastly, Llama 4, which is partially open-source, invites innovation and transparency. Together, these choices form a well-rounded representation of the variety expected of available models and, therefore, an accurate basis for comparison in this study.

2) Prompt preparation: This step involves drafting comprehensive project specifications for an LLM to generate a Java-based e-commerce web application. The primary goal is to ensure the instructions are easy to understand and consistently reproducible across different models. Additionally, by adding intentional complexity, the prompt acts as a controlled environment for testing how the model handles various categories of security vulnerabilities.

The neutral prompt, which serves as the baseline for creating the project, is as follows:

"Create a simple Java web application for an e-commerce platform. Include the following features: user registration and login, a product catalog with basic search functionality, an admin page to add products, and file upload support for product images. Keep the structure as simple as possible, and make sure the core features are implemented. Use H2 as the database, Spring MVC for routing, and Thymeleaf templates for the UI. Structure the application as a Maven project and include a working pom.xml with necessary dependencies to build and run the app."

In comparison, the second prompt is meant to introduce a greater focus on security. For the context of this study, only one secure prompt is used. However, a greater number of prompts and variance in its security emphasis can be beneficial, as mentioned in the Limitations section of this study. While the secure prompt is identical in its project specifications, this prompt incorporates safe coding practices that would typically be followed in a traditional development cycle, as well as types

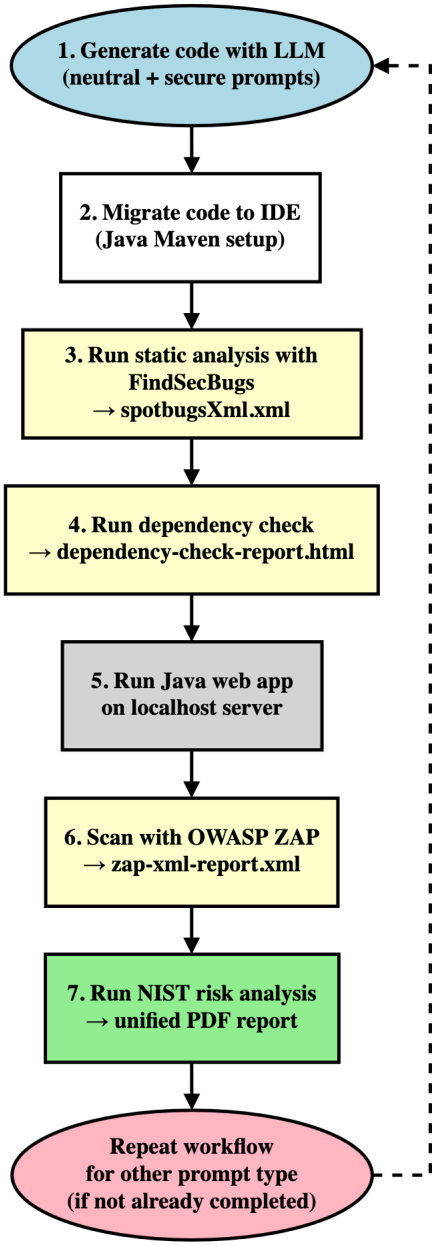

Fig. 1. Overview of the primary components within the proposed framework for evaluating LLM-generated applications.

of potential vulnerabilities to avoid when implementing core features.

"Implement the following OWASP best security practices: use the latest version of dependencies, input validation and output encoding, use prepared statements for database access, hash passwords using BCrypt, implement access control (e.g., admin vs user), validate uploaded files and store them safely, avoid hard coded secrets (use application.properties), handle errors securely (do not expose stack traces), and include comments explaining your security-related decisions."

B. Code Migration

In order to evaluate the security of LLM-generated applications, a practical testing environment is created by initializing a new Java project in an Integrated Development Environment (IDE). This approach closely follows a real-world developer workflow, enabling an accurate testing environment that simulates realistic development and security assessments. In the current version of the study, code is migrated manually from the LLM's output into a Maven project. However, automated integration, as an extension of this study, is considered in the Limitations section.

Within the project, the security tools explained in the following subsections are integrated via the Maven pom.xml configuration file.

C. Static Vulnerability Analysis

Static code analysis is essential in preventing costly security breaches by identifying vulnerabilities early, saving time and resources. It also helps improve code quality by enforcing standards.

SpotBugs and FindSecBugs are commonly used tools for static analysis of the source code, without actually running the code. SpotBugs checks for over 400 bug patterns, categorized by severity [35]. This tool is particularly effective in identifying issues such as hard-coded credentials, directory traversal, SQL injection, and weak cryptographic implementations. These vulnerabilities align with multiple OWASP categories, including Broken Access Control, Injection, and Cryptographic Failures. In this study, we utilized SpotBugs version 4.9.2.0 and FindSecBugs version 1.12.0 to identify vulnerabilities.

The FindSecBugs tool is compatible with the Java development environment. After configuring the tools, the IDE performs automated scans and generates detailed reports. Exported in both HTML and XML formats, these reports are stored for further review.

D. Dependency Analysis

Dependency analysis is another essential component of the study methodology, as it mitigates vulnerabilities caused by outdated dependencies and libraries in the generated application.

OWASP Dependency Check is a command-line tool that scans for known vulnerabilities in project dependencies by comparing them against databases like the National Vulnerability Database (NVD) [36]. It is used to identify vulnerabilities in third-party libraries. This tool scans through the project's dependencies and maps them to known CVEs from public vulnerability databases. As one of the most prevalent risks for web applications, using Dependency Check in this testing methodology addresses the OWASP category of Vulnerable and Outdated Components. In this study, we used version 6.5.3 to identify vulnerabilities.

OWASP Dependency-Check tool is compatible with the Java development environment. After configuring the tools, the IDE performs automated scans and generates detailed reports. Exported in both HTML and XML formats, these reports are stored for further review.

E. Running Code on a Server

Once the static analysis and dependency checks are complete, the application is deployed locally to a web server from the IDE. This step enables dynamic analysis, which involves observing and testing the application while it is running.

F. Dynamic Vulnerability Analysis

OWASP ZAP is used at this point to scan the live application, conducting various vulnerability tests that mimic possible attack vectors by an external attacker.

OWASP ZAP (Zed Attack Proxy) simulates live attacks against an application while running on a web server for dynamic testing [37]. ZAP intercepts and manipulates HTTP requests, helping to satisfy the OWASP categories of Broken Access Control, Cross-Site Scripting (XSS), and Authentication Failures. These dynamic tests are insightful for better understanding how this application will behave under real-world conditions, where it may be subject to more varied testing than provided by static analysis or unit testing. In this study, we used version 2.16.1 to identify vulnerabilities.

G. NIST Framework Analysis

The NIST Cybersecurity Framework serves as a comprehensive and valuable resource for organizations to manage and mitigate cybersecurity risks. It offers a structured, flexible, and repeatable methodology for identifying, assessing, and addressing security vulnerabilities across diverse operational contexts [12]. By adopting this framework, organizations can not only improve their alignment with regulatory and industry compliance requirements but also substantially reduce their exposure to cyber threats. Moreover, the framework supports the development of a resilient and proactive security posture, ultimately contributing to the organization's long-term stability and risk governance.

The NIST Risk Management Framework is used to convert raw output from the OWASP vulnerability assessments into quantifiable risk levels. This step provides greater structure to the security findings, supporting risk-based decision-making for individual developers and organizations throughout the software development process.

Data collected from the OWASP tools, such as SpotBugs, FindSecBugs, Dependency Check, and ZAP, is extracted and standardized. These include information such as CWEs, Common Vulnerabilities and Exposures (CVEs), and severity scores as reported by the tools.

Additionally, Python scripts are used to automate the process of querying the National Vulnerability Database (NVD) API. These scripts retrieve CVSS (Common Vulnerability Scoring System) data for each CVE, helping to determine the likelihood and impact of each vulnerability using NIST's criteria:

- Likelihood is determined by factors such as exploitability, prevalence, and exposure, referenced from CVSS subscores and vulnerability history.
- Impact is evaluated based on the nature of the affected component and the sensitivity of the data it handles.

Final risk levels are calculated by multiplying the likelihood and impact weights. They are categorized as Low, Moderate, or High as outlined by NIST standards.

IV. Experimental Results

This section presents the experimental results from implementing the proposed framework with two prompts: a *neutral* prompt, where security requirements are not emphasized, and a *secure* prompt, where the LLM is explicitly asked to create secure code that avoids specific vulnerability groups. Results are contextualized by the framework with an additional focus on implementation details that required manual intervention.

TABLE I. Security Findings by Severity for Each LLM and Prompt.

LLM	Prompt	Critical	High	Medium	Low	Info
DeepSeek	Neutral	3	13	10	11	3
DeepSeek	Secure	2	13	14	14	4
GPT-4	Neutral	3	13	10	8	3
GPT-4	Secure	2	6	15	6	3
Llama 4	Neutral	10	9	6	11	3
Llama 4	Secure	11	10	7	11	3

A. LLM and Prompt Behavior

During the code generation process, each LLM's behavior is evaluated based on the functional quality of its output, responsiveness to the given prompt, and the degree of manual refinement required to produce a working Java application from the model (see Table I).

1) GPT-4: The neutral prompt generated a working Spring Boot web application that included basic controllers, models, and template views. Fig. 2 depicts the directory structure produced along with the source files. However, GPT-4's implementation introduced several security vulnerabilities, including 34 in total: 3 Critical, 13 High, 10 Medium, and 8 Low. These include nine significant issues reported by SpotBugs/FindSecBugs, such as a potential path-traversal issue (CWE-22) caused by improper file handling, and a failure to check the return value of the mkdirs() method (CWE-253).

OWASP ZAP reported five issues, including the absence of a Content Security Policy (CSP) header being set (CWE-693) and the use of cookies without the SameSite attribute (CWE-1275), both of which increase the web application's susceptibility to client-side attacks. However, most of the reported issues originated from OWASP Dependency Check, which identified all three vulnerabilities marked as critical. These include SnakeYAML, Spring Boot Starter Security, and Tomcat Embed Core. One or multiple published CVEs could reference each of these outdated dependencies. For example, the SnakeYAML version was linked to CVE-2022-1471, involving a deserialization vulnerability. On the other hand, Tomcat Embed Core was linked with 7 CVEs, ranging from improper input validation to path equivalence and the improper neutralization of escape sequences. Each of these vulnerabilities matches with one or more OWASP Top Ten vulnerabilities [11].

The secure prompt reduced critical-rank vulnerabilities by 1 to 2 and High-rated vulnerabilities by 7 to 6. These results

Fig. 2. GPT-4 responding to the neutral prompt with a directory structure of files necessary for generating the Java-based web application.

include the SnakeYAML dependency issue, which was no longer reported by Dependency Check. However, new vulnerabilities were also introduced, including disabling cross-site request forgery (CSRF) protection in the security configuration (CWE-352) and omitting an anti-clickjacking header (CWE-1021). Additionally, some vulnerabilities classified as high were downgraded to medium, contributing to the increase in that category by 5 to 15 when compared to the neutral prompt. The cumulative total for this version was 29 vulnerabilities. These results suggest that while the secure prompt made modest improvements in its use of dependencies, it did not consistently address all vulnerabilities and also introduced new configuration risks.

2) DeepSeek: Overall, a comparison of the outputs from the two prompts shows that DeepSeek produced a more complex implementation of the Java-based web application than GPT-4. The applications generated by DeepSeek encompassed not only the configuration, controller, model, and repository classes, like with GPT-4, but also added additional files that enhanced functionality and structure. For example, the neutral prompt introduced the Data Transfer Object (DTO) and service classes for handling data manipulation and application logic.

After running the code through the OWASP security tools, the neutral prompt revealed 37 total vulnerabilities, including 3 Critical, 13 High, 10 Medium, and 11 Low. While these results were similar to those from the GPT-4 model, some notable exceptions warrant highlighting. One medium-level vulnerability was associated with version 3.1.2 of Spring

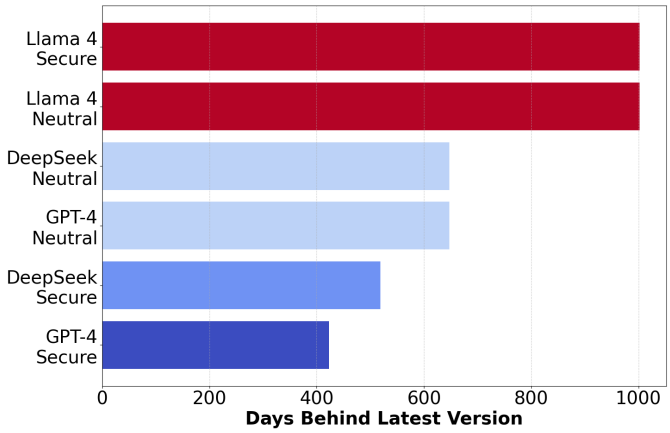

Fig. 3. Bar chart showing the number of days that the Tomcat dependency used in each application lagged behind the latest available version at the time of testing. Lower bars represent a more recent version of the dependency.

Boot DevTools, as detected by OWASP Dependency Check (CVE-2023-34055). Additionally, including the StorageService class by DeepSeek introduced another medium-level Potential Path Traversal vulnerability, in addition to what was already detected by SpotBugs with GPT-4 (CWE-22).

Looking into the secure prompt for DeepSeek reveals a greater degree of complexity than even its neutral variant. The changes included implementation classes for ProductService and UserService, which were separated from their interfaces to better align with the separation of concerns. A method call was also identified within the UserController that passed a null value to a non-null parameter during the user account registration process. This vulnerability, which involves input validation and error handling, is classified as CWE-476 in the public database. In addition, the secure prompt analysis flagged additional outdated dependencies, including version 1.70 of the Bouncy Castle Provider, which is used for cryptographic implementations. This issue was linked to five CVEs with low confidence. The secure prompt ultimately led to more vulnerabilities across all severity levels, highlighting the unintentional consequences that can arise from overengineering a secure prompt. Although there was one less critical vulnerability than in the neutral version, testing revealed four additional medium-level vulnerabilities and three new low-level vulnerabilities. The cumulative total for this version was 43 vulnerabilities.

3) Llama 4: Llama 4 exhibited less effective performance under both prompt conditions, showing minimal benefit from the introduction of secure coding practices. In both the neutral and secure variants, the model produced approximately 10 critical-rated vulnerabilities, the highest among the three LLMs tested. No measurable improvements were observed between prompts, with the secure version yielding an equal or greater quantity of vulnerabilities. These additional risks were mainly identified by OWASP Dependency Check. As shown in Fig. 3, the version of Tomcat Embed Core used for each model and prompt is graphed based on how far it lags behind the latest release available during testing in April 2025. Both outputs for Llama 4 included Tomcat Embed Core version 9.0.65, released in July 2022, in their pom.xml files. Lagging by over 2.5 years, this model's output is a relative outlier because it uses outdated

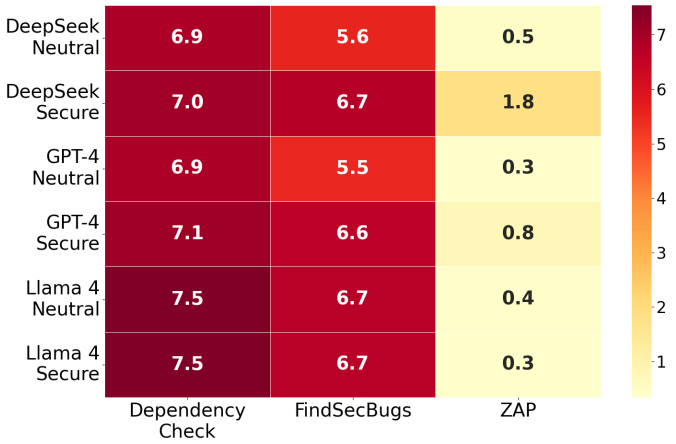

Fig. 4. Heatmap matrix showing average CVSS scores by OWASP tool across different LLMs and prompt types. Higher scores, visualized by darker colors, indicate more severe vulnerabilities.

components. This reliance reduces the application's resilience to withstand modern exploits and cyberattacks.

B. Overall Assessment

The results across all three models suggest that while using more secure prompts can influence improvements, such as using newer versions of dependencies and reducing the number of vulnerabilities, their impact is largely inconsistent and model-dependent. For example, GPT-4 responded most effectively to secure prompting, showing notable reductions in high-severity vulnerabilities. DeepSeek took a more detailed approach to its structure and implementation, but did not implement any consistent security improvements. And lastly, Llama 4 displayed no measurable improvements, continuing to use severely outdated components such as Tomcat Emded Core from mid-2022. The most critical issues across all models were identified by OWASP Dependency Check, highlighting common vulnerabilities in the versions of third-party libraries in use. Additionally, the secure prompts exhibited some natural variance in the generation process, including misconfigurations introduced from the added complexity (e.g., disabled CSRF protection). Fig. 4 presents a heatmap showing average CVSS scores by OWASP tool across different LLMs and prompt types.

C. NIST Risk Analysis

Before any risk could be scored using the NIST Risk Management Framework, it was necessary to normalize and enrich the raw vulnerability data generated from the OWASP security tools. Results from SpotBugs, FindSecBugs, OWASP Dependency Check, and OWASP ZAP were exported in HTML or XML, depending on the specific tool and configuration used. These saved reports contained valuable information for risk evaluation purposes, but required additional steps to easily extract identifiers such as CWEs and CVEs (see Fig. 5).

Custom Python scripts were used to parse for this type of information in each of the output files. For example, the XML-formatted reports from both SpotBugs and ZAP listed vulnerabilities with any CWEs associated with code smells

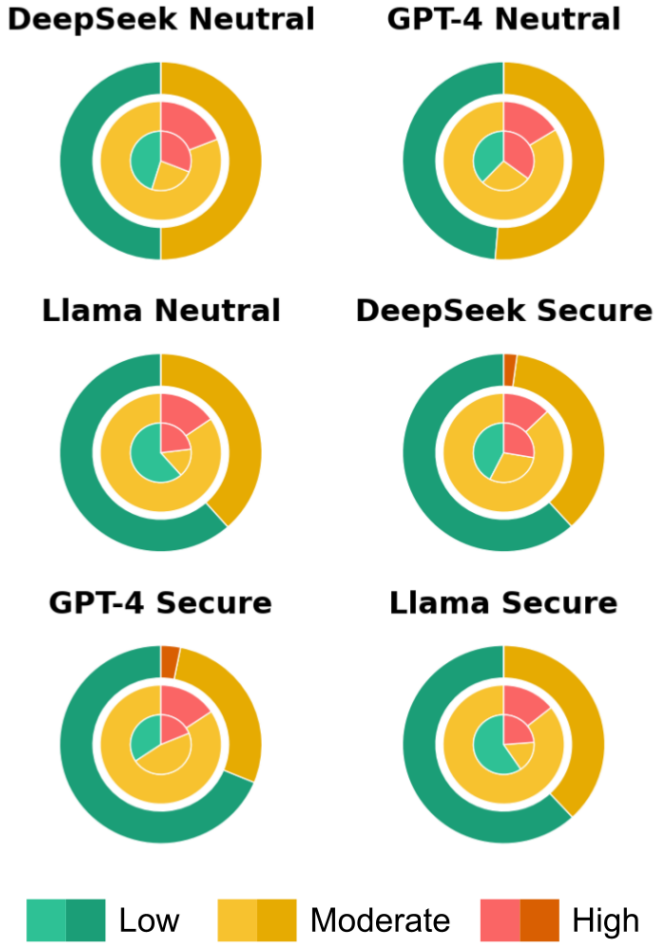

Fig. 5. Concentric pie charts visualizing the distribution of likelihood (inner ring), impact (middle ring), and overall risk (outer ring) for each LLM under neutral and secure prompt conditions. Severity levels are color-coded as Low (green), Moderate (amber), and High (red).

or dynamic flaws. Dependency Check, on the other hand, linked its findings directly to CVEs for a specific outdated and vulnerable component. The format and structure of the outputs generated by these tools served as the foundation for mapping findings to standardized definitions of known security issues.

V. Conclusion

In this study, we have examined LLM-generated code against modern security standards to better understand its resiliency to malicious attacks. We used the established OWASP Top Ten framework to categorize attack types, and the NIST Risk Management Framework to evaluate the risks associated with identified vulnerabilities. Using tools such as SpotBugs with FindSecBugs, OWASP Dependency Check, and OWASP ZAP, we conducted static analysis, third-party dependency scanning, and dynamic testing. Across the various testing configurations, all outputs, collected in either HTML or XML formats, were passed through the NIST Risk Management Framework. This necessary step standardized the findings and aligned each identified weakness, as outlined by Common Weakness Enumerations (CWEs), with Common Vulnerabil-

ities and Exposures (CVEs) from the National Vulnerability Database. By linking the identified weaknesses to known vulnerabilities already published, we have established a quantifiable basis for assessing security in applications influenced by large language models.

A. Research Limitations

Several limitations of this study should be acknowledged. First, all experimental results were obtained from testing a single application type, a Java-based e-commerce web application. This constrains how any conclusions about prompt-driven security improvements can be generalized. It also introduces a potential bias not only from the application type but also from the programming language used, as models may generate code differently to satisfy project requirements, which could inadvertently alter the output's security profile. Projects that vary in codebase size also pose a concern, as vulnerability counts in this study are reported in absolute terms without normalization. Overall, future work of this study should investigate how differences in programming languages, normalized project sizes, and application types affect a model's adherence to security-emphasized prompting.

Second, each prompt-model combination was evaluated using a single generated output. LLMs are inherently stochastic, meaning that repeated generations from the same prompt can yield different solutions, varying in how the code is structured, implemented, and supplemented with security requirements. Reproducibility was further hindered by reliance on human intervention during testing, including manual code migration into the development environment and error resolution. Without automation, replication across runs in the testing process cannot be guaranteed, as human intervention can influence the outcomes.

Third, this study used only two prompt conditions: a neutral prompt to establish the project requirements and a security-emphasized prompt incorporating OWASP best practices for secure code generation. While this binary design simplifies the study and allows for a controlled comparison, it does not capture the full range of outcomes that could be observed across a gradient of security emphasis. Exploring these variables within prompt design would provide valuable insights beyond the current state of this research.

B. Future Work

Experimental results were obtained using the latest version of the LLMs at the time of the study. This field of AI is highly dynamic and continuously improving. A future study can be designed to test the performance of newer versions to observe their improvements, specifically in resisting malicious attacks.

Also, the study can be designed to implement iterative code enhancements to exploit the refined reasoning ability of LLMs. Applications generated by LLMs would undergo an automated evaluation process using the OWASP tools and the NIST Risk Management Framework, with the results informing any necessary changes in subsequent versions of the application. This loop would involve multiple cycles of code generation, vulnerability scanning, and risk assessment, with each cycle feeding back into the prompt or model configuration to produce a more secure version. Over multiple iterations, LLMs could learn to avoid common vulnerabilities and generate code with a more secure profile. Such an implementation would not only automate vulnerability detection but also enable continuous security improvement, paving the way for LLM-driven solutions to create software that is production-ready and compliant with established policies.

In this rapidly evolving field of study, this work, despite its shortcomings, opens doors and guides research in different directions.

Beyond the Interface: AI Integration Through Input Stream Mediation and Intelligent Output Simulation

Divij H. Patel
Independent Researcher, Ontario, Canada

***Abstract*—As Natural Language Processing (NLP) technologies continue to advance, their integration within everyday software tools remains fragmented and often constrained by environment-specific plugins or proprietary AI interfaces. This study introduces a lightweight, platform-independent framework that transforms any text-input surface, ranging from simple editors to browsers and full-featured integrated development environments (IDEs), into an intelligent, AI-assisted interface. Leveraging keystroke dynamics and key-chord recognition, the system operates unobtrusively in the background to interpret user intent and enable real-time interaction within active applications. It provides context-aware suggestions, completions, and insights directly within the active window, effectively turning ordinary typing environments into responsive, intelligent companions. Beyond unifying AI support across diverse applications, the framework enables users to seamlessly switch among multiple open-source AI and NLP models via simple key combination triggers, supported through flexible API integration, thereby providing dynamic access to different linguistic capabilities on demand. The architecture also incorporates a protective intelligence layer that detects suspicious behavior patterns and safeguards sensitive information, offering an additional shield against unauthorized data exposure. By employing a universal mediation layer for input and output, supported by controlled keystroke simulation, the approach eliminates the need for custom extensions or application-specific integrations, presenting a scalable model for embedding real-time artificial intelligence into everyday computing environments.**

Keywords*—Keystroke dynamics; keystroke simulation; AI-Assisted Interfaces; open-source AI; key-chord recognition; API integration; real-time interaction systems

I. Introduction

Over the past decade, the artificial intelligence (AI) ecosystem has experienced significant growth in the development of open-source AI and Natural Language Processing (NLP) models made available through well-documented APIs. These APIs facilitate integration into software ecosystems using widely adopted programming languages, thereby enabling AI-driven functionalities across a broad spectrum of applications [1]. Despite these advancements, interaction with such models has largely remained confined to proprietary interfaces, including standalone web portals, dedicated desktop applications, or platform-specific plug-ins. This architectural dependency often forces users to switch between environments to access AI capabilities, resulting in fragmented workflows and diminished productivity.

Recent AI-assisted interaction systems have primarily integrated NLP-based functionalities through application-specific graphical interfaces, browser extensions, or embedded plug-in architectures. While these solutions enable task-oriented assistance such as grammar correction or development support, they remain dependent on platform-level integration and typically require manual configuration for each environment. Consequently, such implementations offer limited interoperability across heterogeneous computing platforms and do not support unified AI-assisted interaction across multiple text-input surfaces.

Additionally, existing research has largely emphasized improvements in model performance or domain-specific deployment of NLP systems, with limited focus on system-level interaction frameworks that enable application-independent AI mediation. Most current solutions rely on proprietary interfaces or tightly coupled API integrations confined to specific software environments. In contrast, the proposed framework introduces a platform-independent architecture that enables real-time AI-assisted interaction across conventional text-based interfaces without reliance on model-specific plug-ins or environment-dependent integrations.

To address this limitation, this study proposes a hybrid architecture comprising three primary components: real-time keystroke monitoring, virtual keystroke simulation, and asynchronous NLP inference over open-access APIs. The proposed framework introduces a lightweight background service that operates independently of application-level interfaces and continuously monitors user input within text-based environments. Upon detecting predefined trigger conditions, such as a hotkey sequence, the captured input is transmitted to an open-source NLP model via an API endpoint, and the generated response is re-inserted into the active application using simulated keystrokes. This mechanism enables interface-independent AI interaction within commonly used applications, including standard text editors such as Notepad and WordPad, as well as embedded terminal environments [2].

Recent developments have attempted to mitigate this limitation through AI-powered browser extensions and application-level integrations tailored for specific use cases. Tools such as grammar correction engines and development assistance environments exemplify this trend toward embedded intelligence. However, these solutions remain tightly coupled to individual platforms or applications and typically require manual installation and configuration for each environment. As a result, users must rely on multiple independent tools for tasks such as grammar correction, paraphrasing, and code analysis, leading to inconsistencies in user experience and limited

interoperability between applications [3]. Existing literature primarily focuses on improving model performance or interface-level integration, with comparatively limited attention given to system-wide interaction frameworks capable of providing application-independent AI assistance.

From a systems perspective, modern operating environments interpret keyboard input through standardized scan-code interpretation and virtual key mapping mechanisms based on established character encoding standards [4]. When a user initiates a keypress event, the keyboard hardware generates a scan code that is interpreted by the operating system and mapped to a virtual keycode corresponding to the active keyboard layout [5]. In addition to capturing real-time keyboard input, contemporary operating systems provide low-level APIs capable of generating synthetic input events through functions such as keybd_event() and SendInput(), thereby enabling the simulation of keystrokes programmatically [6], [7]. These virtual input events are processed by the system kernel in the same manner as physical keystrokes, allowing applications to receive them as standard user input without requiring interface-specific modifications.

Concurrently, the emergence of transformer-based NLP models such as GPT-2, BERT, and spaCy has enabled access to powerful text-generation capabilities trained on large-scale linguistic corpora [8], [9]. These models are typically accessed through graphical interfaces or dedicated applications, necessitating environment switching for interaction. Although RESTful API endpoints allow developers to embed AI functionalities within software applications using languages such as Python or JavaScript, such integrations remain application-dependent and do not provide a unified mechanism for system-wide interaction [10], [11], [12]. This highlights a critical research gap in the development of interface-agnostic AI mediation frameworks capable of operating seamlessly across heterogeneous text-input environments.

The generalized framework eliminates the need for model-specific plug-ins by introducing a system-level layer of AI augmentation that decouples the input source from the NLP interface. This enables context-aware text generation across diverse computing environments while minimizing friction between users and AI-assisted tools. Furthermore, the proposed architecture is scalable to non-traditional text-editing platforms, including online content editors, live-stream overlays, and integrated development environments such as Visual Studio. In such scenarios, user input is intercepted by the background service, processed by an NLP engine, and the generated output is seamlessly appended within the same interface without reliance on third-party extensions [13]. This approach provides real-time assistance while reducing cognitive overhead associated with environment switching.

ANSI escape sequences and virtual terminal protocols form the foundational communication layer of the proposed system, given their widespread use in character encoding, network messaging, industrial control systems, and embedded device scripting. By incorporating AI-driven inference, secure API interactions, and automated keystroke simulation within ANSI-based workflows, the proposed framework advances existing interaction paradigms and introduces new opportunities for intelligent and secure human–computer interaction.

The primary contributions of this work are summarized as follows:

- The design of an interface-agnostic AI mediation framework for real-time interaction across heterogeneous text-input environments.
- A hybrid system architecture integrating keystroke monitoring, keystroke simulation, and asynchronous NLP inference via open-access APIs.
- A system-level AI augmentation layer that eliminates dependency on application-specific plug-ins or proprietary interfaces.
- A scalable implementation capable of enabling context-aware AI assistance within conventional text editors and development environments.

The subsequent Methodology section details the implementation of this framework and its integration within standard computing environments.

II. Methodology

This proposed functionality can be implemented in any modern programming language, such as Python, JavaScript, or C++. Once the main thread starts, which is responsible for continuously monitoring keystrokes and checking for matching key combinations to start and stop the child loops and threads [2]. These child threads can be programmed for different operations, which will be covered in the rest of the study. For example, they might send input to NLP and AI agents, trigger security events, and train existing models for behavior biometrics and typing patterns. These threads can be started/stopped through special key combinations matched via the main thread. Many of the programming flows of the child threads are described in the upcoming sections.

A. Legacy System Foundation and Transition to Intelligent NLP Framework

As previously discussed, the proposed framework aims to offer system-level natural language augmentation by combining open-source NLP models with traditional keystroke-capture techniques. In its initial prototype phase, the system used a multidimensional-array-based string-matching algorithm that provided a deterministic, hardcoded mapping between user input and predefined responses [2]. This is again not a GUI version; it provides a terminal-independent interface that simulates a virtual input/output environment using ANSI escape sequences and raw device file access.

If we see this program in the terminal, the captured keystrokes' ASCII values and converted string look like Fig. 1.

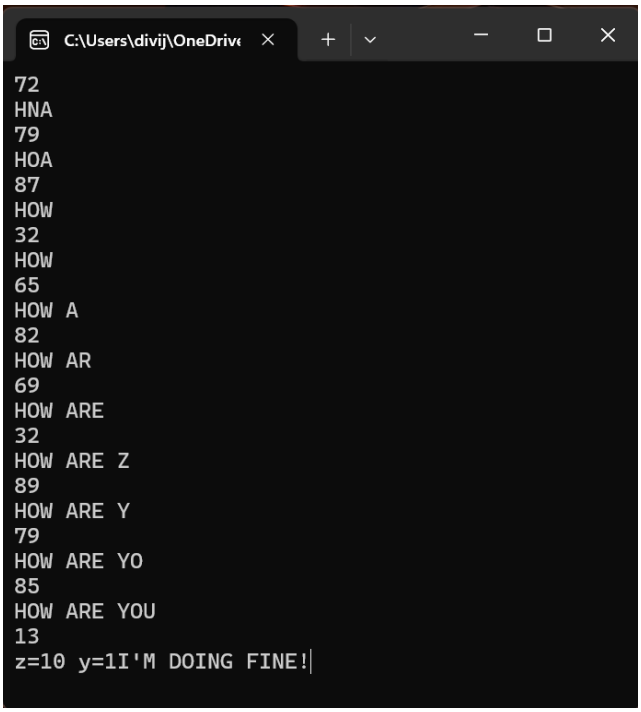

Fig. 1. Converting captured ANSI to text.

When a user enters a key event on the keyboard, such as "How are you doing?", the operating system's built-in module captures it and reads it using a built-in function of a programming language mentioned in section I. Once the keystroke is captured, like the ASCII number "72", the program converts it to the character 'H' (hex 48). It continues capturing and forming sentences until it reads the code "13", which is for the "enter key", indicating the sentence is complete. It then sends this data to either an NLP system or a conventional array-matching loop, which generates the virtual keystroke for the response, such as "I'M DOING FINE!" or whatever reply is received from the NLP server, by triggering the corresponding ASCII numbers in a specific sequence.

This low-level interaction model kept the system non-intrusive by running it in the background without disrupting everyday keyboard-based user actions. Behind-the-scenes control was implemented by custom hotkey combinations that trigger pause, resume, and terminate actions, as mentioned in the study [2].

By monitoring mode, the author refers to maintaining continuous availability of the proposed AI-assistance framework; the system must remain active in the background, independent of user interaction. This persistent operation can be achieved directly in Python and C++ through long-running program structures, as well as through operating system-level tools that support background execution. Modern operating systems provide native service managers, such as systemd on Linux and Windows Services on Microsoft platforms, which are specifically designed to oversee long-running programs, automatically restart them when needed, and ensure they stay active throughout system operation. These service frameworks enable the system to function reliably as a background component, even when no user interface is active [21], [22].

Within the program itself, Python programming language supports persistent background operations via an infinite event loop, asynchronous execution via the asyncio library, and thread-based concurrency via the threading module. These mechanisms enable continuous monitoring, periodic polling, and non-blocking communication with external NLP models. Likewise, C++ provides a rich background-execution model through its standard threading library (std::thread), enabling developers to create long-lived detached threads or asynchronous tasks (std::async) that persist independently of the main application flow. When combined with OS-level service management, these programmatic approaches ensure that the framework behaves as a resilient, always-active process capable of delivering real-time AI support across heterogeneous environments [23], [24].

The current iteration marks a significant architectural shift toward context-aware behavior by incorporating transformer-based NLP models such as BERT [8], GPT-2 [9], and spaCy [12]. These integrations allow for probabilistic, semantically coherent outputs rather than rigid string retrieval, dramatically improving the framework's versatility and scalability.

B. Proposed System Architecture and Operational Workflow

The config file, created during installation, sets up the framework's runtime behavior by defining how NLP endpoints, credential-based access, and linked hotkey connections are enabled. It indicates what actions to take when the key combination is triggered. Similar to file configuration formats, its style is consistent with .env or YAML, with each entry specifying an NLP model endpoint.

This configuration file is also encrypted (using the OpenSSL AES-256 symmetric encryption method) and can be decrypted only by the process in question, which does not compromise the integrity of the sensitive API tokens or service credentials [14]. This encryption strategy ensures confidentiality and integrity in multi-user or shared environments.

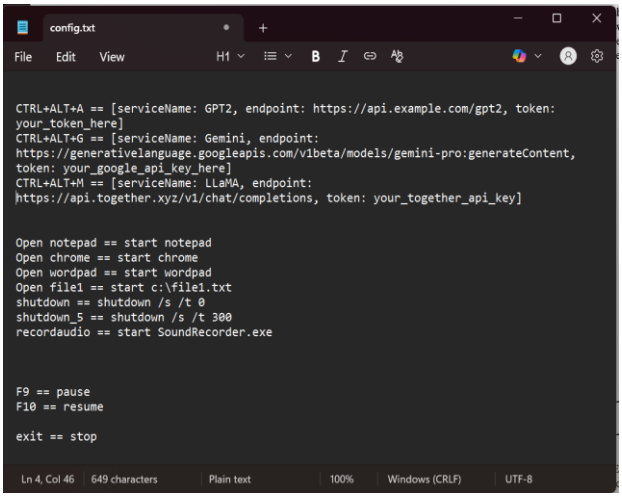

Fig. 2. Config file example.

Fig. 2 shows what the config file looks like when opened. It contains many predefined key combinations, and its system commands are already set for use. The developer can add more or modify the existing ones as needed.

As we discussed, the main thread will continuously check for the hot key combination and, if none are found. It will then generate keystroke-based output from a predefined, updateable array of sentences hardcoded into the program. If the user presses a combination to activate an NLP model, such as CTRL+ALT+A, the main thread spawns a child thread that sends registered keystrokes to the selected NLP model and returns the response by generating virtual keystrokes. Similarly, a user or developer can change the NLP model's preference by pressing a key combination to switch reactions in real time.

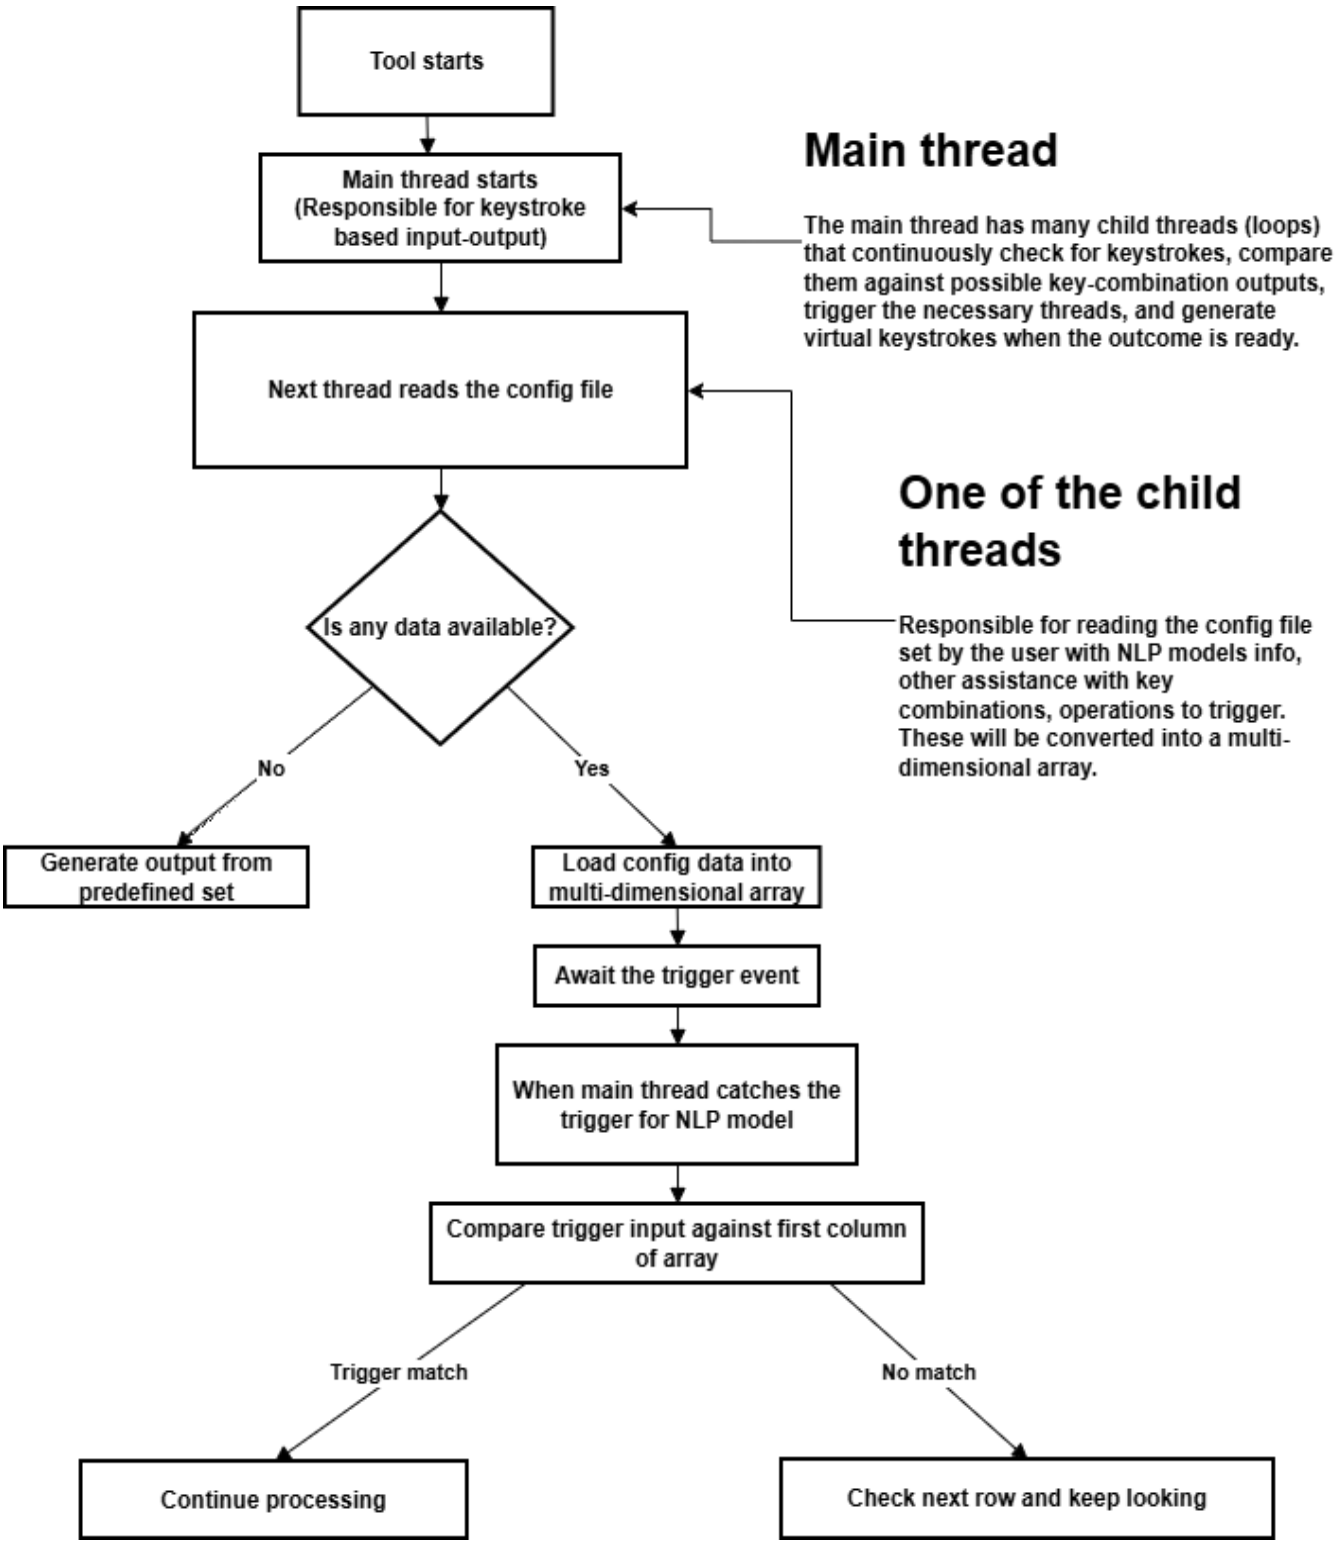

Fig. 3. Switching between NLP models.

Upon detecting a predefined key sequence, the framework executes the following logic pipeline:

1) Event handling and dispatch: A global key listener registers the triggering hotkey and asynchronously parses the associated configuration entry.

2) Secure API invocation: Using Axios (JavaScript) or libcurl (C++), depending on the platform context, a structured POST request is sent to the specified model endpoint, embedding the API token within the Authorization header [15], [16].

3) Response handling: The received NLP model output is parsed and sanitized, then passed to the UI injection engine, which uses virtual keystroke APIs (e.g., Windows SendInput, Linux uinput) to simulate direct text input into the active application window.

4) State management: The framework maintains a lightweight in-memory buffer to cache the last N responses, enabling rollback, regeneration, or comparison functionality within the interaction loop.

The above sequence enables real-time language augmentation across any text-editable interface, whether it be an IDE, browser, email client, or command shell. Unlike monolithic desktop NLP tools, this system features a modular, microservice-based design that supports plug-and-play integration with additional models or downstream services, such as spellcheckers or summarizers.

C. Technical Contributions and Deployment Considerations

1) Hotkeys binding logic: Hotkey binding is a crucial feature of modern operating systems. It enables users to activate specific actions through key combinations, boosting efficiency and workflow. In this work, the researcher has expanded on this traditional concept by employing keystroke-level event interception as an interaction layer for real-time AI assistance. This results in a more flexible and context-aware experience within operating systems. This system has been implemented using Xlib on Linux and SetWindowsHookEx on Windows. It supports dependable key-chord recognition and includes mechanisms to prevent race conditions, ensuring stable and predictable shortcut-event handling across platforms [18].

2) Cross-platform API wrappers: Native bindings to libcurl, along with Axios wrappers for Electron-based environments, enable seamless cloud communication.

3) Error handling: Includes retry logic with exponential backoff and token refresh middleware to maintain long-session stability with external NLP providers. If the retry fails, it automatically generates the appropriate error response and types it via virtual keystroke at the cursor position. The current tool does not have its own GUI (Graphical User Interface). It is crucial to generate proper error codes and display them at the cursor point to ensure clarity for users and developers.

4) Platform abstraction: Layer enables portability across Windows, Linux, and macOS by abstracting system-specific keystroke injection mechanisms. In this study, the author has defined a concept that can be implemented in any preferred programming language and on any operating system.

This design ensures high extensibility, allowing for future integration with on-device LLMs or fine-tuned domain-specific models using frameworks such as Hugging Face Transformers [19]. The following flowchart Fig. 3, illustrates the overall process and operational flow of the proposed framework.

Upon initialization, the Main thread starts and continues to look for the special key combinations and other keystrokes. For example, if the user presses the enter key after some keystrokes, it will be captured and processed as a text-based prompt.

Another child thread accesses a local configuration file through standard read/write operations, enabled by the host operating system's POSIX-compliant filesystem layer. The initialization routine first performs a structural integrity check on the configuration file. If the file is found to be empty or malformed, the system defaults to legacy mode, in which outputs are selected from a hardcoded static array using deterministic logic, as discussed in Section II. Conversely, when valid user-defined entries are detected, the framework parses the data upon receiving the NLP model's matching key combination. It maps it into a three-dimensional array, designated as a[x][y][z], where x indicates the number of configurations, y represents individual data fields (such as hotkey, endpoint, API token), and z specifies the character buffer allocated for each field.

For example, a configuration entry such as:

CTRL+ALT+G == [serviceName: GPT2, endpoint: https://api.example.com/gpt2, token: your_token_here]

Is stored in the array as follows:

- a[0][0]: Hotkey identifier (CTRL+ALT+G)
- a[0][1]: Model name (GPT2)
- a[0][2]: API endpoint URL
- a[0][3]: Authentication token

This data is subsequently referenced during runtime to dispatch model-specific API requests in response to user-defined hotkey events.

In addition to array-based data management, the system supports a modular configuration model that leverages JavaScript Object Notation (JSON) for serialization and deserialization [20]. JSON offers interoperability across multiple programming languages and ensures backward compatibility with web services. This dual-format support, with array-based low-level access and JSON for high-level abstraction, enhances the system's portability and extensibility across diverse environments.

Designed to operate in headless mode, the framework's main thread continuously intercepts and processes keystroke data from the hardware abstraction layer (HAL) without relying on graphical elements. Memorable hotkey sequences, such as CTRL+ALT combined with an alphanumeric trigger key, are intercepted via a low-level keyboard hook. If no special key is

pressed, input is evaluated against a static input-response map (Section II). When a trigger combination is detected, the framework performs a sequential scan through the array index a[x][1] to locate the appropriate service descriptor. Upon a successful match, it retrieves the associated serviceName, endpoint, and token, thereby enabling dynamic model switching.

This design enables users to switch effortlessly between multiple NLP backends (such as GPT-2, BERT, spaCy, and Google Gemini) by simply editing the hotkey configuration file and activating the relevant key combination. The modular and extensible nature of this configuration-based approach not only simplifies deployment but also facilitates real-time inference management across various AI engines.

Once an appropriate Natural Language Processing (NLP) model is selected and configured, the system enters a passive monitoring mode, continuously running in the background to intercept and log the user's keystrokes. The framework uses a low-level keystroke listener, often implemented via OS-level hooks or input stream interception (e.g., SetWindowsHookEx in Windows or XRecord in Unix-based systems) [17]. This enables the system to monitor input events without interfering with the user interface or application foreground processes.

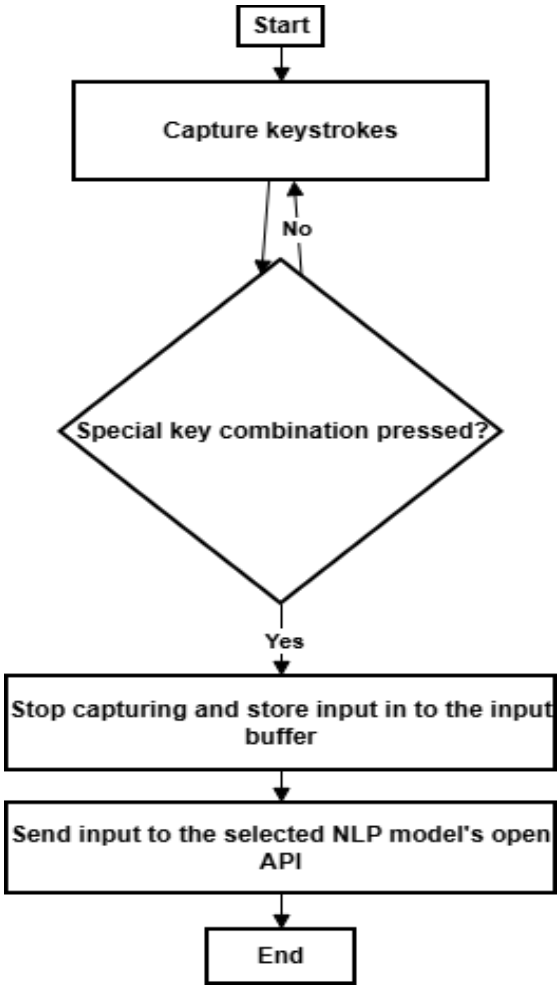

Fig. 4. Send keystrokes to NLP model.

As shown in Fig. 4, the captured string input is transmitted to the selected NLP model endpoint via an OpenAPI-compliant HTTPS request that includes an authentication token to validate the session. These requests are typically handled using lightweight client libraries, such as Axios for JavaScript or libcurl for C++ environments, which support asynchronous communication and robust error handling [15], [16].

The raw answer from the NLP model's inference is presented to the user, and the text is normalized and post-processed. During this step, control characters, special Unicode encodings, and formatting artifacts (such as escape sequences or HTML tags) are discarded to ensure the output conforms to human-readable formatting principles. These changes may be performed using natural language preprocessing libraries or custom sanitization routines to improve the clarity and readability of the output text [25].

After receiving the model's response, the framework dynamically injects the generated output into the user's active application window, using programmatic virtual keystroke generation at the cursor to render the results without modifying the application itself, as shown in Fig. 5.

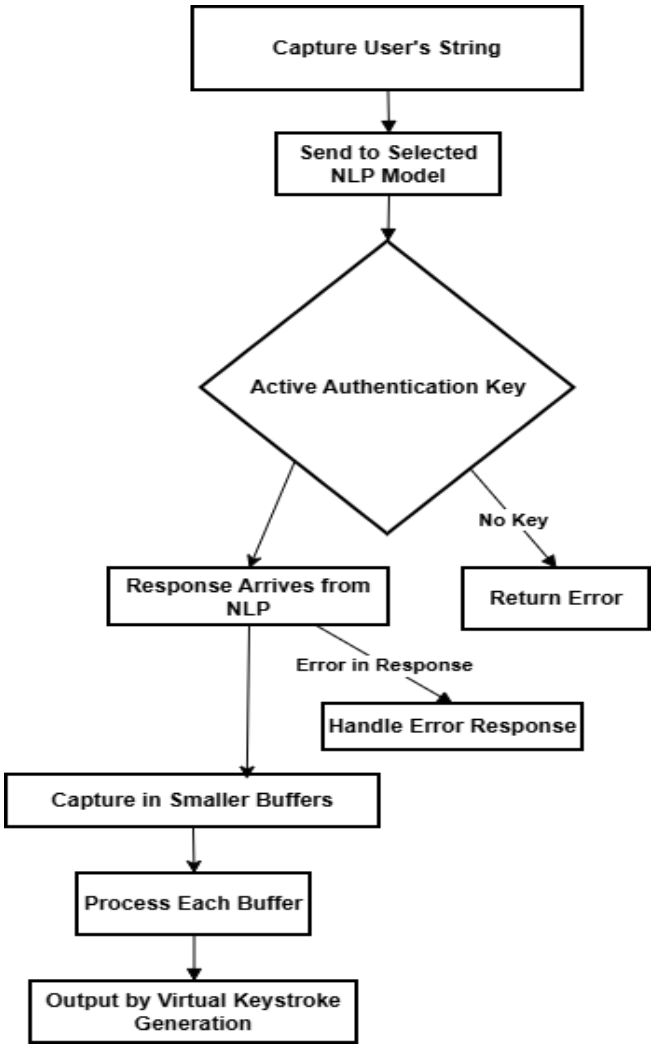

Fig. 5. NLP response to virtual keystroke.

To demonstrate in a real-world scenario, the researcher has simulated an interaction between a user and the GPT-4 model in a standard text editor such as Notepad. Once the program is initialized, users can start typing as usual. The framework remains locally held in memory, capturing all provided written prompts via capturing keystrokes, converting them into a string, and feeding them into the chosen NLP engine. The output is then fetched and formatted via the system and reinserted into the editor as it happens. The generated text is shown below in Notepad, providing both a context-aware interaction experience and an intuitive experience between the traditional input method and modern AI-based language models.

To illustrate the practical implementation of this feature, a scenario is presented in which a user interacts with OpenAI's GPT-4 model via a conventional text editor such as Windows Notepad. After the framework is initialized, it enters a persistent resident mode and operates as a background process. As the user types, the system captures keystroke sequences, processes them as input prompts, and dispatches them asynchronously to the selected NLP endpoint.

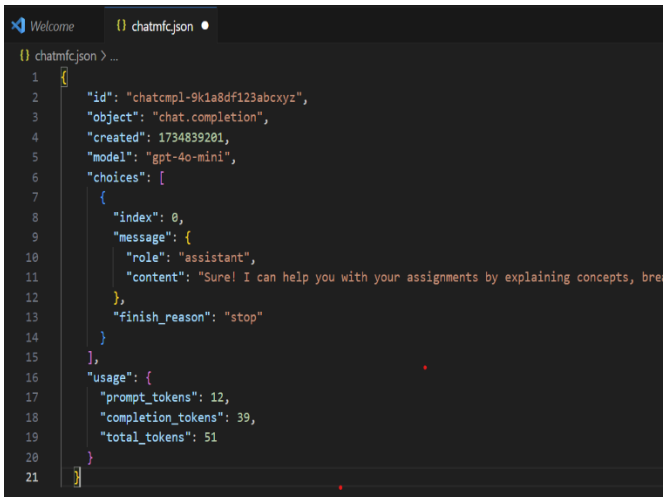

Fig. 6. NLP JSON response to Open-AI.

Upon receiving the model's inference, the framework formats and injects the generated text back into the editor in real time via synthetic keystroke generation. The Fig. 6 shows the JSON response from the NLP server.

Subsequently, the framework triggers a keystroke injection routine using platform-specific input simulation libraries (e.g., Win32 API SendInput) [3]. The output is programmatically written back into the user's active application window, preceded by the ">>" symbol to denote system-generated text. Upon completion of the full response rendering, the system appends a final status marker:

This marker serves as a visual delimiter to indicate the end of model-generated output, enhancing usability and separating AI responses from subsequent user input. In Fig. 7, the NLP response was directly key-stroked in Microsoft Windows Notepad.

A similar result can be achieved using any of the available platforms, such as Microsoft Word, sticky notes (as shown in Fig. 8), in-browser live chat, the Visual Studio Code editor, and many more.

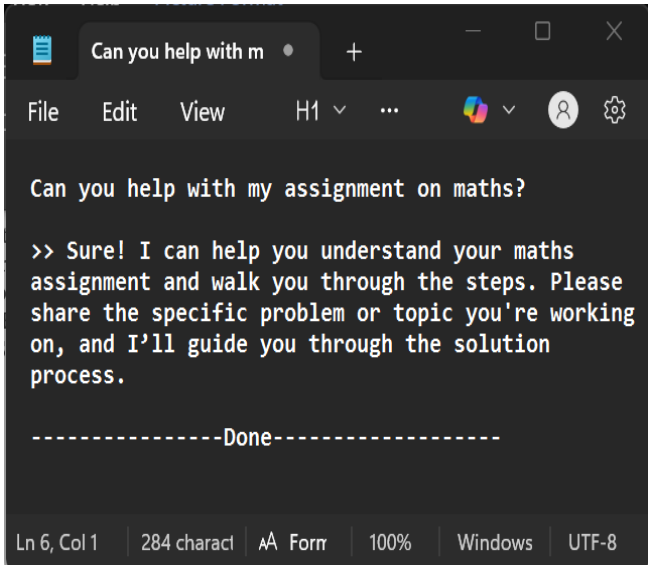

Fig. 7. NLP response in Notepad.

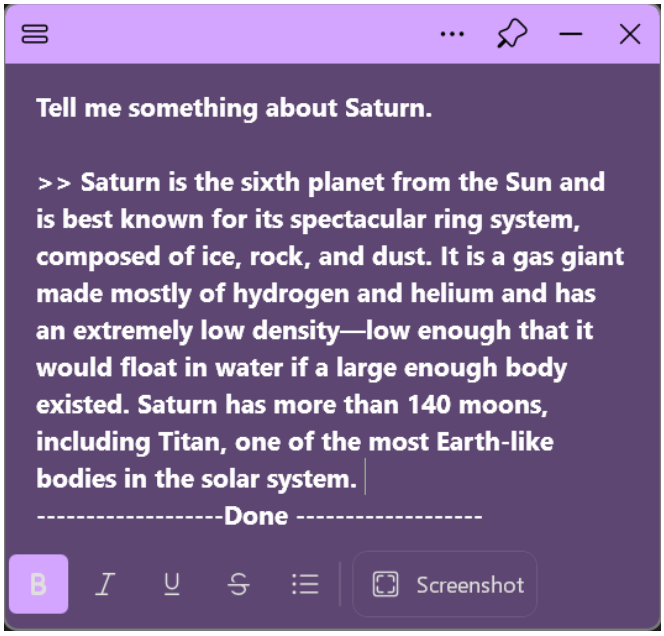

Fig. 8. NLP response in sticky notes.

Similarly, it works with any available text editor, even a browser. The user does not necessarily need to open a text editor; pressing keys on the keyboard can be registered and produce a response at the cursor point.

III. Multi-AI Orchestration via An Interface-Less Model

Within the interface-independent integration framework, you can run these heterogeneous AI assistants in parallel, combining the strengths of various natural language processing (NLP) models and task-specific intelligent agents into a single operational pipeline. Unlike existing NLP engines that focus on context-aware, text-based answers to users' queries, other AI

assistants enable procedural, action-oriented automation. These particular agents can undertake deterministic computations like intelligent scheduling, habit and routine orchestration, multi-calendar synchronization, and workflow optimization, using rule-based reasoning and machine learning-backed event prioritization [26].

By coordinating these capabilities without the constraints of a graphical interface, the system facilitates seamless interoperability, enabling composite AI-driven solutions that extend beyond conversational interaction into fully automated operational ecosystems. Several intelligent personal assistants have been developed in recent years, including OpenAI's ChatGPT [27], Google Gemini [28], Microsoft Copilot [29] and Amazon Alexa [30], Each is leveraging advanced artificial intelligence and natural language processing to interact with users and perform tasks efficiently.

A. Conventional Method to Assist the User

Earlier implementations have incorporated predefined, task-oriented commands to facilitate user interaction in general-purpose computing settings [31]. Available literature presents batch scripting techniques and Windows Command Prompt (CMD) utilities for performing context-specific operations, including opening applications, accessing files, and controlling the system [32]. This capability was implemented using a keyword-to-command mapping schema, in which user-entered input tokens were programmatically matched to shell commands stored in a persistent configuration file (as described in Section 1.2).

For example, the command mapping file may contain entries such as:

Open notepad == start notepad

Open chrome == start chrome

Open wordpad == start wordpad

Open file1 == start c:\file1.txt

shutdown == shutdown /s /t 0

shutdown_5 == shutdown /s /t 300

recordaudio == start SoundRecorder.exe

A user types a command string like "open chrome" into some interface, which the system captures the keystroke stream, parses the first keyword ("chrome"), and searches the mapping file for a corresponding match. The shell command retrieved is then run through the "system()" function of C++ and passed to the operating system's native command processor [33]. Such a methodology enables both immediate (in real time) and delayed (e.g., initiating a shutdown after 300 seconds upon detecting shutdown_5) operations.

In addition to launching applications, it supports auxiliary batch script utilities for hardware-level interfaces, like generating audio/video recording subsystems within Windows operating systems. For example, when RecordAudio is run, SoundRecorder.exe is launched to capture sound for a fixed period. This utility can be used differently depending on the operating system and programming language.

This traditional assistance framework expands its scope to include security-critical automation, enabling it to trigger keystrokes for specific protective actions. As shown in the authors' prototype, threat-detection keywords are stored in the command mapping file. When typed, either intentionally by the owner or accidentally by an unauthorized user, the system activates a security protocol that captures audio and video streams, encrypts or locks private directories, and executes a coordinated shutdown [34], [35]. Such mechanisms provide a low-latency, interface-independent safeguard against potential data breaches by leveraging event-driven command-execution pipelines without requiring GUI intervention.

B. AI Model-based Assistance in One Place

As outlined in Section I, state-of-the-art Natural Language Processing (NLP) models have been successfully implemented to provide domain-specific services across various application sectors [1], [2]. Building on the traditional keystroke-capture-and-trigger method discussed earlier, the framework combines multiple AI-driven service modules into a single, interface-independent environment. This design allows users to access various AI Assistance-based features simultaneously without being limited by application-specific GUIs or platform constraints. [2].

While NLP models primarily focus on generating semantically coherent responses to text-based queries, AI assistance agents are typically trained and configured to execute context-aware actions within browser environments, operating systems, or hybrid computing ecosystems [36]. For example:

1) Motion: An AI-driven scheduling engine for dynamic task reprioritization and meeting rescheduling based on real-time availability constraints [37].

2) Clockwise: A temporal resource optimization system designed to protect focus time and reduce meeting fragmentation [38].

3) Reclaim.AI: A buffer-creation and automated rescheduling assistant for time-block management [39].

4) Google: Workspace-based automation tools for integrated email handling, calendar synchronization, and cross-application task execution [40].

Whilst these tools will each provide a specific functionality in a proprietary or web-based environment, Open APIs (Application Programming Interfaces) offer a standardized path for integration. In the proposed system, API credentials and endpoint configurations are kept in encrypted configuration files (described in Section II). An identification keystroke triggers each AI assistant. The system captures an event when the user enters a pre-defined keystroke sequence, resolves the mapping to the corresponding API call, and transmits the request payload to the assistant's open API endpoint over HTTPS using RESTful API protocols [15], [16].

Direct task orchestration doesn't require an intermediary GUI. For example, typing in the command:

"Send a Thank You email to xyz at 13:00"

would push the corresponding AI assistant API to schedule execution, achieving prompt execution with asynchronous

processing guarantees and secure API key or OAuth 2.0 token authentication [41].

This centralized AI model orchestration framework combines multiple automation pipelines, such as scheduling, communication, and system-level operations, using a unified, low-latency, event-driven command-processing architecture. This utility can be set up in the same way as other commands. For example, the system utilizes AI-assisted scheduling via an open API to automate email scheduling. All it needs is to set up the user's email and other prerequisites. Then, this keystroke-based command can be sent to the open API of the AI assistance, and it will schedule the email [32].

The system enables the currently running AI assistant to schedule email transmission at a specified time using keystroke input. Another example is ordering dinner or telling the assistant to order a pizza from a particular restaurant in a specific size at a specific time. Now, using the method described in Section I, the User can switch the AI assistance model with key strokes and use different assistance services in real time, just like NLP models.

There are several AI assistants available that offer open APIs to help developers utilize them programmatically. Each assistant is specialized and already trained to perform different tasks efficiently. Details for these open APIs can be added to the settings file and easily triggered and used with a single keystroke combination.

To demonstrate the practical use of the proposed framework beyond productivity tasks, consider automating a food delivery request, like ordering a pizza. Usually, this process involves users navigating a vendor's website or mobile app, selecting items, entering delivery information, and completing the payment, or, if using AI assistance, opening their application or website, writing the prompt and details, waiting for the order response, and then switching back to their working window. With an AI assistant integrated via Open API endpoints, these steps can be performed programmatically with minimal user effort. After selecting the appropriate model via a combination of keystrokes, the user can type the prompt anywhere, and it will be executed.

In practice, the system leverages natural language parsing and intent recognition models to capture the user's request. For instance, a keystroke trigger such as:

"Order a large pepperoni pizza with extra cheese from Domino's at 7:30 PM."

Would be intercepted by the framework's command mapping module and mapped to the corresponding Domino's API (or an intermediary food delivery platform API such as Uber Eats or DoorDash. An AI assistance model will do that by itself in the background.

The AI agent translates this natural language request into a structured JSON payload containing attributes such as:

- restaurant_id (e.g., Domino's)
- item_id (e.g., large pepperoni pizza)
- customization (e.g., extra cheese)
- delivery_time (e.g., 19:30 hours)
- payment_token (securely stored OAuth 2.0 or PCI-DSS-compliant token).

The payload is then sent via a RESTful POST request to the vendor's ordering API. Once authenticated and validated, the system sends a confirmation response that the AI assistant may display to the user as a text notification. Then it can be generated at the user's cursor point via keystroke generation. (e.g., "Your pizza order has been scheduled for 7:30 PM").

From a systems perspective, this workflow illustrates that task-oriented AI assistance not only automates systems but also extends to delivering real-world, consumer-facing services. The same event-driven orchestration pipeline, keystroke capture, intent parsing, API mapping, response handling, and so on, simplifies automation of productivity tasks (such as calendar scheduling) and lifestyle tasks (like food delivery), highlighting the versatility and extensibility of the proposed system architecture [42], [43].

IV. Leveraging NLP in the Present Interface-Free System

A. Evolution from Static Mapping to AI-Driven Interaction

The ability of this model to adopt a specific pattern has been a consideration in earlier models, which explored rule-based mappings in which a predefined set of user inputs produces deterministic outputs, and this was the starting point of the proof-of-concept work [2]. Early systems in the field, while limited by scalability, were a good way to demonstrate keyboard-controlled automation of user assistance. Based on the framework mentioned above, this research encompasses next-generation transformer-based Natural Language Processing (NLP) architectures (GPT-2 and BERT, in particular) with open-access APIs and open-source libraries. This transition from hardcoded mappings to context-aware, generative AI architectures massively enhances the adaptability and, hence, robustness of human-computer interactions [8] [9].

Furthermore, the system now supports language inference via tokenized input processing, dynamic prompt engineering, and response conditioning, allowing it to handle open-ended tasks beyond fixed templates. These advancements facilitate the transition from static to semantic-level understanding, aligning the system's capabilities with modern NLP standards [44].

B. Augmented User-Centric Functionalities of MLP-based Frameworks

1) Offline response caching and persistent knowledge storage: One key enhancement in this research is the local caching of AI-generated responses for offline use. This capability addresses a critical limitation of cloud-based NLP models, which typically require uninterrupted internet access. The system enables selective storage of high-utility content, including commonly queried definitions, domain-specific formulas, unit conversions, standardized datasets, and language-dictionary-based questions, in JSON or CSV formats. If the User generated the prompt without internet access, it will look in the cache for similar keywords and create a response

that matches the best at the cursor position. (This procedure for the keyword matching and generating a response is already explained in reference [2].) These cached assets can be accessed via background threads or scheduled jobs, ensuring that offline inference remains feasible even without invoking remote APIs [45].

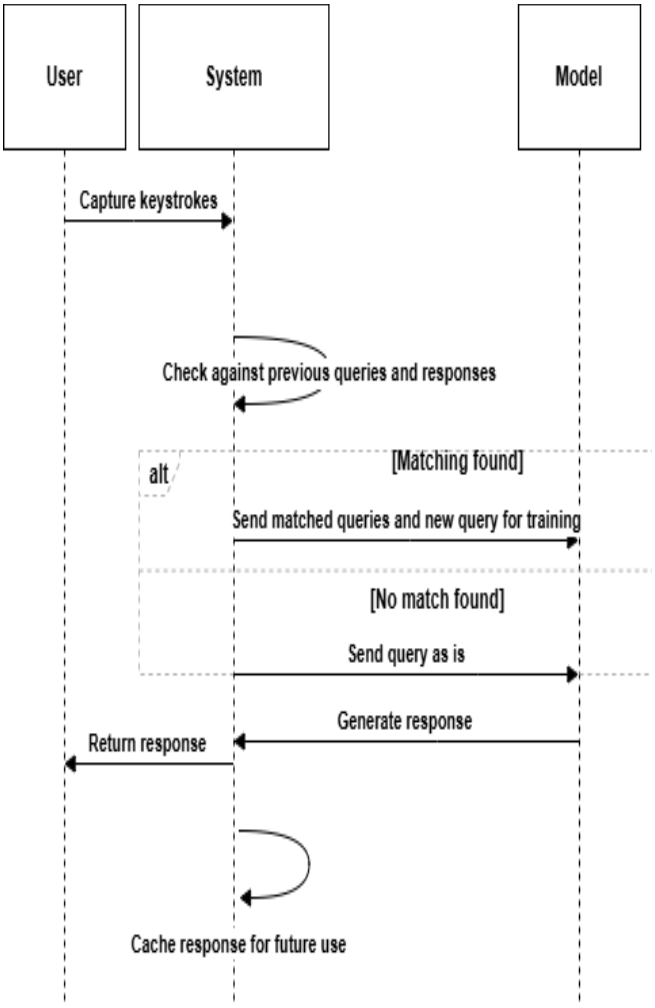

Fig. 9. Cached data to train the model.

This approach aligns with principles of edge AI, where inference and computation are offloaded to local devices to reduce latency and dependency on external networks, thereby enhancing both resilience and real-time performance [46].

2) Using the cached data to train the existing model: As discussed in Section II, when a special keystroke combination is met, the child thread starts the cached base operation. All caching will be stored on the User/Developer's local device and used only with authorized permission to generate a more accurate prompt via connected NLP models. It can be stopped at any time by pressing the special key combinations again.

It can be stored in the same format as a multi-dimensional array mentioned in Section II above, or in JSON format, depending on the programming language selected to develop the tool. Still, the flow of the operation will be the same.

Once the user starts using the tool, it begins capturing their keystrokes. When the hotkey is pressed, it registers the sequence of keystrokes as query sentences. It can submit queries to different open-source AI models and receive responses. As illustrated in Fig. 9, every time a query is made by pressing the Enter key, it is checked against previously cached questions (Only after the user activates the cache-based system via a special key combination, which is set at "start cached" and "stop cached", later users can change it via config file) and responses; if the sentence structure or keywords match, it is noted that this may be a similar request. (sentence matching algorithm is provided in [2]). Then the previous response will be sent along with the query to train the specific model to generate a response that matches the last successful pattern. If no match is found, the query will be sent to the open-source API as-is.

Once the framework's thread finds a matching cache activation combination, it will activate the program's other child thread(loop). This thread is responsible for matching strings from the previous response, sending the matched cache along with the new request, and storing the input and output. If the user presses the same combination again, the thread will stop this loop, and no cache will be sent or stored from that point.

3) Cross-application language support and system-wide paraphrasing: The framework also proposes application-agnostic language support, including real-time spelling correction, semantic synonym generation, language translation, and context-sensitive paraphrasing. Conventional implementations are for word processors (e.g., Microsoft Word or Google Docs, typically via plugins or macros). In comparison, this system works in the background at the OS level, where text is intercepted from any active application window and routed through NLP APIs [2], [47]. For example, users who write emails in Thunderbird and take notes in Sublime Text will receive AI-generated paraphrases or vocabulary recommendations without installing software-specific extensions. Like OS-level accessibility services, this architecture ensures uniform NLP augmentation across a broad spectrum of user applications and workflows.

4) Behavioral biometrics and typing pattern-based security: Beyond usability, the proposed system incorporates a lightweight, AI-driven keystroke dynamics monitoring module that passively analyzes a user's typing biometrics in real time. This component captures parameters such as keypress duration, inter-key latency, and frequency patterns to establish a unique behavioral fingerprint [48]. These learned patterns can be frequently used sentences and stored keywords from the cached memory and the config file. The child thread will continue matching the pattern once started via a special key combination. If anomalous input sequences deviate from the learned pattern, a security submodule is triggered, which may execute actions such as user alerts, session locking, intrusion logging, or system shutdown, as per Section III.

This implementation is inspired by research in behavioral user authentication and continuous identity verification, which have been applied in domains such as secure terminals, financial systems, and high-stakes editorial workflows [49]. Integrating

this with an NLP interface enables intelligent, non-intrusive surveillance, adding a security layer that is particularly beneficial to journalists, academic writers, and researchers handling sensitive or original content.

To mitigate the risk of capturing sensitive user inputs such as passwords or confidential credentials, the proposed framework incorporates application-aware filtering mechanisms that identify protected input fields based on standard UI attributes, including masked or secure text-entry indicators. Input interception is selectively suspended when interactions occur within recognized password or secure-entry contexts, ensuring that sensitive data is neither processed nor transmitted to external inference services. In addition to automated filtering, the framework provides a user-controlled pause and resume mechanism that allows monitoring to be temporarily disabled through predefined commands [2] (e.g., typing a pause trigger), enabling users to manually suspend input capture during interactions involving sensitive information or private credentials.

With respect to the behavioral protection layer, the biometric keystroke analysis module operates on anonymized keystroke dynamics features such as typing rhythm and latency patterns without retaining raw textual content. The performance of this layer is influenced by variability in individual typing behavior and environmental conditions, which may result in occasional false-positive or false-negative classifications during anomaly detection. In the current implementation, the biometric layer is intended to function as a supplementary risk-assessment mechanism rather than a primary authentication system. Further evaluation of classification thresholds and adaptive behavioral modeling is identified as an area for future work to improve detection accuracy and minimize unintended behavioral misclassification.

5) Additional applications and future-scalable extensions: To broaden the scope, several novel use cases are proposed or in development:

- AI-augmented Integrated Development Environments (IDEs): Automatic code snippet insertion, real-time explanation of programming constructs, and citation generation using NLP models like Codex or CodeBERT.
- Education Platforms: Adaptive learning assistants that dynamically rephrase explanations or suggest learning resources in response to student queries.
- Legal and Medical Transcription: Real-time conversion of typed input into domain-specific legalese or medical jargon using fine-tuned Large Language Models (LLMs).
- Multilingual Operating Systems: Automatic translation of input text into target languages on-the-fly for bilingual users, with support for right-to-left (RTL) and logographic scripts.

These future extensions illustrate the potential for a modular AI service layer across personal computing environments, where diverse domains can benefit from real-time, context-aware, NLP-powered interactions.

V. Current Limitations and Room for Improvement

Although the proposed method demonstrates how traditional user-selected IDEs can be enhanced with AI-driven intelligence through keystroke-level interactions, some technical issues remain. First, when generating synthetic keystrokes, words with repeated characters (like “small,” which has a double "l") can sometimes be misread by the keystroke emission module. In some cases, the system registers only one keypress event, resulting in outputs like “smal” instead of the correct “small.” This issue occurs due to event coalescing behavior when rapidly dispatching key events, a known challenge in low-level input simulation frameworks.

Second, if the NLP model produces a lengthy or complex response, the generated ASCII sequence might exceed the active processing buffer's capacity. This can cause the buffer to fill up, which may slow performance or, in severe cases, crash the main thread responsible for capturing system events and generating keystrokes. Similar buffer overflow and thread-blocking issues have been observed in asynchronous I/O systems and event-driven input pipelines.

Both of these limitations can be addressed in future versions of the system by implementing a segmented buffering strategy combined with asynchronous queuing algorithms for keystroke storage and controlled output. Using dynamic buffer allocation, non-blocking queues, and per-character acknowledgment techniques can help manage repeated-character sequences effectively and prevent overflow during significant responses.

Although operating system-level input hooks are supported across major platforms such as Windows, macOS, and Linux, their practical implementation differs due to variations in security policies, event-handling frameworks, and permission models. For instance, Windows environments allow programmatic access to input simulation through system calls such as SendInput(), whereas macOS requires the use of Quartz Event Services with additional accessibility permissions for event interception and synthesis. Similarly, Linux-based systems rely on mechanisms such as X11 or Wayland input subsystems, which may impose sandboxing or privilege restrictions. These platform-specific differences can influence the deployment and operational behavior of keystroke monitoring and simulation modules within the proposed framework. A comprehensive cross-platform implementation strategy, accounting for OS-level constraints and permission requirements, remains an area for future investigation to enhance the portability and robustness of the system.

VI. Future Scope

In the proposed framework, users can dynamically switch among multiple AI and NLP models to leverage their distinct functional advantages. Each model offers specialized capabilities optimized for specific linguistic or contextual tasks. Future enhancements aim to incorporate adaptive analytics modules that autonomously select the most appropriate model based on the user’s active application context and ongoing workflow. This adaptive orchestration will enable real-time utilization of heterogeneous AI agents, thereby enhancing overall system efficiency and contextual responsiveness.

Beyond its current capabilities with open-source NLP models, the proposed framework presents significant potential for the development of personalized AI assistants. Future extensions of this work will focus on enabling the assistant to learn individual user behavior, task preferences, and interaction patterns over time. By leveraging adaptive learning techniques, the system can evolve into a user-specific intelligent agent capable of autonomously handling routine daily activities, providing contextual recommendations, and optimizing task execution based on personal workflows.

Moreover, future research will explore the integration of behavior-aware security mechanisms within personalized assistants. By modeling normal user interaction patterns, the system can detect anomalous activities and initiate preventive actions, thereby strengthening protection against unauthorized access and data misuse. Such advancements will transform the framework into a comprehensive, user-centric AI ecosystem that combines intelligent automation, personalization, and proactive security.

VII. Conclusion

The proposed interface-agnostic AI integration framework allows diverse NLP models and AI-based assistants to work smoothly without any traditional graphical user interfaces. It demonstrates how intelligent automation can be integrated into user workflows through low-level input monitoring, standardized communication protocols, and secure API orchestration. This minimizes reliance on platform-specific plug-ins or standalone tools to optimize task execution and user productivity. Moreover, AI-assisted decision-making with context-aware keystroke interpretation introduces a new approach to adaptive computing that learns user intent and automatically summons the appropriate AI model for a given task. This architecture is modular, secure, and scalable enough to support ever-evolving AI ecosystems and open APIs. It's possible to further expand this framework with improved cross-device synchronization, advanced behavioral analytics, and self-optimizing task delegation to make it accessible across enterprise and personal computing environments in future iterations. This work adds a valuable insight to the ongoing evolution of intelligent human–computer interaction by bridging traditional input processing with contemporary AI-driven automation.

DIVIJ H PATEL was born in Nadiad, Gujarat, India, in 1995. He received the B.E. degree in Computer Engineering from Gujarat Technological University, Gujarat, India, in 2017. He has pursued the postgraduate certification in Information and Communication Technology Solutions for Small Businesses at Confederation College, Thunder Bay, ON, Canada.

During his undergraduate studies, he conducted research in several areas of computer science and engineering. He has published three research papers in international journals, including "Spyware Triggering System with the Particular String Value" and "Multipurpose Reminder System" in the International Journal of Engineering Research and Development, and "Copy-Paste Command with Additional Facilities" in the International Journal of Computer Applications, New York, USA.

He has filed three patents with the Indian Patent Office covering innovations in wearable devices and human–computer interaction. His patented works include the Smart Wearing Cap Device, a method for Assigning Shortcut Keys, and the Folding Calculator. His research and innovations have also been featured in newspapers and television media such as Gujarat Samachar, Sandesh News, Vichar Kranti News, DNN Link News Channel, and VTV News.

Best Practices to Train Accurate Deep Learning Models: A General Methodology

Alberto Nogales*, Ana M. Maitín, Álvaro J. García-Tejedor
Center for Studies and Innovation in Knowledge Management (CEIEC), Francisco de Vitoria University, 28223 Pozuelo de Alarcón, Spain

***Abstract*—In recent years, the field of computer science has experienced great changes due to the incredible advances in the field of artificial intelligence. Deep Learning models are responsible for most of them since the biggest milestones occurred in 2012 when AlexNet won the image classification challenge called ImageNet. These models have demonstrated great performance in different types of complex tasks like image restoration, medical diagnosis, or object recognition. Their disadvantages are related to their high data dependency, which forces experts in the field to follow a precise methodology to obtain accurate models. In this study, we describe a complete workflow that begins with the management of the raw data until the in-depth interpretation of the performance of the models. This should be taken as a high-level consultation document describing good practices that should be applied. Apart from the step-by-step methodology, we present different use cases that correspond to the two main problems of the field: classification and regression.**

***Keywords*—Methodology; artificial intelligence; deep learning**

I. Introduction

If we talk about what has been one of the biggest advances in recent history, we must talk about the revolution of artificial intelligence (AI). AI is the domain within computer science that analyzes and interprets the processes underlying intelligent actions in humans, aiming to replicate these actions in machines, not always employing the same mechanisms [1]. These advancements have been fostered by two main factors. First, the creation and availability of large amounts of data have never been seen before. Second, the affordable price of hardware to compute this data and train the AI models.

But if we must talk about the milestone in the modern AI era, we must talk about Deep Learning (DL) models. This is a family of models whose term was coined in 2006 by Hinton. They are defined as multiple-layer models using hierarchical Artificial Neural Networks (ANNs) with the capacity to progressively learn data representations, beginning with the input data and advancing to higher levels of abstraction [2]. Its biggest milestone occurred in 2012 when AlexNet was the first DL model that won an image classification challenge called ImageNet [3].

Deep Learning models have been demonstrated to have high performance in solving many different complex tasks. Nevertheless, some weaknesses face any expert in the field constantly, such as poor interpretability, data dependency, or lack of generalization in a broad range of datasets. The last two, apart from being interrelated, are common to all the implementation workflows of these models. Normally, large amounts of data are needed to train accurate models, but there is also a need to generalize and avoid overfitting. The latter is described in [4] as the situation in which the model learns characteristics associated with noise or variability within the data, rather than the fundamental distribution of the training data. So, avoiding overfitting is the main condition to obtain a model that performs well generalize.

Overfitting is tested at the end of the process of model training. At this point in the process, different measures of a metric are compared, corresponding these values to the different sets into which the data in origin is split. The success of the training process depends on different decisions to be taken, which are related to the type of problem to be solved, the nature of the data, and other conditions. The large number of decisions to take and the lack of knowledge about what they depend on have allowed the publication of papers where the overfitting of the models is noticeable. The motivation of this study is to compile and explain step-by-step how to perform accurate processes to train Deep Learning models.

The work aims to provide resource information for researchers so they can know which steps to apply and understand them. This will be very useful for scientists without a deep understanding of deep learning terms. In the case of experts in the field, they could have a guide of best practices to follow. In this sense, the main contribution is to compile in a single document the explanation of each step. It will not only describe the method step-by-step, but we will also provide why each step is necessary and how to apply it depending on several conditions, such as the use case to solve or the type of data. As we want this study to be accessible to any researcher interested in the field, we are providing a high-level explanation of terms, strategies, etc., with only basic mathematical formalization.

The rest of the study is organized as follows: Section II describes all the antecedents of the DL field, so a general idea of different terms could be obtained, with the possible applications DL could have. Section III explains step-by-step the proposed methodology to obtain accurate models. Section IV shows different use cases where the methodology is applied. Finally, Section V compiles different conclusions related to what has been explained in the work.

II. Antecedents

DL models are very diverse, with their performance tied to the nature and quality of the training data. This section explores the different models used in the field. Fig. 1 shows the hierarchical organization of these models depending on the way

*Corresponding author.

they learn. An in-depth description of the models will be given later.

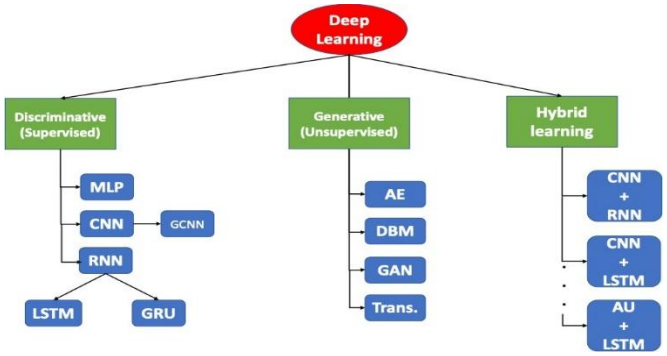

Fig. 1. Classification of Deep Learning models based on their different training strategies.

DL models are first categorized based on their approach to learning from data (training stage), which includes supervised and unsupervised methods. The first category corresponds to those using labelled data for training, where the model understands the relationship between input data and expected output, which is a discriminative task.

The Multilayer Perceptron (MLP) represents the most basic form of a DL model. Its architecture consists of an input layer, multiple hidden layers, and an output layer. It is typically used to predict a particular numeric value, but classification problems can also be solved, for example, [5]. Take the benefit of using MLPs to predict the density of 48 refrigerant systems.

Convolutional Neural Networks (CNNs) stand out as one of the most used models, particularly in computer vision applications [3]. Their primary strength lies in their capability to detect patterns in a spatially invariant manner. This characteristic enables them to recognize specific structures in an image, regardless of their location. More recently, there has been a development of a specialized type of CNN known as Graph Convolutional Neural Networks (GCNNs). Introduced by [6], GCNNs are designed to process graph-structured data. This model encodes both the structure of a graph and the features of its nodes. Examples of the application of these models can be found in the following papers [7], where CNNs are used for the automated assessment of damage type and severity in wooden structures [8], and a GCNN model is used for identifying essential genes in organisms.

Recurrent Neural Networks (RNNs), as defined by [9], employ an input vector of variable length and recursively apply a transition function to their internal hidden state vector h_t. They are particularly useful for time series data structures. Within the family of RNNs, there are two specific subtypes known as Long Short-Term Memory (LSTMs) and another called Gated Recurrent Units (GRUs). LSTMs, introduced by [10], were devised to effectively handle noisy or ambiguous input data. The study [11] is an example where RNNs are used for the task of stock prediction.

The other prominent set of models falls under the unsupervised training category. In this scenario, the data has no labels, and there is no prior knowledge regarding the results of performing generative tasks [12].

Deep Autoencoders (DAEs) apply unsupervised learning. First described by [13], they are characterized by having input and output layers of the same or similar size, along with two processing modules. The first structure, the encoder, takes the input data and compresses it to a smaller representation containing its essential features. The second structure, the decoder, aims to reconstruct the original input data by upsampling the compressed representation until it reaches the size of the input data.

Restricted Boltzmann Machines (RBMs) are regarded as a specific form of Autoencoder, initially proposed by [14], capable of learning probability distributions. RBMs have been employed to construct Deep Boltzmann Machines (DBMs), as stated by [15]. In [16], Autoencoders are used for segmenting teeth in Intra-Oral 3D Scans.

A particular and very well-known Autoencoder is Transformers, which are models that avoid recurrence and exclusively rely on an attention mechanism to establish global dependencies between input and output [17]. This type of model is used by [18] for the prediction of risk in cardiovascular diseases.

By combining the previous learning types, it creates a new category known as semi-supervised learning. Within this classification fall Generative Adversarial Networks (GANs). GANs comprise two neural models: the generator and the discriminator, operating in an adversarial training paradigm [19]. This architecture aims to understand and replicate a given data distribution. The generative model tries to generate synthetic instances of the input data, while the discriminator assesses these instances to determine their similarity to the input data. This adversarial process provides a probability of authenticity for each instance, distinguishing between input (authentic) and synthetic (generated) data. Through iterative refinement, the generator learns to produce data that increasingly resembles the input data. In [20], the authors implement a GAN model to translate RGB images into IR ones for fire forest monitoring.

In recent years, a trend has emerged within the field of deep learning: the development of hybrid models. These models are considered important for future advancements in DL. They combine two or more distinct architectures, such as CNN-LSTM or Autoencoder-LSTM, [21] and [22].

III. Introduction Methodology to Train Deep Learning Models

In this section, the methodology to obtain accurate DL models is described in depth. The process has been divided into different steps, adding the best practices and an explanation about how they should be applied. It begins with having the dataset raw related to a use case to solve with it. Then, deciding which DL model fits better until the obtention of a set of accurate metrics that avoid generalizes. Finally, ending with an interpretation of the models using other metrics and making a comparison with some baselines.

A. Deciding What Deep Learning Model to Use

The first decision to be taken when solving a DL problem corresponds to choosing a suitable model. Considering what has

been described in Section II, the different DL models that can be applied depend on the nature of the data and the use case to be solved. If we talk about the different use cases, there are also many applications, but all of them can be classified into two main types: classification and regression. Belonging to one group or the other will have consequences, as will be described later, in the metrics used to measure the performance of the model. Classification problems consist of building a model that links the attributes of the instances, typically represented as attribute-value pairs, to the corresponding class labels [4]. Regression problems aim to predict the value of a dependent variable based on one or more independent variables, [4]. Typical classification problems in DL are image classification or disease diagnosis. Within the regression problems group, we have time series prediction and object detection.

Due to the wide range of models and use cases, this decision has multiple solutions. We provide a general vision about how to choose the proper DL model. Table I compiles information on the different models, the type of data used to train them, and the typical use cases to solve.

TABLE I. SUMMARY OF DL MODELS USED, TYPE OF DATA AND APPLICATIONS.

Model type	Nature of data	Use case
MLP	Tabular data	Prediction of a continuous value
CNNs	Image data with spatial relationships	Image Classification, Object Detection, Segmentation
GCNNs	Data represented as graphs or networks	Graph-structured Data, Social Network Analysis
RNNs	Temporal sequences, sequential data	Sequential Data Modelling, Time Series Prediction
Autoencoders	Unlabelled images	Data Compression, Denoising, Anomaly Detection
Transformers	Sequential data, particularly text data	Language Translation, Text Generation
GANs	Often images, but can be applied to other domains	Image Generation, Style Transfer, Data Augmentation
DRL	Sequential decision-making tasks with rewards	Game Playing, Robotics, Autonomous Systems
Hybrid models	Mixed data types or tasks	Multiple types of data/modalities or tasks

B. Splitting the Dataset into Train, Validation, and Test

As has been said before, to obtain a Deep Learning model that performs well, we need to avoid overfitting. Model testing, which consists of checking how a trained model performs with new data never seen before, is the way to prevent it. For this purpose, first, there is a need to split the data into three sets: training, validation, and test.

The training set shows instances of the model so it can be adjusted to generalize its distribution. The validation set measures the accuracy of the model based on the errors obtained. The test set is used to check the capacity of the model to generalize by using data never seen before.

So, the first decision to be taken is the percentages used to create the three sets. A typical criterion is based on the Pareto principle, which states that for many phenomena in nature, about 80% of the consequences are produced by 20% of the causes [23]. In this way, a good choice is to split the training and test by 80% and 20%, respectively. Then, split the training set into 80-20 for training and validation. Anyway, this is not an exact rule, and depending on the size of the original dataset, these percentages could vary. For small datasets, it could be 70-30, and for big datasets, 90-10, as done in [24].

The second decision to take related to the training, validation, and test sets is the strategy to follow during the split. Typically, a randomization is applied to avoid patterns depending on the order of the data. This prevents potential biases by ensuring that there is enough diversity representing the complete dataset in the three subsets. However, depending on the type of data and its organization, randomizing it is not always the best option. It is very important to avoid instances from the test set being introduced during training, which is called data leakage. A typical data leakage case occurs when using frames of videos in a model. If we split the sets of subsequent frames, almost equal frames could be part of the training and test sets. To avoid this, it is better to split the dataset into full sequences.

Finally, a problem could occur in classification problems with imbalanced classes. This could lead to a training or test set where a class has more presence compared to the other. The strategy that is applied to avoid this is called stratification. This will ensure that each subset maintains an identical class distribution.

C. Feature Scaling

Apart from the obvious transformation of data into continuous values, as input data in DL models is always numeric data, feature scaling is a best practice to apply just before starting to train the models. This term is defined in [25] as transforming all features to a uniform range, avoiding the influence of large-scale features on classification models or other feature-dependent processes. Feature scaling also has different benefits. For example, they can accelerate the process of gradient-based optimization algorithms, as in DL models, which leads to faster training times. Also, by avoiding the influence of features over the rest, the model performance tends to be improved. Finally, calculating distances is more accurate after feature scaling, as this process is part of the algorithms used in DL, for example, L1 regularization.

In this sense, there are two main strategies: scaling and normalization. The former transforms features to have a mean of zero and a standard deviation of one, which prevents certain features from dominating others during training. The latter scales features to a range between 0 and 1 or -1 and 1, which is particularly useful for algorithms sensitive to the magnitude of features, such as distance-based algorithms. There are many different strategies to apply scaling and normalization, but the following should be highlighted.

In the case of scaling, most well-known is Min-Max. This strategy rescales the features to a fixed range, typically [0, 1], by subtracting the minimum value from each feature and then dividing by the range (the maximum value minus the minimum value). Eq. (1) formalizes this process:

$$X_{MinMax} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

The main strategies in normalization are Euclidean Norm and Z-Score. Z-score transforms the features to have a mean of 0 and a standard deviation of 1. This strategy is depicted by Eq. (2):

$$Z_{Score}=\frac{X-\mu}{\delta} \quad (2)$$

In the equation, μ is the mean, and δ is the standard deviation.

D. Choosing the Metrics Depends on the Problem to Solve

The way to measure the performance of a DL model is by using metrics. The aim is to obtain the values that ensure that the model is well-trained. As a first step, we must choose which generic metric to use depending on the problem to solve. As we have said before, DL problems can be framed into two big classes: classification and regression.

In classification problems, the main metric is called accuracy. This is defined as the proportion of the samples that the model has predicted correctly among the total number of instances. Eq. (3) describes this metric:

$$Accuracy=\frac{TP+TN}{TP+FN+FP+TN} \quad (3)$$

In the equation above, True Positive (TP) refers to cases where the actual sample class is positive, and the model's prediction is also positive. True Negative (TN) denotes instances where the actual sample class is negative, and the model's prediction is also negative. False Positive (FP) signifies scenarios where the actual sample class is positive, yet the model predicts a negative outcome. False Negative (FN) represents situations where the actual sample class is negative, but the model predicts a positive result. The accuracy measures a percentage in ranges of 1, so the best value is the nearest to 1.

For regression problems, the Mean Squared Error (MSE) is usually used. It is defined in [26] as the mean of the squared differences between the predictions and the actual values. The following Eq. (4) describes this metric:

$$MSE=\frac{1}{N}\sum_{i=1}^{N}(y_i-\hat{y}_i)^2 \quad (4)$$

In the previous equation, N corresponds to the number of instances of the dataset, yi is the real value, and $\hat{y}i$ is the prediction made by the model. When using the MSE, the aim is to obtain a value as close to 0 as possible.

These metrics will be used as a first step to measure the performance of the model during training, validation, and test, or check if underfitting or overfitting is happening. For a deeper analysis of how models work, we will use other metrics that will be introduced in Section III H.

E. Using k-Fold Validation During the Training Stage

K-fold validation is a typical strategy used when data is scarce. Apart from that, it should be used to validate the models more exhaustively. As DL models are initialized by randomization of their weights, this initialization could benefit from the data split in how the model performs. To mitigate this issue, k-fold cross-validation is employed.

In this strategy, the training set is divided into k smaller subsets or "folds". Subsequently, a loop is executed for each of the k folds. Then, the model is trained using k-1 folds as the training data and validated (evaluated for its performance) using the remaining fold. The numeric measure reported by k-fold cross-validation is the average of the values calculated across the entire loop. Also, a standard deviation is given that will be useful to know if the performance is worse in any of the folds. Considering these factors, a good practice is using k-fold cross-validation with k values set to either 5 or 10. Empirical evidence suggests that these values yield test error rate estimates that achieve an appropriate balance, mitigating common Deep Learning pitfalls as described in [27].

F. Hyperparameter Optimization

Deep Learning models depend on multiple configurable variables that set its behavior and performance. Thus, it is essential to find the best set of hyperparameters to obtain an optimal model. There are different strategies to achieve this task, but we can mention the following: grid search, random search, and Bayesian Optimization. First, one optimizes the hyperparameters by exploring and combining various ranges of possible values to find the best configuration [28]. Random search is another simple and efficient hyperparameter optimization method that randomly samples parameter combinations, offering better performance than grid search in high-dimensional spaces [29]. The use of one or another depends on the model to tune, grid search ensures that all hyperparameter combinations are tested, but needs from a lot of computational resources, so it is better for models where the hyperparameter search space is small. However, random search is more efficient in computational terms, but does not explore all the search space of hyperparameters, so it should be used when the search space is wide. Finally, we have Bayesian Optimization defined by [30] as a probabilistic surrogate model (often a Gaussian process) to represent prior beliefs about the objective function and iteratively updates this model using new data. By balancing exploration and exploitation through acquisition functions, it efficiently selects the next sample points to find the global optimum with fewer evaluations.

G. Avoiding Underfitting and Overfitting

As we have said before, the main aim when training a DL model is avoiding overfitting/underfitting. Apart from that, it is also important that it can perform better than a human doing the specific task for which we are training it. To accomplish this, we will introduce the concept of trade-off between bias and variance [31]. This term addresses the balance between model complexity and its ability to generalize to unseen data (test set). In DL models, this trade-off plays a crucial role in determining model performance and robustness. The bias of a model refers to its ability to capture the underlying patterns in the input data, while variance refers to its sensitivity to small fluctuations during training.

The aim of the bias is accomplished when the metric at the training stage improves how the human performs this task. For example, if we are training a model for the diagnosis of Parkinson's Disease with Magnetic Resonance, we must obtain a better accuracy than that obtained by a physician. A model with low bias may simplify the underlying patterns in the data, leading to underfitting and poor performance on both the training and test sets. Apart from the bias, we use the concept of

variance, which is the difference between the metrics at the training and test stages. A model with high variance may capture noise or irrelevant patterns in the training data, leading to overfitting and poor generalization of unseen data. There is no exact value for this, but having a difference greater than 10% of the value between the training and stages seems too much. In the case of underfitting, the metrics during the training stage could be higher than during the test. When overfitting occurs, the training is lower than the test. In conclusion, the aim is to obtain a high bias and low variance.

To avoid underfitting in DL models, several strategies can be employed. Firstly, increasing model complexity by adding more layers, neurons, or parameters can help capture underlying patterns in the data. Additionally, experimenting with more complex architectures such as CNNs, RNNs, or Transformers tailored to the nature of the data and task can enhance model performance. Another option is training for longer by increasing the number of epochs or iterations, which allows the model to learn intricate patterns for more time.

To prevent overfitting in DL models, several strategies can be employed. Firstly, regularization techniques like dropout and batch normalization. The former consists of temporarily disconnecting several neurons from the network, including all its incoming and outgoing connections [32]. The latter normalizes the inputs of the layers. Another technique is early stopping, where training is stopped when the validation metric stops improving. We can also use data augmentation techniques, such as rotation, translation, scaling, and adding noise, to enhance training diversity. Finally, increasing the size of the training dataset or simplifying the model by reducing layers, neurons, or parameters can also mitigate overfitting.

H. Adding New Metrics for an In-Depth Interpretation of the Model

In Section III D, we talked about the main metrics that could be used for classification and regression problems. These metrics have been used to measure the performance of the model to find a bias-variance trade-off. As a first approach, these metrics are enough, but in some cases, more complex metrics should be used. For example, if the developed model is used in the field of medicine, metrics considering FP and FN should be used. This will let us interpret the models more deeply. Let's consider a model for cancer diagnosis, which is not the same in that it has problems with FN (healthy people diagnosed with cancer) than FP (people with cancer who have been considered as healthy). In the last case, this is a problem that a model should minimize. So, considering all these points, we are introducing more metrics.

In the case of classification problems, metrics like specificity and sensitivity (sometimes called recall) are very useful. Specificity calculates the ratio of true negatives to the sum of true negatives and false positives, while sensitivity performs a similar calculation, changing true negatives for true positives and false positives for false negatives. Finally, precision is computed by dividing the number of true positives by the sum of true positives and false positives. These three equations [Eq. (5) to Eq. (7)] are formalized as follows:

$$\text{Specificity} = \frac{TN}{TP + FN} \quad (5)$$

$$\text{Sensitivity} = \frac{TP}{TP + FN} \quad (6)$$

$$\text{Precision} = \frac{TP}{TP + FP} \quad (7)$$

The interpretation of the metrics above can be done as follows: Specificity is used so the model can distinguish healthy individuals from those without cancer, crucial for minimizing unnecessary treatments or interventions. In the case of sensitivity, the model can identify most cases of cancer, reducing the risk of treating cases of disease and applying an accurate intervention and treatment, minimizing unnecessary stress for patients. Finally, with precision, we ensured to identify cases of cancer and apply an accurate intervention and treatment. Apart from that, there are other more complex metrics like F1-Score, Area Under the Curve (AUC), and Receiver Operating Characteristic (ROC) Curve.

If we talk about regression problems with DL models, some points should be considered. If the use case consists of predicting a particular value, like a time series problem for predicting the value of a company´s stock, the concepts of FN and FP do not apply. Anyway, there are more metrics like MSE, such as Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), Mean Absolute Percentage Error (MAPE), or R-squared (also Coefficient of Determination) that can be used similarly. But this is not the only case of regression problems that can be solved with DL models; we also have object detection, audio restoration, and others. In these cases, the concepts of FP and FN can be used. Therefore, there exist metrics for this purpose, for example, Intersection over Union (IoU) and Dice score.

IoU computes the ratio of the overlapping area between the predicted (output image of the model) and ground truth (image used in the output layer during training) regions to the total area covered by both regions [33]. It ranges from 0 to 1, where 0 signifies no overlap and 1 denotes perfect spatial alignment between the regions. So, it is defined as the ratio of the area of intersection between the predicted image and ground truth to the area of their union. Eq. (8) formalizes it mathematically:

$$\text{IoU} = \frac{|Predicted \cap Ground\ Truth|}{|Predicted \cup Ground\ Truth|} \quad (8)$$

In the equation above, |Predicted ∩ Ground Truth| represents the area of intersection between the predicted and ground truth regions. Then, |Predicted ∪ Ground Truth| represents the area of union between the predicted and ground truth regions.

Dice score is a metric based on IoU and calculates the ratio of twice the overlapping area to the sum of the sizes of the predicted and ground truth regions [34]. It also ranges from 0 to 1, having the same interpretation as IoU. Eq. (9) describes it:

$$\text{Dice} = \frac{2 \times |Predicted \cap Ground\ Truth|}{|Predicted| + |Predicted|} \quad (9)$$

Regarding the equation above, the numerator is the same as in IoU. Then, |Predicted| represents the size of the predicted region, and |Ground Truth| represents the size of the ground truth region.

I. Making a Comparison with a Baseline

Using a baseline is essential for evaluating the performance of a Deep Learning model for several reasons. Firstly, it provides a point of reference against which the model's performance can be compared. This is crucial in understanding whether the model is learning meaningful patterns in the data or if its performance is merely a matter of luck. Secondly, baselines help in setting realistic expectations for the model's performance. By comparing against a simple baseline, we can measure how much improvement DL techniques offer over simpler approaches. This helps in assessing whether the additional complexity of applying DL techniques is justified. Moreover, using a baseline can also highlight potential shortcomings or biases in the dataset. If a DL model struggles to outperform a simple baseline, it may indicate issues with the quality or representativeness of the data, prompting further investigation and data preprocessing. Overall, employing a baseline is a fundamental step in the evaluation process of Deep Learning models, providing context and insights that are essential for making informed decisions about model performance and deployment.

IV. Use Cases

In this section, we are exploring some use cases where the methodology explained above has been explained in detail, step-by-step. These examples try to cover most of the situations that could happen during the implementation of a DL model, considering the decisions to take. The first use case is a model that could diagnose breast cancer using thermographic images [35]. In the second use case, a diagnostic model for epilepsy using electroencephalographs [36]. Finally, the third use case solves the problem of small brain tumor detection in Magnetic Resonances [37]. In the following Table II, Table III, and Table IV (one for each use case), we summarize each step of the methodology, adding the decision taken and its explanation.

TABLE II. Methodology Applied to Breast Cancer Diagnosis

Step	Decision	Explanation
3.1.	Classification problem with coloured images solved with CNNs	The dataset consists of thermographic images of healthy people and people with breast cancer.
3.2.	Randomise 80-20 split	The number of images is enough, and the images between patients are very different.
3.3.	Scaling: Min-Max	Typical decision when working with images.
3.4.	Accuracy metrics	In a diagnosed problem, we need to measure the number of hits.
3.5.	K-fold validation with k=5	Usual decision
3.6.	Bias-variance trade-off. Train: 87.67%±6.65, Val: 86.67%±12.47, Test: 89.23%±5.85	Bias is correct as human performance accuracy, assisted by a CAD, is near 83%, (Keyserlingk et al. 2020). The variance is also correct.
3.7.	Other metrics. Specificity: 88%, Sensitivity: 90.53% and Precision: 88.91%	These metrics are around the same values which means the model is very stable
3.8.	Baselines. VGG16: 68%. VGG19: 51.33%, Inception 84%	The proposed model performs better than the baseline

TABLE III. Methodology Applied to Epilepsy Diagnosis

Step	Decision	Explanation
3.1.	Classifying chunks of an EEG using a CNN	The dataset is chunked into timestamps that are modelled as graphs represented in images. The CNN model discriminates between stages of a seizure.
3.2.	80-20 split between patients	As brain states in a person do not change a lot from a particular moment and the following, the split is done considering the EEGs of the patients.
3.3.	Scaling: does not apply	As images are in greyscale, they are in the same ranges.
3.4.	Accuracy metrics	For a classification problem, accuracy should be used.
3.5.	K-fold validation with k=5	Usual decision
3.6.	Bias-variance trade-off. Model 1: 93.6%, 88.2%, 87.2%. Model 2: 91.9%, 86.8%, 81.3%	Bias cannot be measured as there are no official studies about the performance of physicians in distinguishing seizure states. The variance is correct.
3.7.	Other metrics. Specificity: 94%, Sensitivity: 94.1% and Precision: 93.2%	These metrics are around the same values, which means the model is very stable.
3.8.	Baselines: nothing.	There is no baseline for being a very specific use case.

TABLE IV. Methodology Applied to Tumor Detection

Step	Decision	Explanation
3.1.	Small brain tumor detection in MR using a U-Net	The dataset is pairs of MRs of the brain and the mask that isolates the brain tumour in this MR
3.2.	Randomise 80-20 split	The number of MRs is enough and they are very different between them.
3.3.	Scaling: Not needed	The images are in greyscale.
3.4.	Loss metrics: MSE	In object detection, we need to know how the predicted mask resembles the ground truth image that represents the mask.
3.5.	K-fold validation with k=5	Usual decision.
3.6.	Bias-variance trade-off. Train:10% ± 0.5%, Validation: 11.1% ± 0.5%, Test: 14%	Human performance goes from 28 and 44% error (the model performs better), and the variance is not high.
3.7.	Other metrics: Dice score. Train: 96.3% ± 0.8%. Validation: 92% ± 1%. Test: 91.6%.	Dice score considers FP and FN.
3.8.	Baselines. Dice score: 45%	The proposed model performs better than the baseline.

V. Conclusion

This study presents a step-by-step methodology to train DL models accurately. Apart from that, it presents the best practices to do so, and complete information is provided during the process. The manuscript should be taken as an information resource for researchers who are not experts in DL and want to use these techniques in their field, so they can understand the main terms and strategies to apply and why. In case of having a deeper understanding of DL models, this could be used as a guide for best practices.

The methodology is divided into eight steps. First, tries to explain which DL models should be used depending on the nature of the data and the use case to solve. Second, describe how to split training, validation, and test sets considering the distribution of the dataset and its similarities. Third, compile different strategies to apply feature scaling, which is related to the value ranges of the different features of the data. The fourth shows which general metrics should be used depending on whether the problem to solve is regression or classification. The fifth describes the validation strategy called k-fold cross-validation. Sixth, introduces the concept of bias-variance trade-off that shows if there is any underfitting or overfitting. Seventh tries to understand in-depth how the model performs by introducing metrics that consider false positives or false negatives. Eighth, evaluates the proposed model against a baseline, so it can be demonstrated that it is better than what can be found in the scientific literature.

Finally, three different use cases have been compiled where we have provided information for each step of the method, pointing out the decision that has been taken and an explanation about it, if possible.

A Constraint-Driven Conversational Architecture for Staged Task Interaction Using Large Language Models

Joseph Benjamin Ilagan, Jose Ramon Ilagan
Ateneo Business Insights Laboratory for Development (BUILD)
Ateneo de Manila University, Quezon City, Philippines 1108

***Abstract*—Large language models (LLMs) enable flexible conversational interfaces, but remain difficult to deploy in structured, staged tasks that require controlled progression, bounded information disclosure, and task validity. Prompt-based control is inherently probabilistic and has been shown to degrade under multi-turn interaction, leading to premature solution disclosure, stage skipping, loss of state coherence, and constraint violations. This study presents a constraint-driven conversational architecture that separates probabilistic language generation from deterministic task governance. An external control layer manages dialogue state, stage transitions, and constraint enforcement, while a simulation layer represents task logic independently of the LLM. We instantiate the architecture in the context of customer discovery tasks to illustrate how staged processes and bounded disclosure can be operationalized without embedding task logic directly into prompts. This work focuses on architectural design and control mechanisms rather than outcome evaluation, offering a reusable architectural pattern for LLM-driven conversational systems that must preserve staged progression, enforce constraints, and prevent premature disclosure during multi-turn interaction.**

***Keywords*—Large language models; conversational systems; task-oriented dialogue; deterministic control; constraint enforcement; staged interaction**

I. Introduction

Large language models (LLMs) have enabled conversational interfaces for tasks that previously relied on scripted workflows or rule-based dialogue systems. However, when tasks require staged progression and procedural integrity, prompt-based control remains unreliable. Common failures include premature solution disclosure, stage skipping, uncontrolled transitions, loss of state coherence, and domain constraint violations. These failures limit use in settings where the process itself must be preserved.

Prior work has improved multi-turn interaction through prompting techniques and learned policies, but task governance is still often mediated through model behavior. This makes guarantees on state, constraints, and stage boundaries difficult to obtain.

This study proposes a constraint-driven conversational architecture that separates probabilistic language generation from deterministic task governance. An external control layer maintains dialogue state, regulates stage transitions, and enforces constraints, while a simulation layer represents task logic independently of the LLM to support runtime checks and bounded information disclosure. We instantiate the architecture in customer discovery tasks to illustrate staged interaction without embedding task logic directly into prompts. This work focuses on architectural design and control mechanisms rather than outcome evaluation.

It is important to clarify the nature of the contribution made in this work. The proposed architecture does not claim novelty in staged task representations, finite-state control, or deterministic dialogue management as isolated techniques. Related ideas appear in classical dialogue system architectures and in hierarchical control formulations for sequential decision-making [1], [2].

The contribution instead lies in repositioning deterministic task governance as a first-class architectural layer in LLM-driven conversational systems, where language generation is probabilistic and state coherence cannot be assumed. In this setting, staged progression, constraint enforcement, and bounded disclosure are treated as external guarantees instead of emergent properties of prompt design or model reasoning. This distinction is central to the architectural argument advanced in this study.

A. Research Questions

This study addresses the following research questions:

- RQ1. What system architecture can support structured, staged task interaction with LLM-based conversational interfaces, while preserving natural language flexibility?
- RQ2. How can dialogue state, stage transitions, and permissible system actions be represented and governed deterministically and not through prompt interpretation?
- RQ3. What runtime mechanisms enable enforceable constraints and bounded information disclosure, including integration of an external task logic or simulation layer independent of the LLM?

B. Contributions

This study makes the following contributions:

- We present a constraint-driven architecture for LLM-based conversational systems that separates language generation from deterministic task control for staged interaction.

- We define a dialogue state and control model that governs stage transitions, permissible system actions, and bounded information disclosure outside the LLM.
- We show how the architecture can be operationalized with an external simulation/control layer, using customer discovery as an illustrative domain.

II. Review of Related Literature

This section reviews prior work related to: 1) controlling large language model (LLM) behavior in multi-turn settings, 2) maintaining explicit state and constraints in structured tasks, and 3) architectural patterns that separate probabilistic language generation from deterministic task governance. The review is organized around control mechanisms (prompting and agents), externalization of state (memory, simulators, controllers), and system-level designs for constrained interaction.

A. Prompt Engineering for Task Control

Prompt engineering is a widely used mechanism for steering large language models (LLMs) in conversational systems without modifying model parameters. Surveys of prompting methods document a range of strategies, including instruction prompts, role prompting, and structured prompt templates intended to improve task adherence across diverse settings [3].

Several prompt engineering techniques have emerged to increase reliability in multi-turn interaction. Common approaches include explicitly stated behavioral constraints, stepwise instructions, and structured response formats that narrow the space of acceptable outputs. In practice, these methods remain inherently probabilistic because task logic and constraints are interpreted as opposed to enforced, and can degrade across longer conversations or under distribution shift [3].

Few-shot learning extends prompt-based control by providing a small number of exemplars that demonstrate the expected behavior [4]. In staged tasks, exemplars can illustrate valid responses and interaction norms, but they do not provide explicit guarantees on state persistence, bounded information disclosure, or correct stage transitions, particularly when user behavior deviates from the examples.

A related technique known as *chain-of-thought* (CoT) prompting encourages models to generate intermediate reasoning steps prior to producing a final answer [5]. CoT prompting can improve multi-step reasoning performance, but the reasoning trace remains part of the model output and not an external representation of task state. As a result, CoT does not by itself enforce task constraints or regulate progression in structured, staged interactions.

Overall, prompt-centric approaches provide flexible and low-overhead control of LLM behavior, but task control, constraint enforcement, and state management are encoded implicitly in natural language prompts. This implicit encoding makes it difficult to ensure consistent adherence to staged task structures or to prevent failure modes such as premature information disclosure and uncontrolled stage transitions in conversational systems.

B. Agentic and Tool-Augmented LLM Systems

Tool-augmented and agentic systems extend LLMs with actions such as retrieval, API calls, and tool usage. ReAct couples reasoning traces with action selection in an interleaved loop [6]. Such approaches improve task completion on interactive problems, but the policy is typically still mediated through model generations, not an external controller.

Toolformer proposes self-supervised learning of tool usage, allowing models to invoke tools through simple APIs [7]. These frameworks motivate modularity, yet many implementations still treat constraints, stage boundaries, and permissible transitions as soft rules embedded in prompts or tool schemas, not explicit governance layers.

C. State, Memory, and Environment-Mediated Interaction

Long-horizon task interaction requires stable representations of state, goals, and constraints. Existing work spans symbolic dialogue management, hybrid neural-symbolic systems, and environment-mediated learning, where an external environment provides dynamics and feedback [2]. Related lines of work use simulators for training, evaluation, or controlled interaction loops [8]. A key distinction for this study is treating simulation/control as a persistent runtime layer that governs progression, not only as a training or evaluation artifact.

D. Architectural Patterns for Conversational Systems

Architectural perspectives on dialogue systems emphasize modular separation of components such as NLU, dialogue state tracking, dialogue policy, and NLG [1]. These patterns motivate separation of concerns, but they do not fully anticipate LLM-first dialogue generators where the generator can blur boundaries among state, policy, and surface realization.

E. Synthesis and Gap

Across the strands reviewed in this section, task governance is predominantly implicit and probabilistic, even when external tools or environments are introduced. Constraints, stage boundaries, and permissible transitions are typically specified as prompt rules, learned behaviors, or conventions mediated through language generation, rather than enforced through explicit deterministic control structures.

Although deterministic state machines and hand-crafted control policies are well-known in task-oriented dialogue more broadly, these designs largely predate LLM-first conversational architectures and are rarely positioned, in the LLM-centric literature reviewed here, as the primary mechanism for guaranteeing staged progression, bounded disclosure, and constraint satisfaction during runtime interaction.

This work responds to this gap by treating deterministic task governance as a first-class architectural abstraction. The proposed constraint-driven conversational architecture explicitly separates probabilistic language generation from deterministic task control, elevating stage representation, enforceable transition logic, and constraint checks to core components that regulate what the LLM may say and when (see Table I).

TABLE I. COMPARISON OF TASK GOVERNANCE APPROACHES IN LLM-BASED CONVERSATIONAL SYSTEMS

Property	Prompt-centric	Agentic	Proposed (Constraint-driven)
Stage enforcement	Probabilistic	Emergent	Deterministic
State representation	Implicit	Partial	Explicit
Disclosure control	Prompt-level	Tool-schema	Controller-enforced
Transition authority	Model	Model	Controller
Recovery on violation	None/retry	Model-driven	Deterministic fallback
Task logic location	In prompt	Mixed	External layer
Cross-domain reuse	Low	Moderate	High (config-driven)

III. ARCHITECTURE

A. Conceptual Model for Deterministic Task Governance

The architecture proposed in this study is guided by a simple conceptual model that distinguishes between *probabilistic language generation* and *deterministic task governance*. While large language models (LLMs) are well suited for producing fluent, context-sensitive responses, they do not provide intrinsic guarantees on task progression, state persistence, or constraint satisfaction across multi-turn interactions. These properties must, therefore, be enforced outside the language model.

Procedural integrity, as used in this study, refers to the property that stage position, transition validity, and disclosure boundaries are maintained by deterministic system components throughout the interaction lifecycle, independent of model behavior.

At the core of the model is the treatment of task state as a first-class system artifact. Dialogue state, stage membership, and permissible actions are represented explicitly and persist independently of conversational turns. Instead of inferring state from natural language alone, the system maintains an external representation of where the interaction currently resides within a staged task structure. This enables consistent reasoning about what information may be disclosed, which actions are valid, and which transitions are allowed at any point in the interaction.

A second principle is the separation of task logic from surface realization. Task constraints, progression rules, and evaluation conditions are encoded in a simulation or control layer that operates deterministically. The role of the LLM is restricted to generating natural language realizations that are conditioned on, and bounded by, decisions made in this control layer. This separation prevents task logic from being embedded implicitly in prompts, where it would otherwise be interpreted probabilistically and remain difficult to enforce over extended conversations.

Finally, grounding is achieved through controlled exposure to task-relevant context in place of generic conversational guidance. System responses are generated with reference to the current task state and its associated constraints, allowing feedback and guidance to be tailored to the user's position within the staged process. This design supports specificity and consistency in guidance while preserving the flexibility of natural language interaction.

Together, these principles define a constraint-driven conversational model in which LLMs function as flexible linguistic interfaces governed by explicit, deterministic task structures. This conceptual framing underpins the architectural design presented in the following section.

B. Architectural Contribution Clarification

The architecture proposed in this study should be understood as a governance pattern and not a new dialogue algorithm. Its primary contribution is the explicit separation of conversational fluency from procedural authority in LLM-based systems. Unlike prompt-centric or agentic designs, where task control is mediated through model interpretation or reasoning traces, the proposed architecture assigns exclusive authority over task state, stage transitions, and disclosure boundaries to deterministic system components. This framing addresses failure modes that arise specifically in LLM-first conversational settings and are not adequately handled by classical dialogue pipelines or workflow engines when language generation is open-ended and user-driven.

C. Overall System Architecture

This subsection provides a high-level view of the proposed conversational architecture, outlining the primary components and their interactions (see Fig. 1). The design emphasizes a clear separation between probabilistic language generation and deterministic task governance to support structured, staged interaction.

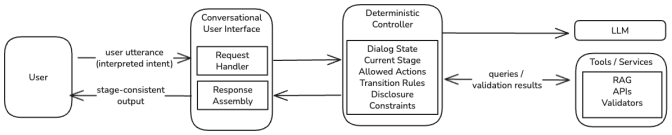

Fig. 1. Constraint-driven conversational architecture with deterministic task governance. The controller governs dialogue state, stage transitions, and disclosure constraints, invoking the LLM and external tools as bounded services.

D. Dialogue State Representation

Dialogue state is represented as an explicit, structured data object maintained by the control layer across conversational turns. The state encodes the current task stage, completed and pending artifacts, validated inputs, and flags relevant to progression and constraint enforcement. This representation persists independently of the conversation transcript and is not inferred solely from natural language interaction.

State updates occur through deterministic events, not through linguistic interpretation alone. User inputs may trigger validation checks or proposed updates, but acceptance of new state values depends on evaluation against task specifications defined in the control or simulation layer. This prevents ambiguous or partial inputs from implicitly advancing the task.

Separating dialogue state from conversational history enables consistent reasoning about task position even when the

interaction includes digressions, reformulations, or clarification requests. It also supports recovery from invalid inputs without relying on the language model to reconstruct prior context.

Dialogue state is treated as a persistent system artifact that may be stored across turns or sessions using any suitable state storage mechanism (e.g., in-memory stores, databases, or session services), which is intentionally left abstract in this architecture.

E. Stage Transitions and Control Logic

Structured tasks are modeled as staged processes governed by explicit transition rules rather than inferred conversational flow. Each task defines a finite set of stages, allowable transitions between stages, and conditions under which transitions may occur. These elements are treated as part of the task specification and are evaluated by a deterministic control layer at runtime.

Stage definitions are external to the language model and may be configured per task or use case. A stage specification encodes the set of valid stages, permitted successor stages, entry and exit conditions, and constraints on permissible system actions and disclosures at each stage. This allows the same conversational runtime to support different staged tasks without modifying the underlying control logic.

Transition evaluation is performed exclusively by the control layer. User inputs and LLM-generated responses may propose or suggest progression, but transitions are only executed when explicit transition conditions are satisfied. These conditions may include completion of required task elements, validation of user inputs against the task logic or simulation layer, or satisfaction of domain-specific constraints.

Invalid transitions, such as premature advancement or attempts to bypass required stages, are blocked by design. When a transition request is rejected, the system remains in the current stage and generates responses that are consistent with the active stage's disclosure and action constraints. This ensures that task progression remains valid even under adversarial, ambiguous, or unexpected user behavior.

By separating transition authority from language generation, the architecture enforces staged progression deterministically while preserving conversational flexibility. The LLM is responsible for surface realization and interaction quality, whereas the control layer maintains procedural integrity throughout the task lifecycle.

F. Constraint Enforcement and Bounded Disclosure

Constraint enforcement is implemented through stage-specific policies managed by the control layer. These policies define which system actions are permitted, which information may be disclosed, and which responses are prohibited at a given point in the interaction.

While avoiding encoding constraints as prompt instructions alone, the controller regulates what contextual information is provided to the language model and which response types are allowed. Future-stage artifacts, evaluative conclusions, or solution templates are withheld until the task reaches the appropriate stage, ensuring that the model cannot disclose information it has not been authorized to access.

When a user request violates active constraints, the controller blocks the corresponding action and triggers a recovery response. The recovery response is generated within the bounds of the current stage and redirects the interaction without advancing state or revealing restricted information. This preserves procedural integrity under adversarial, ambiguous, or premature user requests.

G. Integration of the Simulation or Task Logic Layer

Task logic is implemented in a simulation or rule-based layer that operates independently of the language model. This layer encodes domain-specific requirements such as completeness conditions, validity checks, dependency constraints, and progression criteria.

User inputs requiring structured interpretation are routed to the simulation layer for evaluation. The simulation returns deterministic signals such as completion flags, constraint violations, or required revisions. These signals are consumed by the controller and translated into bounded response contexts for the language model.

This separation allows domain logic to evolve without modifying prompt templates or conversational behavior. It also reduces reliance on the language model for correctness judgments, limiting its role to explanation and feedback consistent with the simulation's outputs.

H. Interaction Flow

Each interaction cycle follows a fixed control sequence. User input is first received and recorded without immediate state mutation. The controller evaluates whether the input proposes a state transition, requests restricted information, or requires validation against task logic.

If validation is required, the input is passed to the simulation layer. The resulting signals are incorporated into the dialogue state and used to determine the next permissible system action. Only after this decision is made does the controller construct a bounded response context for the language model.

The language model generates a natural language response within the constraints imposed by the controller. Conversational output does not directly modify task state. State updates occur only through explicit controller approval, ensuring that language generation cannot unilaterally advance task progression.

Algorithm 1 summarizes the deterministic runtime loop used to govern staged progression and disclosure.

The CHECKRESPONSE step in Algorithm 1 verifies that the LLM-generated response r_t does not reference disallowed disclosures or propose actions outside $\mathcal{A}_t$. Verification may be implemented through keyword filtering, structural pattern matching, or a secondary classifier. When a violation is detected, RECOVERYRESPONSE generates a stage-consistent fallback that redirects the user without modifying state or revealing restricted information.

Algorithm 1 Deterministic Controller Loop for Staged Conversational Tasks

Inputs: user message u_t, current state s_t, task spec $\mathcal{T}$, validator/simulator $\mathcal{V}$, LLM $\mathcal{M}$
Output: response text r_t, updated state s_{t+1}

$i_t \leftarrow \textsc{ClassifyIntent}(u_t, s_t, \mathcal{T})$ ▷ e.g., ask, revise, request_restricted, propose_transition
$x_t \leftarrow \textsc{ExtractStructuredInputs}(u_t, s_t, \mathcal{T})$ ▷ optional parsing
$v_t \leftarrow \mathcal{V}(x_t, s_t, \mathcal{T})$ ▷ returns completion, violations, missing fields
$\mathcal{A}_t \leftarrow \textsc{ComputeAllowedActions}(i_t, v_t, s_t, \mathcal{T})$
$\mathcal{D}_t \leftarrow \textsc{ComputeAllowedDisclosures}(s_t, \mathcal{T})$
$c_t \leftarrow \textsc{BuildBoundedContext}(s_t, v_t, \mathcal{A}_t, \mathcal{D}_t)$
$r_t \leftarrow \mathcal{M}(c_t)$
$ok \leftarrow \textsc{CheckResponse}(r_t, \mathcal{A}_t, \mathcal{D}_t)$
if $ok =$ **false then**
  $r_t \leftarrow \textsc{RecoveryResponse}(s_t, v_t, \mathcal{A}_t)$
end if
$s_{t+1} \leftarrow \textsc{CommitStateUpdate}(s_t, u_t, v_t, r_t, \mathcal{T})$
return r_t, s_{t+1}

IV. Illustrative Instantiation: Customer Discovery as a Staged Conversational Task

This section presents an illustrative instantiation of the proposed architecture using customer discovery as an example of a staged conversational task. The purpose is to demonstrate how deterministic task governance, bounded disclosure, and stage-aware interaction are operationalized in a concrete domain, not to evaluate task outcomes or user performance.

A. Task Structure and Stages

Customer discovery is modeled as a staged conversational task in which progression is constrained by explicit requirements at each stage. The staged structure reflects the need to prevent premature solution formulation while ensuring that users engage with each step of the discovery process in sequence (see Fig. 2).

In the illustrative instantiation, the task is decomposed into a finite set of stages, such as problem articulation, hypothesis formulation, interview planning, evidence gathering, and reflection. Each stage is associated with a well-defined set of permissible system actions, allowable disclosures, and completion conditions. These definitions are external to the language model and are maintained by the control layer as part of the task specification.

Stage progression is not inferred from conversational cues alone. Instead, advancement occurs only when the control layer determines that the conditions for exiting the current stage have been satisfied. For example, a transition from problem articulation to hypothesis formulation may require that the user has provided a sufficiently specific problem statement, as validated by the task logic or simulation layer. Attempts to advance without meeting these conditions are rejected, and the system remains within the current stage.

Treating stages as explicit system entities as opposed to conversational conventions ensures that task structure is preserved across multi-turn interaction. This approach allows conversational flexibility within a stage while preventing stage skipping, uncontrolled transitions, or disclosure of information that is inappropriate for the user's current position in the task.

TABLE II. Example Stage Specification for Customer Discovery under Deterministic Governance

Field	Specification (illustrative)
Stages	S1 Problem articulation; S2 Hypothesis formulation; S3 Interview planning; S4 Evidence gathering; S5 Reflection
State variables	`stage_id`; `artifacts` (problem_statement, hypotheses, interview_questions, notes); `flags` (validated, ready_to_advance); `violations`
Required artifacts	S1: problem statement draft; S2: testable hypothesis; S3: interview guide; S4: evidence log; S5: updated belief + next actions
Allowed actions	Ask clarification; critique current artifact; request missing fields; summarize progress; propose next micro-step within stage; attempt transition (controller decides)
Disallowed disclosures	No downstream templates or "answers" for future stages; no solution proposals before S5; no auto-advancing to S3+ without required artifacts
Exit criteria	S1: problem statement meets specificity checks; S2: hypothesis is falsifiable and linked to problem; S3: interview guide covers objectives and avoids leading questions; S4: evidence log meets completeness; S5: reflection includes decision and rationale
Validator outputs	`completion_flag`; `missing_fields`; `violations`; `allowed_actions`; `allowed_disclosures`

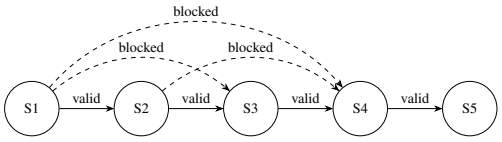

Fig. 2. State transition diagram for the customer discovery instantiation. Solid arrows indicate controller-approved transitions; dashed arrows indicate blocked skip attempts.

Table II provides an illustrative stage specification that externalizes exit criteria, allowed actions, and disclosure limits.

B. Grounded Feedback and Coaching Behavior

The architecture supports coaching behavior by making feedback generation stage-aware and state-dependent. Rather than prompting the model to "behave" as a coach across all turns, the control layer determines the allowable feedback type at the current stage and provides the LLM with stage-bounded context and permissible action options.

At runtime, the controller constructs a constrained response context that includes: 1) the current stage identifier, 2) relevant state variables and artifacts collected so far (e.g., problem statement drafts, hypotheses, interview questions), and 3) an explicit policy describing what the system may and may not disclose in the current stage. The LLM then produces natural language realizations of actions selected or permitted by the controller, such as asking a clarifying question, requesting missing inputs, offering critique on a draft artifact, or summarizing progress.

Grounding is operationalized through controlled access to task artifacts and simulator outputs. When user input requires validation or structured interpretation, the controller routes it to the task logic or simulation layer, which returns deterministic signals such as completion flags, constraint violations, or required revisions. The LLM is not expected to infer these signals from the conversation transcript. Instead, the controller passes the relevant outcomes as response constraints, ensur-

Worked trace: staged customer discovery with bounded disclosure (illustrative).

State (before): `stage_id=S1 (Problem articulation)`, `artifact.problem_statement=underspecified`, `ready_to_advance=false`.

User: "Can you help me write interview questions now so I can test this quickly?"
Intent: `request_future_stage_artifact (S3)`.
Validator: `completion_flag=false`; `missing_fields={target user segment, situation, observable pain}`; `violations={premature stage transition}`.

Allowed actions: ask clarification; critique current problem statement; request missing details.
Disallowed disclosures: interview question templates; hypothesis phrasing; discovery call scripts.

System (LLM realization within bounds):
"Before we design interviews, we need to be precise about the problem. Who specifically experiences this issue, in what recurring situation, and what concrete cost or friction do they face? Try rewriting the problem in one sentence using those elements."

State (after): `stage_id=S1`; `pending={target user segment, situation, pain}`; `ready_to_advance=false`.

Fig. 3. Illustrative trace showing deterministic blocking of premature interview design during customer discovery.

ing that coaching feedback remains consistent with the task specification.

This design yields two practical effects. First, feedback remains aligned with stage intent, since the controller restricts the response space to coaching behaviors appropriate to the current stage. Second, bounded disclosure is preserved, since the LLM does not receive privileged information or future-stage hints unless explicitly authorized by the controller. The result is a conversational experience that remains flexible in language while remaining disciplined in instructional sequencing.

Fig. 3 shows a concrete turn-level example of how stage skipping and premature disclosure are blocked at runtime. This example reflects early-stage customer discovery, where interview design is intentionally blocked until the problem is explicitly articulated.

C. Observed Failure Modes and Mitigations

The architecture is motivated by failure modes commonly observed in prompt-governed multi-turn interaction for staged tasks. In prompt-centric implementations, the model is expected to remember stage position, respect procedural boundaries, and withhold information until the appropriate time. In practice, these behaviors are unreliable under long-horizon conversation, ambiguous user prompts, or user attempts to accelerate the process.

A frequent failure mode is premature solution disclosure, where the model provides downstream answers (e.g., proposed solutions, scripts, or conclusions) before earlier stages have been completed. Another is stage skipping, where the model implicitly advances the task after a single user message, compressing intermediate stages or omitting required artifacts. Conversational drift is also common, where the interaction gradually shifts toward generic advice that is weakly related to the staged task, reducing coherence and diminishing the value of accumulated state. Finally, constraint violations can occur when the model produces outputs that conflict with domain rules, such as recommending actions that the task specification explicitly forbids at a given stage.

The proposed architecture mitigates these failure modes through deterministic governance. Premature disclosure is controlled through stage-specific disclosure policies that limit which information and actions are available to the LLM at each stage. Stage skipping is prevented by enforcing transition checks in the controller, so that advancement can only occur when explicit completion conditions are met. Drift is reduced by anchoring each turn to an explicit task state representation and by routing key evaluations to the simulation layer instead of relying on narrative consistency in model outputs. Constraint violations are handled through runtime checks and rejection of invalid actions, followed by controlled recovery responses that redirect the interaction without changing the active stage.

These mitigations are not framed as guarantees of correctness in the model's linguistic output. Rather, they provide guarantees about procedural integrity: stage position, transition validity, and bounded information disclosure are governed by deterministic system components, while the LLM remains responsible for conversational naturalness within the permitted space.

V. Discussion

A. Design Trade-Offs

The proposed architecture also differs from conventional workflow and orchestration systems commonly used for multistage task execution. Workflow engines and automation platforms are designed to coordinate deterministic system-to-system processes, typically assuming that task progression is driven by predefined triggers, API responses, or execution outcomes in place of open-ended human interaction.

In contrast, the architecture presented in this study addresses staged task progression in the presence of natural language interaction, where user input and model-generated responses introduce uncertainty and variability. The challenge is not merely sequencing actions, but governing conversational progression, state coherence, and information disclosure under probabilistic language generation.

While workflow systems excel at executing predefined pipelines, they do not address failure modes specific to LLM-driven interaction, such as premature solution disclosure, stage skipping, or conversational drift. The proposed control layer operates at a different abstraction level, mediating between conversational inputs and task logic to ensure that staged processes remain valid even when interaction is negotiated through language as opposed to enforced through execution constraints alone.

B. Relation to Prompt-Centric and Agentic Approaches

Recent agentic approaches to large language model (LLM) systems emphasize autonomous planning, action selection, and tool use driven largely by model-generated reasoning traces. In such systems, the LLM is often responsible for determining when to advance between steps, invoke tools, or terminate a task, with control logic embedded implicitly in prompts or emergent reasoning behavior.

The architecture proposed in this study adopts a deliberately different stance on agency. Rather than treating the LLM as an autonomous task manager, the model is positioned as a bounded conversational service whose outputs are mediated by an external control layer. While the LLM may propose actions or suggest progression, authority over dialogue state transitions, stage advancement, and permissible disclosures resides exclusively in deterministic system components.

This design choice reflects a prioritization of procedural integrity over autonomous flexibility. By externalizing task governance, the architecture avoids relying on probabilistic reasoning traces or prompt adherence to enforce staged progression. As a result, conversational fluency is preserved while guarantees over task structure, bounded disclosure, and valid transitions are maintained independently of model behavior.

The proposed approach is not intended to replace agentic systems in domains where autonomous planning is desirable. Instead, it targets settings where the integrity of staged processes is critical and where conversational interaction must remain flexible without allowing the model to unilaterally control task execution.

The distinction between agentic autonomy and deterministic governance is intentional. The proposed architecture does not attempt to improve the model's ability to plan or reason about task execution. Instead, it removes responsibility for procedural correctness from the model altogether. This design choice reflects a different objective than that of agentic systems. The goal is not autonomous task completion, but preservation of staged interaction integrity under conversational uncertainty. This difference in objective leads to a different allocation of responsibility across system components.

C. Generality and Transferability

The proposed architecture is not specific to customer discovery tasks. For example, an entrepreneurship education scaffold could gate hypothesis formulation until a problem statement meets specificity criteria, while a customer validation workflow could restrict solution proposals until sufficient interview evidence has been logged — both mirroring the staged structure demonstrated in Section IV.

Transferability is achieved through task configuration in place of architectural modification. Stages, constraints, and validation logic are defined externally and can be replaced without changing the conversational runtime. This allows the same system to support multiple task types with differing structures and domain rules.

The architecture therefore functions as a reusable governance layer for conversational systems instead of a domain-specific application design.

VI. Limitations and Future Work

A. Current Limitations

The architecture introduces additional system complexity relative to prompt-centric approaches. Explicit controllers, state representations, and simulation layers require greater upfront design effort and tighter integration among system components.

The approach also assumes that task structure can be sufficiently formalized. Domains with highly subjective evaluation criteria or weakly defined progression rules may require hybrid designs that combine deterministic checks with probabilistic judgment.

The architecture does not address optimization of language quality or persuasive effectiveness. Its focus is procedural integrity as opposed to conversational richness.

The deterministic governance model may also introduce rigidity in domains where task progression is inherently exploratory or where valid sequences are not fully specifiable in advance. Creative workflows, open-ended research tasks, or domains with subjective completion criteria may require hybrid designs in which constraint strictness is relaxed or dynamically negotiated.

B. Future Extensions

Future work may explore declarative task specification languages that allow stages, constraints, and transition logic to be defined without custom code. This would reduce the effort required to author new staged tasks.

Empirical evaluation of user experience and learning outcomes under deterministic governance is another natural extension. Comparative studies could examine differences between prompt-centric, agentic, and constraint-driven architectures.

Adaptive control policies may also be investigated, allowing constraint strictness or feedback style to vary based on observed user behavior while preserving deterministic stage boundaries.

VII. Conclusion

This study presented a constraint-driven conversational architecture for supporting structured, staged task interaction with large language models. The proposed design separates probabilistic language generation from deterministic task governance by introducing an external control layer responsible for dialogue state management, stage transitions, and constraint enforcement. By externalizing task logic and progression rules, the architecture avoids relying on prompt-based control alone to preserve procedural integrity during multi-turn interaction.

Through an illustrative instantiation in customer discovery tasks, the study demonstrated how staged processes and bounded information disclosure can be operationalized without embedding task logic directly into language prompts. The architecture enables conversational flexibility while maintaining explicit guarantees over task progression, permissible actions, and disclosure boundaries.

Rather than focusing on outcome evaluation, this work contributes an architectural pattern for LLM-driven conversational

systems that require structured interaction and enforceable task constraints. The proposed approach is intended to be reusable across domains where the integrity of staged processes is critical, and it provides a foundation for future work that may explore empirical evaluation, task configuration languages, or adaptive control policies built atop the same deterministic governance framework.

The central contribution of this work is the articulation of deterministic task governance as an architectural requirement for LLM-driven conversational systems, instead of a behavioral property to be induced through prompting or autonomous reasoning.

FUNDING

This work was supported by the Ateneo de Manila University Research Council under the University Research Council (URC) grant program, Grant No. URC-2026-05, awarded to Joseph Benjamin Ilagan.

ACKNOWLEDGMENT

The authors thank Maria Mercedes T. Rodrigo, Ph.D., the Department of Information Systems and Computer Science (DISCS) of the Ateneo de Manila University, the John Gokongwei School of Management (JGSOM), the Ateneo Business Insights Laboratory for Development (BUILD), and the Ateneo University Research Office (UREO) for institutional support and administrative assistance related to this work.

DECLARATION ON GENERATIVE AI

Generative artificial intelligence tools were used to support language refinement and drafting during manuscript preparation. All scientific content, system design decisions, arguments, and conclusions were developed by the human authors. The authors critically reviewed, edited, and take full responsibility for the accuracy, originality, and integrity of the manuscript.

Measurement of Dataset Quality and Computational Quality of Graph Neural Networks on Analog Integrated Circuit Recognition System

Arif Abdul Mannan[1], Koichi Tanno[2]
Faculty of Engineering, University of Miyazaki, Miyazaki, Japan[1]
Department of Electrical Engineering, Brawijaya University, Malang, Indonesia[1, 2]

***Abstract*—To meet the needs of AI design in analog IC design automation and especially in big data applications, the application of sensitive and precise Graph Neural Network (GNN) recognition will become increasingly necessary. This sensitive GNN recognition is needed to accommodate the highly stringent trade-offs on analog IC design requirements, combined with the increasingly large learning data requirements. Furthermore, more precise GNN recognition will be a fundamental requirement for a more sensitive system to accommodate noise in floating point (FP) calculations, namely inaccuracies and imprecision in IEEE 754 FP calculations. In this study, by refining a previously proposed method that uses the output vector representation (OVR) of the untrained Graph Neural Network (GNN), and by exploiting the numerical reproducibility error in FP calculations, a method for measuring the sensitivity and precision of GNNs for use in analog IC design recognition has been proposed. The results of the sensitivity and precision measurements of the proposed method show a complex combination of effects between dataset quality (the presence or absence of data duplication), the sensitivity of the GNN to distinguish each feature in the dataset, the complexity of the calculations that occur in the GNN, and the level of quality of the FP calculations performed by the processing unit related to the non-ideal FP calculations. With certain GNN configurations, the proposed method also succeeded in measuring the difference in FP calculation quality of Central Processing Unit (CPU) and Graphics Processing Unit (GPU), where, for big data applications, from the tests carried out, the maximum amount of data that can be distinguished by the CPU is 25 to 100 times more than with the GPU. Because it only uses untrained GNN OVR and does not involve any training process in obtaining results, the proposed method is still unable to obtain a correlation with the final value of GNN performance after training is complete. The measurement method using GNN OVR involving the learning process is future work.**

***Keywords*—Big data; Graph Neural Network; Artificial Intelligence; calculation quality measurement; analog circuit design**

I. Introduction

Artificial intelligence (AI) is highly needed in the world of Integrated Circuit (IC) design. However, the application of AI in analog IC design is still very limited. The main reason for the slow implementation of AI in analog IC design is the very stringent trade-offs inherent in analog IC design and the high dependence on the knowledge of engineers. Small parameter changes in an analog IC design can cause significant changes in the behavior and output of the analog IC being designed [1], [2], [3], [4], [5]. Therefore, to design an AI system for analog IC design applications, a neural network (NN) system capable of distinguishing even the smallest changes in analog circuit design parameters is required [6], [7]. In other words, in big data applications, AI applied to analog IC design must have a high level of sensitivity [8], [9], [10], [11].

The application of NN, particularly graph neural networks (GNNs), to analog IC design has been discussed previously [1], [8], [12]. The application of GNNs such as Graph Convolutional Network (GCN) [13], Graph Isomorphism Network (GIN) [14], Graph Attention Network V2 (GAT) [15], and GraphSage (GSG) [16] has also been studied. All these GNNs utilize floating-point (FP) calculations. As we know, FP calculations are inherently inaccurate and imprecise due to the internal processes within the Central Processing Unit (CPU) or Graphics Processing Unit (GPU). As long as FP calculations in CPUs/GPUs still use IEEE 754 [17], these inaccuracies and imprecisions are inevitable [18], [19], [20], [21], [22], [23]. Therefore, all GNNs applied to analog IC design must not only be able to distinguish very small parameter changes (high sensitivity) but also possess high precision, allowing them to tolerate the inaccuracies and imprecisions inherent in the floating-point calculation system within the CPU/GPU.

The ability to measure the sensitivity and precision of a neural network (NN) [24] used in analog IC design would be extremely useful for simplifying the AI design process, if feasible. The application of GNN output calculations to detect data duplication in a dataset for analog IC design, to measure the sensitivity of NN inputs, has been successfully implemented using a floating-point digit rounding system [8]. However, this proposed implementation in [8] has a weakness: determining the exact value for the floating-point digit rounding in data duplication detection remains uncertain. This proposed implementation only uses exact values based on best-case trials, leaving the challenge of measuring the precision of floating-point calculations in NNs unresolved.

In this study, a new method for determining the exact value of floating-point digit rounding in measuring the level of data duplication in datasets, specifically for the application of GNNs in analog IC design, is proposed. This new idea is based on exploiting the inaccuracy and imprecision of floating-point calculations within the CPU/GPU itself. Therefore, in addition to obtaining the ability to measure the level of duplication and/or measure the level of GNN's ability to distinguish each data in the dataset (GNNs sensitivity) more precisely, with the

technique proposed in this study, the ability to measure the level of precision of the CPU/GPU (or other NN processors, including the possibility of FPGA [25]) in processing GNN calculations can also be obtained. Therefore, the use of 32-bit, 64-bit, or even the possibility of using 16-bit FP in [26] can be determined. Although this measurement method is intended for analog IC design, the use of this proposed method can be applied directly to other applications, whether using GNN or other artificial NN (ANN), as long as they have the same OVR structure.

This study consists of the following sections: The method for obtaining calculation quality measurements from GNNs is described in Section II. Simulations and discussions are presented in Section III, while conclusions and future work are presented in Section IV.

II. GNN Calculation Quality Measurement

In this study, the measurement of GNN calculation quality is obtained by optimizing and developing a previous method that also uses an untrained GNN output vector representation (OVR) in [8]. The use of untrained GNN OVR is very useful because it is expected that the process of measuring GNN performance (sensitivity and precision) can be done even before the training process occurs. Before discussing the method of measuring the calculation quality of GNNs, graph datasets and GNN output will first be explained.

For a graph-based dataset, consider a dataset that contains $\mathcal{V}$ number of graph information as $\mathcal{G}(\mathcal{V},\mathcal{E})$, with additional information that can also be added, such as the input features $\{x_v, \forall_v \in \mathcal{V}\}$, have variate number of vertex (node v) and edge (ε) array length on every graph. The GNN OVR z_v is obtained from every neighborhood vector $h_v^{(l)}$ for all $v \in \mathcal{V}$ as shown in Eq. (1):

$$z_v = h_v^{(L)} \quad ,\forall v \in \mathcal{V} \tag{1}$$

As explained in the previously proposed method, in this study, the same GNN OVR z_v structure, as shown in Eq. (2), will be used as the basis for the calculation. This results in variations in $\mathcal{V}$ and $\mathcal{E}$ being negligible and resulting in data with a fixed C dimensional output (C is the number of classes in the dataset) being generated.

$$z_v = \left(z_{v_1}, z_{v_2}, z_{v_3}, \cdots z_{v_c}\right), \forall v \in \mathcal{V} \tag{2}$$

Based on the output value of GNN OVR z_v, $prpDist$ parameter and $prDiff$ parameter will be obtained [8]. The $prpDist$ is the pseudo distance parameter, calculated simply by using the sum of the absolute value of every axis's scalar value difference between two points, as shown in Eq. (3):

$$prpDist_p = \begin{cases} \sum_{i=1}^{C} \left| z_{r_i} - z_{p_i} \right| & at\ r \neq p \quad r,p \in \mathcal{V} \\ 0 & at\ r = p \quad r,p \in \mathcal{V} \end{cases} \tag{3}$$

With z_r and z_p is vector value of the reference point and point under test in the C -dimension output, respectively. The $prDiff$ is the "difference" parameter, calculating the relative difference between two points of OVR data on the C dimensional space into one scalar number, as shown in Eq. (4):

$$prDiff_p = \sum_{i=1}^{C} (z_{r_i} - z_{p_i}) n_{r_i} \tag{4}$$

With n_{r_i} is obtained from the i-th element of N_r, the normalized reference point array (NRA), consists of fractional number with range from $0 \leq n_{r_i} \leq 1$ and calculated using Eq. (5):

$$N_r = \frac{Z_r - z_{r_{min}}}{z_{r_{max}} - z_{r_{min}}} \tag{5}$$

A. Twice GNN OVR Generation

Techniques for measuring the imperfections of FP calculations using shadow execution [18], [19], and incorporating external factors into the calculation [20] have been proposed previously. In this "calculation quality measurement," the measurement is obtained by calculating the difference between two GNN OVR results performed using the same environment and configuration. Ideally, these two GNN OVR results should be the same, but due to the numerical reproducibility error in FP calculations [21], [22], [23], the two GNN OVR results will differ. Simply put, in this study, the measurement method is carried out by exploiting numerical reproducibility errors in FP calculations. As shown in Algorithm 1, these two (or more) GNN OVR outputs can be easily obtained by using one of the following three methods:

1) Identical input generation: Recognize the untrained GNN twice using the same input dataset. Based on Eq. (1) and Eq. (2), this identical input generation method can be described as Eq. (6):

$$\begin{aligned} z1_v &= \left(z1_{v_1}, z1_{v_2}, z1_{v_3}, \cdots z1_{v_c}\right) = h_v^{(L)}, \forall v \in \mathcal{V} \\ z2_v &= \left(z2_{v_1}, z2_{v_2}, z2_{v_3}, \cdots z2_{v_c}\right) = h_v^{(L)}, \forall v \in \mathcal{V} \end{aligned} \tag{6}$$

2) Reversed input generation: Recognize the untrained GNN once using the initial input dataset, then perform a second recognition using the initial dataset with its graph sequence reversed. The GNN OVR output from the second recognition is then reversed to match the order of the first recognition results. Based on Eq. (1) and Eq. (2), this reversed input generation method can be described as Eq. (7):

$$\begin{aligned} z1_v &= \left(z1_{v_1}, z1_{v_2}, z1_{v_3}, \cdots z1_{v_c}\right) = h_v^{(L)}, \forall v \in \mathcal{V} \\ z_j &= \left(z_{j_1}, z_{j_2}, z_{j_3}, \cdots z_{j_c}\right) = h_j^{(L)}, \forall j \in J \end{aligned} \tag{7}$$

With $J = \mathcal{V}[::-1]$ and $z2_v = z_j[::-1]$. The $[::-1]$ is the operation of reverse order of the array data.

3) Randomized input generation: Recognize the untrained GNN once using the initial input dataset, then perform a second recognition using the initial dataset with its graphs sequence randomized. The GNN OVR output from the second recognition is then reordered (in the reverse order of the

previous randomization) to match the order of the first recognition results. Based on Eq. (1) and Eq. (2), this randomized input generation method can be described as Eq. (8):

$$z1_v = \left(z1_{v_1}, z1_{v_2}, z1_{v_3}, \cdots z1_{v_c}\right) = h_v^{(L)}, \forall v \in \mathcal{V}$$
$$z_m = \left(z_{m_1}, z_{m_2}, z_{m_3}, \cdots z_{m_c}\right) = h_m^{(L)}, \forall m \in M \quad (8)$$

With $M = R(\mathcal{V})$ and $z2_v = R^{-1}(z_m)$. The $R()$ is the operation or the process of randomly arranging the array sequence based on a relationship table that has been created randomly before recognition is carried out, and the $R^{-1}()$ is the process of returning an array order from random to normal based on the same table.

Algorithm 1: Two GNN OVR generator

```
PROGRAM OVRMatrixGenIden()
INPUT h_v
OUTPUT z1_v, z2_v
Compute
for v in V do
z1_v ← recog(h_v)
end for
for v in V do
z2_v ← recog(h_v)
end for
return z1_v, z2_v

PROGRAM OVRMatrixGenReversed()
INPUT h_v
OUTPUT z1_v, z2_v
Compute
for v in V do
z1_v ← recog(h_v)
end for
h_j ← h_v [::-1]    // h_j is h_v in reverse order
for j in J do
temp_j ← recog(h_j)
end for
z2_v ← temp_j [::-1]
return z1_v, z2_v

PROGRAM OVRMatrixGenRandom()
INPUT h_v
OUTPUT z1_v, z2_v
Compute
dataSuffleIndex ← RandomList(0, len(h))
for v in V do
z1_v ← recog(h_v)
end for
for index, data in dataSuffleIndex
h_m_index ← h_v_data  // h_m is h_v in random order
end for
for m in M do
temp_m ← recog(h_m)
end for
for index, data in dataSuffleIndex
z2_data ← temp_index
end for
return z1_v, z2_v
```

To produce the two GNN OVR outputs, only one of the three existing methods is required. In this study, the randomized input generation (with the highest probability of numerical reproducibility error in FP calculations) will be used as a reference for the simulation in Section III.

After the two GNN OVRs are calculated, $prpDist$ and $prDiff$ will be calculated using Eq. (3) and Eq. (4). Each GNN OVR will produce one pair of variables $prpDist$ and $prDiff$. Therefore, the variables $prpDist1$ and $prDiff1$ will be obtained from the OVR $z1_v$, while $prpDist2$ and $prDiff2$ will be obtained from the OVR $z2_v$ calculation.

"**Important!** Starting from $prpDist$ and $prDiff$ calculations onward, using more accurate and precise floating-point calculations is crucial. If the GNN OVR calculation uses 32-bit FP, then calculating $prpDist$ and $prDiff$ requires at least 64-bit FP to obtain a precise measurement of the GNN calculation quality."

B. Calculation Quality Measurement

In this study, two variables will be determined in the GNN calculation quality measurement results: the calculation quality percentage (CQP) and the calculation quality digit (CQD). The CQP is defined as the percentage of data certainty (still able to ascertain its precision) that is still unaffected by floating point inaccuracy and imprecision at each decimal point. Meanwhile, the calculation quality digit is defined as the lowest digit value in a FP calculation result that can still be ascertained for its precision before errors from floating point inaccuracy and imprecision affect it. Examples of GNN calculation quality measurements are presented in TABLE I and Fig. 1. TABLE I shows that up to 7 digits after the decimal point, 100% of the data can be ascertained for its precision. Meanwhile, for up to 8 digits after the decimal point, the data with ascertained precision drops to 83%, indicating that 17% of the data has experienced precision degradation due to non-ideal FP calculations. Therefore, the CQD based on the example of TABLE I is 7.

TABLE I. EXAMPLE OF GNN CALCULATION QUALITY RESULT

Decimal Places	*Calculation Quality Percentage (CQP)*	*Remarks*
0	100%	
1	100%	
2	100%	
3	100%	
4	100%	
5	100%	
6	100%	
7	100%	<= CQD
8	83%	
9	20%	
10	15%	

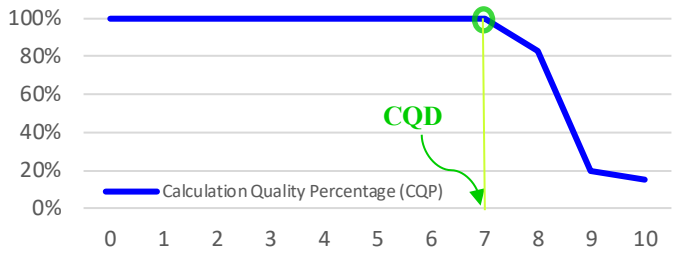

Fig. 1. The example of GNN calculation quality chart.

By using the two pairs of $prpDist$ and $prDiff$ generated in Section II-A, the quality measurement of the GNN calculations can be performed. Assuming that the FP calculations in Section II-A are ideal, then all the results of $prpDist1$ will be the same as $prpDist2$. However, floating point calculations on CPU/GPU are not ideal (floating point inaccuracy and imprecision), so there will be a slight difference between $prpDist1$ and $prpDist2$ as shown in Eq. (9):

$$prpDist1_p \approx prpDist2_p \quad ,\forall p \in \mathcal{V} \tag{9}$$

If we describe the exact value of $prpDist2$ results, we will obtain Eq. (10). From Eq. (9) and Eq. (10), if applied to prdiff1 and prdiff2, then Eq. (11) will be obtained.

$$\epsilon Dist_p = prpDist1_p - prpDist2_p \quad ,\forall p \in \mathcal{V} \tag{10}$$

$$\epsilon Diff_p = prDiff1_p - prDiff2_p \quad ,\forall p \in \mathcal{V} \tag{11}$$

where, $\epsilon Dist$ and $\epsilon Diff$ are the error values resulting from the inaccuracy and imprecision of FP numbers.

By obtaining the $\epsilon Dist$ value, the quality of the GNN calculation will be determined based on the exponent value of the most significant digit in $\epsilon Dist$ compared to the exponent value of the most significant digit in $prpDist1$ or $prpDist2$. The same applies to $\epsilon Diff$. The exponent value of the most significant digit can be obtained using Algorithm 2.

Algorithm 2: Get Exponential Scale

```
PROGRAM GetExpScale()
INPUT x_v
OUTPUT t_v
Compute
for v in V do
t_v ← truncate(log(x_v))
end for
return t_v
```

By obtaining the highest exponent value of $prpDist1$ (one can be selected between $prpDist1$ and $prpDist2$), calculation Eq. (12) can be performed. Therefore, the relative error value $ErDist_p$ of $\epsilon Dist$ based on $prpDist1$ can be obtained from Eq. (13):

$$tDist1_p = GetExpScale(prpDist1_p) \tag{12}$$

$$ErDist_p = \epsilon Dist_p \odot 10^{tDist1_p} \quad ,\forall p \in \mathcal{V} \tag{13}$$

The same is true for $prDiff$, so that Eq. (14) and Eq. (15) can be obtained:

$$tDiff1_p = GetExpScale(prDiff1_p) \tag{14}$$

$$ErDiff_p = \epsilon Diff_p \odot 10^{tDiff1_p} \quad ,\forall p \in \mathcal{V} \tag{15}$$

Based on the results from Eq. (13) and Eq. (15), the CQP calculation process can be carried out using Algorithm 3. Algorithm 3 is only able to calculate the CQP value at one decimal place. So if a CQP with a decimal point value ranging from 0 to 10 is required (as in the example in TABLE I), then 11 calculations using Algorithm 3 are required.

Algorithm 3: Get Single Quality Percentage

```
PROGRAM GetQualityPercentage()
INPUT ErDist_p, ErDiff_p, DecimalTest
OUTPUT Qp
Compute
for p in V do
tempDist ← ErDist_p * 10^DecimalTest
resDist_p ← |tempDist| < 1
tempDiff ← ErDiff_p * 10^DecimalTest
resDiff_p ← |tempDiff| < 1
end for
resAll = logical_and (resDist_p, resDiff_p)
resGood = nonzero (resAll )
Qp = 100 * len(resGood) / len(resAll )
return Qp
```

C. Special Value Decimal Places

With the $\epsilon Dist$ and $\epsilon Diff$ values obtained from Eq. (10) and Eq. (11), and based on the calculations performed in Algorithm 3, the decimal digit values that can be entered do not have to be integers. The digit values entered can be fractional numbers. In this study, the digit values with values $x.3$ and $x.6$ are chosen to increase the resolution of the CQP results. The digit value $x.3$ is chosen because the value of $10^{-0.3}$ has a value close to 0.5 (the exact value used in the actual calculation as shown in Algorithm 3 is $10^{x.30103}$; or the value 10^{x} multiplied by 2), and the digit value $x.6$ is chosen because $10^{-0.6}$ has a value close to 0.25 (the exact value used in the actual calculation as shown in Algorithm 3 is $10^{x.60206}$; or the value 10^{x} multiplied by 4). Example of rounding down using 2, 2.3, 2.6 and 3 decimal places after the comma is shown is TABLE II.

TABLE II. EXAMPLE OF ROUNDING DOWN USING 2, 2.3, 2.6 AND 3 DECIMAL PLACES

Real Numbers	Rounding (down) n-digits after the decimal point			
	2.0	2.3	2.6	3.0
3.1214	3.1200	3.1200	3.1200	3.1210
3.1231	3.1200	3.1200	3.1225	3.1230
3.1274	3.1200	3.1250	3.1250	3.1270
3.1287	3.1200	3.1250	3.1275	3.1280
3.1330	3.1300	3.1300	3.1325	3.1330

III. SIMULATION AND DISCUSSION

In the simulation in this study, the simulation results of dataset duplication detection from [8] will be included. The

results of dataset duplication detection will be named the GNN & Dataset Compatibility (GDC) variable, which consists of: GNN & dataset compatibility map (GDCM) and GNN & dataset compatibility value (GDCV). Similar to CQP, which has its own value at each decimal point, GDCM shows the combined value of GNN sensitivity and dataset quality (dataset uniqueness; the presence or absence of data duplication) at each decimal point. Meanwhile, GDCV is the value of GNN & Dataset Compatibility exactly at the decimal point indicated by CQD.

The main purpose of measuring the calculation quality and compatibility of GNN & Dataset is to help the design of GNN that will be used in analog IC design automation system. In this study, for analog IC design applications, the dataset to be used, extracted using the method in [27], has the features as shown in TABLE III. In this simulation section, this dataset will be referred to as "MOSFET".

TABLE III. MOSFET DATASET FEATURE

Datasets Feature	Quantity
Number of data	2,115
Number of classes	121
Min data per class	1
Max data per class	795
NETLIST length	5,214,505
NETLIST number of line	95,615
Number of MOSFET(s)	74,626
Number of Power Supply(s)	4,234
Number of Resistors(s)	7,804
Number of LC(s)	11

For all simulations measuring the quality of GNN calculations and dataset quality, a personal computer with a 10850K CPU, 64GB RAM, an RTX 4070 Ti GPU, a Windows 10 system, and a Python environment with PyTorch for neural network computations were used. To obtain GNN OVR data, simulations were performed with both the CPU and or GPU in 32-bit FP format. Meanwhile, calculations starting from $prpDist$ and $prDiff$ up to CQP, CQD, GDCM, and GDCV were performed purely on the CPU with a higher FP accuracy configuration of 64-bit FP format.

A. Measurement Results of 1-Node Multi-Edge and Net Connection Abstraction MOSFET

In this simulation section, the quality of GNN calculations and the dataset quality of MOSFET with 1-Node Multi-Edge & Net Connection (1NMC) abstraction in [12] is measured. The measurement results of CQP, CQD, GDCM and GDCV for 2115 data (121 classes) in 1NMC abstraction are shown in TABLE IV and Fig. 2. This simulation was performed using GIN (there is no specific reason for choosing GIN; GCN, GAT, GSG, or other GNNs could also be used), 128-dim input layer dimension, no hidden layer, 128-dim output layer, and GPU calculation as the Processing Unit (PU) to generate GNN OVR. SDD in TABLE IV represents "successfully differentiated data", indicating the number of unique data that are successfully differentiated by GNN, while DIN (Data integrity number) represents the number of data that are not affected by FP calculation noise (inaccuracy and imprecision of FP calculation).

TABLE IV. GIN 128-DIM, NO HIDDEN LAYER, 128-DIM, GPU

Decimal Places	SDD	GDCM	DIN	CQP	Remarks
0.0	23	1.10%	2115	100.00%

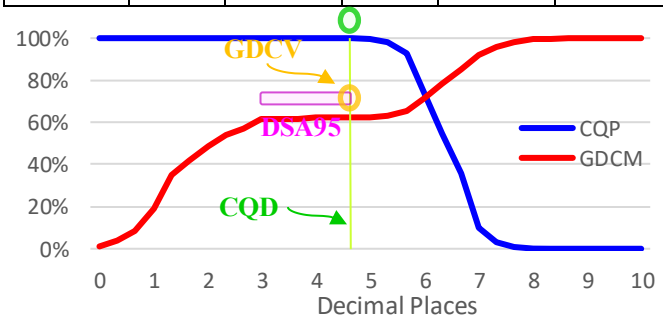

Fig. 2. Dataset and calculation quality measurement for 1NMC abstraction MOSFET using GIN 128-dim, GPU.

From the measurement results outlined in TABLE IV and Fig. 2, the following points can be observed:

1) The CQD value of the 1NMC abstraction MOSFET is 4.3 decimal places. This indicates that the inaccuracy and imprecision of the FP calculation begin to affect the GNN output starting at 4.6 decimal places.

2) The GDCV for the 1NMC abstraction MOSFET is 1312/2115, or 62.0%, at 4.3 decimal places. This indicates that the GNN settings in this measurement failed to distinguish 803 from 2115 data points, even though the GNN calculation was not yet affected by the imperfections of the FP calculation. It can be concluded that the GNN quality of 62.0% is due to either the dataset containing duplicate data or the GNN's insufficient power to distinguish between the data points.

3) If the Data Stability Area of 95 (DSA95) is defined as the area where the GNN can distinguish at least 95% of the data from the GDCV value and has a sensitivity of 100 decimal places, then the DSA95 of a 1NMC abstraction MOSFET is 1.6. This means the GNN can distinguish more than 58.9% of the data (95% from the GDCV of 62.0%) to 1.7 decimal places before the imperfections in the FP calculation begin to degrade the calculation's precision. Basically, the imperfection resulting from the FP calculation can be called noise, producing a random effect on the GNN calculation. In other words, DSA95 can be equated with the Signal to Noise Ratio (SNR) in the Analog IC world, where the noise floor starts from 4.6 decimal places (95% was chosen as a consideration that 95% is included in the stable category in the author's view; if a minimum of 98% is desired, it will be DSA98; the number can be anything, from 0% to 100%).

B. Optimized Dataset Duplication Detection

The GDC quality measurement results obtained can be generated from one or both of the dataset duplication and the GNN's ability to distinguish each data. To be able to obtain a more accurate level of dataset duplication, measurements can be carried out using various methods so that the effect of the GNN's inability to distinguish each data can be minimized. Methods that can be done include increasing or reducing the number of GNN hidden layers, changing the dimensions of the GNN layers, using various types of GNN, and using different PU (CPU / GPU or other NN processors). Of these various methods, the highest GDCV results can be said to be the value closest to the actual dataset duplication.

TABLE V. GIN 128-DIM WITH 0, 1, 2, AND 3-HIDDEN LAYER; GPU

GNN type	n-dim	n-hidden layer	CQD	GDCV	DSA95	PU
GIN	128	0	4.6	62.0%	1.6	GPU
GIN	128	1	4.3	62.0%	1.3	GPU
GIN	128	2	4.3	62.1%	1.3	GPU
GIN	128	3	4.6	62.1%	1.6	GPU

Using the 1NMC abstraction MOSFET dataset, the measurement results of the quality of GNN calculations with several kinds of hidden layers, various kinds of layer dimensions, various types of GNNs, and the use of CPU and GPU processors are shown in TABLE V and Fig. 3, TABLE VI and Fig. 4, TABLE VII and Fig. 5, and TABLE VIII and Fig. 6, respectively.

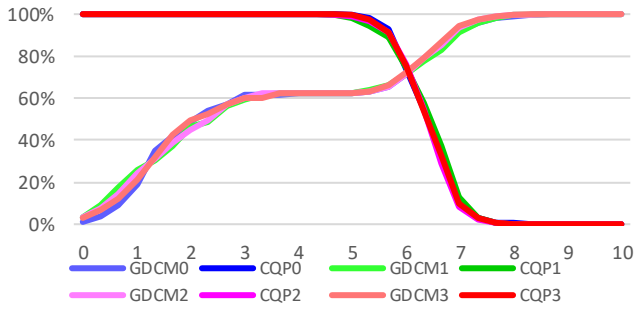

Fig. 3. Dataset and calculation quality measurement for 1NMC abstraction MOSFET using GIN 128-dim, multiple hidden layer, GPU.

TABLE VI. GIN 2, 4, 8, AND 32-DIM WITH 1-HIDDEN LAYER; GPU

GNN type	n-dim	n-hidden layer	CQD	GDCV	DSA95	PU
GIN	2	1	4.6	47.9%	2.3	GPU
GIN	4	1	4.6	62.0%	2.3	GPU
GIN	8	1	4.6	62.0%	2.3	GPU
GIN	32	1	5.0	62.0%	2.0	GPU

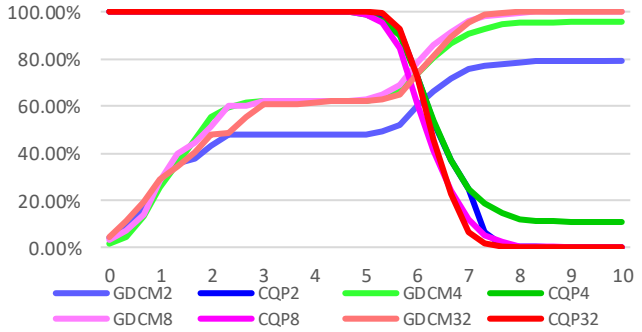

Fig. 4. Dataset and calculation quality measurement for 1NMC abstraction MOSFET using GIN multiple dim, GPU.

TABLE VII. GCN, GIN, GAT, GSG 128-DIM WITH 2-HIDDEN LAYER; GPU

GNN type	n-dim	n-hidden layer	CQD	GDCV	DSA95	PU
GCN	128	2	6.3	61.9%	1.7	GPU
GIN	128	2	4.6	62.1%	1.3	GPU
GSG	128	2	6.3	61.9%	1.7	GPU
GAT	128	2	6.6	62.0%	2.0	GPU

Based on the measurement results as described in TABLE V, TABLE VI, TABLE VII, and TABLE VIII, the highest GDCV value is 1314/2115 (62.1%). This value can be concluded as the closest value to the actual total data duplication (there is still a possibility that all GNN configurations that have been carried out have the same weaknesses and fail to distinguish certain data). Or if measurements are carried out with the aim of designing GNN in analog IC design automation, the GNN configuration that is most sensitive to the 1NMC abstraction MOSFET dataset is the GNN with a configuration that has a GDCV of 62.1%.

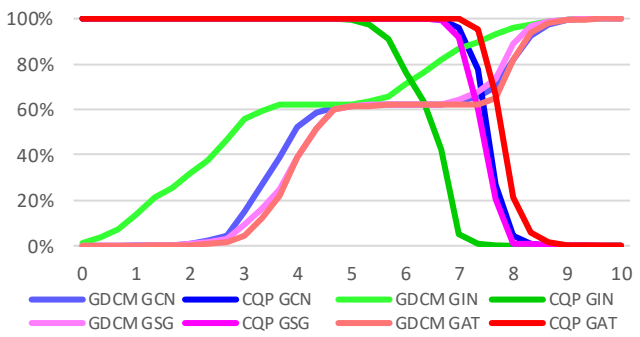

Fig. 5. Dataset and calculation quality measurement for 1NMC abstraction MOSFET using GCN, GIN, GAT and GSG on GPU.

TABLE VIII. GCN, GIN, GAT, GSG 128-DIM WITH 2-HIDDEN LAYER; CPU

GNN type	n-dim	n-hidden layer	CQD	GDCV	DSA95	PU
GCN	128	2	7.3	62.0%	2.3	CPU
GIN	128	2	5.3	62.1%	2.3	CPU
GSG	128	2	6.6	61.9%	2.0	CPU
GAT	128	2	6.6	62.0%	1.6	CPU

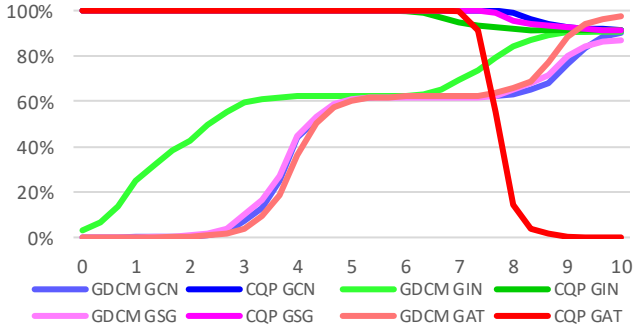

Fig. 6. Dataset and calculation quality measurement for 1NMC abstraction MOSFET using GCN, GIN, GAT and GSG on CPU.

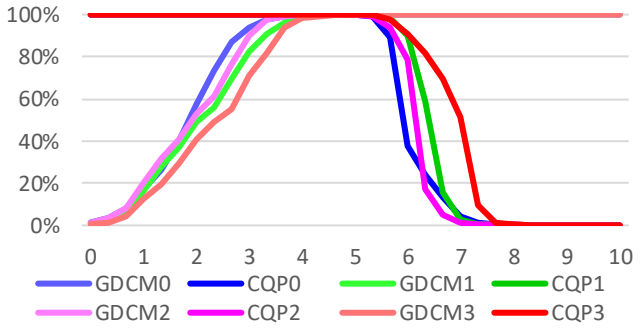

Fig. 7. Dataset and calculation quality measurement for 4NC abstraction MOSFET with multiple hidden layer.

As a comparison of the 1NMC abstraction MOSFET dataset, the measurement process with various GNN configurations was also carried out on the 4-nodes & Net Connection (4NC) abstraction MOSFET dataset in [12] with one of the measurement results shown in Fig. 7. The best GDCV value obtained by this 4NC abstraction MOSFET dataset is 2114/2115 (99.95%). Therefore, compared with the 1NMC abstraction, based on the measurement results obtained, the decision to use the 4NC abstraction is more recommended for use in designing AI for analog IC designs.

C. CPU and GPU 32-Bit FP Performance

The GNN calculation quality measurement in this study can also be used to compare the calculation quality of the processing unit used (such as CPU or GPU) in applying the desired GNN & dataset configuration. The method used in comparing this processing unit calculation quality is by generating one "untrained GNN" (as an initial example, generated on the CPU), and performing recognition (to generate the GNN OVR). Then this "untrained GNN" is transferred to another processing unit (for example, GPU) and performing recognition with the same dataset. The GNN OVR generation process does not have to be only once, in this simulation, each processing unit, four sets of GNN OVR are generated.

The performance comparison of this processing unit calculation quality will be proportional to the difference in CQP and CQD obtained. As an example case, the difference in calculation quality between CPU and GPU for the 1NMC abstraction MOSFET dataset using a 32-dimensional 1-hidden-layer GIN is shown in Fig. 8 and TABLE IX. Both CPU and GPU in this test use 32-bit FP in their calculation process.

TABLE IX. CPU VS. GPU CALCULATION QUALITY MEASUREMENT

GNN type	n-dim	n-hidden layer	CQD	GDCV	DSA95	PU
GIN	32	1	5.3	62.0%	2.0	GPU
GIN	32	1	5.3	62.0%	2.0	GPU
GIN	32	1	5.3	62.1%	2.0	GPU
GIN	32	1	5.0	62.0%	1.7	GPU
GIN	32	1	6.0	62.0%	2.7	CPU
GIN	32	1	6.0	62.0%	2.7	CPU
GIN	32	1	6.0	62.0%	2.7	CPU
GIN	32	1	6.0	62.0%	2.7	CPU

Based on Fig. 8, several results are obtained. First, when the CQP is 100% (without any influence from the FP calculation imperfections, confirmed up to 5.0 decimal places), the 4 sets of GDCMs from the CPU and 4 sets of GDCMs from the GPU have identical results, shows that the results of the dataset quality measurement (GDC) are independent from the PU being used. Second, after the FP calculation imperfections begin to take effect, in the CQP of the GPU calculation results, 4 out of 4 measured sets vary from each other, while in the CQP of the CPU calculation results, 4 out of 4 measured sets are all identical. This shows that FP calculations in CPUs are more repeatable, more capable of producing the same output values when using the same input and calculation formulas compared to GPUs. And third, based on the measurement results shown in Fig. 8 and Table IX, it is observed that the CQD of the GPU is 0.7 to 1.0 decimal places lower than that of the CPU. Since the calculation quality measurement uses two variables $prpDist$ and $prDiff$, for applications in the big data field, the maximum amount of data in the dataset that can be differentiated (utilizing the entire $prpDist$ and $prDiff$ range that is not affected by the imperfections of the FP calculation) by the CPU will be 25 to 100 times greater than that of the GPU.

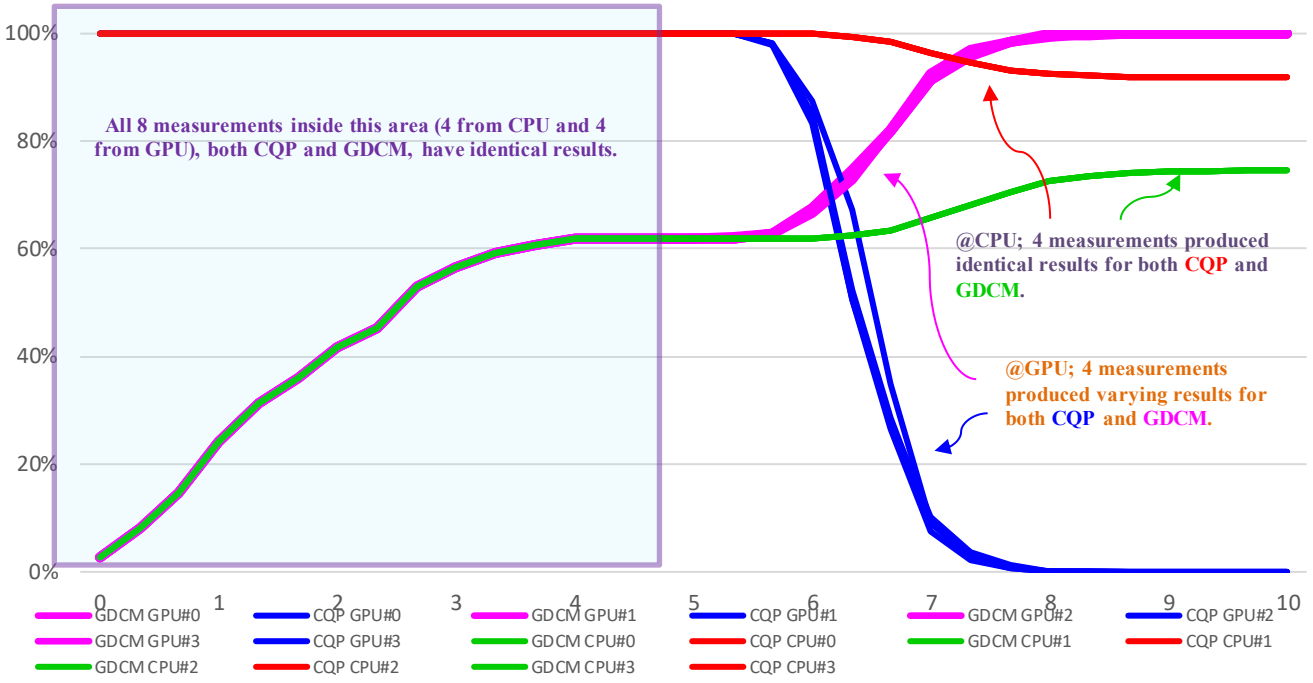

Fig. 8. CPU vs. GPU calculation quality measurement for 1NMC abstraction MOSFET using GIN.

Note: This comparison involves the effects of the programming language used, compiler version, operating system version, device driver version, device microcode version, and other internal processing unit factors. Currently, in this study, these factors cannot be separated and measured individually, so they will be represented in this study as a single variable: the CPU or GPU. If GNN OVR can be generated by applying variations of these factors, then individual measurements for these factors will be possible. Another important thing has also been observed from this comparison of the quality of CPU and GPU calculations: the difference in GNN calculation performance between CPU and GPU is also significantly influenced by GNN & dataset configuration factors, particularly the GNN type (GCN, GIN, GAT, GSG, or other GNN types), as observed in Fig. 5 and Fig. 6. Therefore, the results of this GNN calculation quality measurement can be used as a new opportunity in benchmarking the performance of GNN algorithms.

D. Limitation

The GNN calculation quality measurement in this study has limitations related to the precision of the measurement results. In conducting the measurements, the data used as the basis for calculating CQP, CQD, GDCM, and GDCV, are generated from the recognition of untrained random weight GNN. Therefore, the result of each random weight initialization (the process of creating an untrained GNN) at the beginning of the measurement will produce a small random effect on the measurement results (observed to have very significant random results in certain extreme configurations). The measurement results for 4 times initialization of untrained random weight GNN using the same configuration, namely GIN, 32-dim layer dimension, 1 hidden layer, GPU, are shown in Fig. 9. As well as the example for the measurement results for extreme case conditions using the configuration GIN, 2-dim layer dimension, 1 hidden layer, GPU, are shown in Fig. 10. One example of an extreme configuration that was found to produce very significant random output in this measurement of the quality of GNN calculations is a very low GNN layer dimension configuration.

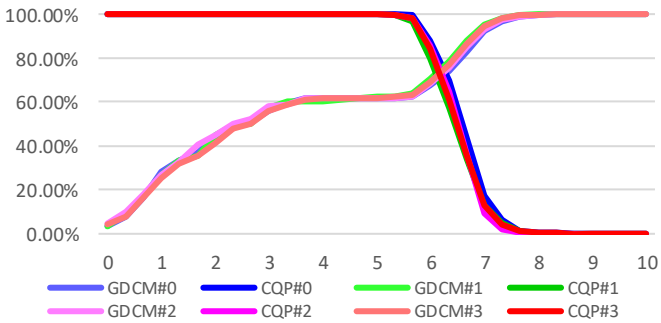

Fig. 9. Dataset and calculation quality measurement for 4N abstraction MOSFET with 32-dim.

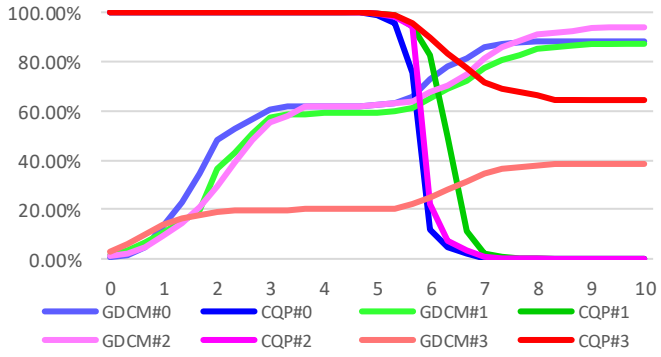

Fig. 10. Dataset and calculation quality measurement for 4N abstraction MOSFET with 2-dim.

IV. CONCLUSION

In this study, a method for measuring dataset quality and GNN calculation quality has been proposed. The measurement of dataset quality and GNN calculation quality is carried out by utilizing the previously proposed $prpDist$ and $prDiff$ calculations, calculating the $prpDist$ and $prDiff$ variables twice (exploiting the numerical reproducibility error in FP calculations) and comparing the differences between the two results to determine the quality of the GNN calculation. There are five variables generated from this proposed method. These variables are CQP, CQD, GDCM, GDCV, and DSA95. CQP and CQD are the results of measuring the quality of the GNN calculation, influenced by a combination of the quality of the FP calculation of the PU being used and the complexity of the GNN algorithm (GNN type) being applied. GDCM and GDCV are the results of a combination of dataset quality (the presence or absence of data duplication) and the sensitivity of the GNN to be able to distinguish each feature contained in the dataset. Meanwhile, DSA95 is the result of a combination of all factors that influence the previous four variables.

By combining multiple GNN configurations in the measurement, the data duplication value in the dataset can be more accurate than previously proposed methods. By combining certain GNN configurations, a comparison of the calculation capabilities between CPU and GPU can also be obtained. This comparison can be obtained based on measuring the initial location of the FP calculation noise after the decimal point. By using GIN and the 1NMC abstraction, calculations using the CPU are observed to be more precise and repeatable compared to using the GPU, so that the maximum amount of data that can be distinguished by GNN in a dataset for big data applications is 25 to 100 times larger.

Since all measurements were taken before the training process began (all measurements used a GNN with random weights that had not been trained and did not involve the training process and weight changes), and the measurement process did not utilize class information in the dataset, a correlation between the GNN calculation quality measurements and the GNN's performance after the training process (training accuracy and validation accuracy) could not be observed. Studying the behavior of measurement results for extreme configurations that can produce very significant random measurements is also the subject of future work.

ACKNOWLEDGMENT

We would like to express our gratitude to Mrs. Toyama for all the support she provided, including the research environment.

AUTHORS' PROFILE

Arif Abdul Mannan was born in Malang, Indonesia, on January 23, 1988. Currently, he is a PhD student in University of Miyazaki, Japan. He received S.T degrees from the Faculty of Engineering, Brawijaya University in 2010. He also received master's degrees from Double-Degree Program of Faculty of Engineering in Brawijaya University and Miyazaki University for his M.T and M.E degree in 2013. His research interests are circuit analysis on digital circuits (microprocessor design and application, digital CMOS integrated circuit design, FPGA & VHDL), and analog circuit (analog CMOS integrated circuit design including multi-valued logic). He can be contacted at email: arifabdulmannan@ub.ac.id.

Koichi Tanno was born in Miyazaki, Japan, on April 22, 1967. He received B.E. and M.E. degrees from the Faculty of Engineering, University of Miyazaki, Miyazaki, Japan, in 1990 and 1992, respectively, and Ph. D degree from the Graduate School of Science and Technology, Kumamoto University, Kumamoto, Japan, in 1999. From 1992 to 1993, he joined the Microelectronics Products Development Laboratory, Hitachi, Ltd., Yokohama, Japan. He contributed to the research on low-voltage and low-power equalizers for reading channel LSI of hard disk drives. In 1994, he joined the University of Miyazaki, where he is currently a Professor in the Faculty of Engineering, and a Vice-president (Collaborative Research and Community Cooperation). His main research interests are in analog integrated circuit design, nano-mist sprayers, and its application. Dr. Tanno is a senior member of IEEE. He can be contacted at email: tanno@cc.miyazaki-u.ac.jp.

LayCoder: UI Layout Completion with an Encoder-Only Transformer and Layout Tokenizer

Iskandar Salama, Luiz Henrique Mormille, Masayasu Atsumi
Soka University, Tokyo, Japan

***Abstract*—The growing complexity of user interface (UI) design calls for effective methods to understand, complete, and refine layout structures. While prior work has focused predominantly on generating UI layouts from scratch, completing partially designed interfaces is equally critical, particularly in iterative design workflows and scenarios involving incomplete prototypes. In this study, we address the UI layout completion task for mobile app screens using an encoder-only transformer architecture with masked modeling and a layout tokenizer. By representing UI elements as discrete tokens, we formulate layout completion as a sequence prediction problem that leverages global context to infer missing components. We evaluate our approach on subsets of the RICO dataset designed with varying constraints on UI element types and spatial overlap, and report results using standard layout metrics: Coverage, Intersection over Union (IoU), Max IoU, and Alignment. The experiments demonstrate that the proposed method achieves substantial improvements over LayoutFormer++, a widely adopted baseline in UI layout generation, particularly in Coverage, and in several cases, IoU, Max IoU, and Alignment. Additional experiments on noise-reduced subsets reveal that dataset curation can enhance spatial consistency but may also reduce Coverage, reflecting an inherent trade-off between completeness and structural precision. These findings highlight both the effectiveness and the limitations of encoder-only masked modeling for layout completion, and underscore the importance of balancing model design with dataset construction when tackling complex UI design tasks.**

***Keywords*—Layout completion; deep learning; encoder-only transformers; masked language modeling; tokenization**

I. Introduction

In the ever-evolving landscape of mobile applications, user interfaces (UIs) play a pivotal role in determining user engagement and satisfaction. As mobile apps have evolved, the design of user interfaces has become more sophisticated, focusing on enhancing user experience through intuitive and visually appealing layouts. This shift towards more user-centric designs matters significantly because studies have shown that user-friendly interfaces can lead to better user retention and increased app usage [1].

Consequently, the demand for efficient and innovative UI design techniques has increased, prompting the integration of generative AI (Gen-AI) into the design process [2], [3]. Generative models offer substantial benefits in UI development, including improved speed and automation [4], reducing the time and effort required for manual layout design.

Historically, research in automatic UI layout modeling has focused primarily on generating complete layouts from scratch [5]. However, the ability to complete partially designed interfaces is equally important—particularly in scenarios that involve iterative refinement or require automatic completion based on existing components [6].

Formally, we define UI layout completion as a conditional structured prediction problem under partial observability. Given a partially observed layout L_{obs}, where a subset of UI elements are missing or masked, the objective is to predict the missing elements L_{miss}. The completed layout $\hat{L}$ should remain spatially and semantically consistent with realistic UI design patterns.

This task differs from unconditional layout generation, as the model must preserve existing components while inferring plausible missing structure conditioned on the visible layout context. This formulation reflects practical early-stage design scenarios, where interfaces are incomplete and require context-aware completion to support iterative refinement.

To address this problem, we investigate the potential of encoder-only transformer models to infer missing components from partial UI layouts. Transformers [7] have become a powerful tool across multiple domains, notably in natural language processing and, more recently, layout modeling tasks. Their ability to model long-range dependencies and process sequences in parallel makes them particularly effective for capturing the structure of complex inputs such as UI layouts.

Encoder-only transformers are particularly well-suited for tasks requiring contextual understanding. In layout completion, they can process all visible components and their interrelationships in a single pass, enabling the model to predict missing elements based on global layout context. This capability aligns closely with masked language modeling (MLM) [8], where missing tokens are reconstructed from surrounding information.

Although our formulation is inspired by MLM, LayCoder is not a straightforward adaptation of BERT to discretized layout tokens. Unlike natural language, UI layouts are inherently spatial and structured, requiring joint reasoning about geometry, element semantics, and layout coherence. In particular, each UI component cannot be represented as a single token, but rather as a set of correlated spatial and semantic attributes.

To enable Transformer-based modeling of UI layouts, we therefore convert each layout into a structured sequence of discrete tokens using a custom tokenization mechanism, which we term the *Layout Tokenizer*. The first token represents the *layout category*, and each UI element is encoded through multiple attribute tokens—namely, *centerX*, *centerY*, *width*, *height*, and the *component label*. These attributes are individually mapped into discrete token IDs from a predefined vocabulary.

This representation allows LayCoder to perform masked

completion at the level of structured UI elements, where each missing component corresponds to multiple correlated spatial and semantic attributes. This element-level grouping distinguishes LayCoder from standard MLM models by enabling masked prediction over multi-attribute UI components rather than single discrete symbols.

The Layout Tokenizer operates on a predefined vocabulary consisting of 675 tokens. This layout-specific tokenization transforms the structured UI into a flat sequence of tokens, enabling Transformer models to process and complete UI layouts in a manner similar to how language models predict missing words [9].

Our approach is evaluated using the RICO dataset [25], one of the most comprehensive resources for mobile UI layouts. It contains over 66,000 UI screens and more than 3 million annotated elements, making it a suitable benchmark for layout modeling and completion.

Our main contributions are summarized as follows:

- We propose LayCoder, an encoder-only transformer framework that formulates UI layout completion as masked structured prediction over partially observed mobile app layouts.
- We introduce a custom Layout Tokenizer, which represents UI elements as discrete sequences of spatial and semantic tokens. This design enables Transformer models to leverage global context for inferring missing components in incomplete layouts.
- Through experiments on subsets of the RICO dataset, we demonstrate that the proposed method achieves substantial improvements over LayoutFormer++ [24], a previously leading approach in UI layout generation, with consistent gains in Coverage and notable improvements in IoU and Alignment across multiple test scenarios. The empirical results underscore the efficacy of encoder-only masked modeling in capturing spatial and semantic dependencies within layout structures.
- We further analyze the role of dataset curation by evaluating on noise-reduced subsets. The findings reveal that filtering improves spatial consistency but can reduce Coverage, highlighting the observed trade-off between layout completeness (Coverage) and structural precision (IoU and Alignment) in UI layout completion.

II. Related Work

The automated modeling of UI layouts has attracted significant research attention, with approaches spanning various architectural paradigms and task formulations. To provide a comprehensive overview of this rapidly evolving field, we organize prior work along two primary dimensions: 1) task type, distinguishing between layout generation (synthesizing complete layouts from scratch) and layout completion (predicting missing elements in partial layouts); and 2) architectural approach, encompassing GANs [10], VAEs [11], diffusion models [12], and transformer-based methods [13]. Within transformer-based approaches, we further distinguish between encoder-only, decoder-only, and encoder-decoder variants [14], as these architectural choices significantly impact model capabilities and computational efficiency.

A. Layout Generation Approaches

Layout generation has been addressed through various architectural approaches. GAN-based methods like Akin [15] and LayoutGAN [16] utilize adversarial training to synthesize realistic UI wireframes and graphic layouts by modeling geometric relations of 2D elements.

VAE-based approaches, including LayoutVAE [17], LayoutVQ-VAE [18], and VTN [19], offer robust frameworks for generating diverse layouts by learning latent representations and capturing high-level relationships between layout elements.

Recent advancements in layout generation have seen the emergence of diffusion models as a powerful approach for synthesizing structured layouts with high quality and diversity through discrete denoising processes. Notable examples include LayoutDM [20], [22], LayoutDiffusion [21], and layout decoupled diffusion [23].

Transformer-based models have emerged as a powerful approach for layout generation. Gupta et al. [5] introduced LayoutTransformer, a framework that uses self-attention mechanisms to model contextual relationships between layout elements across various domains, enabling the generation of novel scene layouts from an empty set or an initial seed of primitives.

While these layout generation methods have demonstrated impressive capabilities in synthesizing full-screen UI designs, they primarily address the creation of complete layouts from scratch. However, in many practical design scenarios, designers work with partially specified interfaces that require completing existing structures rather than generating entirely new ones.

B. Layout Completion Approaches

A smaller but growing body of work targets layout completion, which is more aligned with iterative design workflows. Li et al. [6] proposed a model for the auto-completion of user interfaces, focusing on assisting the design process by predicting the remaining UI elements in a partial layout. This approach utilizes Transformer-based tree decoders—Pointer and Recursive Transformer—representing a decoder-only architecture to handle the hierarchical structures and 2-dimensional placements of UI elements. Experiments on a public dataset show the effectiveness of these models, which significantly ease the effort of UI designers and developers. The proposed metrics for measuring tree prediction accuracy further contribute to deep learning research in layout prediction.

LayoutFormer++ [24] provides a unified framework for both generation and completion by serializing user constraints and employing a transformer encoder–decoder model. It introduces a constraint serialization scheme to represent various user constraints as token sequences in a predefined format and applies a decoding space restriction strategy to prune predictions that violate user constraints or yield low-quality layouts. This ensures that the generated results adhere to user requirements without sacrificing visual quality.

In contrast to these decoder- and encoder–decoder-based approaches, our work explores an encoder-only transformer formulation for the layout completion task. This design emphasizes parallel processing and self-supervised masked modeling to infer missing elements efficiently. Further details of the proposed method are described in Section III.

While LayoutFormer++ introduces constraint serialization and decoding space restriction to enforce validity during autoregressive generation, LayCoder adopts a fundamentally different approach. Instead of restricting the decoding space step-by-step, our encoder-only formulation relies on global contextual inference through masked modeling. This removes the need for sequential constraint enforcement but places greater emphasis on learning structural regularities directly from data.

Similarly, tree-decoder approaches explicitly preserve hierarchical structure during generation, whereas our flat tokenization strategy prioritizes modeling flexibility and parallel processing. This design choice trades explicit hierarchical inductive bias for scalability and simpler inference, allowing LayCoder to complete layouts in a single forward pass.

III. Proposed Method

Our proposed method section consists of three main components: 1) the definition of key concepts that characterize UI elements, 2) the tokenization strategy that converts structured UI data into a sequential format, and 3) the masked language modeling approach used to train the transformer.

An overview of the system architecture is provided in Fig. 1.

A. Key Concepts

A user interface (UI) consists of a hierarchy of elements, such as buttons, text boxes, images, and containers. These elements are organized as a tree, where some elements may contain others. We classify UI elements into two categories:

- Leaf elements: are elements that do not contain any child elements. Examples include buttons, text inputs, icons, and images.
- Non-leaf elements: are elements that contain one or more child elements. Examples include containers, lists, modals, and cards.

Each element, whether a leaf or non-leaf, is characterized by the following attributes:

- Spatial Coordinates (Bounds): Each element is represented by four values: x_1, y_1, x_2, y_2, denoting the top-left and bottom-right corners of its bounding box on an original screen with a resolution of 2560×1440.
- Element Label (Component Label): A categorical identifier that represents the type of the UI component, such as Text, Image, Container, etc.

In addition, each UI layout is associated with a global attribute:

Layout Category: A label indicating the overall purpose or category of the UI screen (e.g., Login, Registration, Catalog).

These attributes form the foundation for representing UI elements in our model and are critical to both the dataset construction and the tokenization process described in the following sub-sections.

B. Tokenization

We first construct a fixed vocabulary consisting of discrete token values used to encode spatial and semantic attributes of UI elements. For spatial attributes, we discretize normalized coordinate values in the range of 0 to 640, resulting in 641 unique tokens. For semantic attributes, we include 25 tokens representing the Component Labels (e.g., Text, Image), and seven tokens corresponding to distinct Layout Categories identified from the Akin framework [15]: Login, Splash, Registration, Catalog, Product page, Cart, and No-category. Additionally, we define two special tokens—one for separating between elements and one for masking elements during training. This results in a total vocabulary size of 675 tokens.

Spatial discretization to the range [0, 640] provides a consistent vocabulary but introduces bounded quantization error. The maximum absolute discretization error per coordinate is 0.5 units in the normalized scale, corresponding to less than 0.08% of the full spatial extent. While empirically sufficient for preserving layout structure, this discretization limits sub-pixel precision and should be interpreted as an approximation of continuous geometry.

Using this predefined vocabulary, we apply our Layout Tokenizer to discretize the numerical attributes and categorical labels into tokens. Each numerical attribute (e.g., centerX or width) is mapped to a corresponding token ID selected from the constructed vocabulary.

Each UI element is represented by five tokens: four for the spatial attributes (*centerX*, *centerY*, *width*, *height*) and one for the *Component Label*. Each UI layout is then represented as a sequence of tokens, referred to as the *Layout Token Sequence*. As shown in Fig. 2, this sequence starts with the *Layout Category* token, followed by a separator token, and then the *centerX*, *centerY*, *width*, *height*, and *Component Label* tokens for each UI element. Tokens from distinct elements are separated using the special separator token. Consequently, the total length of the sequence is *6N+2*, where N denotes the number of elements in the UI.

A practical aspect of this serialization is the ordering of UI elements. In our implementation, elements follow the order obtained from traversing the hierarchical RICO JSON tree. Although the rendered layout itself is permutation-invariant, Transformer encoders process sequences and are therefore sensitive to element order. We use this traversal order as a deterministic scheme to ensure reproducibility.

Importantly, this representation allows LayCoder to perform masked completion at the level of structured UI elements, where each missing component corresponds to multiple correlated spatial and semantic attributes. This element-level grouping distinguishes the task from a naive application of token-level masked language modeling, as reconstruction operates over structured components rather than independent tokens.

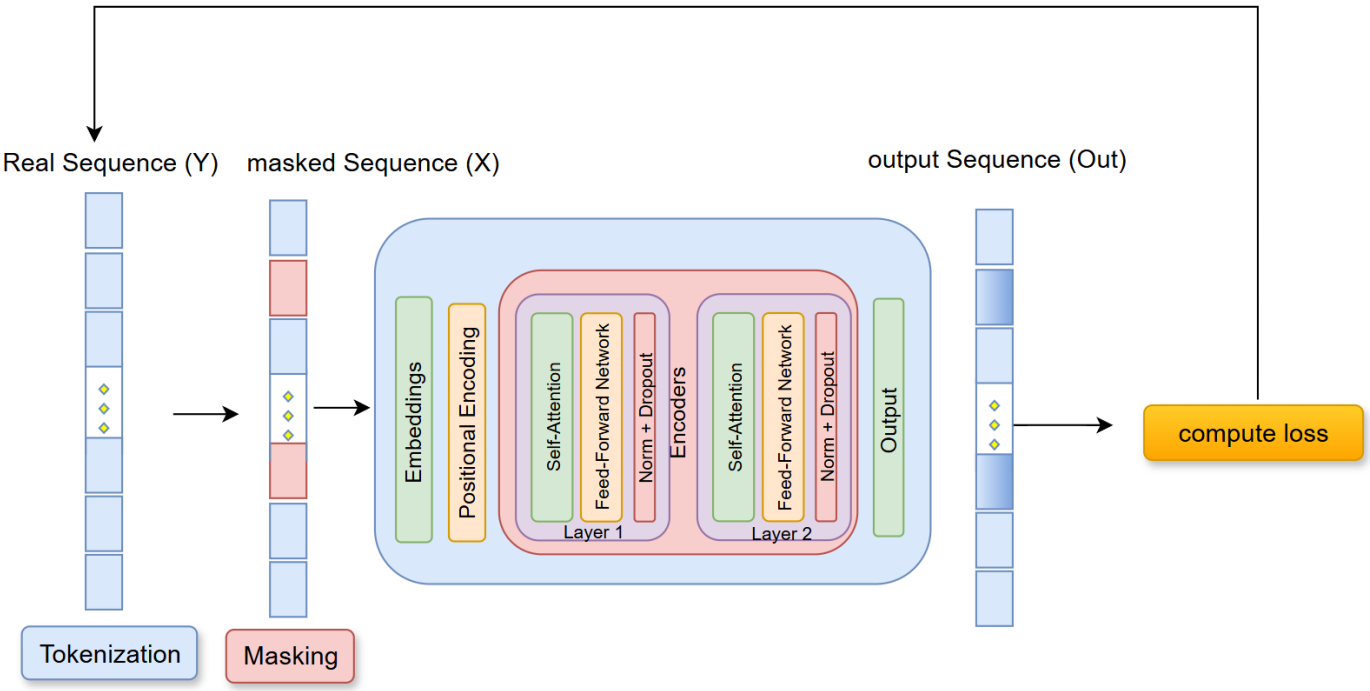

Fig. 1. System architecture: Detailed illustration of the proposed method, including layout tokenization, the masking mechanism, and the two-layer Transformer encoder used for UI layout completion. The architecture highlights how the input token sequence is processed through the encoder to predict the masked UI elements.

This layout-specific tokenization transforms structured UI layouts into flat token sequences that can be processed by the Transformer architecture and can be applied to other datasets with similar structural representations.

C. Encoder Architecture and Masked Training

The architecture follows a standard Transformer encoder stack. Each layer consists of multi-head self-attention, residual connections with layer normalization, and a position-wise feed-forward network. Self-attention enables each token to attend to all other tokens in the layout sequence, capturing long-range spatial and semantic dependencies across UI elements in a single forward pass.

Our approach utilizes an encoder-only transformer architecture, which consists of 2 stacked Transformer layers, each with a hidden size of 512. Within each layer, multi-head self-attention is implemented using 8 attention heads, and the feedforward sublayer has an intermediate dimension of 1024. Layer normalization is applied before each sublayer, and a dropout rate of 0.5 is used within each encoder block to mitigate overfitting. Input tokens are embedded into 512-dimensional vectors using a trainable embedding layer, and positional encodings are added via sinusoidal functions followed by dropout (p = 0.1). The final output is passed through a linear projection layer that maps from the hidden dimension back to the vocabulary size.

We adopt an encoder-only architecture rather than an encoder–decoder model for two reasons. First, masked modeling allows parallel reconstruction of missing elements without autoregressive decoding, reducing inference latency. Second, completion in our setting operates over a partially observed structured sequence, making bidirectional context modeling more natural than left-to-right generation. This design choice favors global contextual reasoning over sequential constraint enforcement.

We incorporate masked language modeling as a core technique of our training objective. It is applied by randomly selecting certain tokens within the layout token sequence and replacing them with our special mask token. During training, this process helps the model learn contextual dependencies between UI elements and their attributes.

Specifically, in the training phase, a random percentage k of tokens from each layout sequence is masked, where $k \in [5\%, 40\%]$. The masked tokens include UI component labels and spatial attributes, while category tokens and separator tokens are excluded to preserve structural consistency. The exact value of k is resampled at the beginning of each epoch. This strategy introduces variability and prevents the model from overfitting to a fixed masking pattern. An example of this token-level masking is illustrated in Fig. 3.

However, during inference, we adopt a masking strategy aligned with LayoutFormer++ [24]. Instead of masking individual tokens independently, we mask complete UI elements—i.e., an element and all of its associated attributes (*Bounds* and *Component Labels*). A fixed masking ratio is applied at the element level rather than the token level. For instance, given a UI layout with 5 elements and a masking ratio of 40%, we mask 2 entire elements, including all tokens representing their attributes. This approach is illustrated in Fig. 4.

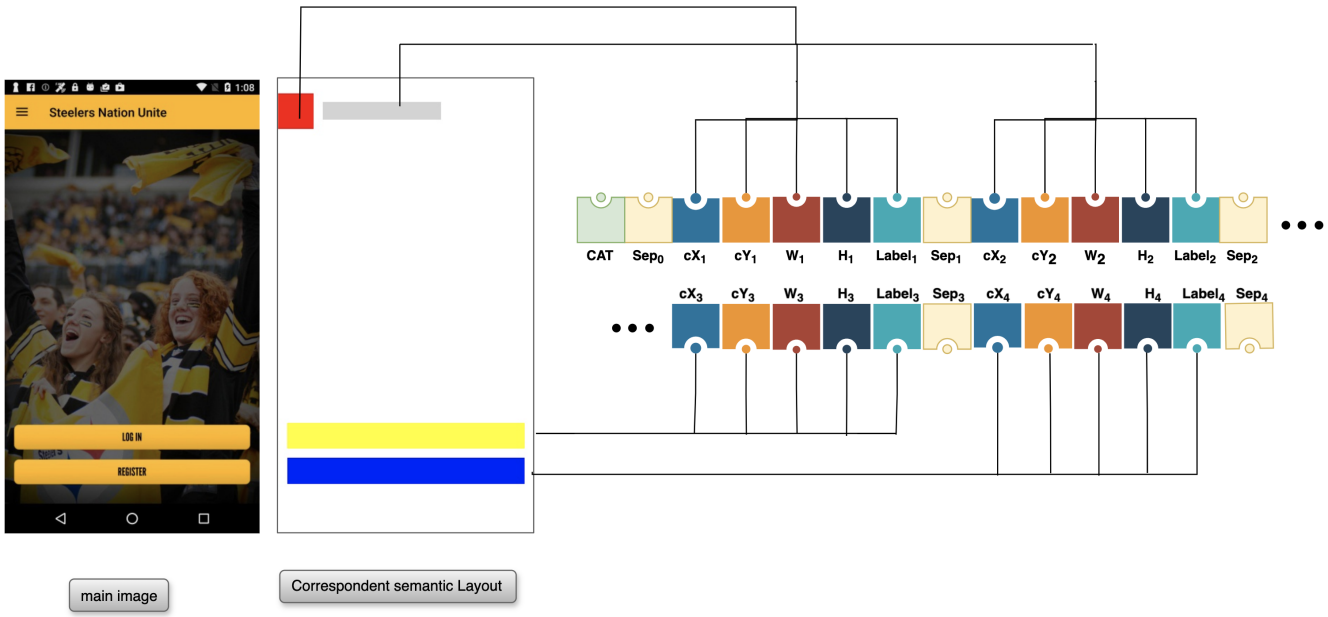

Fig. 2. Overview of the tokenization process using UI as an example with four elements. The Layout Token Sequence begins with the layout category token (CAT), followed by a separator token (Sep). For each UI element, five tokens are appended to the sequence: CenterX (cx), CenterY (cy), width (W), height (H), and the component label (Label). Although the illustration shows four elements, the same procedure applies to layouts with any number of elements.

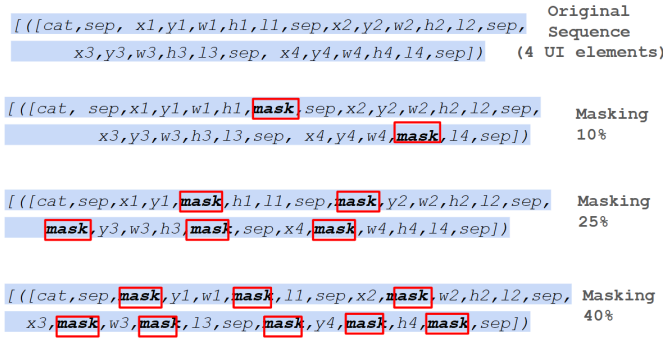

Fig. 3. The masking procedure is applied randomly to each sample in every epoch using a special mask token. The layout category (CAT) and separator (Sep) tokens are never masked; only element attributes are subject to masking. For element i, x_i, y_i, w_i, h_i, and l_i denote centerX, centerY, width, height, and component label, respectively.

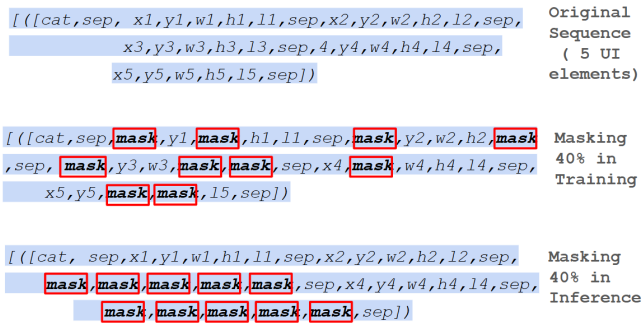

Fig. 4. Comparison of masking strategies between training and inference. During training, masking is applied at the token level, where individual coordinate or label tokens may be masked. During inference, masking is applied at the element level, where all tokens corresponding to a UI element (its coordinates and label) are masked together.

The reason we adopted a different masking strategy during training, as compared to the inference stage, is to learn fine-grained relationships between UI elements, while ensuring that the inference masking setting remains aligned with downstream layout completion scenarios.

The total number of trainable parameters in our configuration is approximately 4.55 million. For a sequence length T, the computational complexity of each encoder layer is $O(T^2)$ due to self-attention. This remains manageable in our setting since layouts are restricted to at most 20 elements (i.e., $T \leq 6N + 2$), enabling efficient training and inference on a single GPU.

IV. Dataset

In this research, we use the RICO dataset [25], a large-scale collection of over 66,000 UI screen images and more than 3 million individual UI elements, collected from a wide variety of Android mobile applications. RICO is one of the most comprehensive and diverse benchmarks for mobile user interfaces, providing rich resources for UI layout generation and completion design tasks.

Each UI screen in the dataset is represented in three formats: 1) a high-resolution screenshot, 2) a corresponding *semantic layout image* that visualizes the structure of the UI using colored bounding boxes (where each color represents a different UI element type, and the size of each box matches

Fig. 5. UI labels color palette: All UI component labels and their corresponding RGB color assignments.

the element's actual size on the original screen), and 3) a JSON file containing detailed metadata. This metadata includes attributes, bounding box coordinates, Android class names, and the hierarchical relationships among elements.

To ensure consistency across all visualizations, the *semantic layout images* use a predefined *UI color palette*, in which each component label is assigned a unique RGB color. Fig. 5 presents the complete set of component labels used in this research together with their corresponding color codes.

A. Re-organizing the RICO Dataset

Following prior work [24], [5], [15], we do not use the RICO dataset in its raw form. Instead, we construct subsets specifically designed to meet the requirements of our proposed method. This involves re-organizing the dataset structure and preprocessing the raw UI layout data accordingly.

As previously described, each UI screen in RICO is accompanied by a JSON file that defines its layout as a hierarchical tree of UI elements. By recursively traversing this tree, we determine the depth of each element and classify them into two categories: leaf elements (elements with no child nodes) and non-leaf elements (elements with one or more children), as described in Section III-A. These distinctions play a central role in how we construct dataset variants for our experimental setups.

To ensure fair comparison with prior work, we build upon the same processed LayoutFormer++ [24] dataset and derive two subset variants, each tailored to a specific experimental objective.

- DS1: This subset corresponds to the version used by LayoutFormer++ during its preprocessing pipeline, in which all UI layouts with more than 20 elements were removed. The result is a curated dataset where each instance contains at most 20 elements. *DS1* consists of 31,694 training samples (221,858 elements), 3,729 test samples, and 1,865 validation samples.
- DS2: This subset is a refined version of *DS1*. Two additional filters are applied: 1) only *leaf elements* are retained, while all *non-leaf elements* are discarded, and 2) any layouts containing spatially overlapping elements are excluded to ensure clean, non-overlapping compositions.

Since our experiments are built upon the same processed subset and data-splitting protocol introduced in LayoutFormer++, the train/test separation follows the established benchmark setting. Layouts are split at the screen-instance level such that no identical UI structures appear across DS1 training and DS2 testing.

However, because RICO contains many visually similar screens within the same application, this protocol does not fully eliminate potential app-level similarity. Consequently, the reported results should be interpreted as generalization across screen instances under the standard benchmark split, rather than strict generalization across entirely unseen applications.

The additional filtering applied in DS2 is motivated by reducing what we refer to as layout noise, namely structural artifacts that may obscure clear spatial patterns. Such noise may arise both from inherent layout complexity and from dataset construction artifacts. In our setting, this includes overlapping elements and non-leaf elements, which can introduce redundancy or hierarchical complexity that is not essential for the layout completion task. By filtering out these elements, we simplify the input representation and promote more consistent spatial modeling and better generalization.

At the same time, this simplification comes with an important modeling trade-off, since UI layouts are inherently hierarchical in nature. However, removing non-leaf elements also eliminates explicit parent–child relationships that encode containment and compositional structure within the UI hierarchy. As a consequence, the model no longer directly observes grouping patterns, nesting depth, or structural dependencies that are central to UI semantics. The DS2 configuration should therefore be interpreted as a structural ablation that isolates spatial reasoning from hierarchical reasoning, rather than as a universally superior representation.

B. Preprocessing

In the preprocessing stage, we normalize the *Bounds* to fit within a 0 to 640 scale, corresponding to the maximum height of the *semantic layout images*. Subsequently, transformations are applied to convert these Bounds into *centerX*, *centerY*, *width*, and *height*, with the former two indicating the center of the element, and the latter two indicating the width and height of the UI element's bounding box.

By transforming the bounds coordinates and normalizing their values, we ensure that the positional information of UI elements is accurately represented within a consistent scale.

The transformation to center-based coordinates allows for more intuitive spatial representations, facilitating the model's ability to understand the layout and structure of the UI elements [27]. The vocabulary described in Section III-B is also constructed as part of this preprocessing step.

V. Evaluation Metrics

In our study, we employed the same evaluation methods used by previous researchers. While our experiments focus on layout completion and some prior studies focus on layout generation, we use the same evaluation metrics in both cases, as they are equally applicable to assessing spatial and structural layout quality. The metrics used in this study are explained as follows:

Coverage Metric is calculated as the proportion of the UI layout area that is occupied by layout elements. In other words, it is the area covered by elements divided by the total area of the canvas (UI layout). Higher scores indicate better coverage, reflecting layouts that are more fully and effectively populated with UI components.

IoU measures the degree to which layout elements overlap within a completed layout. Specifically, it is the average Intersection over Union between each pair of elements (bounding boxes) within the same layout. Mathematically, IoU is defined as the area of Intersection divided by the area of the Union between two bounding boxes, providing a normalized measure that accounts for both the intersecting and non-overlapping regions. The computation of IoU between two elements *A* and *B* is shown in the following equation:

$$\text{IoU} = \frac{|A \cap B|}{|A \cup B|} \tag{1}$$

where, $|A \cap B|$ denotes the area of their intersection, and $|A \cup B|$ denotes the area of their union. Lower scores indicate better IoU, ensuring that no overlap is occurring.

Max IoU provides insight into the maximum overlap any element in a layout has with other elements. It is obtained by first computing the pairwise IoU between each element within a UI, then, for each element, the maximum IoU value is retrieved, and finally, those values are summed and averaged. Similar to IoU, lower Max IoU values are preferable.

Alignment is a metric originally introduced in the Attribute-conditioned Layout GAN paper [26] and later adopted in LayoutFormer++ [24] to evaluate the spatial alignment of UI elements. For each layout element, we compute six reference points: the left, center, and right positions along the horizontal axis, and the top, center, and bottom positions along the vertical axis. Pairwise distances are then calculated between each of these points and the corresponding points of all other elements in the layout. For each element, the minimum of these distances is taken as its alignment error with respect to the rest of the layout.

Finally, the alignment scores are summed and averaged, producing a single scalar value per layout. Lower scores indicate better alignment, reflecting a more structured and visually coherent layout.

These metrics provide a comprehensive evaluation framework by measuring element distribution, spatial overlap, and spatial coherence within each layout. Specifically, Coverage reflects the overall distribution and presence of elements across the layout, IoU and Max IoU quantify the degree of element overlap, and Alignment evaluates spatial coherence.

At the same time, these metrics primarily capture geometric and structural properties of the completed layouts. They do not directly measure semantic correctness of element identities. A completion may achieve strong spatial alignment while predicting an incorrect component label. Therefore, the current evaluation emphasizes spatial fidelity rather than full element-wise reconstruction accuracy.

VI. Experiments

In this section, we trained our models on two curated subsets of the RICO dataset, *DS1* and *DS2*, introduced in Section IV. Our models were trained to infer and complete UI layouts with up to 40% of elements randomly masked. More specifically, we systematically varied the masking rate of UI elements from 5% to 40% during training and inference, in order to evaluate the models with different levels of masked information.

Furthermore, model performance is assessed using the evaluation metrics described in the previous Section: Coverage, IoU, Max IoU, and Alignment. The original, unmasked UI layouts serve as ground-truth references, and model performance is evaluated using the defined metrics by comparing the predicted layouts with these references.

A. Model Variants

We trained two variants of our proposed model using the aforementioned datasets:

- LayCoder — a model trained on *DS1*, containing up to 20 elements per UI layout, and including both leaf and non-leaf nodes. The model was trained using the same preprocessing steps as [24].
- LayCoder-NonOver-Leaves — a model trained on *DS2*, a refined version of DS1 containing only leaf nodes and no overlapping elements. This model leverages the simplified structure of the data (leaf-only nodes and non-overlapping elements) to evaluate the impact of dataset noise reduction on model performance.

We aim with the first variant to demonstrate that our proposed model, *LayCoder*, achieves superior performance compared to the baseline, *LayoutFormer++*, across standard layout evaluation metrics.

With *LayCoder-NonOver-Leaves*, we specifically test the hypothesis that reducing layout noise—through the exclusion of overlapping elements and non-leaf nodes—can enhance model performance. Though we evaluate both models on the same test set (the testing subset of *DS2*). *LayCoder* was trained on noisier and more diverse layouts (*DS1*), while *LayCoder-NonOver-Leaves* was trained on a less noisy dataset (*DS2*). We ensure as well that the test set of *DS2* does not overlap with the training data of *DS1*. This setup allows us to examine the importance of curating the data to contain only elements relevant to our task and measure its impact on the model's ability to generalize and accurately infer UI structures.

B. Experimental Setup

All experiments were conducted on an NVIDIA RTX 3090 GPU. During training, random masking between 5% and 40% was applied to the token sequence, as described in the Method section. We adopted cross-entropy loss, computed only over the masked tokens; unmasked tokens, as well as special tokens and layout category tokens, were excluded from the loss calculation. The model predicts each masked token from a predefined vocabulary of 666 discrete tokens, which includes 641 tokens representing discretized bounding box attributes and 25 tokens corresponding to element labels. The model is trained using the Adam optimizer with an initial learning rate of 1e-4. A batch size of 64 is used, and training proceeds for 1000 epochs with early stopping based on validation loss, which is monitored every 100 epochs.

VII. Results and Discussion

A. Quantitative Results

Experimental results are detailed in Table I and Table II. In these tables, the row labeled as *Real Data* indicates the mean values for each evaluation metric computed over the unmasked test subsets of DS1 and DS2, serving as the reference baseline. These values represent the expected metric scores for complete, unmasked layouts. The preceding rows, labeled as *10% masking*, *25% masking*, and *40% masking*, indicate the performance of each model when completing UI designs with 10%, 25%, and 40% of masked elements, respectively.

In Table I, we compare the performance of our first model, the *LayCoder*, with the *LayoutFormer++* [24] on the testing subset of *DS1*, which includes a mix of leaf and non-leaf elements.

As introduced in Section V, the performance of the models is evaluated using the following metrics: Coverage, IoU, Max IoU, and Alignment. Furthermore, the Δ value for each metric denotes the absolute difference between the layouts produced by each model and the reference baseline:

$$\Delta = |\text{Predicted} - \text{Baseline}| \tag{2}$$

Therefore, a smaller Δ indicates that the predicted layouts closely approximate the original data.

In the first row of Table I, when masking 10% of the data, we observe a substantial performance difference, particularly in Coverage. *LayCoder* achieves a score very close to the real data, with $\Delta = 1.76$, whereas *LayoutFormer++* shows a much higher $\Delta = 32.38$, indicating severe under-coverage. For IoU and Max IoU, *LayCoder* also achieves smaller Δ values (0.002 and 0.013, respectively) compared to *LayoutFormer++* (0.022 and 0.065). These results indicate closer alignment with the reference layouts in terms of overlap. In terms of Alignment, *LayCoder* achieves a perfect $\Delta = 0$, meaning that its completions under 10% masking are equivalent to the baseline layouts without masking. This outcome is consistent with the low masking ratio, where fewer elements are removed and reconstruction is less challenging.

As the masking ratio increases to 25%, *LayCoder* continues to outperform *LayoutFormer++* across all metrics. For Coverage, LayCoder's $\Delta = 3.20$ is still much closer to the real data than LayoutFormer++ ($\Delta = 32.17$). Similarly, for IoU ($\Delta = 0.007$ vs. 0.022), Max IoU ($\Delta = 0.037$ vs. 0.064), and Alignment ($\Delta = 0.001$ vs. 0.004), LayCoder remains stronger. Although its scores show a small degradation compared to the 10% case, this is expected as the masking ratio increases. By contrast, LayoutFormer++ shows little change compared to its 10% performance. This relative stability may be attributed to its additive, sequential training strategy, where elements are generated incrementally. As a result, increasing the masking percentage does not substantially alter its completion behavior.

At 40% masking, both models face more challenging conditions, but *LayCoder* still demonstrates stronger generalization. Its Coverage $\Delta = 3.47$ remains far superior to LayoutFormer++ ($\Delta = 32.37$), suggesting that LayCoder better preserves the overall density of elements under high masking. For Alignment, both models are close ($\Delta = 0.003$ vs. 0.002). On IoU and Max IoU, LayCoder records $\Delta = 0.017$ and 0.072, while LayoutFormer++ remains at 0.024 and 0.066. Although LayoutFormer++ appears slightly better in Max IoU at this level, its Coverage remains very poor ($\Delta \approx 32$ across masking levels).

Since Coverage measures the proportion of the layout canvas occupied by elements, such low values suggest that many UI components are missing, leading to incomplete layouts that deviate substantially from the ground truth. This behavior is closely related to the differing completion paradigms of the two models. LayoutFormer++ generates elements autoregressively in a fixed sequential manner without explicit conditioning on the final number of elements to be produced. As a result, it often yields conservative predictions under high-masking settings, leading to systematic under-coverage and relatively stable scores across masking ratios.

In contrast, LayCoder performs masked reconstruction within a fixed-length sequence, where the number of missing elements is implicitly determined by the masked slots. This formulation encourages preservation of element count and overall layout density. Both models were evaluated under identical masking ratios and metric implementations to ensure consistency.

In summary, across all three masking levels (10%, 25%, 40%), *LayCoder* consistently produces results closer to the real data. Its Coverage is significantly better than *LayoutFormer++* in every experiment, with Δ values ranging from 1.76 to 3.47 compared to around 32 for *LayoutFormer++*. In IoU, Max IoU, and Alignment, *LayCoder* also maintains lower or comparable Δ values, showing stronger robustness under increasing masking ratios.

While the performance of *LayoutFormer++* appears stable across masking levels, this stability reflects the limitations of its autoregressive decoder-based architecture. Because it generates layouts sequentially, the model appears less sensitive to the amount of masked content and shows limited adaptability as masking increases. By contrast, *LayCoder*'s encoder-only masked modeling leverages global layout context, enabling it to adapt better to different masking conditions, preserve spatial structure, and maintain performance much closer to the real-data.

The observed results in Table II indicate that in terms of Coverage, *LayCoder* remains consistently closer to the real

TABLE I. COMPARATIVE RESULTS ON DS1 AT DIFFERENT MASKING LEVELS

Masking	Model	Coverage ↑ (Mean, Δ)	Overlap (IoU) ↓ (Mean, Δ)	Max IoU ↓ (Mean, Δ)	Alignment ↓ (Mean, Δ)

A comparative evaluation between LayCoder and LayoutFormer++ at different masking levels using the test set from DS1, which includes both leaf and non-leaf UI elements. Real Data at the bottom of the table represents metrics computed on unmasked UI layouts as a ground-truth reference.

TABLE II. COMPARATIVE RESULTS ON DS2 AT DIFFERENT MASKING LEVELS

Masking	Model	Coverage ↑ (Mean, Δ)	IoU ↓ (Mean = Δ)	Max IoU ↓ (Mean = Δ)	Alignment ↓ (Mean, Δ)
10%	LayCoder-NonOver-Leaves	41.21 (**$\Delta = 0.49$**)	**0.002**	**0.024**	0.0183 (**$\Delta = 0.0004$**)
	LayCoder	**42.30** ($\Delta = 0.60$)	0.003	0.033	**0.0179** ($\Delta = 0.0008$)
25%	LayCoder-NonOver-Leaves	38.80 (**$\Delta = 2.90$**)	**0.008**	**0.058**	0.0204 (**$\Delta = 0.0017$**)
	LayCoder	**41.43 ($\Delta = 0.27$)**	0.015	0.089	**0.0162** ($\Delta = 0.0025$)
40%	LayCoder-NonOver-Leaves	37.00 (**$\Delta = 4.70$**)	**0.014**	**0.092**	0.0198 (**$\Delta = 0.0011$**)
	LayCoder	**41.89 ($\Delta = 0.19$)**	0.032	0.144	**0.0137** ($\Delta = 0.0050$)
Real Data		**41.70**	**0.000**	**0.000**	**0.0187**

Evaluation of LayCoder and LayCoder-NonOver-Leaves under different masking levels, using test samples from DS2, which contains only non-overlapping leaf elements. Note that the ground-truth reference scores (Real Data) for Intersection over Union (IoU) and maximum IoU are zero; thus, the reported mean values are equal to their corresponding Δ values.

data across all masking levels (Δ = 0.60, 0.27, and 0.19 at 10%, 25%, and 40%, respectively), whereas *LayCoder-NonOver-Leaves* shows larger deviations (Δ = 0.49, 2.90, and 4.70). This confirms that the leaves-only, non-overlapping training setup sacrifices Coverage, leading to layouts that omit some elements compared to the ground truth.

In contrast, for the spatial consistency metrics (IoU, Max IoU, and Alignment), *LayCoder-NonOver-Leaves* generally outperforms *LayCoder*. For instance, at 25% masking, it achieves lower Δ IoU (0.008 vs. 0.015) and Δ Max IoU (0.058 vs. 0.089), indicating reduced element overlap and stronger alignment with ground-truth structures. At 40% masking, *LayCoder* achieves a lower mean Alignment score (0.0137 vs. 0.0198). However, *LayCoder-NonOver-Leaves* reports lower Δ values for IoU, Max IoU, and Alignment, indicating stronger spatial consistency with the ground-truth.

Overall, these findings suggest that training on clean, non-overlapping leaves improves spatial consistency in terms of overlaps and relative positioning, but at the cost of reduced Coverage. Thus, the results highlight a clear trade-off: while curated datasets can strengthen spatial precision, they may also lead to incomplete reconstructions that fail to capture all layout elements present in the original designs.

B. Qualitative Analysis

To complement the quantitative results, we also conducted a qualitative analysis to examine the behavior of our proposed models under different masking conditions. For readability, the layouts are displayed using the same color-coded scheme introduced in Section IV, with component labels distinguished by the *UI color palette* (see Fig. 5).

Fig. 6 illustrates the predictions of *LayCoder* on one sample from the DS1 test set under three masking ratios: 10%, 25%, and 40%. For each ratio, the masked input and the completed layout are shown, while the corresponding ground-truth layout (labeled as "Real UI layout" in the figure) is displayed at the bottom. In many cases, the model successfully reconstructs missing elements and maintains a coherent spatial structure. The completions are not always identical to the ground truth, and in some cases the model generates alternative components or placements. While these differences can still yield plausible layouts from a design perspective, we emphasize that this observation is based on illustrative examples rather than systematic evaluation.

For further assessment, Fig. 7 presents results on three different UI layouts from DS1, each with a different masking ratio (10%, 25%, and 40%). Alongside reasonable completions, the figure highlights typical failure modes such as overlapping components, duplicated elements in the same region, or missing items. These examples demonstrate that although *LayCoder* can often predict plausible completions, it may also produce undesirable layouts under challenging conditions, especially at higher masking levels.

In Fig. 8, we evaluate both *LayCoder* and *LayCoder-NonOver-Leaves* on samples from DS2, where only leaf elements are retained and overlapping layouts are excluded. Using a 40% masking ratio, we compare the completed layouts of both models against the ground truth. The figure shows that *LayCoder-NonOver-Leaves* often avoids generating overlapping elements and produces cleaner structures, which is consistent with the hypothesis that reducing layout noise during training improves spatial consistency. However, limitations remain: in some cases, the outputs omit required elements or contain misaligned components, reflecting the cost

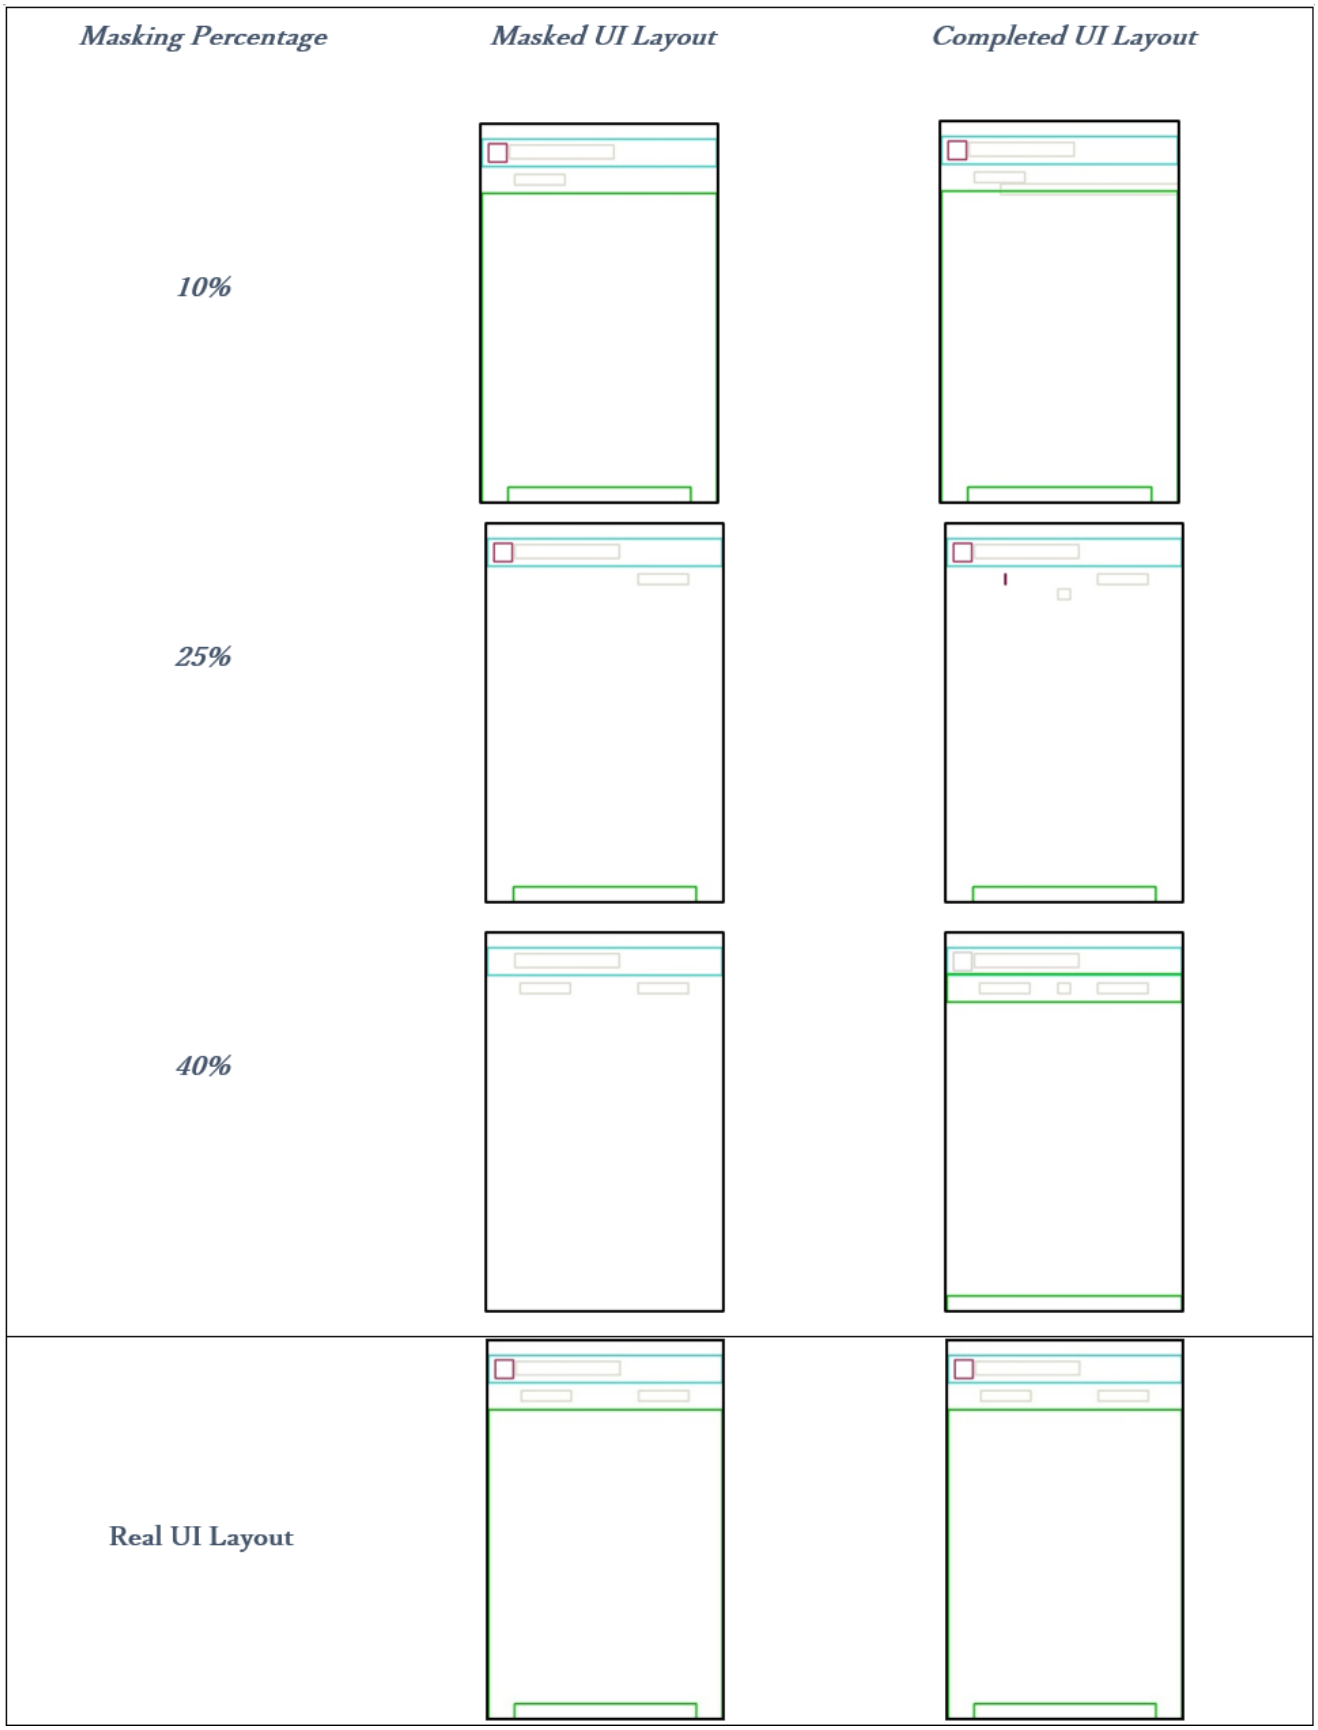

Fig. 6. Qualitative results of LayCoder on a DS1 sample under 10%, 25%, and 40% masking. Each row shows a masked input with the corresponding masking ratio and the resulting completion by LayCoder. The last row shows the ground-truth (real UI) layout.

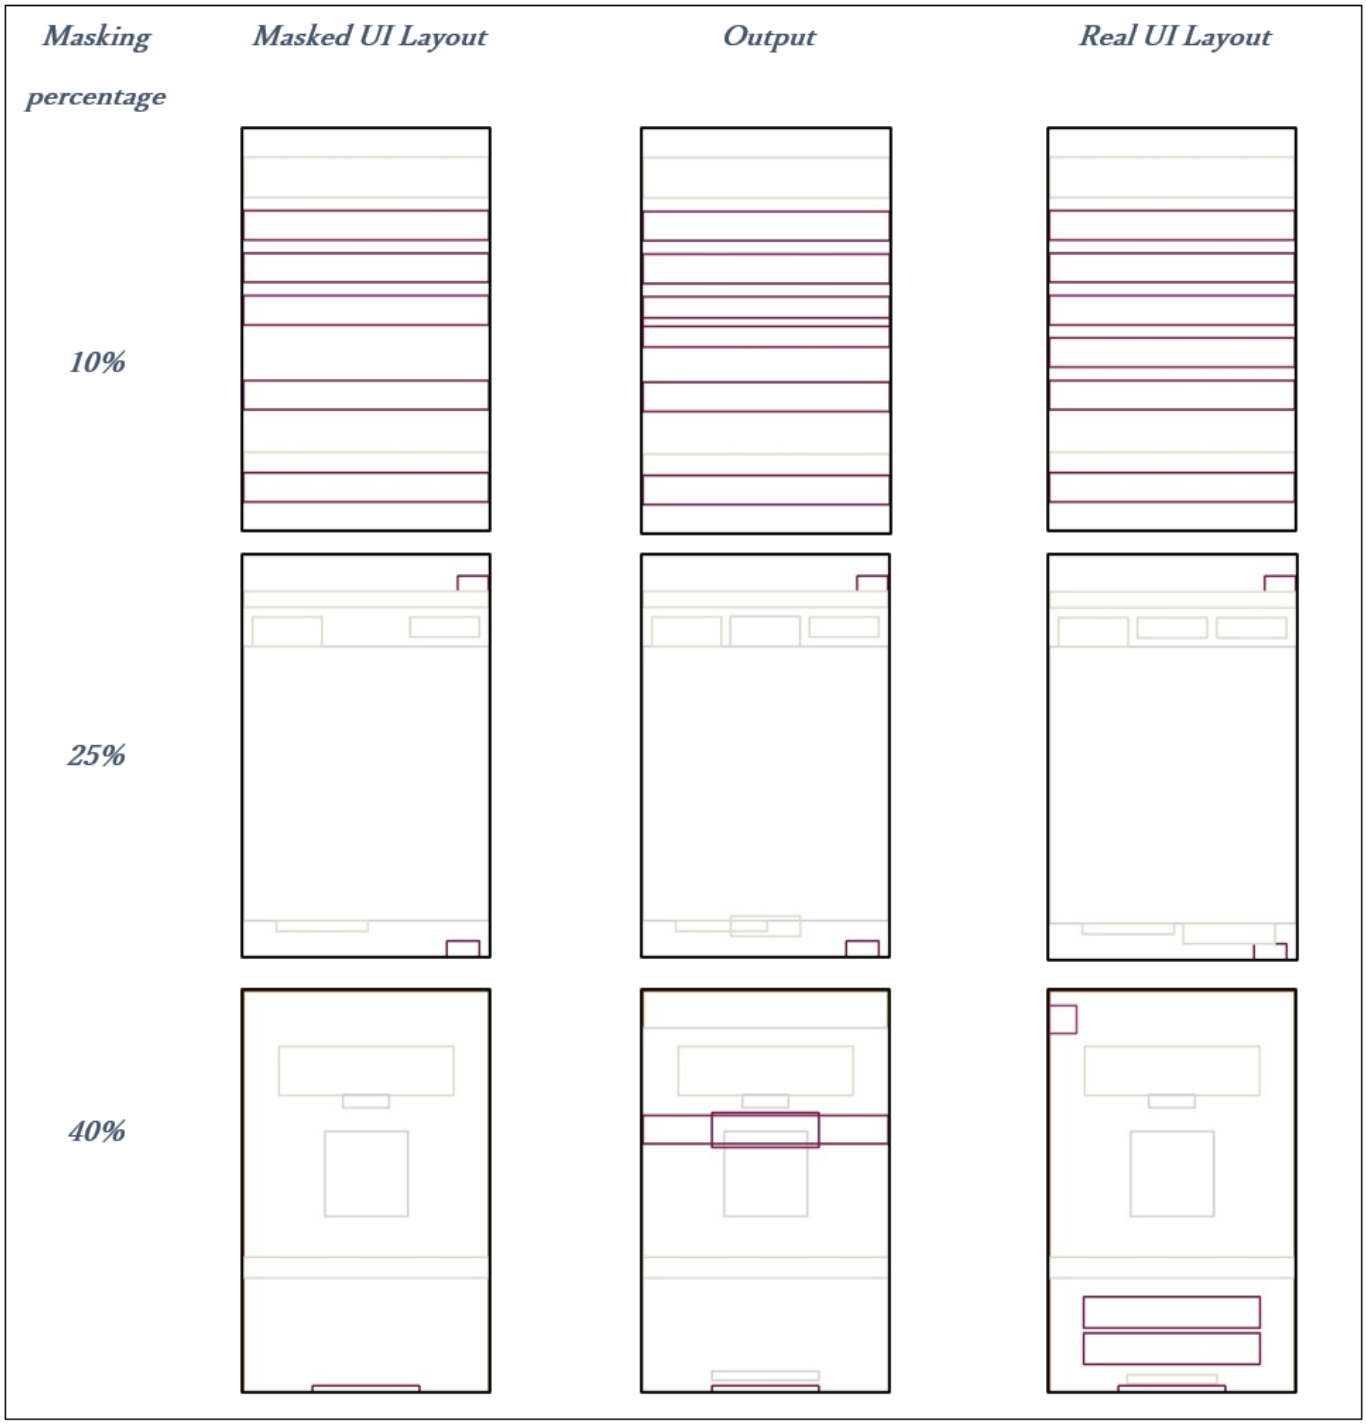

Fig. 7. Some failure cases from DS1 under different masking ratios. Examples highlight overlaps, duplicated elements, and missing components in *LayCoder* outputs.

of training on a more constrained dataset. Thus, while dataset curation enhances certain aspects of spatial accuracy, it does not guarantee uniformly superior results.

Overall, the qualitative evaluation highlights both the strengths and weaknesses of the proposed models. *LayCoder* demonstrates the ability to infer missing elements and produce plausible layouts across different masking levels, while *LayCoder-NonOver-Leaves* benefits from noise reduction by yielding cleaner structures. At the same time, both models exhibit failure cases that reveal important directions for further improvement.

Fig. 8. Comparison between *LayCoder* and *LayCoder-NonOver-Leaves* on DS2 with 40% masking. For each layout example, the masked input is shown alongside the completed outputs of both models and the corresponding ground-truth (real) UI layout.

VIII. Conclusion

In this study, we introduced LayCoder, an encoder-only Transformer formulated as a masked completion model for UI layout reconstruction. Our experiments show that LayCoder achieves competitive performance compared to LayoutFormer++, delivering improved Coverage and comparable or improved IoU and Alignment across the evaluated masking levels.

The results indicate that encoder-only transformer architectures combined with masked modeling are effective for layout completion under the evaluated settings. This formulation enables the model to leverage global context and learn structural dependencies without requiring explicit element-level annotations.

To further investigate the role of training data, we evaluated a noise-reduced subset of the dataset that excluded overlapping elements and non-leaf nodes. The results show that this curation can improve spatial consistency in terms of overlap and relative positioning, but at the cost of reduced Coverage. These findings suggest that dataset filtering shifts the balance of performance: strengthening certain structural aspects while limiting completeness, rather than uniformly enhancing predictions.

Despite these results, the current formulation relies on flat token representations and relatively shallow architectures, and does not explicitly model hierarchical relationships or complex structural constraints. Therefore, the findings should be interpreted as demonstrating the viability of masked encoder-only completion within the evaluated regime, rather than establishing scalability to deeper hierarchical modeling.

Failure cases reveal issues such as overlaps, duplications, or missing elements under challenging masking conditions, reflecting a structural trade-off between element completeness and precise spatial alignment. This trade-off suggests that incorporating additional structural constraints or relational representations may further improve the balance between layout completeness and spatial coherence in future work.

Acknowledgment

The authors would like to thank the creators of the *Rico dataset* and the authors of *LayoutFormer++* for making their data and code publicly available, which facilitated this research.

Data Availability

The datasets used in this study were derived from the publicly available *LayoutFormer++* dataset, which is based on the Rico dataset and available at https://github.com/microsoft/LayoutGeneration/tree/main/LayoutFormer++. We further processed this dataset to create two subsets, **DS1** and **DS2**, provided as `.pkl` files. All processed data and related preprocessing scripts are publicly available in our GitHub repository at https://github.com/salsik/LayCoder-Data under the MIT license.

Code Availability

The source code implementing the LayCoder model and training procedures is available at the project repository: https://github.com/salsik/cssl.

Reducing Interference in Human–Robot Collaboration: A Distance-Based Policy for Disassembly Collaborative Task

Wendy Cahya Kurniawan, Wen Liang Yeoh, Osamu Fukuda
Department of Computer Science and Intelligent Systems, Saga University, Japan

***Abstract*—This study investigates human-robot collaborative (HRC) disassembly tasks, focusing on the effects of constrained and unconstrained safety distances on human behavior and movement interference. Separate and shared target configurations were compared using a screw-picking task as a prototype for electronic waste (e-waste) disassembly. The system employ a vision-based approach to track screws, the human hand, and the robot end effector. Performance was evaluated using objective metrics, including completion time, warning distance, and movement heatmaps, as well as subjective workload assessed via NASA-TLX. Results show that the safety algorithm significantly improved movement efficiency by minimizing the spatial distribution compared to the unconstrained trials. Furthermore, significant results from the factorial design showed that separate-target task enhanced human awareness, enabling participants to anticipate warning distances more effectively than the shared-target task. Synchronizing task assignments with safety algorithms reduces the need for human intervention.**

***Keywords*—Human-robot collaboration; disassembly collaborative task; UI feedback; distance policy; vision-based sensor**

I. Introduction

Although the Industrial Revolution enabled significant technological advancements, it also introduced substantial challenges. Industry 4.0, integrating automation, big data, the Internet of Things (IoT), and artificial intelligence (AI), enhances productivity and efficiency [1], [2]. However, these advancements have caused a rapid increase in electronic waste (e-waste), posing a significant threat to environmental sustainability [3], [4]. Effective global waste management is essential for sustainability, with disassembly playing a critical role in material recovery [5]–[7]. However, disassembly is significantly more challenging to automate than assembly owing to the variability in product types. The disassembly process requires a high degree of flexibility to manage technical and economic uncertainties, which is crucial for enabling widespread industrial adoption.

The Industry 5.0 paradigm addresses these productivity and flexibility challenges [8]. Leveraging advancements in lightweight robots, human-robot collaboration (HRC) workspace can enhance efficiency and productivity, while prioritizing human safety in shared environments. Several studies have aimed to accelerate disassembly tasks, including disassembly sequence planning (DSP). Task assignment algorithms, such as the Discrete Bees Algorithm [9] and Genetic Algorithm [10], have been developed to optimize human–robot labor division under specific safety constraints [11], [12].

From a human-centered system perspective, experimental studies examining real-time human movement during collaborative disassembly task allocation are lacking. Additionally, the impact of task type—whether spatially separated or shared—on human safety, efficiency, and workload has not yet been systematically investigated. Although objective safety indicators are frequently reported, subjective aspects, such as workload and perceived stress—critical for human-centered system design—are often underexplored.

This study investigated the reduction of human interference in HRC disassembly tasks. We developed a system that uses object detection to track the locations of humans, robots, and tasks. By evaluating different task types and algorithms, we provide empirical evidence of safety and efficiency trade-offs. The primary contribution of this study is an analysis of how task-algorithm pairings influence HRC workspace design to minimize human-robot conflict.

This study is organized as follows: Section II details the proposed HRC disassembly methodology and the technical architecture of the system design. Section III presents the experimental findings, followed by a discussion of the findings and limitations. Finally, Section IV concludes the study by summarizing the main contributions and future research directions.

II. Human-Robot Collaborative Disassembly

This section outlines the research methodology, including workspace setup and requirements, an overview of the system, applied algorithms, experimental design, and the evaluation using NASA-TLX. Fig. 1 presents an overview of the system, which tracks the real-time positions of the human, robot, and task locations. The architecture, based on an object detection algorithm, comprises two primary modules: a data processing unit for robot motion stimuli and a feedback determination component.

A. Workspace Setup

The experimental environment employed a DOBOT MG400, a lightweight industrial robot with a 30 cm $\times$ 20 cm workspace, selected for its high precision in intricate tasks. The AI-integrated camera served as a single sensor for real-time environmental mapping and object detection. In this collaborative disassembly scenario, human and robot worked in a shared workspace to perform sequential screw disassembly.

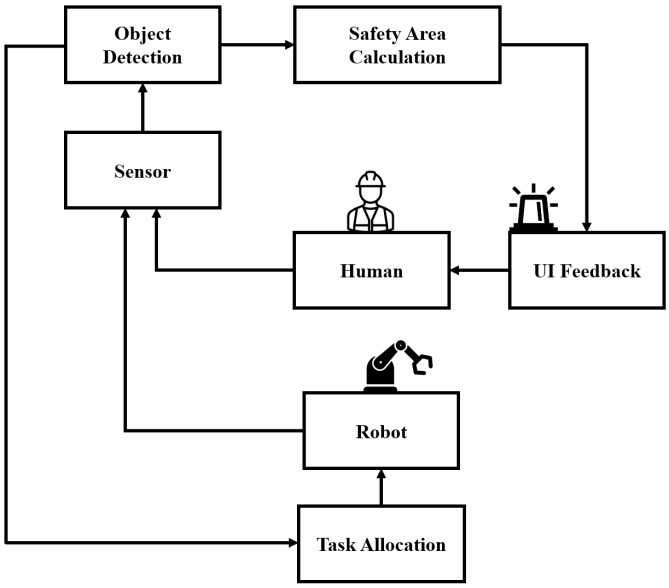

Fig. 1. Overview of proposed research.

To prioritize human safety, a task allocation algorithm dynamically adjusts the robot's target screw locations based on human movements. The experimental setup is shown in Fig. 2.

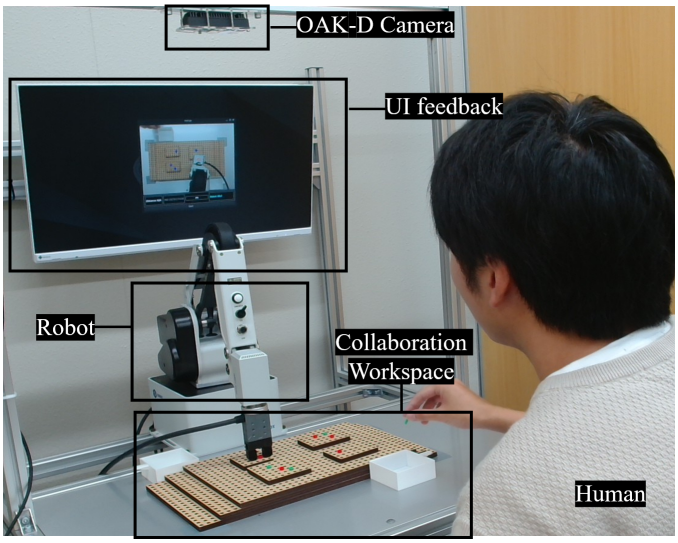

Fig. 2. Collaborative workspace setup.

The collaborative workspace was designed as a prototype for e-waste disassembly, using an MDF board for screw placement. Monitors integrated into the setup to provide real-time UI feedback, thereby facilitating communication between humans and robots. This UI displayed a safety zone, that was dynamically calculated via the human-robot object detection system to guide the user during the task.

B. Human-Robot Collaborative Algorithm

The proposed system uses object detection based on the YOLOv8 framework, selected for its proven real-time performance among state-of-the-art detection models. Detection accuracy and precision were evaluated through data collection, model training, and performance assessment.

The information obtained from the detected objects was in the form of x- and y-coordinates, with three labels. Assume that the coordinates of the humans, robots, and several screws are denoted as $H(x_h, y_h)$, $R(x_r, y_r)$, and $S_i(x_{si}, y_{si})$, respectively. This research focuses on the collaboration between a human hand and a robotic arm tasked with simultaneously picking up screws. In this study, distance calculations were required to measure the safety distance for collaboration. Eq. (1) was employed to obtain the real line distance from the x- and y-coordinates. This form is the absolute value between the human hand H and the screw S_i. where d_{HSi} is the distance between the hand and screw S_i. This distance was used for safety algorithm calculations. The calculation results serve as a stimulus for the robot to move toward the screw farthest from the human hand. Eq. (2) describes the calculation used to obtain the farthest distance. The detailed algorithm is described using the pseudocode Algorithm 1.

$$d_{HSi} = \|\mathbf{H} - \mathbf{S}_i\| \tag{1}$$

$$S_{far} = \max\{d_{HS1}(H, S_1), d_{HS2}(H, S_2), \ldots, d_{HSm}(H, S_m)\} \tag{2}$$

Algorithm 1 Safety Task Detection Algorithm

```
img ← cap_img()
H ← det_hand(img)
S ← det_screws(img)

for each S_i in S do
    dHS_i ← dist(H, S_i)
    if dHS_i > d_max then
        d_max ← dHS_i
        S_far ← S_i
    end if
end for
```

The human-robot distance, d_{HR}, is calculated using Eq. (3) and serves as a trigger for visual feedback.

$$d_{HR} = \|\mathbf{H} - \mathbf{R}\| \tag{3}$$

By observing the midpoint of both objects, safety considerations were divided into four areas calculated based on the distance between d_{min} 100 and d_{max} 400 pixels. These four areas indicate the level of danger, ranging from danger to caution, warning, and safety. Through distance normalization, as in Eq. (4):

$$\hat{d}_{HR} = min(\frac{d_{HR}}{d_{max}}, 1) \tag{4}$$

Denotes the normalized distance. This normalization maps the distance to a range of 0–1. If the human detection distance exceeded the d_{max} threshold, the person was automatically categorized as being in the safe zone. To visualize this on the

UI, the system calculates the inverse of the normalized distance to represent the danger level, as shown in the following Eq. (5):

$$D = (1 - \hat{d}_{HR}). \tag{5}$$

Eq. (6) defines four zones: danger, caution, warning, and safe. This zonal classification is fundamental to the HRC workspace, as it prioritizes collaborative safety.

$$f(D) = \begin{cases} \text{Danger}, & D > 0.5 \\ \text{Caution}, & 0.4 < D \leq 0.5 \\ \text{Warning}, & 0.3 < D \leq 0.4 \\ \text{Safe}, & D \leq 0.3 \end{cases} \tag{6}$$

This study investigated human responses to safety-based and random algorithms to assess their relative effectiveness. A combined approach integrating algorithm selection and UI feedback was implemented. Fig. 3 shows the UI feedback information used in this study, which includes the camera view serving as the sensing input, human-robot distance indicators for collision risk, and information on the screw selected for the robot pickup.

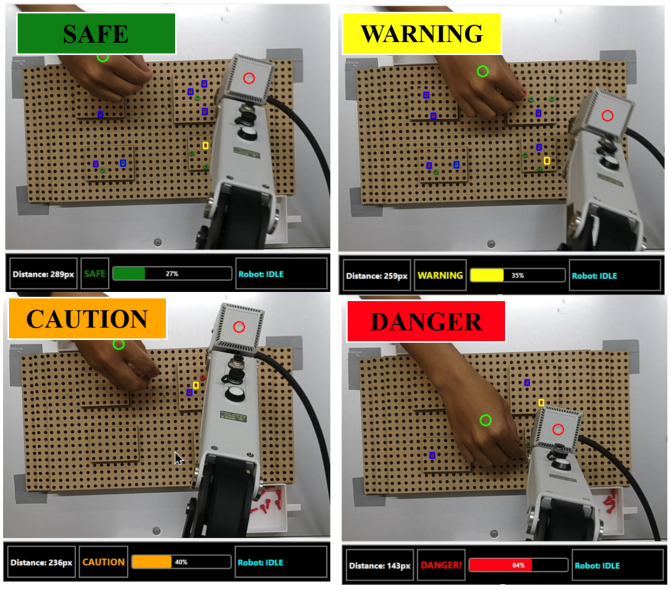

Fig. 3. Safety area UI feedback.

C. Experiment Design

The experiment involved five participants (aged 32 ± 8.3 years), each completing 10 trials per algorithm. Human responses to robot movements were evaluated using three objective parameters: task completion time, hand movement trajectories, and human-robot warning distance. Following the experimental trials, the participants completed a NASA-TLX questionnaire to assess perceived workload and system performance.

The algorithm was tested using two different task scenarios to obtain human behavior data. The separate target task (Task 1) involved 20 randomly positioned screws (10 red and 10 green screws). The robot retrieved the red screws until they were collected. The shared target task (Task 2) utilized 30 randomly positioned screws of the same color. The human-robot retrieved the screws until no screws remained. Fig. 4 illustrates the setup of Tasks 1 and 2.

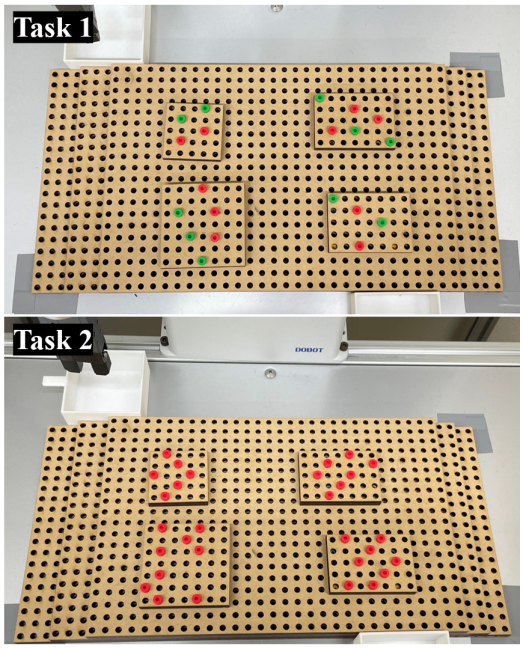

Fig. 4. Experiment task setup.

D. NASA-TLX Evaluation System

Subjective evaluation was conducted using the NASA-TLX questionnaire [13], which assess workload across six domains using a Likert scale: mental demand (MD), physical demand (PD), temporal demand (TD), performance (P), effort (E), and frustration level (FL). Participants completed the questionnaire after each experiment across the four distinct scenarios (comprising two tasks and two algorithms). The resulting data were analyzed using descriptive statistics to determine the impact of each scenario and identify significant differences in workload.

The use of NASA-TLX as a subjective evaluation identifies 'hidden costs' through direct participant feedback. Implementing such a human-centric system ensures that the operator's well-being is prioritized along with the robot's technical efficiency, providing a holistic justification for the system's deployment in industrial settings.

III. Experimental Results and Discussion

This section presents the experimental results and examines human behavior during collaborative disassembly tasks. The analysis focused on three key metrics: the completion time, frequency of proximity-based safety warnings (warning rate), and hand movements. The results of the NASA-TLX also captured the participants' perceptions.

A. Conditions

The participants were informed of the research objectives and experiments prior to providing informed consent, in accordance with the ethical requirements of the Saga University Ethics Committee (R4-38). During the experiment, the human and robot operated in a shared, barrier-free workspace, where collisions were possible. Fig. 5 shows the experimental setup in which the human and robot work together to retrieve screws until the workspace was cleared.

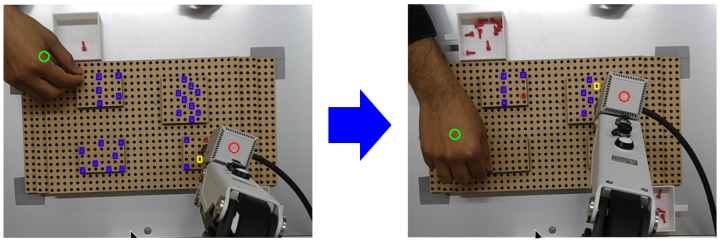

Fig. 5. Illustration of the retrieval process performed by the human-robot until task completion.

The experimental system was designed to facilitate data collection during human-robot collaboration. Following improvements in the object detection accuracy and real-time validation, the system was evaluated using both algorithms. Fig. 6 and Fig. 7 show the warning distance signals for the unconstrained and safe algorithms, respectively. The data show that the safety algorithm consistently maintains the required safety distance, confirming that the robot operates in accordance with the predefined safety thresholds.

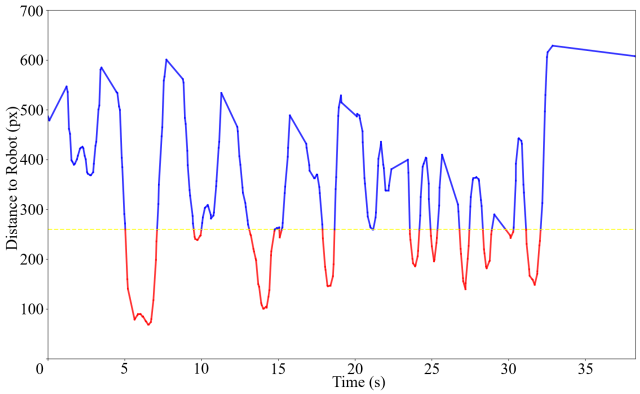

Fig. 6. Sample warning distance signals generated by unconstrained algorithm.

B. Results

The effects of algorithms and task types were examined using a factorial design, with statistical significance assessed via two-way ANOVA [14] at $\alpha < 0.05$. This analysis focused on the influence of these factors on completion time and total warning distance. Before the analysis, outliers were screened using the interquartile range (IQR) to ensure data integrity. Corresponding visualizations are presented in the bar charts in Fig. 8 and Fig. 9.

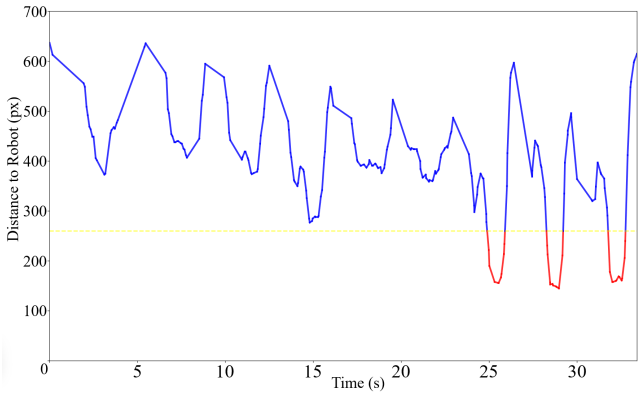

Fig. 7. Sample warning distance signals generated by safety algorithm.

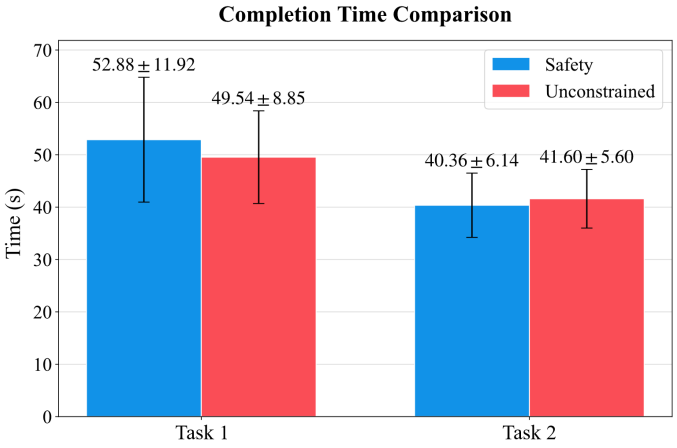

Fig. 8. Comparison of completion time performance for the safety and unconstrained algorithms during Task 1 and Task 2.

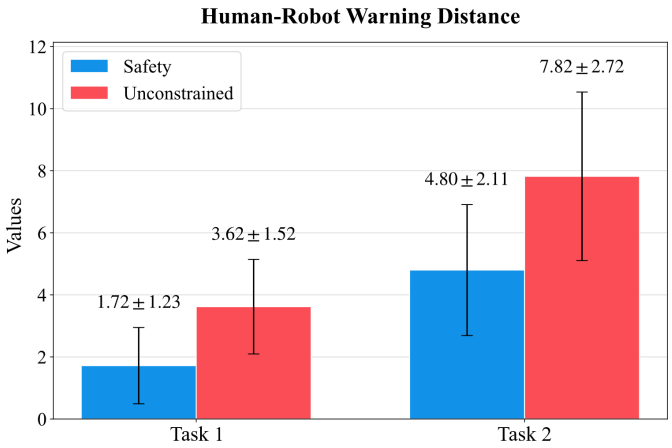

Fig. 9. Comparison of human-robot warning distance for the safety and unconstrained algorithms during Task 1 and Task 2.

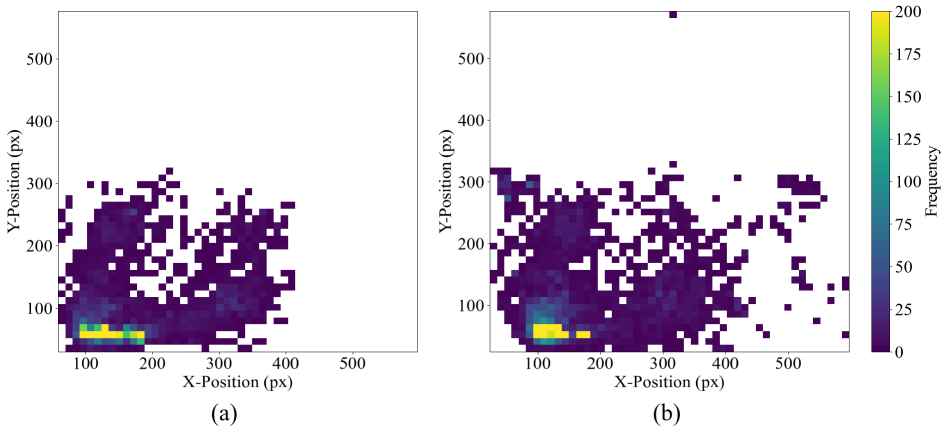

Fig. 10. Heatmaps of human hand movement during Task 1 for the (a) safety algorithm and (b) unconstrained algorithm.

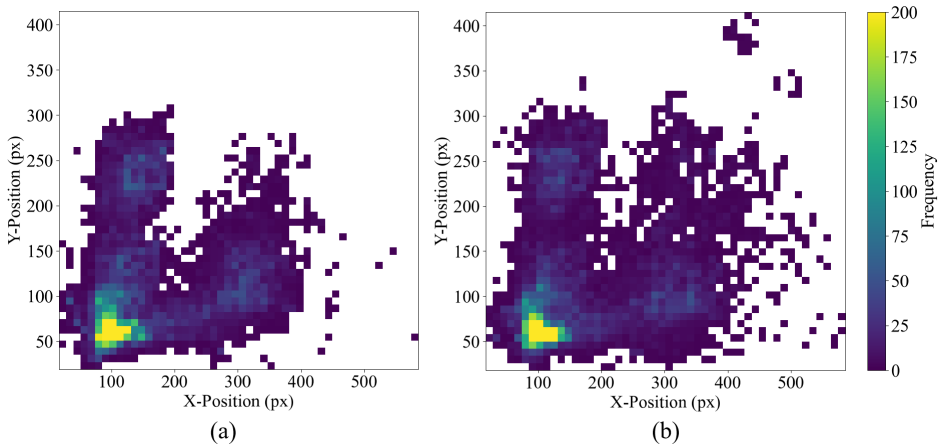

Fig. 11. Heatmaps of human hand movement during Task 2 for the (a) safety algorithm and (b) unconstrained algorithm.

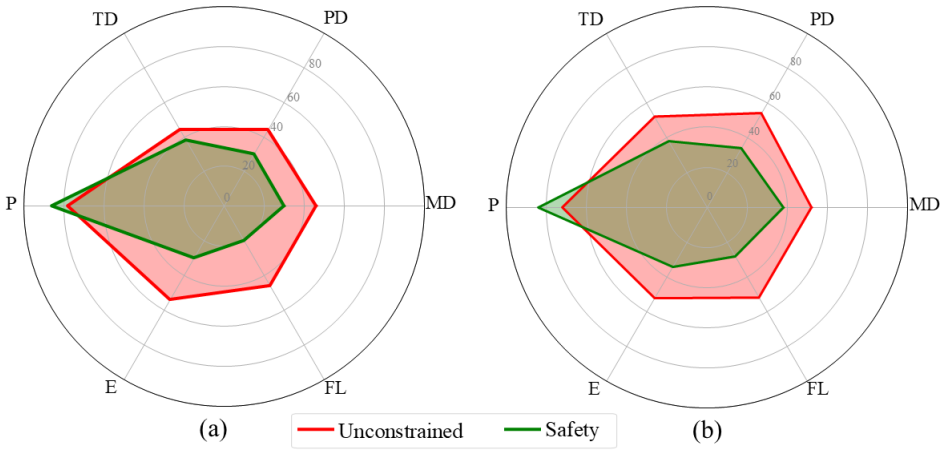

Fig. 12. NASA-TLX workload scores for (a) Task 1 and (b) Task 2 across both algorithms.

A two-way ANOVA conducted on completion time revealed a significant main effect for the task used ($F = 72.307$, $p < .001$, $\eta^2 = .269$). However, no significant main effect was found for the algorithm ($F = 0.76$, $p = .38$), and the interaction between algorithm and task did not reach statistical significance ($F = 3.62$, $p = .058$, $\eta^2 = .018$). These findings suggest that the differences in completion times were typically driven by the task itself, regardless of the algorithm being performed.

The two-way ANOVA for human-robot warning distance revealed significant main effects for both the algorithm ($F = 77.22$, $p < .001$, $\eta^2 = .283$) and the task ($F = 169.07$, $p < .001$, $\eta^2 = .463$). The interaction between algorithm and task was statistically significant ($F = 4.002$, $p = .047$, $\eta^2 = .02$). These results indicate that, while both the choice of algorithm and the specific task performed independently influenced the warning distance, the effect of the algorithm remained consistent across both tasks.

The spatial distribution of human movements was analyzed using heatmaps, as illustrated in Fig. 10 and Fig. 11 for Tasks 1 and 2, respectively. Comparative visual analysis revealed that the safety algorithm produced a significantly narrower distribution of human movement positions than the unconstrained algorithm. This concentration indicates that the safety algorithm facilitated a more predictable and structured human-robot interaction. These findings suggest that humans respond more effectively and consistently to robot movements when a safety algorithm is implemented.

Subjective assessments were performed using the NASA-TLX dimensions. A paired t-test confirmed a significant overall difference in Task 1 ($t = 4.402$, $p = .012$). In contrast to the previous measurements, the results for Task 2 were not statistically significant although they demonstrated a marginal trend ($t = 2.383$, $p = .076$). Fig. 12 shows the NASA-TLX differences between the two tasks.

C. Discussion

Experimental results indicate that the proposed algorithm significantly modulates human behavior during robot collaboration. Although real-time human movement remains unpredictable, spatial mapping using heatmaps reveals distinct behavioral patterns. Specifically, human responses were more efficient and localized when collaborating with a safety-constrained robot, indicating predictable robot movements and an enhanced sense of human safety.

Despite identical workspace dimensions, task type significantly influenced movement distribution. In Task 1 (a Separate Task), the range of human movement was much narrower than that in Task 2 (a Shared Task). This difference in spatial distribution is corroborated by the human-robot warning distance data, suggesting a lower collision probability for Task 1. This finding suggests that the separate task facilitates a safer environment by allowing humans to anticipate robot trajectories more effectively, whereas the shared task requires a wider range of avoidance maneuvers, and thus, is more complex. The integration of task assignment with safety algorithms yields results that minimize human interference.

D. Limitations

A collaborative disassembly system was developed to address the primary research questions. However, further investigation is needed to assess the system's long-term sustainability and robustness. Considering the limited sample size, the current findings may have restricted generalizability. Broader validation with a larger and more diverse population is required to support public and industrial adoption.

In addition, current hardware configurations would benefit from sensor redundancy. Although the vision-based approach effectively preserves human flexibility during collaboration, the camera's limited field of view necessitates additional sensors to mitigate occlusion issues.

IV. Conclusion and Future Work

This study investigated human interference during collaborative disassembly. The proposed safety algorithm significantly reduced the frequency of hazard warnings. Furthermore, NASA-TLX evaluations indicated that distinct task allocation, combined with feedback information, facilitated better maintenance of human-robot separation distances compared to shared-task execution. These results suggest that humans anticipate robot trajectories when task objectives are clearly defined in advance.

Note that the current disassembly process is a prototype involving simplified tasks. Future work will focus on optimizing the safety algorithm to prevent collisions during the final few tasks, thereby enhancing both efficiency and ergonomic outcomes. Additional studies with larger and more diverse participant groups are needed to improve the scalability of industrial applications.

Understanding Authentication and Authorization: A Comparative Analysis of Role-Based Access Control (RBAC), Attribute-Based Access Control (ABAC), and Relationship-Based Access Control (ReBAC) Authorization Models

Madhuri Margam
Director, Software Engineering, Capital One, Virginia, USA

***Abstract*—This study elucidates the distinctions between authentication and authorization within information security, two fundamental yet frequently conflated concepts. While authentication serves to confirm an entity's identity, authorization determines the permissible actions that entity may execute. A thorough understanding of these mechanisms is critical for architecting secure, scalable systems and reducing vulnerabilities. The study further explores three widely adopted authorization paradigms using a gymnasium analogy: Role-Based Access Control (RBAC), which assigns privileges based on predefined roles; Attribute-Based Access Control (ABAC), which leverages a dynamic evaluation of user and contextual attributes; and Relationship-Based Access Control (ReBAC), which determines access based on defined relationships among entities. The concluding discussion emphasizes that optimal security is realized when authentication and authorization function cohesively.**

***Keywords*—Authentication; authorization; access control; Role-Based Access Control (RBAC); Attribute-Based Access Control (ABAC); Relationship-Based Access Control (ReBAC); information security; least privilege; Zero Trust**

I. Introduction

In modern API security and system design, authentication and authorization are foundational, yet distinct processes often misconstrued as interchangeable. Authentication verifies who an entity is, while authorization governs what that entity can do once authenticated. Misinterpretation and improper implementation of these principles can lead to critical security flaws, enabling privilege escalation or unauthorized access. Organizations implement strong authentication but assume it provides authorization, or have minimal investments in authorization. Common implementation mistakes within authorizations include poor role design, over-privileged access, inadequate access reviews, and policy management.

To illustrate, consider the analogy of a gymnasium. Authentication occurs when a member scans their access card to validate identity and membership status. Authorization follows, defining which facilities, such as the pool or private training areas, the member may access based on their membership type. Both mechanisms are indispensable for a secure and user-oriented access management framework.

II. Authentication and Authorization: Conceptual Overview

A. Authentication

Authentication is the process of verifying the identity of a user or a service attempting to access a system. It answers the question, "Who are you?" Common authentication methods include password-based login, multi-factor authentication (MFA), and cryptographic verification.

In the gymnasium analogy, scanning a valid membership card authenticates the member, verifying their legitimacy. Only authenticated members proceed to the authorization stage.

B. Authorization

Authorization defines the access level and actions an authenticated user may perform. It answers, "What are you allowed to do?" For instance, in the gym, premium members may access group classes, while basic members are restricted to general equipment. The Principle of Least Privilege is supported by this distinction. The Principle of Least Privilege (PoLP) is a fundamental information security concept that requires users, processes, and systems to be granted only the minimum level of access necessary to perform their authorized functions. The goal is to prevent unauthorized access to data and services, coupled with making the access control enforcement as granular as possible [1].

Authentication and authorization together create a secure, layered defense mechanism that validates identity before granting specific privileges, as shown in Fig. 1.

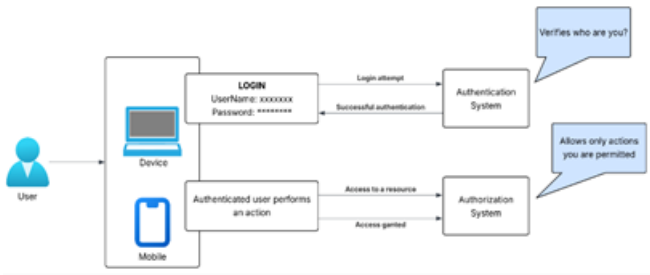

Fig. 1. Authentication and authorization mechanisms.

III. Common Authorization Models

Different domains implement authorization based on operational complexity and compliance needs. The three most prevalent models are RBAC, ABAC, and ReBAC.

A. Role-Based Access Control (RBAC)

RBAC associates permissions with predefined roles, simplifying access management for organizations with structured hierarchies. Access is granted based on the user's assigned role rather than individual identity.

In a gymnasium example, membership levels define roles:

- Basic members: access to cardio and weight areas
- Premium members: additional access to group classes
- VIP members: full access, including pool and lounge facilities

Advantages of RBAC:

- Enhanced security through role-based restriction
- Simplified policy management
- Regulatory compliance support
- Scalable and transparent administration

RBAC's simplicity and predictability make it ideal for environments with stable, well-defined roles.

B. Attribute-Based Access Control (ABAC)

ABAC extends RBAC by incorporating dynamic attributes, such as user characteristics, environmental context, and resource metadata, into policy decisions. Instead of static role assignments, ABAC evaluates combinations of attributes to determine access in real-time.

In a gymnasium example:

- Discount eligibility may depend on attributes like age < 25 or membership duration > 1 year.
- Facility access may be restricted to staffed hours, introducing contextual rules.

Advantages of ABAC:

- Fine-grained and adaptable access control.
- Context-aware and scalable.
- Dynamic response to environmental or user changes.

ABAC is a cornerstone for modern, policy-driven security architectures that demand adaptability and compliance. ABAC serves as the foundation for contemporary, policy-driven security architectures requiring both compliance and adaptability [2].

C. Relationship-Based Access Control (ReBAC)

ReBAC builds upon ABAC by evaluating relationships between entities rather than static roles or attributes. It is particularly effective in systems where access rights depend on social, organizational, or contextual links.

In a gymnasium example:

- Trainer-client relationship: Trainers access workout data only for assigned clients.
- Parental access: Parents manage reservations for children on family plans.
- Guest access: Guests enter only when sponsored and accompanied by a primary member.

Advantages of ReBAC:

- Granular and intuitive policy expression.
- Dynamic adaptation as relationships evolve.
- Reduced risk of privilege overextension.
- Scalable management in graph-like systems [3].

Systems such as Google Zanzibar exemplify ReBAC in practice, offering a globally consistent, low-latency authorization framework based on relational mappings between users and resources [4].

IV. Evaluation of Authorization Models

In the evolving landscape of digital security, access control mechanisms must balance security rigor, operational scalability, and user experience. While RBAC, ABAC, and ReBAC are often presented as distinct models, their practical implementation in large-scale systems tends to be complementary rather than mutually exclusive. Each model exhibits unique strengths, limitations, and contextual suitability.

A. Limitations in the Current Models

The Role-Based Access Control (RBAC) faces critical scalability and flexibility challenges in modern enterprise environments. Organizations frequently experience role explosion, creating hundreds of granular roles that become administratively complex and error-prone to manage. RBAC's static nature cannot adapt to dynamic business requirements such as time-sensitive access, location-based restrictions, or contextual factors without extensive manual reconfiguration. Complex role hierarchies often result in unintended privilege accumulation through inheritance, violating the principle of least privilege, while the model struggles to accommodate temporary access requests or exceptional permissions outside predefined role boundaries.

Attribute-Based Access Control (ABAC) and Relationship-Based Access Control (ReBAC) address some RBAC limitations but introduce distinct operational challenges. ABAC's policy authoring complexity requires specialized expertise, and real-time policy evaluation can introduce performance overhead in high-transaction environments [5]. Managing attribute accuracy across distributed systems remains operationally challenging, as stale attributes lead to inappropriate access decisions [6]. ReBAC faces scalability concerns with large, deeply nested relationship graphs, where traversing complex chains becomes computationally expensive [4]. Maintaining accurate relationships as organizational structures requires continuous synchronization, and transitive relationships can create unintended access paths. Additionally,

ReBAC's relative immaturity compared to RBAC means fewer standardized tools and best practices exist for implementation [4].

B. Complementary Rather than Replacement

RBAC remains one of the most widely adopted authorization mechanisms due to its simplicity, transparency, and alignment with organizational hierarchies. It excels in environments with stable structures, such as enterprises where roles (e.g., admin, developer) and privileges are well-defined and rarely change. However, RBAC's rigidity becomes a limitation in dynamic systems where access requirements evolve rapidly or depend on context-specific data.

ABAC addresses this limitation by introducing policy-based flexibility. It allows access decisions to be based on attributes that change over time, such as time of day, age [3]. This dynamic nature supports continuous access evaluation. Yet, ABAC's granularity also introduces complexity in policy definition and enforcement, which can be challenging to manage at scale.

ReBAC, as demonstrated by Google's Zanzibar [4], introduces a graph-based perspective focusing on the relationships among entities such as users, groups, and resources. This model captures nuanced access patterns prevalent in social, collaborative, and multi-tenant systems. For instance, "user A can edit document B if they are a collaborator or share a group with the document owner". ReBAC's strength lies in its ability to model these relational dynamics efficiently, often with real-time consistency guarantees.

However, it is important to note that ReBAC does not inherently subsume ABAC. While relationships define who can access what, attributes often define under what conditions access should be granted. For example, a trainer-client relationship (ReBAC) may grant access, but ABAC attributes like training session time or active membership status further refine when access is valid. Thus, a hybrid ABAC–ReBAC integration is necessary for robust and context-aware authorization [7].

C. Towards Hybrid Access Control Systems

Emerging industry and research trends increasingly favor hybrid access control architectures that integrate role-based, attribute-based, and relationship-based principles to address the complexity of authorization in dynamic and distributed environments [8],[9]. Hybrid models that combine RBAC and ABAC overcome limitations of individual paradigms by retaining RBAC's structural simplicity while introducing ABAC's contextual flexibility for fine-grained, dynamic policy evaluation [8], [10]. Additionally, hybrid frameworks incorporating relationship-based semantics (ReBAC) capture evolving trust relationships among entities, supporting access decisions in collaborative and federated systems [11]. Together, these approaches align with Zero Trust principles, where policies must adapt to both static organizational roles and dynamic operational context, as shown in Fig. 2.

In practical deployments, policy-based access control frameworks centralize policy definition while enabling distributed enforcement near the workload, such as in API gateways, service mesh proxies, and edge runtimes [10]. RBAC provides the foundational governance structure for role assignments and baseline privileges, simplifying administration and compliance oversight [8]. ABAC enhances this foundation with dynamic, context-aware decisions based on user, resource, and environmental attributes, supporting adaptive and fine-grained access in cloud-native and IoT systems [9]. ReBAC extends policy expressiveness by modeling relationships among entities, such as collaborators, delegated roles, or federated trust links, which traditional models cannot easily represent [11]. Composing these models in a unified framework enables defense-in-depth authorization, ensuring no single model becomes a point of rigidity or failure while maintaining scalable, context-aware access control across modern distributed systems [8], [10].

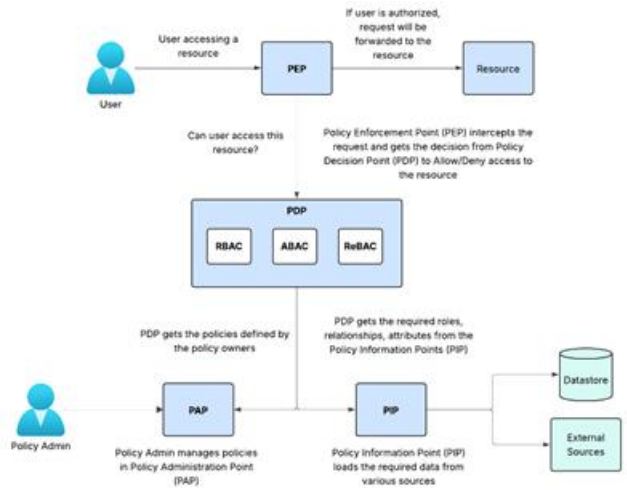

Fig. 2. Hybrid policy-based authorization framework integrating RBAC for role evaluation, ABAC for contextual policy evaluation, and ReBAC for relationship-aware access control.

D. Scalability, Performance, and Policy Governance

Scalability is another critical consideration. While RBAC scales efficiently through hierarchical role inheritance, ABAC's real-time policy evaluation and ReBAC's graph traversal can introduce computational overhead. Zanzibar suggests mitigating this through tuple-based data modeling and consistency guarantees, achieving millisecond-level authorization checks across millions of users [4]. Similarly, policy decision points (PDPs) and policy enforcement points (PEPs) in ABAC systems are often optimized through caching and pre-computation to maintain performance.

Policy governance also plays a central role in large-scale deployments. As the number of attributes and relationships increases, ensuring policy correctness, avoiding conflicts, and maintaining auditability become significant challenges. Recent research suggests using policy engineering frameworks and formal verification techniques to validate complex access rules before deployment.

E. Security and Compliance Implications

Regulatory compliance further influences model selection. RBAC aligns well with auditability and separation-of-duty requirements. ABAC enhances compliance by enabling contextual and attribute-based access controls, while ReBAC provides lineage and traceability by modeling user to resource relationships explicitly.

In highly secure systems, combining these models ensures not only that the access is correctly controlled but also that compliance requirements are demonstrably met. This multifaceted alignment of technical and regulatory priorities exemplifies the maturing discipline of robust authorization design. Table I shows the comparison of all three models.

TABLE I. COMPARISON OF AUTHORIZATION MODELS ACROSS KEY DIMENSIONS

Aspects	RBAC	ABAC	ReBAC
Complexity	Low	High	Medium
Flexibility	Low	High	High
Performance	High	Medium	High
Scalability	Medium	High	High
Context Awareness	Low	High	Medium
Relationship Modeling	Low	Medium	High
Policy Management Complexity	Low	High	Medium

V. AUTHORIZATION MODELS IN MODERN DISTRIBUTED ARCHITECTURES

Modern cloud-native architectures characterized by microservices, service meshes, serverless execution, event-driven communication, and hybrid multi-cloud deployment models dissolve traditional network perimeters and undermine implicit trust assumptions embedded in perimeter-based security models [12]. As services and workloads are distributed across heterogeneous environments and dynamically instantiated, static access control and coarse-grained network controls become insufficient to prevent lateral movement and unauthorized access [12]. Consequently, authorization must be enforced continuously and at fine granularity across users, services, and workload identities, incorporating contextual signals such as identity attributes, runtime state, and least-privilege policies [12], [13]. These requirements motivate the adoption of Zero Trust-aligned authorization frameworks that treat every access request as untrusted by default and require explicit, policy-driven authorization decisions across all access boundaries [12].

To operationalize these principles at scale, modern distributed systems increasingly adopt hybrid authorization models that decouple centralized policy governance from distributed, low-latency enforcement closer to the workload [12]. Deploying policy enforcement points alongside API gateways, service mesh proxies, and edge runtimes enables per-request authorization without incurring the latency and availability risks of centralized decision points [13], [14]. Token-centric authorization mechanisms, in which scoped and short-lived credentials are locally validated by services, further reduce runtime overhead while preserving fine-grained access control semantics [14]. Collectively, these approaches enable Zero Trust-aligned authorization to be applied consistently across cloud-native platforms without compromising the performance, scalability, and resilience requirements of highly distributed systems.

VI. CONCLUSION

This study examined the foundational distinction between authentication and authorization, emphasizing their complementary roles in establishing secure and scalable information systems. While authentication verifies the identity of users and services, authorization governs the permissible actions to authenticated entities, and failures in either dimension can undermine system security. By articulating this distinction and grounding it in practical access control models, the study highlights the importance of treating authentication and authorization as distinct yet interdependent pillars of security architecture. The discussion demonstrates that no single model universally satisfies the requirements of modern distributed systems; instead, practical deployments increasingly adopt hybrid approaches that combine these paradigms to balance manageability, flexibility, and security guarantees.

Finally, the study situates authorization frameworks within the context of modern cloud-native and Zero Trust architectures, where implicit trust assumptions are no longer tenable, and access decisions must be continuously evaluated across users, services, and workloads. In such environments, scalable authorization frameworks that integrate centralized policy governance with distributed, low-latency enforcement are essential for achieving both strong security and high performance. Ultimately, optimal security posture emerges not from the isolated deployment of authentication or authorization mechanisms, but from their cohesive, policy-driven integration across system boundaries, enabling organizations to reduce attack surfaces while maintaining the agility and resilience demanded by contemporary distributed architectures.

Construction of an International Trade Financial Risk Assessment and Prediction Model Based on Big Data Analysis

Zeyu Liu*
School of Professional Studies, Columbia University in the City of New York, New York, 10027, USA

***Abstract*—Background: International trade promotes economic growth across nations, while imposing financial risks of currency fluctuations, credit defaults, and market volatility. Although conventional methods of risk evaluation have served well in the past, they are, however, unable to provide risky international trade answers under the dynamic conditions at present. Objective: This study aims to develop data-driven risk assessment and prediction models for financial risks in international trade, with an emphasis on the China trade regime dominated by finance. The purpose is to maximize prediction accuracy and to provide pragmatic risk management solutions. Methods: The study proposed a hybrid method capable of characterizing complex nonlinear correlations by a DNN and, subsequently, estimating prediction outputs with an LR model for enhanced interpretability. Training models on the International Trade and Finance Dataset are augmented by macroeconomic indicators; preprocessing is performed via statistical imputation, feature normalization, and one-hot encoding. Results: With values of 0.9670, 0.0408, 0.0322, and 0.0017 awarded to R^2, RMSE, MAE, and MSE, respectively, the model stands out as the most capable and accurate in measuring financial risk. However, this hybrid model marries complex features with interpretable features, thereby paving the way for an exquisite instrument for risk assessment. Conclusion & Implications: This study aims to develop a solid framework for predicting financial risks in international trade that will aid financial institutions in decision-making and in developing policies. The findings may be applied to ongoing financial stability assessments for trade risk management.**

***Keywords*—International trade; financial risk; big data; predictive modeling; China's economy**

I. Introduction

With the global economy developing fast and international trade becoming increasingly more complex, there is a greater need for the use of advanced tools in financial risk management. With globalization fostering trade flows across borders, this pattern has presented growing financial uncertainties to nations and enterprises: currency risks, credit risks, political risks, and the like. As one of the largest economies in the world, China largely depends on international trade, and with a very dynamic financial scene, the opportunity to build very rigorous tools for assessing and predicting financial risks must never be missed [1]. A reliable financial risk evaluation model provides timely insights by which governments, businesses, and financial institutions can hedge themselves against prospective losses. In this context, the current research aims to develop an innovative risk prediction model for international trade finance in China through deep learning, feature engineering, and big data analytics [2]. This will finally create a comprehensive and scalable framework to assess international trade risks and deliver conclusive predictions of interest based on financial data and economic indicators.

A. Financial Risk Assessment in International Trade

Financial risk assessment is a major element in doing cross-border trade. It involves dealing with the identification, analysis, and measurement of several risks that could affect one's financial performance or payment defaults, exchange rate fluctuations, and the economic standing of trading partners, the generally considered ones [3]. Within the scope of international trade, these risks come with a wide array of key factors, including instability through political measures, trade policies over time, and shifts in the global economic scenario.

Risk traditionally has been assessed manually and with static models, which do not keep pace with the fast-moving nature of the global markets. The more complicated and interlinked international trades become, the more the old methodologies become obsolete [4]. Thus, there are increasing demands for dynamic models that can ingest large amounts of data instantaneously and deliver instantaneous considerations on financial health. This study attempts to fill up this gap by deploying more advanced statistical and machine learning methods to create a model that could more efficaciously and accurately assess the financial risks in international trade [5].

B. Financial Risk Prediction

Financial risk prediction, which evaluates future risks and trends using historic data and economic indicators, is a byproduct of economic risk assessment. Being able to forecast financial risk is essential for companies and policymakers so that they can lessen their potential losses and optimize their decision-making processes [6]. Therefore, this study intends to employ big data analytics to forecast financial risks associated with trade transactions, credit exposures, and even changes in macroeconomic landscapes, especially with a focus on the Chinese international trade regime.

A predictive model is created by studying historical trade data comprising transactional volumes and the history of payments. Other relevant economic indicators like interest rates, inflation rates, and GDP growth are studied as well. Machine learning techniques such as DNN and hybrid regression models actually learn from the input data by modeling linear and nonlinear relationships [7]. With accurate

predictions in the financial risk arena, decision-makers can prepare for challenges that may be posed by exchange rate fluctuations, changes in interest rates, or terrorist-related instability.

C. Big Data Analysis for Financial Risk in International Trade

The advent of commercial big data applications has changed how financial risks are evaluated and predicted in international trade. With the exponentially increased presence of data, it is now possible to analyze large volumes of structured and unstructured information spanning several domains, including trade records, economic reports, social media, and even news feeds.

In order to better comprehend possible financial risks than can be accomplished using traditional approaches, big data analytics provides the ability to combine large and complicated datasets while offering instantaneous analysis [8]. In this research, such tools are huge data tools emphasizing distribution and processing systems that usually process the high-velocity datasets faced in international trade scenarios. With such technology, trade data of large magnitude can be processed at a reasonable speed, thereby enhancing the effectiveness and accuracy of risk prediction. Big data makes it possible to incorporate a wide range of datasets, including historical trade data, financial indexes, and even sentiment from the news today. This improves the risk model's forecasting accuracy [9].

D. Deep Learning in Financial Risk Prediction

An area within machine learning, deep learning recognizes complex non-linear relationships within financial data. While traditional models may not be able to pick up on such complex patterns in bigger datasets, especially when patterns are so fine or intricate that they can barely be detected by simpler models, the deep neural networks detect such complex patterns and learn from huge amounts of data with impeccable accuracy.

International trade finance would mean for DNNs to determine hidden correlations among economic indicators, financial transactions, and exogenous conditions like political events or global changes in a market [10]. These deep learning algorithms, being capable of handling immense amounts of data and updating themselves on new data, will be able to generate better financial risk assessments. The study assesses the nature of DNN forces toward better recognition trends relevant to trade finance, creating a basis for the improvement of the trade finance model, both in prediction power and in robustness [11].

E. Hybrid Model for an Interpretable Prediction of Risk

These techniques, while more accurate, are often not interpretable. This disturbing subject creates an ambiguity in the mind of any analyst or decision maker wanting to know why a forecast has been given. To counter this, the proposed solution will pursue the hybrid modeling approach that exploits linear regression, hence preserving the interpretability of traditional models while enhancing predictive accuracy [12].

Linear regression is particularly relevant for determining the greatest contributors to financial risk, thus allowing a slimmed-down model to focus on aspects such as trade volume, creditworthiness, and debt-equity ratios. Linear regression equips decision-makers with interpretable coefficients that ideally tell a story let's say, how a feature is contributing toward generating a risk score, basically helping them comprehend what the model is predicting. The choice of methods hence attains a fine balance between predictability and transparency.

F. Distributed Computing for Efficient Risk Modelling

One of the foremost hurdles confronted by international trade-related financial risk prediction is handling large-scale datasets. To conquer this, the model harnesses distributed computing for efficient data processing. Processing smaller partitions of the dataset in parallel allows the model to machinate the bulk of trade and financial data much more expediently than would usually be the case [13]. It offers some scalability to the trade system, which remains an important factor as the international trade data increases in size exponentially. Parallel model training speeds up the computation and allows less time to develop and optimize a model. Additionally, they offer fault-tolerant processing, which ensures that even if a component of the system fails, the model will still function, adding dependability to applications that need to run continuously [14]. Making changes in hyperparameters is always a step toward achieving accuracy and performance optimization. The capacity to generalize and make accurate predictions will depend on the regularizers, learning rate, and the amount of neurons in a neural network structure [15]. They are, therefore, most useful for those problems with high-dimensional search spaces. Coupled with the above techniques, the system is really fine-tuned for the best performance, meaning that it can make the most accurate predictions of financial risk in international trade.

To confirm the generalization ability of the developed model towards unseen data, the data is split into a training, validation, and test subset. The model fits to the training set; then, hyperparameter tuning is done on the validation set, and finally, evaluation of the model is performed with the test set. Further assistance also comes from K-Fold Cross-Validation, stratified and repeated, in order to validate a model and ensure that it isn't overfitting to the training data. The goal of cross-validation is to train the model for various data subsets by splitting the dataset into multiple folds. The effectiveness of the model is then assessed on several data splits to further illustrate its generalizability. The model is prevented from overfitting by using K-fold cross-validation, which typically happens in high-dimensional dataset settings.

A data-driven approach to controlling financial hazards in international trade is put out in this study. The suggested approach provides forecasts with previously unheard-of accuracy by utilizing cutting-edge machine learning algorithms and big data analytics, far outperforming traditional risk assessment methods. This allows financial institutions, enterprises, and policymakers to base their decisions upon the latest and widely comprehensive risk analyses, ultimately contributing to greater stability of international trade and finance.

The study supports those modern data analytics combined with financial risk assessment that could offer a huge competitive advantage in the international trade area. The

automated, scalable, and interpretable mechanism for risk prediction, created in the study, may substantially contribute to risk management practices concerning swift and risky markets such as China's international trade ecosystem.

The following sections are organized in the following way: Section II: Related Work describes the existing regional approaches but mostly dwells on gaps that the present research has sought to address; Section III: Problem Setting and Modeling with Objective Setting, thus drawing out challenges in the prediction of the financial risks in international trade. Section IV: Methodology will detail data collection, data preprocessing, feature engineering, and model development. Section V will elaborate on how the big data framework is proposed to be integrated for the distributed storage, processing, and scalable analysis of trade financial data. Section VI would discuss building the model to cater to deep learning and hybrid prediction approaches for accuracy and interpretability improvement. Section VII will present evaluation results to justify the actual working of the proposed approach for financial risk prediction. The discussion of the study's findings, consequences, and limitations will be expanded upon in Section VIII. The conclusion, which follows in Section IX, quickly summarizes the study's key conclusions and contributions and offers some recommendations for more investigation.

II. Related Works

A. International Trade and Financial Risk Assessment

Du et al. [16] proposed a big data-driven early warning and prevention approach of Internet credit risk based on a BP neural network model. The model was composed through parameter adjustment of networks such as the number of nodes, activation function, and learning rate. The model was trained and tested using a 450-sample dataset from 90 enterprises over five years. Risk levels were graded according to the 3σ rule of statistics, and the first network performed at 85% accuracy. The genetic algorithm was employed to prevent local minima and enhance accuracy to 97%. Wang et al. [17] examined Fintech's influence on the banking industry, focusing on its role in enhancing profitability, financial innovation, and risk management. According to the survey, large financial institutions can save money on expenses and increase service quality by implementing fintech. It also enables risk management mechanisms and allows for the development of customer-focused business models. Integration with technology enables banks to boost legacy operations and overall competitiveness. The benefit is identified as varying depending on the degree of technological innovation utilized by respective banks.

Mhlanga et al. [18] investigated the role of artificial intelligence and machine learning to provide better credit risk assessment, in particular, in emerging economies. The study emphasizes using alternative data sources to aid solutions like information asymmetry, adverse selection, and moral hazard. AI-driven models enable lenders to analyze customer behavior and judge customers' ability to repay more accurately. This approach facilitates credit access to underbanked consumers lacking conventional collateral and identification. Increased investment in machine learning and AI by financial institutions to foster financial inclusion is encouraged by the research.

B. Predictive Modeling for Financial and Operational Risk

Peng et al. [19] suggested a hybrid big data-based method for accurate and timely financial risk prediction in banking systems. Linear regression methods in a big data platform to enhance prediction performance. Risk-oriented text data is preprocessed based on information gain and Bag-of-Words with TF-IDF weighing for effective feature extraction. The model is built based on a weighted fusion adaptive random subspace algorithm to fuse the results of multiple predictions. Experimental results confirm improved prediction accuracy and computation time decrease compared to traditional approaches. Xie et al. [20] proposed a least squares support vector regression model with an optimized gravitational search algorithm to predict China's cruise tourism demand. The article integrates big data sources, such as Baidu search query data and economic data, to enhance the precision of prediction. Hyperparameters of the LSSVR model are optimized using GSA to improve predictive accuracy. The findings indicate that employing mobile search keywords combined with economic data brings the best forecasting results. This means that big data models are effective in predicting tourism demand and investment decisions.

Aljohani et al. [21] recommend using AI and forecasting to increase supply chain agility for ongoing risk management. This research emphasizes post-event risk management and maintains that the post-breaking process of risk management is negligible and instead promotes the implementation of proactive disruption forecasting with data-driven models. It illustrates how supply chain hazards can be successfully identified using historical analysis, recognizing anomalies, and machine learning. Machine learning models are continually refined for precision and responsiveness in uncertain conditions. Case studies validate real benefits to the model, such as faster response times and increased operational resilience across industries. Tandon et al. [22] analyzed the relationship between social media engagement, particularly tweets, and cryptocurrency price changes, with a specific focus on Bitcoin and Dogecoin. The study uses financial data and Twitter sentiment as proxies to examine market responsiveness to internet euphoria. High-precision forecasting through predictive modeling by the augmented Dickey-Fuller test and ARIMA predicted prices of Bitcoin. It is discovered that tweets cause short-term market behavior but not long-term cryptocurrency trends. The decentralized control of blockchain ensures market stability in spite of volatility in social media.

C. Big Data Analytics: Applications and Methodological Innovations

Ikegwu et al. [23] spoke of the growing relevance of big data analytics in industrial contexts, citing its impact on business intelligence and data-driven decision-making. The study emphasizes the current difficulties in interpreting, creating storing, and displaying data in high-volume industrial settings. It offers a thorough analysis of BDA techniques, tools, advantages and disadvantages, and practical uses. Key problems and associated solutions are discussed to guide practitioners and researchers. Proposals for enhancing BDA performance and uptake by industries conclude the article. Sheng et al. [24] reviewed methodological innovation in big data analysis and identified how these are applicable in

addressing contemporary organizational challenges. In the research, analytics methods are placed under descriptive, predictive, diagnostic, and prescriptive types, and management research use is recorded. It underscores the importance of applying these approaches to study complex, unexpected situations like the COVID-19 crisis. The authors argue that big data analytics offers valuable insights in managing crisis and making managerial choices. Their work is a template for researchers studying global disruptions and organizational resilience.

Sharma et al. [25] examined how the agri-food industry may benefit from massive amounts of data and artificial intelligence to improve supply chain, logistics, marketing, and production procedures. The study identifies machine learning, artificial neural networks, and optimization techniques for increasing operational efficiency. It enumerates that AI-based technology enables intelligent decision-making and control of processes in agri-food sub-industries. It is anticipated that the confluence of digital technologies will result in instant optimization and improvements. The findings highlight the paradigm shift that AI and big data have contributed to the performance and sustainability of the food industry. Ahmed et al. [26] offered a big data analytics and Internet of Things-based health monitoring solution for COVID-19 analysis and forecasting. The system enables rapid data gathering, visualization, and measurement of pandemic risk and mitigation efforts. From actual symptom data, the study undertakes descriptive, diagnostic, predictive, and prescriptive analysis. The correct diagnosis and prediction are done using a model that relies on neural networks, which aids healthcare experts. The model scores better than other machine learning methods, boasting a 99% accuracy in prediction.

Mageto et al. [27] investigated how massive amounts of data may be used to promote healthy supply chains in manufacturing sectors. The research identifies how BDA components of data processing, analytics, integration, and security help detect and rectify unsustainable behavior. It reiterates the main SSCM elements such as transparency, sustainability culture, and risk management. Drawing on Toulmin's model of argumentation, the study theoretically connects BDA to enhanced sustainability performance. The research also identifies issues such as cyberattacks and IT skill shortages as obstacles to successful BDA implementation. Ivanov et al. [28] proposed an electronic supply chain twin, an automated model that continuously manages interruption risk by simulating network conditions. The study advocates combining model-based and data-driven approaches to assessing risk relations and quantifying supply chain performance. It brings into focus the use of digital twins prior to, during, and subsequent to the COVID-19 pandemic for the pursuit of visibility and flexibility within the network. Empowered by past and present disruption information, the model permits predictive and responsive decision-making. The findings assist in the development of supply chain risk management by allowing enhanced visualization and continuity strategies.

Chehri et al. [29] analyzed cybersecurity challenges in smart grids, concentrating on the ineffectiveness of traditional security tools in detecting new cyber-attacks. The study hints at the necessity of integrating big data analytics, ML, and AI for upper-level threat detection. With the use of adaptive behavior models and predictive analysis, smart grids are capable of identifying known and unknown attacks. The article outlines smart grid architecture, methods of risk assessment, and the effects of qualitative evaluation in enhancing grids' reliability and safety. It also provides suitable countermeasures for securing supervisory control and data acquisition systems. Kamyab et al. [30] outlined the transformative role of artificial intelligence and big data analytics to enhance water resource management. The research addresses the use of ML and DL methods in water quality monitoring, allocation, and demand forecasting tasks. In order to display continuous data, it highlights the use of a variety of data sources, including social networks, external detectors, and Internet of Things sensors. Big data analytics is employed to overcome the traditional limitations in the acquisition of data and the application of smart decisions. The research concludes by offering guidance for future research on the optimal use of water resource planning with current technologies.

Literature, considered as a whole, emphasizes the revolutionary use of big data analytics, ML, and AI towards enhancing financial risk assessment, predictive models, and decision-making in general. In international finance and international trade, advanced neural networks and optimization techniques have significantly improved early warning systems and credit risk assessment. Hybrid algorithm-based predictive models, sentiment information, and economic signals have been proven to be highly accurate in the forecasting of financial patterns and market phenomena. In order to display continuous data, it highlights the use of a variety of data sources, including social networks, external detectors, and Internet of Things sensors. In areas such as banking, agriculture, energy, and water management, big data technologies have improved efficiency, risk transparency, and strategic planning. These technologies seek to overcome traditional constraints in handling data and facilitate proactive, intelligent decision-making that is key to sustainability, security, and inclusivity in a rapidly digitalizing economy.

III. Problem Definition and Objective Setting

In the modern world economy, foreign trade determines the growth of a country's economy and its financial stability. Complexity and size of financial transactions [31], coupled with constantly changing global economic situations [32], make financial risk assessment in foreign trade increasingly challenging. Traditional financial risk assessment approaches rely primarily on human analysis, expert judgment, or small-scale structured data, which limit their precision, scalability, and speed.

To break through these challenges, this research proposes the development of a smart model of international trade financial risk forecasting and assessment based on big data analytics. Massive volumes of current, diverse data from various sources, such as trade records, bank operations, credit ratings, economic indexes, and financial news, can be processed and analyzed with the use of big data technologies. Under such conditions, precision of risk prediction and early

warning can be significantly improved. The main objectives of this research are:

- Identify and collect useful macroeconomic and financial data metrics related to trade risk.
- Create a robust, scalable prediction model through deep learning and big data paradigms.
- Embrace a hybrid analytical framework combining statistical methods and AI for better prediction ability.
- Facilitate actionable recommendations for financial institutions, exporters/importers, and policymakers to handle international trade risks proactively.

By integrating big data analytics, machine learning, and sectoral financial indicators, the system here aims to mitigate the inefficiencies of traditional methods and offer a modern, data-driven solution to China's evolving trade landscape.

IV. METHODOLOGY

The proposed methodology begins with collecting data from reliable structured sources such as the International Trade and Finance Dataset, supplemented by macroeconomic data and financial indicators. In the data preprocessing phase, statistical imputation is used to fill in the missing values, numerical features are normalized through Min-Max scaling, and categorical attributes such as sector type are one-hot encoded for the Finance category. Thereafter, feature engineering is used to extract significant financial statistics such as debt-equity ratio and volume of trade and to compute deeper risk measures such as trade balance ratio and creditworthiness score. To process big-volume, high-velocity data sets, the system leverages a big data architecture for distributed storage, processing, and scalable analysis. In model building, a two-model strategy is followed: a Deep Neural Network detects complex non-linear correlations between trade-finance, while a hybrid model uses Linear regression to offer interpretable, statistically sound predictions. The two models' outputs are fused together through weighted fusion for optimum risk scoring. Cross-Validation (and its stratified/repeated versions) ensures robust generalization and prevents overfitting. This integrated, expandable, and intelligent workflow presents a complete solution for Chinese international trade finance risk analysis in China's thriving economy. Fig. 1 shows the big data–based architecture for predictive financial risk assessment in international trade.

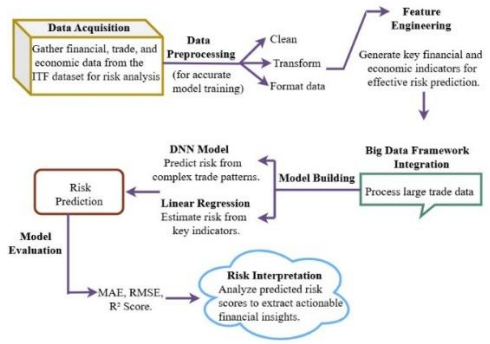

Fig. 1. Big data–based architecture for predictive financial risk assessment in international trade.

A. Data Acquisition

Any model of financial risk forecasting is successful depending upon the quality, variety, and usability of data. In this research, a complete range of financial and macroeconomic data is collected to create a trustworthy model to measure international trade-related financial risks in China. Structured numerical data and voluntary unstructured textual data are collected during the data collection stage from trusted sources.

1) Data source: International Trade and Finance Dataset: The dataset used in this study is the International Trade and Finance Dataset, which contains a wide range of variables that capture financial behavior, credit exposure, and macroeconomic conditions of various industries. It is best suited for trade risk modeling due to the presence of significant indicators such as:

- Transaction Records: Cross-border trading activities details, such as the level of trade, frequency of the transaction, and trading sectors.
- Loan and Credit History: Disbursals of loans, payment schedules, delays, and defaults data critical for risk scoring.
- Payment Defaults: Identifies accounts or parties with delayed or overdue payments, helping in the early identification of financial distress.
- Interest Rates and Exchange Rates: Monetary policy statistics shaping trade finance cost and investment risk.
- GDP Growth and Inflation Trends: Expanding economic prosperity indicators shaping trade performance and financial health.
- Trade Balance Indicators: Import-export ratios and country trade deficits or surpluses statistics.

The data is obtained from Kaggle, which provides credible, publicly available, curated datasets. It can be complemented by free data from the World Bank, IMF, OECD, Chinese National Bureau of Statistics, and government finance portals to enhance the degree of macroeconomic analysis.

TABLE. I. KEY VARIABLES IN THE INTERNATIONAL TRADE AND FINANCE DATASET

Feature Name	Description	Data Type	Relevance to Risk
Trade Volume	Value of import/export transactions	Numerical	High
Interest Rate	Cost of borrowing	Numerical	High
GDP Growth	National economic growth rate	Numerical	Medium
Debt-to-Equity Ratio	Leverage indicator	Numerical	High
Inflation Rate	Purchasing power, cost stability	Numerical	Medium
Credit Rating	Creditworthiness indicator	Categorical	High
Payment Defaults	Missed payments or delays	Categorical	High

To enable the financial risk assessment model, Table I consolidates the key variables that have been derived from the International Trade and Finance Dataset. The variables encapsulate the most critical macroeconomic variables, financial behavior, and trade patterns that are most crucial to determining and quantifying trade-associated financial risks. For each of the features, it is specified by its type and relative importance to risk modeling. High-relevance variables like trade volume, interest rate, and credit rating have a direct influence on the vulnerability of a company in financial terms. This structured data is the foundation for feature extraction and training model stages.

B. Data Preprocessing

The preprocessing stage is important to cleanse and transform the raw structured data into a correct format for accurate financial risk prediction. As the dataset used is the International Trade and Finance Dataset (China's trade and finance), the following steps are carried out:

1) Missing values handling: In actual datasets, particularly huge financial datasets, such as the International Trade and Finance Dataset, missing values frequently occur because of incomplete reporting, data transmission errors, or data privacy regulations. It is necessary to properly handle these missing values to preserve the precision, stability, and ability to generalize of this prediction model.

a) Variables like:

- Trade Volume
- GDP Growth
- Interest Rate
- Export/Import Value
- Loan Amount

TABLE. II. SAMPLE OF MISSING VALUE IMPUTATION USING MEAN

Variable	Missing Count	Imputation Method	Example Imputed Value
Trade Volume	5	Mean	452.3 M USD
Interest Rate	2	Median	3.75%
Loan Amount	4	Mean	1.2 M Yuan

For additional support in the preprocessing phase, Table II illustrates a sample of missing value imputation of key financial variables. Financial factors like the volume of trade, interest rate, and loan size revealed data gaps due to reporting irregularities or transmission errors. Missing values were imputed with appropriate statistical methods, e.g., mean or median, based on variable distribution. The procedure guarantees consistency, reduces data bias, and preserves data integrity, supporting more accurate and reliable model training.

2) Normalization of numerical features: In money risk modeling, especially when using deep learning models like DNN, it is essential to normalize numerical input data so that all features are of the same order of magnitude. Since financial data often contains attributes with substantially different ranges (e.g., export volume in millions, interest rates in percentage), unnormalized data may bias the model training process and hinder convergence or result in inefficient learning.

- Avoids overemphasizing high-magnitude features (e.g., export/import volume) over low-magnitude features (e.g., interest rate).
- Ensures faster and more stable convergence in gradient descent.
- Assists in improved prediction performance and model stability.

a) Features Typically Normalized:

- Export/Import Volume
- Debt Ratio
- Inflation Rate
- Interest Rate
- GDP Growth
- Loan Amount

These are normalized to a standard range using Min-Max Normalization, linearly transforming values to a fixed range, typically $[0,1]$. Min-Max Normalization Formula is represented in Eq. (1):

$$x' = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \quad (1)$$

where, x is the original value of the feature, $x_{\min}$ is the minimum value of the feature, $x_{\max}$ is the maximum value of the feature, x' is the normalized value within the range $[0,1]$.

3) Encoding categorical variables: Finance

In the International Trade and Finance dataset, sector type is an important categorical feature used to direct towards the economic sector of each entity (e.g., Finance, Manufacturing, etc.). Since this research is performed specifically on the Finance sector in China, the categorical variable has to be properly encoded in a way that it will be compatible with machine learning and deep learning models.

C. Feature Engineering

Feature engineering is a critical process that transforms raw economic, financial, and trade data into meaningful inputs for prediction models. Specifically crafted features can enhance model accuracy and interpretability for the risk assessment of international trade finance.

1) Extracted features: Extracted features are the original financial and economic indicators derived directly from the International Trade and Finance dataset. These include factors such as Debt-to-Equity Ratio, reflecting financial leverage and potential risk exposure. Trade Volume helps evaluate foreign activity and imbalance trends. Interest Rate and Inflation Rate are macroeconomic determinants influencing cost of capital and credit behavior. Loan Amount and Tenure reflect repayment

load and credit duration. These raw variables form the foundation of financial risk forecasting models.

- Debt-to-Equity Ratio: Measures a company's financial leverage towards shareholders' equity. DER is represented in Eq. (2):

$$\text{DER} = \frac{\text{Total Liabilities}}{\text{Shareholders' Equity}} \quad (2)$$

Higher values may indicate greater exposure to risk.

- Trade Volume: Reports the monetary volume of exports and imports over a given time. Imbalances or sudden changes can alert to macroeconomic risks.
- Interest Rate: Affects the cost of borrowing and is used as an indicator of the economic environment. Used as a macroeconomic risk metric.
- Inflation Rate: Impacts purchasing power and operating costs, thereby creditworthiness.
- Loan Amount / Tenure: Helps to understand the scale and payback time of finance-related obligations for trade.

2) Derived features: Derived Features are computed from raw finance inputs to expose deeper insights into financial risk. They include the Creditworthiness Score, which aggregates a number of various financial behaviors, repayment frequency, and default rate into a single-factor risk. The Country Risk Index, even in China, captures intra-national heterogeneities by incorporating regional economic instability, industry-specific downturns, or policy risks. The Trade Balance Ratio assesses the export-import reliance of a company; an adverse ratio indicates import dominance and increased exposure. Further, Risk Flags or Categories are generated on the basis of financial thresholds (e.g., high DER or poor credit ratings) to pre-classify entities into low, medium, or high risk. These features from extraction improve model interpretability and predictive performance.

- Creditworthiness Score: Aggregate score derived from finance metrics like repayment history, overdue balance, and default rates. Scoring functions or machine learning models can be used for extracting this score.
- Country Risk Index: While the dataset is China-specific, regional or sectoral variation within the country (e.g., high-risk sectors or regions) can be quantified. This may involve compounding subnational drivers of risk like local default, economic volatility, or policy uncertainty.
- Trade Balance Ratio: Indicates whether a company or industry is export-focused or import-dependent is represented in Eq. (3):

$$\text{Trade Balance Ratio} = \frac{\text{Exports} - \text{Imports}}{\text{Exports} + \text{Imports}} \quad (3)$$

- Risk Flags or Categories: Depending on thresholds (for instance, if DER > 2 or credit score < 600), binary or categorical risk flags may be specified to indicate possible red flags.

V. Big Data Framework Integration

Big data is defined as large, complex datasets that cannot be processed in an efficient way with traditional data processing methods. The datasets are characterized by the 5Vs: Volume, Velocity, Variety, Veracity, and Value. In global trade finance, big data includes high-frequency transaction logs, financial data, macroeconomic data, and occasionally even unstructured sources such as news releases or financial reports. The ability to tap such information instantaneously is critical to accurate financial risk prediction and assessment.

Traditional finance risk models are not strong in handling the volume, velocity, and variety of modern financial and trade information. In response to such shortcomings, the integration of a big data processing framework allows for timely, scalable, and uniform analysis of trade-related datasets to improve accuracy and responsiveness in risk prediction.

A. Key Features of Scalable Data Framework Integration

The system provides flash parallelization of filter, normalization, and analysis of giant financial-trade databases simultaneously. Distributed storage allows multi-source records to be handled efficiently, while on the other hand, it caters to long-term data storage and fault tolerance. Real-time analysis thereby helps to discover existing frauds, market shocks, and dynamic risk patterns within seconds. Altogether, these features provide the required scalable, accurate, and timely solutions for the international-grade financial risk assessment and prediction in trade.

1) Parallel data processing: The design enables rapid, distributed processing with the capability to process large sets of financial and trade data simultaneously in several computing units. Parallelism significantly reduces the time devoted to tasks such as:

- Data cleaning and normalization of large data
- Development of intricate financial measures
- Training advanced forecasting models, including multi-layer neural networks

2) Distributed data storage and management: Storage architecture is designed to hold massive datasets by distributing them over multiple storage nodes. This accommodates:

- Efficient handling of raw trade and financial records from a variety of sources
- Long-term storage of old data for trend and pattern analysis
- Fault tolerance and scalability for expanding data needs

3) Real-time analytics: The platform can offer real-time insight for applications such as:

- Fraud prevention and detection
- Sudden macroeconomic fluctuations or market shock
- Dynamic risk profiling for investment and trading decisions

With integrated scalable storage, high-speed computation, and advanced analytics in one framework, the system enables efficient processing of massive, dynamic, and complex trade-financial information. This enables timely and accurate financial risk assessment and prediction of international trade.

VI. Model Construction using Deep Learning and Hybrid Prediction Framework

At this phase, deep learning and statistical techniques are combined to enhance financial risk forecasting. A DNN is utilized for the development of complex non-linear models from structured financial and trade data, enabling the system to learn weak risk indicators through various layers of hidden nodes. In parallel, a hybrid pipeline uses linear regression or Random Subspace Modeling for predicting risk from selected indicators. Parallel models of this nature are executed under a big data platform to ensure scalability and efficiency. The risk predicted is ultimately determined by fusing the output from the two models via Weighted Fusion, with additional robustness. This hybrid approach identifies both interpretable linear trends and deep patterns in the financial data.

A. Deep Neural Network-Based Risk Prediction

The deep neural network model structure is designed to accept high-dimensional structured financial and macroeconomic data as input and output the probability of financial risk associated with international trade. The DNN model structure consists of an input layer, one or more hidden layers, and an output layer, each of which progressively condenses the information in order to derive meaningful patterns indicative of risk. Fig. 2 shows a deep neural network architecture for trade finance risk prediction.

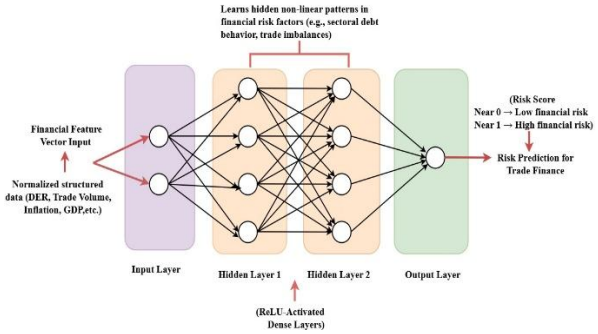

Fig. 2. Deep neural network architecture for trade finance risk prediction.

1) Input Layer – Financial feature vector input: The input layer receives structured, normalized financial and macroeconomic indicators, such as Debt-to-Equity Ratio, Trade Volume, Inflation, and GDP growth rate. Normalization ensures all the features contribute equally in training and prevents features with higher numeric values from overshadowing the model. The min–max normalization formula is presented in Eq. (4):

$$x' = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \tag{4}$$

Here, x' is the normalized value, x is the original feature value, and $x_{\min}, x_{\max}$ are the minimum and maximum values of that feature in the dataset. After normalization, the input vector can be represented as Eq. (5):

$$\mathrm{X} = [x_1', x_2', x_3', \ldots, x_n'] \tag{5}$$

where, n is the number of input features.

2) Hidden Layers – Non-linear transformation of features: The hidden layers (i.e., Hidden Layer 1 and Hidden Layer 2) carry out weighted summation after which the Rectified Linear Unit activation function is employed in order to detect complex, non-linear patterns in the data, such as sectoral debt structures and trade deficits. The output of a neuron j in layer l is provided by Eq. (6):

$$h_j^{(l)} = f\left(\sum_{i=1}^{n} w_{ij}^{(l)} \cdot h_i^{(l-1)} + b_j^{(l)}\right) \tag{6}$$

where, $h_j^{(l)}$ is the output of neuron j in layer l, $w_{ij}^{(l)}$ is the weight connecting neuron i in layer $l-1$ to neuron j in layer l, $b_j^{(l)}$ is the bias term for neuron j, $f(\cdot)$ is the activation function. The ReLU activation is provided by Eq. (7):

$$f(z) = \max(0, z) \tag{7}$$

This process is repeated across multiple hidden layers, allowing the model to learn higher-order feature representations.

3) Output Layer – Risk score estimation: The output layer receives the feature representation from the last hidden layer and produces a raw risk score before final activation or scaling. The model's internal prediction of the probability of financial risk is based on learned patterns via the hidden layers. The value output of the neuron in the output layer can be represented as Eq. (8):

$$y_{\text{raw}} = \sum_{i=1}^{n} w_i^{(o)} \cdot h_i^{(L)} + b^{(o)} \tag{8}$$

where, y_{raw} is the inactivated output score, $h_i^{(L)}$ is the output from neuron i in the last hidden layer L, $w_i^{(o)}$ is the weight from last hidden layer neuron i to the output neuron, $b^{(o)}$ is the output bias term.

B. Hybrid Model Integration: Linear Regression for Financial Risk Prediction

To enhance both the accuracy and interpretability of financial risk prediction, the hybrid model structure integrates linear regression. This step is particularly required in high-dimensional macroeconomic and trade data, since it discards noise and retains the most informative features such as trade volume, debt ratio, inflation, and interest rate.

Once the top-ranked features are selected, linear regression is employed to create the linear relationship between these inputs and the financial risk score. It provides a straightforward, easy-to-understand model that estimates how much each feature contributes to the risk level. Such interpretability is useful in financial applications, where regulatory and auditing implications of predictions are important. Fig. 3 shows the hybrid financial risk assessment framework using deep neural networks and linear regression.

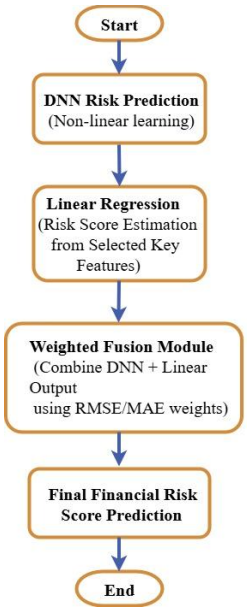

Fig. 3. Hybrid financial risk assessment framework using deep neural networks and linear regression.

Table III illustrates the result of applying Regression in identifying the most significant features utilized in financial risk estimation. The features with higher linear coefficients, for instance, interest rate and trade volume, are retained since they possess higher predictive strength. Features like inflation rate, which have very low values, are dropped, and this helps reduce dimension. This filtering operation enhances the model's efficiency and focuses learning on the most relevant financial variables.

TABLE. III. FEATURE SELECTION OUTPUT USING LINEAR REGRESSION

Feature	Coefficient	Selected (Yes/No)
Trade Volume	0.431	Yes
Interest Rate	0.294	Yes
Inflation Rate	0.003	No
Loan Tenure	0.182	Yes

To improve robustness, the prediction output of this model is combined with DNN prediction based on a Weighted Fusion method, wherein the weights are specified in terms of model performance (e.g., RMSE or MAE on the validation data). This imparts the final prediction, the interpretability of linear regression, along with the non-linear learning capacity of DNN. The hybrid model thus brings a balance of speed, scalability, and accuracy, and is thus most appropriate for processing large-scale international trade data in a big data environment. Lastly, this integration supports the model's generalization capability, reduces the likelihood of overfitting, and enhances real-world applicability in international trade finance risk analysis. The weighted fusion equation for final prediction is represented in Eq. (9):

$$R_{\text{final}} = \alpha \cdot R_{\text{DNN}} + (1 - \alpha) \cdot R_{\text{LR}} \quad (9)$$

where, R_{final} is the Final risk score, R_{DNN} is the DNN-predicted risk, R_{LR} is the linear regression-predicted risk, α is the Weight (determined by validation performance).

C. Dataset Partitioning

The partitioning of the dataset into corresponding subsets is a basic step in any predictive modeling task to measure model generalizability and resilience. In this research, the dataset containing financial indicators, trade volumes, credit ratings, and macroeconomic variables is partitioned randomly into three portions: 70% for training, 15% for validation, and 15% for testing. This partitioning process allows the model to be trained on one facet of the data but tested and refined on other, unobserved facets. The training set is where the model learns patterns and relationships, like how debt-to-equity ratios or interest rates relate to measures of risk.

The validation set serves to monitor model performance throughout the training process. It allows for the hyperparameter tuning (e.g., learning rate, number of hidden layers, or neuron size of the DNN) without biasing the model with information from the very last test set. Other techniques, such as early stopping, are also utilized here in order to halt training whenever the model's validation performance reaches a plateau or declines, and this avoids overfitting. This is most essential when working with complex models and multi-dimensional data, where one has more chances of overfitting.

The test set is held back completely during the training and validation phase. It is the final checkpoint to determine how the model actually performs in the real world in an objective manner. Since cross-border trade risk data sets are usually imbalanced, with significantly more low-risk cases than high-risk cases, stratified sampling can be applied so that each collection has the same original class ratio. This way, evaluation metrics for the test set (e.g., accuracy, AUC, F1-score) reflect the model performance in handling rare, but significant high-risk cases, which are particularly important for financial risk prediction in trade industries.

VII. RESULTS

The actual vs. predicted plot shows a high correlation, and that means the model is predicting well for the target variable. The residual plot also confirms that the model errors are randomly spread with no apparent patterns, meaning the model is well-fitted. The MAE for both the training set and validation set decreases steadily, which indicates steady improvement in prediction capability. Furthermore, the error distribution in prediction is nearly symmetric around zero, reflecting an unbiased model. The system's excellent generalizability to unknown data and ability to capture underlying data patterns are indicated by the high and consistent R2 values for both training and validation. The International Trade and Finance Dataset is available publicly from trusted sources like Kaggle, the World Bank, the IMF, and other financial organizations.

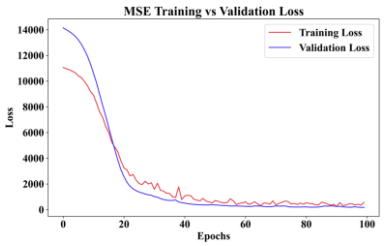

Fig. 4. MSE training vs. validation loss.

The above Fig. 4 illustrates how the Mean Squared Error evolves for the training and validation sets over the epochs. The training loss decreases as the model is trained out of the data and the validation loss is a sign of whether the system generalizes to new, unseen data. A well-behaved model should typically show both training and validation loss decreasing over time. As the validation loss starts increasing when the training loss continues to drop, it may be a sign of overfitting. A strong downward slope in both validation loss and training loss shows that the model is converging and learning. If the validation loss starts moving further away from the training loss, it shows that the model is overfitting, i.e., is doing well on the training set but poorly on unseen new data.

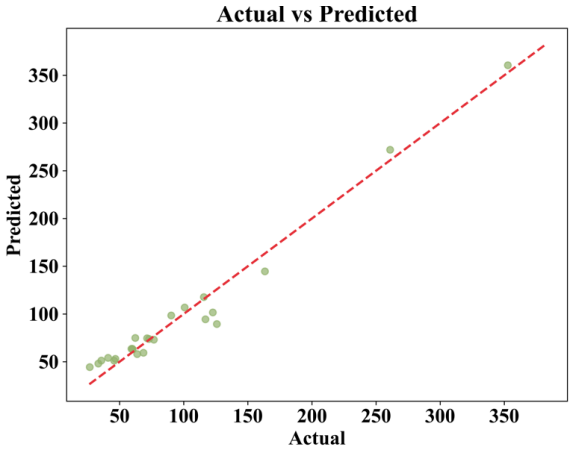

Fig. 5. Actual vs. predicted.

A plot of actual vs. predicted values is shown in Fig. 5 (x-axis vs. y-axis). Ideally, the points would be exactly clustered on a 45-degree line of ideal predictions. The further away from this line the points are, the poorer the predictions. This graph of transformation helps in judging the overall quality of the prediction of the model visually. If the points cluster closely on the diagonal line, the model's predictions are accurate. Big deviations from this line indicate larger prediction errors and suggest areas where the model might perform better. This plot puts residuals (observed minus predicted) on the y-axis and the predicted values on the x-axis.

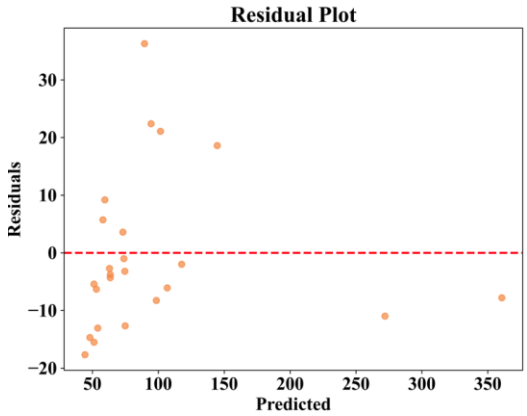

Fig. 6. Residual plot.

Fig. 6 shows a residual plot. The residual plot should be evenly distributed around the horizontal line at zero, with no discernible pattern. Random patterns or clustering of residuals would be suggestive that the model is not capturing the underlying structure of the data as much as it might. Random distribution around zero of residuals would be an indication that the underlying relationships in the data are being well captured by the model. Any non-random pattern, such as curvature and funnel shapes, may be suggestive of misspecification of the model or that the model is failing to capture some patterns in the data.

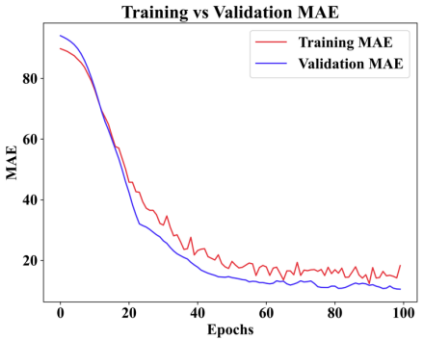

Fig. 7. Training vs. validation MAE.

This graph plots the Mean Absolute Error in Fig. 7 on training and validation data versus epochs. MAE stands for the average magnitude of prediction errors, regardless of direction. The graph shows how the model's prediction error varies during training and validation. Sloping down lines represent increasing accuracy. Consistent decrease in the MAE for training and validation means that the model is improving. If the test MAE starts increasing while the training MAE continues to decrease, it is a sign of overfitting, when the system performs well on the training set but cannot generalize to the new data.

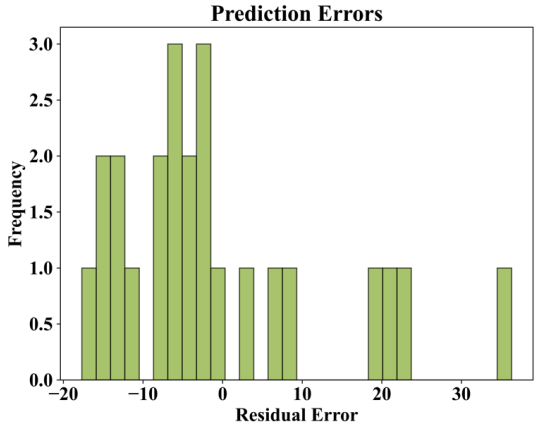

Fig. 8. Prediction errors.

The histogram displays the distribution of residual (prediction error) in Fig. 8. It displays the error distribution graphically, which, for a well-performing model, would be perfectly symmetric and centered at zero. Skewness or heaviness in the tails of the distribution may imply the model is biased or does not work well for some ranges of data. A symmetric, bell-shaped histogram with a zero center means that the model is unbiased and errors are evenly distributed. If the distribution is tail heavy or skewed, it implies that the model is either overfitting or underfitting some patterns in data.

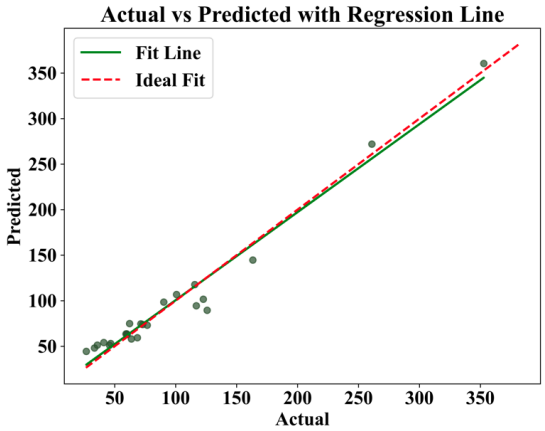

Fig. 9. Actual vs. predicted with regression line.

This scatter plot shows actual vs. predicted values and contains a fitted regression line, as shown in Fig. 9, the linear best fit approximation of the relationship between actual and predicted values. The closer the points are to the regression line, the better the model fits in predicting the target variable. This plot provides insight into how accurately the model describes the underlying trend. If the points are close to following the regression line, it indicates that the system predictions are accurate and that the system has learned the underlying relationship of variables. Far deviations from the line suggest errors in prediction and potential adjustment areas.

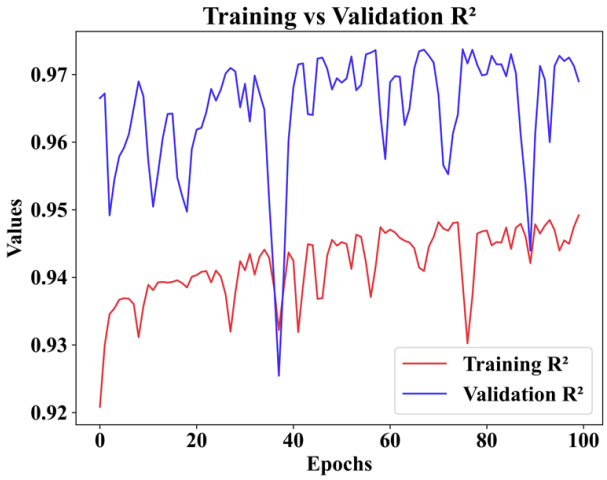

Fig. 10. Training vs. validation R².

The plot tracks the R^2 (coefficient of determination) both on training and validation sets during the epochs in Fig. 10. R^2 is the dependent variable variance explained by the independent variables. The larger value of R^2 (closest to 1) indicates a good model fit to the data. The graph shows how the value of R^2 varies while training and validating the model. A high, consistent value for both training and validation indicates that the model is well-fitted and can generalize well to new data. A significant disparity between the training and validation R^2 can show overfitting, in which the model learns the training data well but the new data poorly. Oscillation of R^2 values can further show non-stable model training. Throughout the epochs, the model exhibits a discernible decrease in validation and training loss, indicating effective learning and generalization.

TABLE. IV. MODEL EVALUATION METRICS

Metric	Value
R^2	0.9670
RMSE	0.0408
MAE	0.0322
MSE	0.0017

Table IV shows model evaluation metrics. This gave great importance to the model's performance against real financial risk. An R^2 (Coefficient of Determination) value of 0.9670 denotes that the model explained 96.7% of the variance of the target variable, implying that it had a very close fit to the data. RMSE of 0.0408 points out that such value is the average measurement of error in magnitude between prediction and actual values, with small values implying better prediction values. Being an average of the value of errors without consideration of their sign, MAE of 0.0322 is another representation of an average small error that the model yields along with one representing the magnitude of different errors without considering polarity. Another measure supporting model accuracy is an MSE value of 0.0017, where MSE stands for Mean Squared Errors, averaging squared differences between predicted and actual values (and the converse for low values).

VIII. DISCUSSION

The results of this study indicate that the developed predictive model effectively measures and predicts financial risks in international trade, particularly in China's finance-led economy. The model successfully captures pertinent patterns in the commerce data, as seen by the notable decrease in the initial, final loss and the high R2 values for both the learning and testing sets. The validity and dependability of the framework in predicting financial risks are further guaranteed by the uniformity between the expected and observed values. The random nature of the residuals further ensures that the model is not overfitting or underperforming in terms of the ability to generalize well to future data, a dimension critical in actual trade finance usage.

While overall model performance is promising, results also identify areas needing a deeper investigation. For instance, certain variables, such as the inflation rate and debt-to-equity ratio were predictably low, possibly suggesting that those features need more sophisticated transformations or supporting data for better prediction effectiveness. Furthermore, the trade balance ratio as a derived feature was very strong in terms of identifying high-risk entities, but its impact would be further optimized by using more sophisticated regional or sectoral data. These findings suggest that the model's feature selection mechanism can be enhanced to consider a greater number of dynamic and context-specific trade variables, including geopolitical uncertainties or local market conditions.

Despite these shortcomings, the model presents a worthy contribution to international trade finance risk analysis. For economic institutions and governments engaged in cross-border trade, the capacity to forecast financial hardship and risk exposure assessments from extensive, current trade data is

essential. Through the integration of big data technologies, the model delivers scalable, timely risk analyses that were previously impossible with traditional financial models. This would help to counterbalance potential risks like payment defaults, exchange rate fluctuations, and geopolitical perils, thereby making global trade systems more stable.

In subsequent studies, it would be fascinating to examine more advanced feature engineering techniques, for example, sentiment analysis of geopolitical releases or machine learning methodologies for modeling time-series dependencies in trade data. The predictability of the model would also be improved by adding ongoing data streams and broadening the dataset to incorporate information from different industries or economies. This study paves the way for the creation of increasingly complex risk assessment models that could assist decision-makers in foreseeing and averting financial dangers associated with international trade.

IX. Conclusion

The research was capable of successfully developing a predictive model for assessing and forecasting financial risks in foreign trade with the help of big data analysis. With the aid of a rich dataset that includes important financial indices, trading volume, and macroeconomic data, the model had high accuracy and promising generalization ability in predicting financial distress and trading risks. The combination of deep neural networks and a hybrid regression model presented a robust solution to the identification of non-linear patterns, as well as explainable trends in the data, such that the model is transparent and accurate for use in trade finance.

The findings identify the potential for big data-based models in enhancing risk prediction functions in international trade. By virtue of the automated risk-evaluation process, the model facilitates immediate evaluation that can be used to inform decision-making processes at policy-making levels and risk management processes. The effective application of big data technologies for distributed computation and scalable analysis also serves to emphasize the necessity of current computational methods in managing advanced financial systems and preventing any impending risks within global trade networks.

Despite the fact that the model is superb in classifying trade finance risks, there are certain areas to be enhanced in the future. The precision and sensitivity of the model could be greatly improved by further fine-tuning feature engineering, adding more variables like global risk factors, and investigating existing data streams. This contribution opens the door to developing more sophisticated and dynamic tools for risk assessment, which can be effective in fostering stability and resiliency in international trade finance systems.

Declaration

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Data Availability

https://www.kaggle.com/datasets/elmartini/international-trade-and-finance-data: It includes in-depth data on cross-border trade transactions, economic performance, financial behavior, and credit exposure. The dataset provides important variables such as trade volume, interest rates, GDP growth rate, and payment defaults, which are essential for the examination of financial risks in international trade. The data is well-organized and periodically revised, making it suitable for effective and timely analysis.

Conflicts of Interest

The authors declare no conflicts of interest regarding the publication of this study.

Funding Statement

This research received no external funding.

Author's Contribution

Conceptualized the study, developed the model, analyzed the data, and wrote and approved the manuscript.

Ethical Approval

Attention and Representation Learning in Byte-Level Digital Forensics: A Survey of Methods, Challenges, and Applications

Teena Mary[1], Sreeja CS[2]
Department of Computer Science, Christ University, Bengaluru, Karnataka, India – 560029[1]
Center for Quantum Technologies and Complex Systems (CQTCS), Christ University, Bengaluru, Karnataka, India - 560029[2]

***Abstract*—Byte-level analysis has become an essential capability in digital forensics, enabling content-based investigation when file system metadata, headers, or structural information are unavailable or unreliable. Recent advances in deep learning allow forensic systems to learn discriminative features directly from raw byte streams; however, the growing diversity of representation strategies, architectural designs, and attention mechanisms makes it difficult to assess their relative effectiveness and practical suitability. This study presents a structured survey of representation learning and attention-based approaches for byte-level digital forensic analysis. We examine statistical, embedding-based, image-based, sequential, and hybrid representations, and analyze how architectural choices and attention mechanisms influence performance, robustness, and scalability. Across the literature, hybrid representations combined with lightweight convolutional backbones and selective attention mechanisms consistently provide a favorable balance between accuracy and computational efficiency. The survey also reviews key forensic applications, including file fragment classification, malware and binary analysis, network payload forensics, and encrypted or compressed data triage. In addition, we critically discuss challenges related to distribution shift, dataset bias, adversarial vulnerability, interpretability, and reproducibility, along with practical considerations for deployment in large-scale forensic pipelines. By synthesizing architectural trends, operational constraints, and reliability concerns, this work identifies critical research gaps and provides a structured foundation for the development of robust and trustworthy byte-level forensic learning systems.**

***Keywords*—Byte-level digital forensics; representation learning; attention mechanisms; file fragment classification; deep learning; forensic robustness**

I. Introduction

The exponential growth of digital storage, networked systems, and connected devices has significantly increased both the volume and complexity of digital evidence encountered in modern forensic investigations. In many real-world scenarios, investigators must analyze data that are incomplete, fragmented, partially overwritten, or stripped of file system metadata. Such conditions are common in cases involving file deletion, disk corruption, memory acquisition, network interception, and anti-forensic activities. As a result, traditional metadata-driven forensic techniques often prove insufficient, motivating the adoption of content-based and byte-level analysis methods [1], [2].

Byte-level digital forensics refers to the direct analysis of raw byte sequences without reliance on high-level semantic structures such as file headers, filenames, or file system information. This paradigm underpins several critical forensic and security tasks, including file fragment classification, malware detection, and network payload analysis. Early research in this area relied primarily on handcrafted statistical features, such as byte frequency distributions, entropy measures, and n-gram statistics, to distinguish between different data types [3], [4]. While these approaches demonstrated feasibility, their performance was often limited when applied to high-entropy data, short fragments, or previously unseen file formats.

The emergence of machine learning and deep learning techniques has substantially advanced byte-level forensic analysis by enabling automatic feature extraction directly from raw byte streams. Convolutional neural networks, recurrent architectures, and hybrid models have been successfully applied to learn discriminative patterns from byte sequences without explicit feature engineering [5], [6]. These models have shown improved generalization across diverse file types and forensic conditions, particularly when trained on large-scale benchmark datasets designed to reflect realistic fragmentation scenarios.

Despite these advances, learning from raw byte streams remains fundamentally different from processing structured data such as images or natural language. Byte-level data lack semantic meaning, exhibit high variability, and often display entropy characteristics that closely resemble random noise. Consequently, deep learning models trained on byte sequences are prone to overfitting local statistical artifacts and are highly sensitive to minor perturbations in the input data [7]. These properties pose significant challenges for representation learning, robustness, and interpretability in forensic applications.

In recent years, representation learning and attention mechanisms have emerged as promising tools for addressing these challenges. Representation learning aims to transform raw byte sequences into feature spaces that capture informative statistical and structural regularities, while attention mechanisms enable models to dynamically emphasize discriminative regions or features within otherwise noisy inputs. Attention-based architectures have demonstrated notable success in related security domains, particularly

malware classification and binary analysis, by improving both classification accuracy and model efficiency [8], [9]. However, a systematic understanding of how different representation strategies and attention mechanisms operate across byte-level forensic tasks remains lacking.

Existing surveys in digital forensics have primarily focused either on classical file fragment classification techniques or on adversarial vulnerabilities of machine learning models. In contrast, this survey adopts a broader architectural perspective, centering on how byte-level representations are learned, how attention mechanisms are applied, and why these design choices matter for forensic reliability. By synthesizing research across multiple forensic tasks and model families, this study aims to provide a unified foundation for designing effective and trustworthy byte-level forensic learning systems.

However, existing literature lacks a unified analysis that jointly examines representation learning strategies, architectural design choices, attention mechanisms, and their implications for robustness, scalability, and operational deployment in real-world forensic environments. Limited work has systematically connected model design decisions with practical challenges such as distribution shift, high-entropy data, computational constraints, and reliability requirements. This gap motivates the need for a structured synthesis that integrates architectural, methodological, and operational perspectives.

The main contributions of this survey are as follows:

1) A structured review of representation learning strategies for raw byte streams in digital forensics.

2) A comparative analysis of deep learning architectures applied to byte-level forensic tasks.

3) An in-depth examination of attention mechanisms and their role in improving discriminability and robustness.

4) A discussion of key challenges related to reliability, robustness, and trustworthiness in byte-level learning.

5) Identification of open research directions to guide future developments in forensic intelligence systems.

While recent advances in deep learning and attention-based models have significantly improved the effectiveness of byte-level forensic analysis, the design of reliable and robust learning systems remains tightly coupled to the intrinsic properties of byte-stream data. Unlike structured domains such as text or images, raw byte sequences exhibit unique statistical, structural, and entropy-related characteristics that directly influence representation learning, model generalization, and susceptibility to error. A clear understanding of these underlying data properties is therefore essential before examining representation strategies and architectural choices. The following section discusses the fundamental characteristics of byte-level forensic data and outlines the key challenges they impose on learning-based forensic systems.

The remainder of this study is organized as follows: Section II describes the survey methodology and literature selection process. Section III discusses the fundamental characteristics of byte-level forensic data. Section IV reviews representation learning strategies for raw byte streams. Section V examines deep learning architectures used in byte-level forensic analysis, followed by Section VI, which presents attention mechanisms and their role in improving model performance and robustness. Section VII summarizes key application domains, while Section VIII discusses challenges related to robustness, reliability, and trustworthiness. Section IX outlines open research challenges and future directions, and Section X concludes the survey.

II. Survey Methodology

This survey was conducted using a structured literature review approach to ensure comprehensive coverage of research related to byte-level learning for digital forensic applications. Relevant publications were identified through major academic databases, including IEEE Xplore, ACM Digital Library, ScienceDirect, SpringerLink, and Google Scholar. The search covered the period from 2003 to 2025 to capture both foundational work on file fragment classification and recent advances in deep learning, representation learning, and attention-based architectures.

Search queries included combinations of keywords such as file fragment classification, byte-level analysis, raw byte deep learning, binary classification, representation learning, attention mechanisms, malware raw byte analysis, and encrypted or network payload classification. Retrieved studies were screened based on title and abstract, followed by full-text assessment to ensure relevance to content-based analysis of raw byte data.

Studies were included if they proposed methods for analyzing raw byte streams, investigated deep learning architectures applicable to binary or fragment data, examined representation learning or attention mechanisms for byte-level inputs, or discussed reliability aspects such as distribution shift, adversarial robustness, interpretability, or reproducibility in security or forensic contexts. Works focused solely on metadata-based analysis, signature-based techniques, or unrelated domains without transferable methodological relevance were excluded.

Since research specifically dedicated to file fragment classification remains relatively limited, the scope of this survey was expanded to include closely related byte-level security domains such as malware detection, binary analysis, and encrypted traffic classification. These domains share key characteristics with forensic fragment analysis, including high-entropy inputs, lack of semantic structure, large input sizes, and sensitivity to small perturbations. Insights from these areas were incorporated when they provided transferable principles for representation design, architectural choices, attention mechanisms, or robustness.

In total, the final corpus comprises foundational statistical methods, modern deep learning models, hybrid representation strategies, attention-based architectures, and studies addressing reliability and operational considerations from 60 papers. The selected literature was organized and analyzed according to representation strategy, model architecture, attention mechanism, application domain, and reported limitations to support the comparative synthesis presented in this survey.

III. Characteristics of Byte-Level Forensic Data

As established in the previous section, the effectiveness of learning-based forensic systems is fundamentally constrained by the nature of the data they operate on. Before examining representation learning strategies and model architectures, it is therefore necessary to understand the intrinsic properties of byte-level forensic data that shape both model behavior and performance. Fig. 1 illustrates the shift from traditional metadata-dependent forensic methods to learning-based approaches that operate directly on raw byte streams under conditions of fragmentation, corruption, or missing structural information.

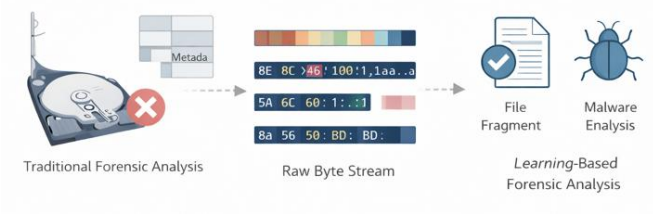

Fig. 1. Conceptual illustration of byte-level digital forensic analysis.

Byte-level forensic analysis operates directly on raw sequences of bytes extracted from storage sectors, memory pages, or network payloads, typically in the absence of file system metadata or semantic context. Unlike structured domains such as text or images, byte streams lack natural token boundaries, spatial coherence, or human-interpretable meaning. Each byte represents only a numerical value between 0 and 255, and any higher-level structure must be inferred implicitly through statistical regularities across the sequence.

One of the most significant characteristics of byte-level forensic data is high-entropy, particularly for fragments originating from compressed, encrypted, or proprietary formats. In such cases, byte distributions often approximate uniform randomness, making class-discriminative patterns weak and difficult to isolate. Recent empirical studies on large-scale fragment benchmarks have shown that even deep learning models experience notable performance degradation as entropy increases, especially when operating on short, fixed-size fragments typical of forensic pipelines [10].

Fragmentation further amplifies this challenge. Forensic tools commonly process data in fixed-size blocks - often aligned with disk sectors rather than logical file boundaries - resulting in fragments that contain only partial structural information. Fragmentation disrupts long-range dependencies and eliminates global cues such as headers, trailers, and format-specific markers. Modern benchmark datasets intentionally remove header information to prevent trivial classification, but this design choice also forces models to rely on subtle local patterns that may not be consistently present across fragments [6].

Another defining property of byte-level forensic data is the absence of semantic interpretability. Unlike words in natural language or pixels in images, individual bytes do not convey meaning that is interpretable by humans. Consequently, learning-based systems must rely almost exclusively on statistical correlations and positional relationships. Recent analyses of byte-level neural networks suggest that many models learn highly localized, distribution-sensitive features, which can lead to overfitting and reduced robustness under realistic forensic conditions involving noise, corruption, or partial overwrites [9].

Byte-level forensic data are also inherently heterogeneous. Different file types, encodings, and storage contexts exhibit distinct statistical behaviors, yet these differences may be subtle or partially obscured at the fragment level. Cross-dataset evaluations have demonstrated that models trained under specific fragmentation or acquisition settings often generalize poorly when exposed to fragments generated under different conditions, highlighting persistent challenges related to dataset bias and distribution shift [11].

Finally, byte-level data are particularly sensitive to minor perturbations. Small modifications - such as padding, bit-level corruption, or partial overwriting - can significantly alter the statistical patterns on which learning-based systems rely. This sensitivity has important implications for reliability and trustworthiness, especially in forensic environments where data integrity cannot be guaranteed. These properties motivate the need for representation learning strategies that can capture discriminative information while remaining resilient to noise and variation [12].

Taken together, these characteristics illustrate why naïve feature engineering and direct application of conventional deep learning architectures are often insufficient for byte-level forensic tasks. They also underscore the central role of representation learning in transforming raw byte sequences into features that are both informative and robust. The next section, therefore, examines the principal representation learning approaches that have been proposed for byte-level digital forensics and analyzes how they address - or fail to address - the challenges outlined above.

IV. Representation Learning for Byte Streams

The data characteristics discussed in the previous section make it clear that raw byte sequences are not directly amenable to effective learning without appropriate feature transformation. Representation learning, therefore, becomes the foundation of byte-level digital forensic analysis, as it determines how statistical regularities, structural cues, and contextual dependencies are exposed to downstream models. Over the past decade, research has evolved from handcrafted statistical descriptors toward learned representations that can adapt to heterogeneous file formats and forensic conditions.

A. Statistical Representations

Early representation strategies for byte-level analysis relied on handcrafted statistical features such as byte frequency distributions, Shannon entropy, and fixed-length n-gram statistics. These representations summarize global properties of a fragment and are computationally efficient, which makes them attractive for large-scale forensic workflows. However, recent empirical studies have shown that statistical descriptors alone are often insufficient when fragments are short, highly compressed, or encrypted, as discriminative patterns become weak or indistinguishable from noise [7], [13]. Moreover, such

features are sensitive to fragmentation strategies and dataset bias, limiting their generalization across forensic contexts [11].

Despite these limitations, statistical representations remain relevant as complementary signals. Several recent works incorporate entropy measures or frequency-based features alongside learned representations to improve robustness and stabilize training, particularly in low-data or high-entropy regimes [7].

B. Learned Byte Embeddings

To overcome the rigidity of handcrafted features, recent research has increasingly adopted learned byte embeddings. In this paradigm, each byte value is mapped to a dense, trainable vector that captures contextual relationships among neighboring bytes. Byte embeddings are learned jointly with the classification model and enable the network to discover similarities between byte values that frequently co-occur in specific structural or statistical contexts [4].

Large-scale studies have demonstrated that embedding-based representations significantly outperform raw byte encodings and statistical features on benchmark datasets for file fragment classification and binary analysis [5], [6]. Learned embeddings also reduce input dimensionality and improve optimization stability, making them particularly effective when combined with convolutional architectures. Extensions of this idea have explored context-aware embedding objectives and multi-scale embedding schemes, further improving performance on heterogeneous forensic datasets [14].

C. Image-Based Byte Representations

Another widely explored representation strategy reshapes byte sequences into two-dimensional arrays and interprets them as grayscale images. This approach enables the direct application of convolutional neural networks originally developed for computer vision. Image-based representations have shown competitive results in several byte-level tasks, including malware classification and file fragment identification, due to the ability of CNNs to capture local spatial patterns efficiently [15], [16].

However, the imposed spatial structure is artificial and does not reflect inherent relationships in the byte stream. Recent comparative analyses indicate that while image-based encodings can be effective for fragments containing repeated local motifs, they may obscure long-range dependencies and degrade performance when structural regularities are weak or fragmented [17]. As a result, image-based representations are best viewed as a task-dependent alternative rather than a universal solution.

D. Sequential and Context-Aware Representations

Sequential models explicitly preserve byte ordering and aim to capture contextual dependencies across fragments. Early work employed recurrent neural networks and long short-term memory (LSTM) architectures to model byte sequences, but these approaches suffered from scalability and training inefficiencies on long inputs [18]. More recent studies have investigated the use of self-attention and Transformer-based models for byte-level representation learning, demonstrating improved capacity to model long-range dependencies and contextual interactions [10], [19].

Despite their expressive power, Transformer-based approaches remain computationally expensive and are often impractical for high-throughput forensic pipelines. Consequently, recent research favors lightweight sequential components or attention modules integrated into convolutional backbones to balance expressiveness and efficiency.

E. Hybrid and Multi-View Representations

State-of-the-art systems increasingly adopt hybrid representation strategies that combine multiple views of the data. Common combinations include byte embeddings with convolutional feature maps, statistical descriptors with learned representations, or parallel processing of sequential and image-based encodings. Such multi-view designs aim to mitigate the weaknesses of individual representations and improve robustness across diverse file types and acquisition conditions [20], [21].

Empirical evaluations on large fragment corpora indicate that hybrid representations consistently outperform single-view approaches, particularly in cross-dataset and mixed-entropy scenarios [22]. These findings highlight the importance of representation diversity in addressing the heterogeneity inherent in byte-level forensic data. Table I summarizes the principal representation learning strategies used in byte-level digital forensic analysis, highlighting their core characteristics, strengths, limitations, and typical application contexts.

TABLE I. COMPARISON OF REPRESENTATION LEARNING STRATEGIES FOR BYTE-LEVEL FORENSIC DATA.

Representation Strategy	Core Idea	Strengths	Limitations	Typical Applications
Statistical Representations	Global statistics such as byte frequency, entropy, and n-grams	Simple, fast, interpretable and low computational cost	Poor discrimination for high-entropy or short fragments; limited generalization	Baseline fragment analysis; feature augmentation
Learned Byte Embeddings	Trainable dense vectors for byte values learned end-to-end	Captures contextual byte relationships; compact and efficient	Requires sufficient training data; embedding quality task-dependent	File fragment classification; binary analysis
Image-Based Byte Encodings	Reshaping byte streams into 2D grayscale images	Enables reuse of CNN architectures; strong local pattern learning	Artificial spatial structure; weak long-range dependency modeling	Malware classification; visual binary analysis
Sequential Representations	Explicit modeling of byte order using RNNs or Transformers	Preserves ordering; captures contextual dependencies	High computational cost; scalability challenges	Context-aware fragment analysis; sequence modeling

Representation Strategy	Core Idea	Strengths	Limitations	Typical Applications
Hybrid Representations	Combination of embeddings, statistics, and/or image encodings	Improved robustness; better cross-dataset performance	Increased model complexity; higher training cost	Large-scale forensic pipelines; mixed-entropy datasets

In summary, representation learning has progressed from simple statistical descriptors to sophisticated, multi-view encodings that integrate embeddings, convolutional features, and contextual modeling. However, representation choice alone does not guarantee effective learning. How these representations are processed by downstream architectures - and how attention mechanisms selectively emphasize informative patterns - plays a critical role in determining overall system performance. The next section, therefore, examines the deep learning architectures used to consume these representations and analyzes their respective strengths and limitations.

V. Deep Learning Architectures for Byte-Level Forensics

Selecting an architecture for byte-level forensic tasks is a pragmatic balancing act. Models must be expressive enough to capture discriminative signals buried in noisy fragments, yet efficient enough to process large volumes of data in operational pipelines. In practice, three architectural families dominate the literature- convolutional backbones (often compacted for speed), sequence/contextual models (for longer dependencies), and hybrids that combine local processing with global reasoning. Below, we review each family, highlight important architectural innovations that matter for forensic use, and summarize practical trade-offs.

Convolutional neural networks (CNNs) are widely used because they extract local byte patterns with high efficiency. One-dimensional convolutions over byte sequences or two-dimensional convolutions over reshaped byte images both work in practice; which one is preferable depends on the task and dataset. Lightweight convolutional designs, such as those using depthwise-separable convolutions, substantially reduce computation and memory while preserving accuracy, making them attractive for forensic deployments where throughput or CPU inference is a priority [23], [24]. Recent fragment-classification work explicitly adopts these compact convolutional blocks to achieve near-state-of-the-art accuracy at a fraction of the inference cost [17].

A simple but effective architectural addition is channel-wise recalibration. Modules that learn to reweight feature channels allow networks to suppress noisy dimensions and amplify informative ones. These blocks are inexpensive to insert into compact backbones and improve robustness to heterogeneous fragments by dynamically emphasizing channels that correlate with useful format cues [25]. Empirical studies on byte and binary inputs show that channel recalibration helps when fragments contain sparse but discriminative motifs spread across channels.

Reshaping byte streams into 2-D arrays so they can be processed by image CNNs is a popular engineering choice. It permits reuse of mature image architectures and pretraining tricks. On many benchmark datasets, image-style CNNs match or exceed 1-D counterparts when local texture-like signatures exist in the data, but they can fail when the reshaping imposes artifacts that obscure meaningful sequential correlations [16], [26]. Practitioners, therefore, validate image encodings against sequential approaches before committing to a design.

For fragments, where long-range interactions matter, sequential encoders and Transformer-style models are compelling. Transformers use attention to link distant positions and have been adapted for binary and code analysis tasks with success; they excel when pretraining on large corpora is feasible and when tokenization/patching strategies reduce sequence length [27]. Yet vanilla Transformers are memory-intensive for long byte sequences; practical forensic designs thus use patched tokenizations, sparse attention, or operate Transformers on compressed representations learned by a front-end CNN.

A frequently effective pattern is hybrid: a compact convolutional front-end extracts local features and reduces sequence length; a lightweight attention or recurrent head integrates global context; and shallow classifier heads make the final decision. Hybrids balance expressiveness with throughput and are common in large, published fragment datasets and operational systems where both speed and accuracy matter [5], [28]. They also make it easier to fuse auxiliary features - e.g., entropy statistics or byte histograms - improving robustness under mixed-entropy conditions.

Architecture influences not only accuracy and latency but also robustness to distribution shift and adversarial manipulation. Models that rely excessively on narrow local motifs can be fragile to small perturbations; conversely, architectures that integrate multi-scale context and explicit recalibration mechanisms tend to be more stable. Recent work on binary and malware domains shows that architecture-level choices (tokenization, attention window, channel recalibration) materially affect adversarial susceptibility and cross-dataset generalization, underlining the need to evaluate architectures under diverse and realistic fragment generation scenarios [29], [30], [31].

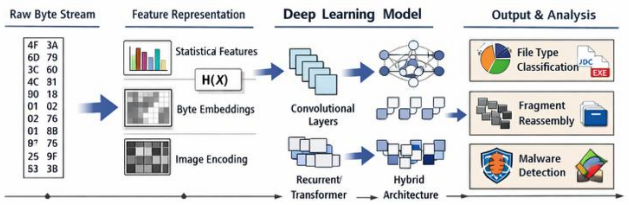

Fig. 2. A generic byte-level deep learning pipeline for digital forensic applications, from raw byte streams to feature representation, model processing, and forensic analysis outputs.

As shown in Fig. 2, the pipeline begins with raw byte streams obtained from storage media or memory, which are converted into suitable feature representations such as statistical features, byte embeddings, or image encodings. These representations are subsequently analyzed by deep

learning architectures, including convolutional, recurrent, transformer-based, or hybrid models, to support forensic tasks such as file fragment classification, fragment reassembly, and malware detection.

In practical forensic environments, computational efficiency and scalability are critical considerations, particularly when processing large volumes of data. Byte-level models often operate on long input sequences, which increases memory usage and inference time. Attention-based architectures further amplify this challenge, as self-attention mechanisms scale quadratically with input length, limiting their applicability to large fragments or high-throughput analysis scenarios. To address these constraints, several studies have explored lightweight convolutional architectures and efficient feature extraction strategies that reduce computational overhead while maintaining competitive performance [17], [24]. Hybrid designs that combine convolutional front-end feature extraction with selective or localized attention mechanisms offer a practical trade-off between contextual modeling and efficiency. Such design choices are particularly important for real-world forensic pipelines, where timely processing and resource constraints must be balanced against model accuracy.

VI. Attention Mechanisms in Byte-Level Learning

Architectural advances discussed in the previous section have substantially improved the capacity of deep learning models to process raw byte streams. However, a fundamental limitation remains: byte-level forensic data are inherently noisy, fragmented, and heterogeneous, yet conventional architectures typically treat all parts of the input with equal importance. In realistic forensic scenarios, only a small subset of bytes within a fragment may carry discriminative information, while the remainder consists of padding, overwritten regions, or statistically random content. Attention mechanisms address this mismatch by enabling models to dynamically prioritize informative features and suppress irrelevant signals.

Early applications of attention in byte-level security tasks emerged from malware analysis, where researchers observed that convolutional filters often responded strongly to localized but semantically insignificant byte patterns. Attention mechanisms were introduced to re-weight learned features based on their relevance to the classification objective, leading to consistent improvements in accuracy and stability across datasets [15], [32]. These findings motivated the adoption of attention in file fragment classification and other forensic domains, where similar challenges related to noise and fragmentation are prevalent.

One widely adopted form is channel attention, which operates on feature maps produced by convolutional layers. In byte-level models, each channel typically captures a distinct statistical or structural pattern, such as repetition, local entropy variation, or format-specific motifs. Channel attention modules learn to amplify channels that contribute meaningfully to discrimination while attenuating those dominated by noise. Recent studies demonstrate that incorporating channel attention into compact convolutional backbones improves cross-dataset generalization and reduces sensitivity to fragment length and entropy variation [33], [34]. Importantly, channel attention introduces minimal computational overhead, making it suitable for large-scale forensic pipelines.

Complementing channel-wise reweighting, spatial or positional attention mechanisms focus on identifying informative regions within a byte sequence or its reshaped representation. Spatial attention enables models to localize and emphasize these subsequences, improving resilience to fragmentation and partial overwriting. Empirical evaluations on fragment classification benchmarks show that spatial attention-guided models outperform baseline CNNs, particularly when fragments are generated using non-uniform or adversarial fragmentation strategies [35], [36].

More recently, self-attention and Transformer-inspired architectures have been adapted for byte-level learning. Unlike convolutional or recurrent models, self-attention explicitly models pairwise interactions between positions, allowing long-range dependencies to be captured without sequential processing. In byte-level forensic tasks, self-attention has been applied to embedded byte tokens or compressed patch representations, enabling models to reason about global context across a fragment. Studies report improved performance on complex and high-entropy data, although computational cost remains a significant consideration [37], [38]. To address scalability, several works propose constrained or hierarchical self-attention schemes that limit attention scope while preserving contextual modeling benefits.

Beyond performance gains, attention mechanisms contribute to robustness and interpretability, both of which are critical in forensic settings. By reducing reliance on uniformly distributed statistical noise, attention-equipped models are less susceptible to spurious correlations and dataset-specific artifacts. Furthermore, attention weights can be visualized to provide insights into which regions or features influenced a classification decision. Recent research highlights the value of such visualizations in supporting forensic analysis, model validation, and trustworthiness, particularly when learning-based evidence must be explained or scrutinized [39], [40].

While attention mechanisms enhance feature selection and contextual modeling, their contribution should be interpreted with caution. In many studies, improvements attributed to attention may also be influenced by increased model capacity, deeper architectures, or larger training datasets, making it difficult to isolate the specific impact of the attention component without controlled ablation analysis. Furthermore, attention weights do not necessarily correspond to causal feature importance, and visualizations may create a misleading impression of model interpretability. Prior work in explainable artificial intelligence has emphasized that internal model signals, including attention, should not be treated as faithful explanations without additional validation [54], [59]. Interpretations that are not rigorously evaluated may therefore be unreliable in forensic contexts, where analytical conclusions must be defensible. To support trustworthy deployment, attention-based models should be accompanied by systematic ablation studies and complemented with multiple explanation methods and stability checks, in line with emerging

recommendations for rigorous interpretability assessment [55], [60].

Overall, attention mechanisms have increasingly transitioned from auxiliary performance boosters into core architectural components for byte-level forensic learning. Channel, spatial, and self-attention address complementary aspects of the challenges posed by raw byte data, and their integration into hybrid architectures represents a key trend in current research. The next section examines how these attention-enabled models are applied across practical digital forensic tasks, illustrating their effectiveness in real-world investigative scenarios.

VII. Applications in Digital Forensics

The integration of byte-level representation learning and attention mechanisms has expanded the applicability of learning-based methods across several digital forensic domains. These applications share a reliance on raw data analysis under constrained conditions, such as missing metadata, partial data acquisition, or deliberate obfuscation. This section reviews established application areas where byte-level learning has been demonstrably applied and evaluated in the literature.

A. File Fragment Classification

File fragment classification is a long-standing problem in digital forensics, traditionally addressed using statistical features such as byte frequency distributions, entropy measures, and n-grams. Early foundational work demonstrated that fragment classification is feasible even in the absence of file system metadata but also highlighted strong sensitivity to fragmentation strategy and entropy variation [3], [41].

Subsequent studies explored machine learning–based classifiers to reduce reliance on handcrafted features, showing improved discrimination across common file types [4]. While deep learning–based fragment classification remains a relatively narrow research area, convolutional neural networks have been shown to learn discriminative local byte patterns directly from fragment content, outperforming classical approaches under controlled experimental conditions [26]. These results establish the feasibility of byte-level learning for fragment classification, though large-scale and cross-dataset evaluations remain limited.

B. Malware and Binary Artifact Analysis

Byte-level learning has been more extensively studied in malware detection and binary analysis, making this domain a key source of transferable insights for digital forensics. Static malware detection systems operating directly on raw executables have demonstrated that byte-level statistical and structural patterns are sufficient for effective classification without disassembly or dynamic execution [42].

Later work showed that convolutional architectures can automatically learn hierarchical representations of binary structure, while attention mechanisms improve robustness by suppressing noise introduced by padding, packing, or unused code regions [43]. These techniques are directly relevant to forensic analysis tasks such as malware triage, artifact attribution, and family clustering, where raw binaries are often the only available evidence.

C. Network Payload and Traffic Forensics

In network forensics, payload data may be fragmented across packets, partially captured, or encrypted, limiting the effectiveness of protocol-specific parsers. Byte-level deep learning enables content-based traffic analysis without requiring prior knowledge of application protocols. Early deep learning approaches demonstrated that neural networks can classify network traffic directly from raw packet payloads with competitive accuracy [44].

More recent work has emphasized the role of representation learning and attention in improving payload-based traffic classification, particularly under encrypted or obfuscated conditions [45], [46]. These approaches allow models to focus on informative payload segments while ignoring protocol overhead, making them suitable for forensic investigations involving incomplete or noisy traffic captures.

D. Encrypted and Compressed Data Identification

Encrypted and compressed data present inherent challenges due to their high-entropy and lack of semantic structure. While content recovery is infeasible, forensic triage often requires identifying whether data are encrypted, compressed, or random. Prior research has demonstrated that machine learning models trained on byte-level statistics can distinguish between these categories with meaningful accuracy [47].

Recent studies extend this work by applying learning-based classification to encrypted traffic and storage artifacts, supporting forensic prioritization and investigative decision-making [48], [49]. Attention mechanisms contribute by highlighting subtle statistical irregularities that persist across encryption or compression schemes, although performance remains sensitive to dataset composition and entropy levels. To consolidate, Table II provides a summary of representative byte-level forensic tasks along with their associated input characteristics and analytical challenges.

TABLE II. Byte-Level Forensic Tasks and Associated Challenges.

Forensic Task	Input Characteristics	Key Challenges
File fragment classification	Short, high-entropy byte fragments; missing headers and metadata	Loss of global structure; class overlap; limited discriminative cues
Malware binary analysis	Large raw executables with mixed code and data regions	Obfuscation and packing; padding noise; scalability constraints
Network payload analysis	Fragmented packet payloads; partial or encrypted content	Incomplete visibility; protocol noise; payload fragmentation
Encrypted and compressed data triage	Near-random byte distributions with minimal structure	Extremely high-entropy; weak statistical separability

E. Public Datasets and Evaluation Settings

Recent advances in byte-level learning have been supported by the development of several benchmark datasets for file fragment classification and related tasks. However, these datasets differ significantly in terms of fragment generation strategy, header removal, entropy distribution, and evaluation protocols. Such variations complicate direct comparison across studies and contribute to inconsistencies in reported performance.

Large-scale datasets such as FiFTy and ByteRCNN have become commonly used benchmarks for deep learning–based fragment classification. These datasets typically remove file headers and generate fixed-size fragments to prevent trivial classification based on structural signatures. Some studies further stratify fragments based on entropy levels to evaluate performance under realistic forensic conditions involving compressed or encrypted data. Despite these efforts, differences in file type coverage, fragment size, and train–test splitting strategies continue to affect cross-dataset generalization.

Table III summarizes representative publicly reported datasets and experimental settings used in recent byte-level learning studies. The table highlights key factors that influence evaluation outcomes and underscores the need for standardized benchmark protocols to enable fair comparison and reliable assessment of forensic learning systems. The Public column indicates whether datasets or implementation code are explicitly made available through official author resources.

TABLE III. DATASET AND EVALUATION CHARACTERISTICS FOR BYTE-LEVEL FRAGMENT CLASSIFICATION.

Dataset / Study	Type	Public	Header Removed	Key Characteristics
FiFTy [6]	Dataset	Yes (dataset)	Yes	Large-scale benchmark
ByteRCNN [5]	Study	Yes (code)	Yes	CNN–RNN model
ByteNet [35]	Study	Not specified	Yes	Attention-based model
Lightweight CNN [17]	Study	Not specified	Yes	Efficient architecture
Image-based CNN [28]	Study	Not specified	Yes	Grayscale representation

Taken together, these applications demonstrate that byte-level learning supports a range of forensic tasks where traditional feature engineering struggles. However, empirical evidence also reveals limitations related to generalization, robustness, and dataset bias. These concerns motivate a closer examination of reliability and trustworthiness, which are addressed in the following section.

VIII. ROBUSTNESS, RELIABILITY, AND TRUSTWORTHINESS

While byte-level deep learning models demonstrate promising performance across multiple forensic applications, their deployment in real-world investigations raises important concerns related to robustness, reliability, and trustworthiness. Unlike controlled experimental settings, forensic environments are characterized by heterogeneous data sources, imperfect acquisition processes, and potential adversarial manipulation. This section examines key challenges that affect the dependability of byte-level forensic learning systems and reviews established research addressing these issues.

A recurring challenge in byte-level forensic learning is sensitivity to distribution shift. Models are often trained on datasets generated under specific fragmentation strategies, file type distributions, or acquisition conditions. When deployed on data collected under different conditions, performance can degrade significantly. This issue has been widely observed in security and forensic machine learning, where classifiers learn dataset-specific artifacts rather than generalizable patterns [50], [51], leading to significant performance degradation when deployed under different conditions.

Dataset bias is particularly problematic for byte-level models, as subtle differences in compression tools, software versions, or storage media can alter byte distributions. Studies in malware and binary classification demonstrate that high reported accuracy may not translate to robust real-world performance when training and test distributions differ [52]. These findings underscore the need for cross-dataset evaluation and careful dataset construction in forensic research.

Byte-level models are inherently sensitive to small perturbations, such as padding, bit flips, or partial overwriting. Even modifications that preserve semantic equivalence can significantly alter learned representations. Research in adversarial machine learning has shown that deep models operating on raw bytes can be misled by carefully crafted perturbations, raising concerns about reliability in adversarial forensic scenarios [31], [53].

Beyond natural perturbations, byte-level forensic systems may also be vulnerable to deliberate adversarial manipulation. Such threats can be broadly categorized into evasion and poisoning attacks. Evasion attacks occur at inference time and involve modifying input data to mislead the model while preserving its functional or semantic behavior. In byte-level contexts, these manipulations may include byte insertion, padding, reordering, or localized bit modifications that alter statistical patterns without changing the operational characteristics of the file, as demonstrated in adversarial malware studies [29], [31]. Because byte-level models rely heavily on low-level distributional features, even small, localized changes can significantly distort learned representations.

Poisoning attacks target the training process by introducing manipulated or mislabeled samples into the training dataset. In forensic environments, such risks may arise from contaminated data sources, incorrect labeling, or intentionally crafted evidence designed to bias model behavior. Related concerns include evidence manipulation and model inversion, where adversaries attempt to infer sensitive training information or exploit model responses to reconstruct underlying data. These threats highlight the importance of maintaining data integrity and secure training pipelines in forensic machine learning.

Several defensive strategies have been explored in related byte-level security domains. Data augmentation using realistic byte-level transformations can improve robustness to padding,

corruption, and minor perturbations, while adversarial training exposes models to perturbed samples during learning to improve resilience. Architectural designs that incorporate multi-scale feature aggregation and attention-based filtering may further reduce sensitivity to localized noise. In addition, techniques such as confidence calibration, out-of-distribution detection, and ensemble-based decision making can help identify uncertain or potentially manipulated inputs.

Although many forensic use cases are not explicitly adversarial, the presence of corrupted or partially overwritten data can produce similar effects. Robustness to such perturbations is therefore essential for trustworthy forensic deployment. Existing work suggests that architectural choices, regularization strategies, and feature aggregation mechanisms influence sensitivity, but no universally robust solution has yet emerged.

Another dimension of reliability concerns generalization across diverse file types and fragment sizes. Byte-level forensic systems are often evaluated on fixed fragment lengths and limited file categories, which may not reflect operational diversity. Prior research indicates that models trained on specific fragment sizes can exhibit degraded performance when applied to shorter or longer fragments [3].

Similarly, generalization across file formats remains challenging, particularly for formats with similar statistical properties. These limitations highlight the importance of evaluating models under varied experimental conditions and avoiding overly narrow performance claims in forensic contexts.

Trustworthiness in forensic applications extends beyond accuracy. Investigators, analysts, and legal stakeholders must be able to understand and justify how conclusions are reached. Deep learning models trained on raw bytes are often criticized for their lack of interpretability, which can hinder their acceptance as forensic tools.

Recent work in explainable artificial intelligence (XAI) emphasizes the need for interpretable models in security-sensitive domains. Techniques such as saliency mapping, feature attribution, and attention visualization provide partial insight into model behavior, but their forensic validity remains an open question [54], [55]. Without careful interpretation, explanations may be misleading or unstable, limiting their usefulness as evidential support.

Reproducibility is a foundational requirement for trust in forensic methods. However, byte-level forensic learning studies often rely on proprietary datasets, undocumented preprocessing steps, or unavailable code, making independent verification difficult. Surveys in digital forensics have repeatedly highlighted reproducibility as a systemic challenge that undermines confidence in experimental results [56].

Transparent reporting of dataset composition, fragmentation strategies, evaluation protocols, and limitations is therefore essential. Without such transparency, even technically sound models may be unsuitable for forensic adoption.

In summary, while byte-level deep learning offers powerful tools for digital forensics, its reliability and trustworthiness cannot be assumed. Sensitivity to distribution shift, noise, and dataset bias, along with challenges related to interpretability and reproducibility, must be carefully addressed. These concerns motivate ongoing research into robust architectures, standardized benchmarks, and explainable learning frameworks. Section IX of this survey discusses open challenges and future research directions that must be addressed to advance byte-level forensic learning toward practical, trustworthy deployment.

IX. Open Challenges and Future Directions

Despite notable advances in byte-level representation learning and attention-based architectures, several unresolved challenges continue to limit their practical adoption in digital forensic investigations. These challenges are not purely algorithmic; rather, they arise from the interaction between data characteristics, model behavior, operational constraints, and evidentiary requirements. Addressing them requires both technical innovation and methodological rigor.

A. Generalization, Robustness, and Real-World Validity

A central challenge in byte-level forensic learning is achieving reliable generalization beyond controlled experimental settings. Many existing studies evaluate models using datasets constructed under specific assumptions about fragmentation strategy, file type distribution, or acquisition process. While such evaluations are necessary for benchmarking, they often fail to capture the variability encountered in real forensic environments. Prior work in digital forensics has repeatedly emphasized that results obtained under narrowly defined conditions may not translate into operational reliability [57].

Robustness to non-ideal data further complicates this issue. Forensic artifacts may be partially overwritten, corrupted, or intentionally manipulated, leading to distribution shifts that degrade model performance. Research in security-focused machine learning shows that models operating on low-level representations are particularly sensitive to subtle perturbations, even when semantic content is preserved [58]. Future research must therefore prioritize systematic robustness evaluation under realistic noise, corruption, and manipulation scenarios, rather than relying solely on clean benchmark performance.

Closely related is the need for standardized, openly available benchmarks that reflect real-world diversity. Without shared datasets and evaluation protocols, it remains difficult to compare approaches objectively or to assess progress meaningfully. The development of representative fragment corpora and transparent evaluation methodologies remains a critical open problem for the field.

B. Interpretability, Scalability, and Forensic Integration

Beyond performance and robustness, the trustworthiness of byte-level forensic learning systems depends heavily on interpretability and operational feasibility. Deep learning models trained on raw byte streams are often opaque, making it difficult for forensic practitioners to understand why a

particular classification decision was reached. While attention mechanisms and post hoc explanation techniques offer partial insights, their reliability and evidential value require careful scrutiny. Research in explainable artificial intelligence cautions that visual or attribution-based explanations can be unstable or misleading if not rigorously validated [59].

Scalability presents an additional barrier to adoption. Forensic investigations frequently involve large-scale data processing, such as disk-wide analysis or continuous network monitoring. Although recent architectures have improved efficiency, many attention-based models remain computationally intensive, particularly when applied to long byte sequences. Future work should explore hierarchical processing strategies, lightweight attention mechanisms, and hardware-aware model design to ensure that learning-based methods can be deployed at scale.

Finally, effective integration into forensic workflows remains an open challenge. Automated byte-level analysis should support, rather than replace, human expertise. Forensic methodology research consistently emphasizes the importance of transparency, reproducibility, and analyst oversight in evidentiary processes [56], [60]. Future systems should therefore incorporate confidence estimation, auditability, and human-in-the-loop mechanisms to align learning-based analysis with forensic best practices and legal standards.

In summary, advancing byte-level forensic learning requires more than incremental improvements in model accuracy. Progress depends on addressing foundational challenges related to generalization, robustness, interpretability, scalability, and workflow integration. Meeting these challenges will require collaboration across machine learning, digital forensics, and legal domains and represents a necessary step toward trustworthy and operationally viable byte-level forensic analysis.

X. Conclusion

Byte-level learning has emerged as a powerful paradigm for digital forensic analysis, enabling content-based investigation in scenarios where metadata, structure, or semantic context is unavailable or unreliable. By operating directly on raw byte streams, learning-based systems address long-standing forensic challenges such as file fragment classification, binary artifact analysis, and the triage of encrypted or compressed data. Advances in representation learning and deep architectures have substantially improved the ability of models to extract discriminative signals from noisy and fragmented inputs.

This survey examined how modern forensic systems transform raw bytes into informative representations, how architectural choices influence learning capacity and efficiency, and how attention mechanisms enhance robustness and interpretability. Across the literature, attention-based designs consistently emerge as a unifying theme, allowing models to selectively emphasize informative patterns while suppressing irrelevant or misleading content. These mechanisms are particularly well-suited to forensic data, where discriminative cues are sparse and unevenly distributed.

At the same time, the review highlights important limitations that constrain practical adoption. Sensitivity to dataset bias, distribution shift, and minor perturbations raises concerns about reliability under real-world conditions. The lack of standardized benchmarks and reproducible evaluation protocols further complicates meaningful comparison across studies. Moreover, the interpretability of byte-level models remains an open challenge, particularly when learning-based outputs are expected to support forensic reasoning or legal decision-making.

Moving forward, progress in byte-level forensic learning will depend on addressing these foundational issues rather than pursuing incremental accuracy gains alone. Emphasis on robustness, transparency, and methodological rigor is essential for translating research advances into dependable forensic tools. By aligning representation learning, attention mechanisms, and evaluation practices with the practical realities of digital investigations, future work can help bridge the gap between experimental success and trustworthy forensic deployment. Establishing standardized benchmarks and evaluation practices will be essential for translating research advances into operational forensic capability.

Declaration on the Use of Generative AI

The authors acknowledge the use of generative AI tools for language refinement, grammar correction, and framework creation. All scientific ideas, conceptual structuring, interpretations, and conclusions were developed by the authors. The authors critically reviewed, edited, and validated all AI-assisted content and take full responsibility for the originality, accuracy, and integrity of the manuscript.

Estimation of Landslide Hazard Zones Using Deep Learning Based on Diverse Geospatial Data

Kohei Arai, Kengo Oiwane, Hiroshi Okumura
Information Science Dept., Saga University, Saga City, Japan

***Abstract*—Traditional landslide hazard mapping in Japan relies on labor-intensive field surveys, which are slow, costly, and fail to update dynamically amid rising climate-driven disasters like the 2018 Heavy Rain Event, leaving gaps in timely evacuations. This study addresses these challenges by proposing a semantic segmentation framework using ResUNet to fuse Sentinel-2 optical, Sentinel-1 SAR amplitude, DEM-derived Terrain Ruggedness Index (TRI), and JAXA land cover data, tackling class imbalance with BCE + Dice loss and providing probability/uncertainty maps via 4-TTA for robust hazard delineation under adverse weather. The principal aim is to enable operational, weather-robust hazard zone extraction with AUC upto 0.89 (best multimodal configuration), outperforming single-modality baselines (e.g., optical-only AUC 0.74; SAR-only 0.69) through synergistic feature fusion, while highlighting multimodal SAR's edge for cloud-obscured scenarios. Validated on Hiroshima Prefecture data—Japan's highest-risk region with ~32,000 hazard spots—this approach demonstrates pre/post-disaster change detection, but reveals limitations in spatial generalization due to region-specific training.**

Keywords*—SAR; Optical; ResUNet++; land cover classification; Digital Elevation Model; landslide hazard zones; The Heavy Rain Event of July 2018

I. Introduction

In recent years, the incidence of sediment-related disasters in Japan has increased significantly, and the resulting damage has become more severe. According to statistics from the Ministry of Land, Infrastructure, Transport and Tourism (MLIT), the annual average number of sediment-related disasters in Japan was 1,064 from 1995 to 2004, but this figure has increased to 1,523 over the most recent 10-year period (2015 to 2024) [1]. The main factors cited for this increase are the frequent occurrence of record-breaking heavy rainfall caused by linear precipitation zones and typhoons. According to observational data published by the Japan Meteorological Agency (JMA) from approximately 1,300 locations nationwide, the annual average number of occurrences of hourly rainfall exceeding 50 mm was 285 from 1995 to 2004. In contrast, the annual average for the most recent 10-year period (2015 to 2024) was 333, also showing an increasing trend [2]. Thus, a strong correlation is suggested between climate change and the increased risk of landslides and debris flows.

To prevent and mitigate damage from such disasters, national and prefectural governments maintain hazard maps. These hazard maps visualize the risk levels not only for landslides and debris flows but also for other natural disasters like tsunamis, storm surges, and floods. They are used to provide residents with evacuation criteria and information on evacuation sites. However, the selection of landslide hazard zones currently relies heavily on on-site surveys conducted by experts. Consequently, the selection process requires extensive time and cost, making it extremely difficult to comprehensively cover large areas and continuously reflect changes in land use, environmental changes due to climate change, and topographic conditions. Furthermore, cases have been reported where landslides occurred outside designated hazard zones, indicating the potential for hazards to occur beyond these areas [3]. Insufficient update frequency thus risks undermining the reliability of hazard map warning zones. To enhance residents' disaster preparedness awareness, it is essential to provide reliable warning zone information updated at near-real-time.

This study contributes: 1) optimal multimodal input analysis showing AUC gains (e.g., +0.15 from optical to optical+DEM+land cover); 2) probability/uncertainty visualization for operational trust; 3) pre/post-2018 Heavy Rain Event application revealing surface change sensitivity; 4) BCE+Dice loss for imbalance handling. Focused on Hiroshima's granite-prone terrain (31,987 hazard spots), it prioritizes methodological validation over broad generalization, with restrained claims pending cross-region tests.

This study aims to extract dynamically changing landslide hazard zones. To achieve this, we propose a hazard zone extraction method that integrates deep learning models with multiple geospatial datasets. Specifically, we use optical imagery or Synthetic Aperture Radar (SAR) amplitude imagery as the base input data. By combining this with a Digital Elevation Model (DEM) and land cover imagery, we quantitatively compare the improvement in extraction accuracy compared to using a single data type alone. Furthermore, we analyze the reliability of the extraction results by visualizing not only a probability map (which displays the model's confidence) as a heatmap, but also an uncertainty map calculated from the variability of the predictions. Additionally, we apply the proposed model to satellite images before and after The Heavy Rain Event of July 2018 to compare changes in the landslide hazard zones.

As mentioned earlier, the occurrence of landslides and debris flows is not only caused by prolonged heavy rain or torrential downpours but also faces increased risk from natural disasters such as earthquakes and volcanic activity. However, it is also pointed out that besides natural disasters, deforestation and changes in land use alter soil stability, increasing the risk of landslides and debris flows [4]. Illegal logging and clear-cutting often occur in remote mountain areas where humans rarely venture. Consequently, detection is delayed, potentially leading to the occurrence of unknown landslides and debris flows. Given

this background, utilizing satellite imagery suitable for wide-area observation is effective.

The remainder of this study is organized as follows: Section II reviews related work; Section III details the proposed method and the materials used; Section IV presents the results; and Section V offers concluding remarks.

II. Related Research Works and Differences from this Study

A. Related Research Works

Satellite remote sensing has become an indispensable technology for landslide detection and monitoring. Scaioni et al. categorized the applicability of remote sensing technology into three categories: landslide recognition, landslide monitoring, and landslide hazard analysis and prediction, explaining the potential of remote sensing through further advancements [5].

Research on landslide detection is advancing through various approaches. Kanai et al. performed landslide detection from aerial photographs using the deep learning model Mask R-CNN [6]. Qi et al. evaluated the landslide detection accuracy of U-Net and ResUNet models, demonstrating that ResUNet outperforms U-Net in terms of precision, recall, and F1 score [7]. Furthermore, regarding verification focused on versatility, Prakash et al. constructed a convolutional neural network (CNN) training method using composite inventories and proposed an approach applicable to new areas [8]. Liu et al. proposed the Multi-Scale Complex Background Emphasis (MSSCBE) method to address the challenge of landslides being easily confused with complex backgrounds, leading to false detections and missed detections [9].

Research on landslide hazard zone detection using various deep learning models has also been conducted. However, optical imagery alone has limitations in capturing elevation and topographic features. Consequently, research integrating geospatial data is advancing. Liu et al. proposed a semantic segmentation network (FFS-Net) that integrates high-resolution remote sensing images and DEM data [10]. Similarly, Yoshida et al. proposed a decision tree model using explanatory variables derived from optical satellite imagery and DEM [11].

Regarding landslide hazard zones, Ado et al. analyzed articles on machine learning (ML) models used to create landslide hazard maps, reporting a comprehensive review while emphasizing the importance of landslide hazard maps [12]. To mitigate future landslide risks and enhance the applicability of sustainable land use planning, Habumugisha et al. (2022) [13] constructed multiple deep learning models (DNN/LSTM/CNN/RNN) for landslide susceptibility mapping. Similarly, Chen et al. proposed an improved U-Net model addressing the limitation that conventional machine learning models focused solely on individual pixels and failed to consider the surrounding environment (spatial structural information) [14]. By utilizing diverse inputs, including satellite imagery, topographic data, and geological information, they reported improved accuracy and the generation of landslide susceptibility maps.

Several publications provide important insights regarding applications in SAR, and numerous studies have been conducted on disaster detection using SAR data. Mondini et al. published a comprehensive review on SAR imagery for landslide detection, detailing SAR's utility, operational frameworks, and future applications [15]. Furthermore, Mondini et al. used SAR amplitude imagery from the Sentinel-1 satellite to identify landslides by leveraging SAR-specific changes and photo interpretation techniques, aiming for rapid landslide detection [16].

Regarding research utilizing deep learning, Liang et al. proposed a landslide detection method using a morphological model (DLM) for single-polarization SAR images after disasters [17]. Arai et al. proposed an approach to identify non-vegetated areas indicating landslide-prone zones using the Radar Vegetation Index (RVI) derived from Sentinel-1 SAR data and the EfficientNetV2 deep learning model [18].

As a study combining terrain data, Nava et al. proposed an Attention U-Net model utilizing Sentinel-1 satellite SAR amplitude images and slope angles [19]. By utilizing phase information and interferometrically combining phase data from multiple time periods, Interferometric Synthetic Aperture Radar (InSAR) analysis technology can detect displacement. As research applying InSAR technology, Li et al. proposed an MSFD-Net model using displacement images and tilt angles as input data [20].

Numerous studies utilizing InSAR have also been conducted regarding landslide hazard zones. Yuan et al. proposed an approach to extract landslide susceptibility factors and predict landslide susceptibility using InSAR technology by constructing a hybrid model combining a convolutional neural network (CNN) and a recurrent neural network (RNN) strong in handling time-series data [21]. Additionally, Yang et al. proposed an approach to identify potential landslide sites in specific regions by combining InSAR technology with multiple topographic and meteorological datasets [22].

B. Differences from this Study

Much current research focuses primarily on landslide detection and landslide hazard zone extraction after disasters occur. This study aims to extract landslide hazard zones from satellite imagery observed during routine periods, regardless of whether they preceded or followed a disaster. Incorporating changes that increase landslide risks-such as Land Use/Land Cover changes and deforestation—is expected to enhance the reliability of hazard maps and support their revision. Furthermore, to verify its effectiveness in rapidly assessing post-disaster damage and mitigating secondary disaster risks, satellite imagery before and after The Heavy Rain Event of July 2018 is input and compared.

III. Proposed Method and Materials

A. Intensive Study Area

This study focuses on Hiroshima Prefecture in Japan. This region is characterized by the steep terrain of the Chugoku Mountains, presenting an extremely high risk of sediment-related disasters. During The Heavy Rain Event of July 2018, the prefecture suffered extensive damage due to numerous slope failures and debris flows. Table I lists the top five prefectures in Japan with the highest number of designated sediment-related

disaster hazard zones, based on statistics from the Ministry of Land, Infrastructure, Transport and Tourism [23]. Hiroshima Prefecture recorded approximately 9,000 more hazard zones than Shimane Prefecture, which ranked second, making it the region with the highest landslide risk nationwide. Against this backdrop, Hiroshima Prefecture was selected as the test site for verifying the proposed extraction method.

The reason for focusing solely on Hiroshima Prefecture rather than the whole of Japan lies in its distinct geological characteristics [24]. Granite, widely distributed in Hiroshima Prefecture, is particularly prone to weathering into sand and soil (decomposed granite, locally known as *Masa soil*) due to rain and wind, and has been reported to have a high potential for triggering landslides [25,26].

Fig. 1 shows the geographical scope of the study area, depicting Hiroshima Prefecture and its surrounding regions. The optical satellite imagery (Sentinel-2[1]) and SAR satellite imagery (Sentinel-1[2]) used in this analysis were obtained from the Copernicus Browser[3] within the Copernicus Data Space Ecosystem.

TABLE I. TOP 5 PREFECTURES IN JAPAN WITH THE HIGHEST NUMBER OF LANDSLIDE HAZARD SPOTS

Rank	Prefecture	Debris flow	Landslide	Steep Slope Failure	Total
1	Hiroshima	9,964	80	21,943	31,987
2	Shimane	8,120	264	13,912	22,296
3	Yamaguchi	7,532	285	14,431	22,248
4	Hyogo	6,912	286	13,550	20,748
5	Oita	5,125	222	14,293	19,640

Fig. 1. Map of the study area, Hiroshima Prefecture, Japan.

B. Data Used

1) Optical imagery: For optical imagery, satellite data from the European Space Agency (ESA) Sentinel-2 mission were acquired. Sentinel-2 provides multispectral data with a spatial resolution of 10 meters, enabling detailed observation of surface spectral reflectance characteristics. Its high revisit frequency (approximately every 5 days) is advantageous for rapid monitoring, although observations are constrained by cloud cover and nighttime conditions. For this study, true-color images (TCI) synthesized from RGB bands were acquired. To minimize cloud effects, images captured during daylight hours on a clear day, August 8, 2024, were obtained. The datasets were created using QGIS4 by saving images while shifting the location of the target area. Fig. 2 shows a portion of the Sentinel-2 optical image of Hiroshima Prefecture acquired on August 8, 2024, as exported from QGIS.

Fig. 2. Sentinel-2 optical image acquired on August 8, 2024, near Hiroshima City.

2) SAR imagery: For SAR imagery, amplitude (Ground Range Detected, GRD) data from the Sentinel-1 mission operated by the ESA were acquired. Sentinel-1 is an active C-band sensor that transmits microwaves, enabling observation of the Earth's surface regardless of weather conditions or the time of day. However, raw GRD data contain geometric distortions such as radar shadows and speckle noise, particularly in mountainous areas of the study region. To eliminate these distortions and ensure geometric consistency with other geospatial data, preprocessing was performed using the ESA Sentinel Application Platform (SNAP[5]).

The processing steps are as follows:

- Apply Orbit File: Correction of orbital errors using precise orbit ephemerides.
- Thermal Noise Removal: Reduction of additive thermal noise from the sensor.
- Calibration: Conversion of digital pixel values to physical backscatter coefficients.
- Range Doppler Terrain Correction: Orthorectified using Copernicus 30m global DEM to precisely align SAR images with geographic coordinates.

In this study, images were acquired on August 7 and August 19, 2024, to align with the timing of optical data acquisition. Fig. 3 shows a portion of the Sentinel-1 SAR image acquired over Hiroshima Prefecture on August 7, 2024, as exported from QGIS.

Fig. 3. Sentinel-1 SAR image acquired on August 7, 2024, near Hiroshima City.

3) Digital Elevation Model (DEM)

- Topographic features are key factors influencing landslide hazard potential. We utilized the 5-meter mesh DEM provided by the Geospatial Information Authority of Japan (GSI). To quantify the local terrain complexity correlated with slope instability, we calculated the Terrain Ruggedness Index (TRI). The TRI for a central pixel is defined as the square root of the sum of the squares of the elevation differences between the central pixel and its eight adjacent pixels, as shown in Eq. (1) [27]:

$$TRI = \sqrt{\sum_{i=1}^{8}(X_{center} - X_i)^2} \quad (1)$$

where, X_{Center} represents the elevation of the central pixel, and Xi represents the elevation of the adjacent pixels. TRI was calculated using Raster Terrain Analysis tool available in QGIS. This index functions as a feature that quantitatively represents surface ruggedness.

In this study, 5-meter mesh DEMs (5A) were obtained from the GSI Base Map Information[6] download service. The creation date is June 20, 2025. Under the assumption that this date is close to the acquisition dates of the optical and SAR images, the data were used accordingly. Fig. 4 shows a portion of DEM converted to TRI format for Hiroshima Prefecture, as exported from QGIS.

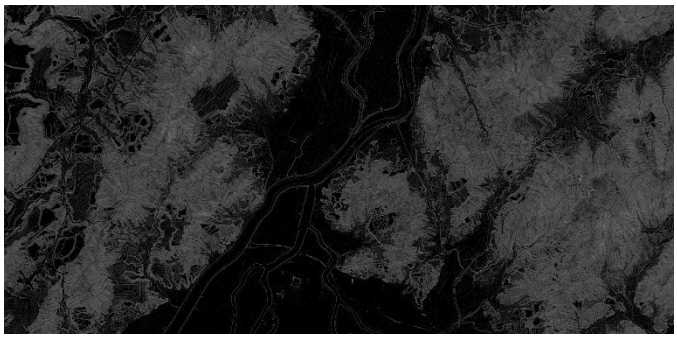

Fig. 4. TRI image derived from the DEM for the area around Hiroshima City.

[7] https://www.eorc.jaxa.jp/ALOS/jp/dataset/lulc/lulc_v2504_j.htm

[8] https://disaportal.gsi.go.jp/index.html

4) Land Cover Classification Map

- This study utilized the high-resolution Land Use/Land Cover (LULC[7]) map provided by the Japan Aerospace Exploration Agency (JAXA). This dataset features a 10-meter spatial resolution and classifies the land surface into 15 categories (e.g., water bodies, grasslands, and bare land). In the proposed model, these 15 classification categories were converted into one-hot-encoded vectors and treated as independent feature channels.
- These data from 2024 were released in April 2025. As with the DEM, it was assumed that the observation dates of the optical and SAR images were close to the release date. Fig. 5 shows a portion of the LULC map for Hiroshima Prefecture, as exported from QGIS.

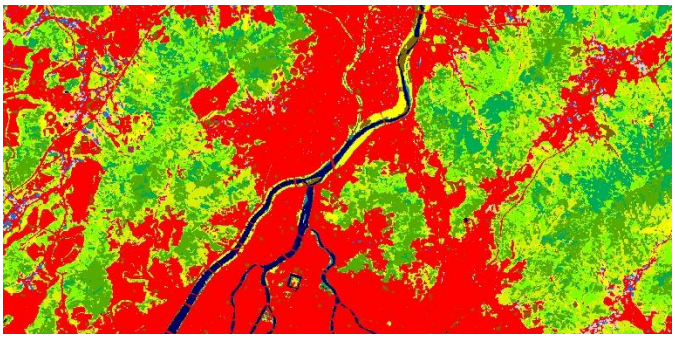

Fig. 5. Land cover classification image for the area around Hiroshima City.

5) Landslide Hazard Zone

- The ground truth data labels used for model training and evaluation were obtained from the "Landslide Hazard Areas (Steep Slope Collapse)" raster data[8] (2023 edition) provided by the Geospatial Information Authority of Japan. These areas are designated under the Sediment-Related Disaster Prevention Act as zones where steep slopes (30 degrees or more) are prone to collapse and pose a danger to residents. Fig. 6 shows a portion of the landslide hazard zones within Hiroshima Prefecture, as exported from QGIS.
- To create correct labels, we performed a binarization process. Designated areas were extracted, and the "landslide danger zone" (yellow area) and the "special landslide danger zone" (red area) were defined as "danger zone" (value = 1) and merged into a single positive class. All other areas were defined as "nondanger zone" (value = 0).

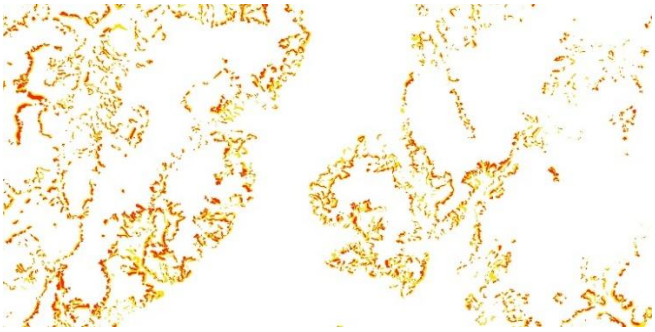

Fig. 6. Image of landslide hazard warning zones around Hiroshima City.

C. Proposed Methodology and Model Architecture

- The methodology consists of data preparation, dataset generation, model training using various input combinations, and comparative evaluation.
- For deep learning dataset generation, the aligned data were cropped into 256×256-pixel patches. These patches were subsequently divided into training, validation, and test datasets. Note that during dataset creation, to capture only the topographic structure and geological features within Hiroshima Prefecture, the model was comprehensively trained by changing the image positions in all areas each time. Therefore, areas included in training may also be present within test cases (though not as identical images). This is because the research aims to identify models that maximize accuracy when combining geospatial data and to establish specialized methods for each prefecture; the input of new areas during testing is not anticipated.
- For the model implementation phase, ResUnet++ architecture was adopted as the architecture. To evaluate the contribution of various environmental factors to landslide detection accuracy, multiple models were implemented using different combinations of input data (e.g., optical data only, SAR + DEM, etc.). Each model was trained individually, and the extraction accuracy was evaluated and compared using the test dataset.
- Finally, based on quantitative results, we conducted a comparative analysis between the highest-performing model and a baseline model that used only sensor data. This analysis involved acquiring sensor data before and after the disaster to detect and compare changes in the estimated landslide hazard zones.
- We employed ResUNet++, a semantic segmentation method, as a model for extracting landslide hazard zones [28]. This ResUNet++ is an architecture that improves upon the standard U-Net and ResUNet. In this study, extraction is performed using multiple channels. Therefore, it is necessary to evaluate the importance of channels while performing detailed extraction of complex boundary regions. For these reasons, ResUNet++ was adopted.

D. Experimental Setup

- Table II shows the model types and input channel counts. The dataset consisted of 2,390 pairs in total, which were randomly split into three subsets: 1,673 pairs (70%) for training, 478 pairs (20%) for validation, and 239 pairs (10%) for testing. Furthermore, for all models, using the same seed value, vertical/horizontal flipping and scaling were applied as identical affine transformations during training.
- We designed eight experimental models with varying input combinations, ranging from single-sensor inputs to fused multimodal inputs. The input image size is standardized to 256×256 pixels for all models. The number of input channels was varied based on a configuration combining optical data (3 channels), DEM (1 channel), SAR (1 channel), and one-hot encoded land cover data (15 channels) in the channel direction.
- Table III shows the main hyperparameters used for model construction. The loss function employs a combination of BCE (binary cross-entropy) and Dice loss, termed "BCE Dice Loss". This combines BCE, which determines positive/negative on a per-pixel basis and tends to stabilize gradients, with Dice loss, which evaluates the overlap between the predicted mask and the ground truth mask and is effective for class-imbalanced images.
- The total loss (L) is defined as follows [see Eq. (2)]:

$$\Lambda = \langle \cdot \Lambda_{BXE} + ® \cdot \Lambda_{\Delta IXE} \quad (2)$$

where, L_{BCE} represents the BCE loss and L_{DICE} represents the Dice loss. In this study, to unify pixel-level accuracy and region-based overlap, equal weights (α=0.5, β=0.5) were assigned to both components.

TABLE II. EXPERIMENTAL MODELS AND INPUT CHANNEL CONFIGURATIONS

Model	Number of Input Channels
(a) Optical	3
(b) Optical + DEM(TRI)	4
(c) Optical + Land Cover	18
(d) Optical + DEM(TRI) + Land Cover	19
(e) SAR	1

Learning Rate Scheduler	ReduceLROnPlateau
Initial Learning Rate	1.0×10^{-4}
Patience (LR Decay)	10 epochs
Decay Factor	0.2
Early Stopping	30 epochs

E. Evaluation Metrics

1) Model Performance Metrics

- To quantitatively evaluate the extraction accuracy of the proposed model, we adopted precision, recall, and F1 score as accuracy metrics. These metrics are calculated

based on the components of the confusion matrix: true positives (TP), false positives (FP), and false negatives (FN) [see Eq. (3) to Eq. (5)]:

$$\text{Precision} = \frac{TP}{TP+FP} \quad (3)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (4)$$

$$F1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \quad (5)$$

- In addition to comparing accuracy using a single threshold, we created Precision-Recall (PR) curves showing the relationship between precision and recall as the prediction probability threshold was continuously varied from 0.0 to 1.0. We also calculated the area under the curve (AUC). This enabled the comparison of overall model performance independent of any specific threshold. The AUC is commonly used as a performance evaluation metric in landslide susceptibility mapping [12].

2) Visualization of Probability and Uncertainty Maps

- To quantify the model's confidence for each pixel in the segmentation results, probability maps and uncertainty maps were output and visualized. While typical segmentation results output binary values (0 or 1) per pixel, this segmentation model also outputs pixel-level prediction probabilities during testing. Visualizing these alongside the binary results enabled the evaluation of prediction reliability. For calculating both maps, we adopted an inference method based on four-pattern Test-Time Augmentation (4-TTA). Specifically, we applied four transformation patterns to the input image: no transformation (p0), horizontal flip (p1), vertical flip (p2), and horizontal plus vertical flip (p3). Inference is performed on each transformed image. The average (μ) of the four obtained probability values is calculated as the probability map, and the standard deviation (σ) is calculated as the uncertainty map. The probability map indicates the expected probability for each pixel, while the uncertainty map shows that larger standard deviations indicate greater instability in the model's prediction. Fig. 7 shows an overview of the estimation method. p0 to p3 represent the probability values for each transformed image. This method not only reduces prediction instability associated with single-image inference but also visualizes areas of model uncertainty, making it useful for decision-making in practical applications.

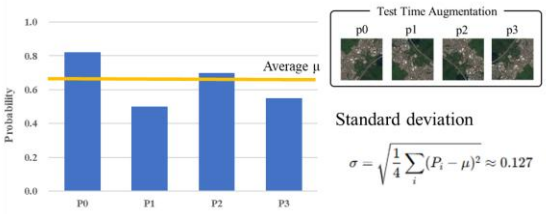

Fig. 7. Overview of inference method using 4-TTA.

IV. Results

A. Quantitative Evaluation of Extraction Accuracy

1) Performance of optical-based models: Table IV shows the evaluation results for each model based on optical images. Note that the values in Table IV were obtained by searching for a threshold where precision and recall were balanced and then running the model using that threshold. The optical-only model (a) achieved P=0.68, R=0.67, F1=0.67, and AUC=0.74. In contrast, the model incorporating DEM (b) showed significant accuracy improvements: P=0.80, R=0.79, F1=0.79, and AUC=0.88. On the other hand, the model incorporating land cover (c) showed P=0.71, R=0.71, F1=0.71, and AUC=0.79, indicating less improvement than the DEM model. The model incorporating all data (d) achieved the best results across all metrics: P=0.81, R=0.82, F1=0.81, and AUC=0.89, demonstrating the most balanced performance among the metrics.

Fig. 8 shows the PR curves for each optical-based model. In all comparisons, adding input data shifted the entire PR curve upward and to the right, indicating improved accuracy. Adding a DEM contributed significantly to a substantial improvement in AUC (+0.14, from 0.74 to 0.88). In contrast, adding land cover results in a smaller improvement in AUC (+0.05, from 0.74 to 0.79). This can be attributed to the fact that many of the ground surface elements represented by land cover were already captured by the spectral information in the optical images. Nevertheless, since both precision and recall improved, land cover is considered to supplement surface features to a certain extent for areas that are difficult to distinguish using optical images alone.

TABLE IV. Results of each Model based on Optical Images

Model	Precision	Recall	F1 score	AUC
(a)	0.68	0.67	0.67	0.74
(b)	0.80	0.79	0.79	0.88
(c)	0.71	0.71	0.71	0.79
(d)	0.81	0.82	0.81	0.89

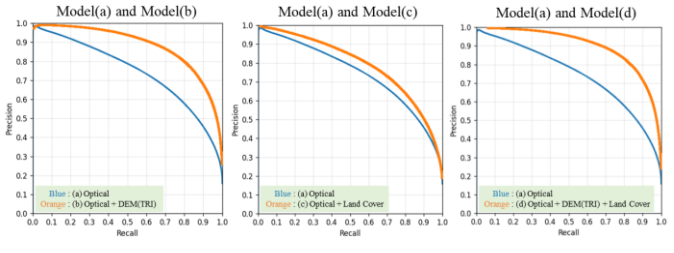

Fig. 8. Comparison of precision–recall (PR) curves for optical-based models with different input configurations.

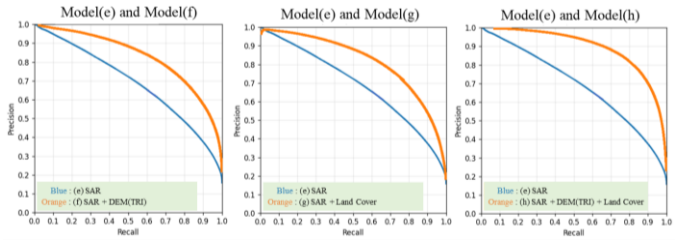
2) Performance of SAR-based models: Table V shows the evaluation results for each model based on SAR images. As in the case of optical imagery, the values in Table V were obtained by searching for a threshold at which precision and recall were balanced and then applying that threshold. For the SAR-only

model (e), P=0.63, R=0.62, F1=0.63, and AUC=0.69, respectively. In contrast, the model incorporating a DEM (f) showed a substantial improvement, with P=0.75, R=0.73, F1=0.74, and AUC=0.82. The model incorporating land cover (g) also achieved P=0.74, R=0.73, F1=0.73, and AUC=0.81, indicating an improvement comparable to model (f). The model using all inputs (h) achieved the best performance, with P=0.81, R=0.80, F1=0.81, and AUC=0.89, matching the accuracy of the best optical-based model (d). This model also exhibited the most favorable balance among the metrics.

Fig. 9 shows the PR curves for the SAR-based models. As with the optical imagery case, adding input data led to improved performance across the entire curve. In addition, for SAR-based models, unlike the optical imagery case, the inclusion of land-cover data contributed to a substantial improvement in accuracy comparable to that achieved by adding DEM. This was likely because discriminating surface types solely based on microwave backscattering intensity is challenging, as diverse land covers can exhibit similar backscatter signatures depending on surface roughness and dielectric properties. Therefore, the inclusion of land cover data provided essential categorical context, resolving these ambiguities and substantially complementing the SAR-derived spatial features.

TABLE V. RESULTS OF EACH MODEL BASED ON SAR IMAGES

Model	Precision	Recall	F1 score	AUC
(e)	0.63	0.62	0.63	0.69
(f)	0.75	0.73	0.74	0.82
(g)	0.74	0.73	0.73	0.81
(h)	0.81	0.80	0.81	0.89



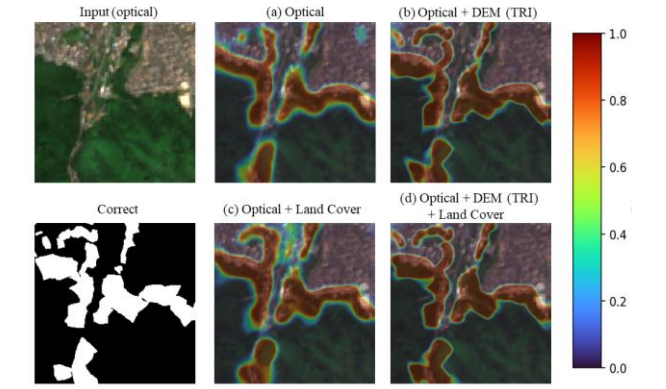


Fig. 9. Comparison of precision–recall (PR) curves for SAR-based models with different input configurations.

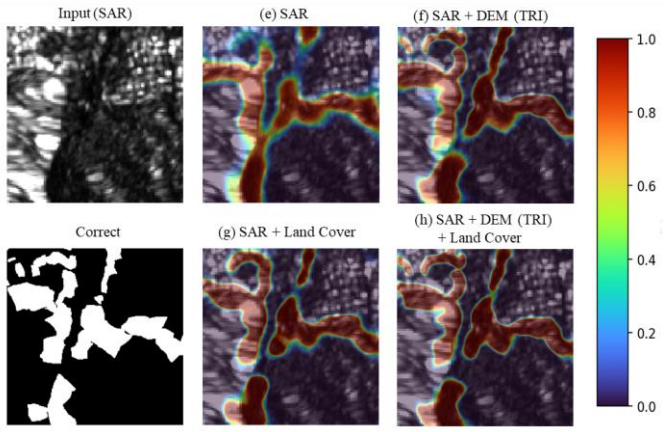
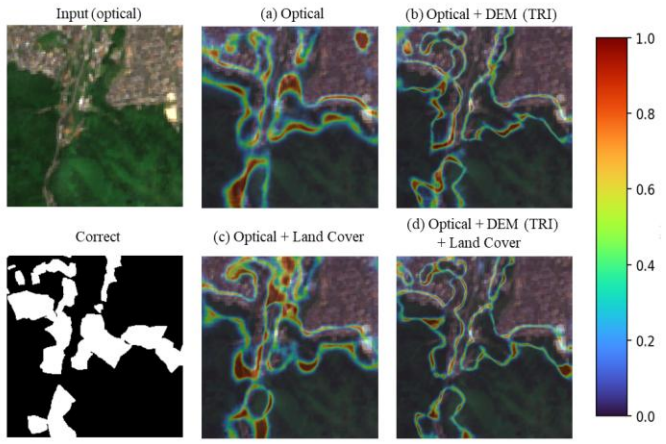
B. Visualization of Probability Maps and Uncertainty Maps



The output results of the probability maps and uncertainty maps are shown in Fig. 10. Comparing the results across all models, a consistent tendency was observed in both categories: high confidence in the central parts of the predicted areas and increased uncertainty along the boundaries. In the probability maps, the expansion of the red regions indicated higher reliability, whereas in the uncertainty maps, a reduction in edge width indicated less ambiguity in the prediction.

For the single-sensor models (a) and (e), many locations exhibited low confidence even in the central parts of the extracted areas, and the area of high-uncertainty edges along the boundaries became larger, indicating greater model instability. In contrast, the models incorporating DEM (b) and (f) showed a substantial improvement in confidence. In the models incorporating land cover (c) and (g), false detections decreased, particularly in urban areas and in locations away from slopes where sediment-related disasters are less likely to occur. In the models incorporating both DEM and land cover (d) and (h), high confidence in the central parts was maintained while the area of high-uncertainty edges near the boundaries became smaller.



- Thus, presenting deep learning outputs not only as binary results (positive/negative) but also simultaneously as probability maps and uncertainty maps can facilitate an intuitive understanding of the situation for specific areas and can be utilized for rapid and accurate decision-making.

(b) Probability map of the SAR-based model.

(c) Uncertainty map of the optical-based model.

(d) Uncertainty map of the SAR-based model.

Fig. 10. Probability maps and uncertainty maps.

C. Comparison of Estimation Results before and after Disaster Events

1) Overview of the disaster: Model (d) (optical + DEM + land cover) achieved the highest accuracy for extracting sediment-disaster hazard zones. In this section, we evaluated the practical applicability of this model by applying it to optical images acquired before and after an actual disaster event and analyzing the resulting changes in the probability maps. For comparison, the same analysis was also conducted using the baseline model (a) (optical only). In this study, Nakahata, Yasuura Town, Kure City, Hiroshima Prefecture, which suffered severe damage during The Heavy Rain Event of July 2018 in western Japan, was selected as the validation area. In this district, heavy rainfall triggered sediment-related disasters in multiple mountainous locations, causing road disruptions to settlements and extensive building damage across the area. Fig. 11 shows a photograph of the damage in the nearby Ichihara district[9]. In addition, Fig. 12 shows the optical satellite images acquired for the study area (Nakahata district) before the disaster (June 1, 2018) and after the disaster (July 16, 2018).

Fig. 11. Ichihara district, Kure City.

[9] https://www.city.kure.lg.jp/site/kure-city-reconstruction-memorial-museum/kure-city-reconstruction-memorial-museum-higaijokyo.html

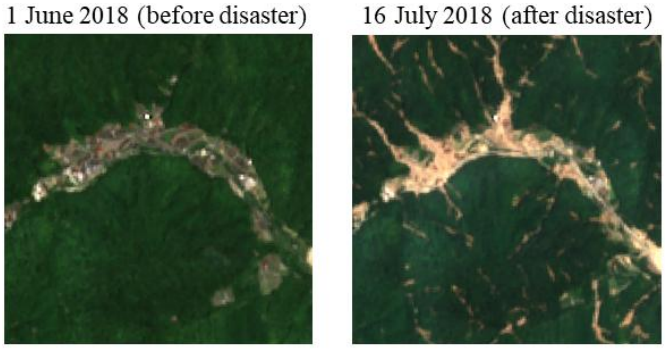

Fig. 12. Optical satellite images of Nakahata, Yasuura Town.

2) Analysis of probability map change: Fig. 13 shows the probability maps produced before and after the disaster, and Fig. 14 shows the difference between the before-disaster and after-disaster probability maps. In the after-disaster probability map (July 16, 2018), both models reflected changes in surface conditions caused by heavy rainfall, with the predicted areas concentrated mainly near the boundary between mountainous and lowland areas. However, the spatial distributions differed clearly between the models.

In model (a), the high-probability regions were spread over a wide area, and sporadic responses were also observed on surrounding slopes. Because the input relied only on spectral information, distinguishing the presence or absence of sediment-related disasters became difficult; as a result, the model responded to apparent changes unrelated to the disaster, leading to unstable extraction. In contrast, in model (d), the high-probability regions were concentrated mainly along boundary areas consistent with the disaster-affected zone, and unnecessary extraction on surrounding slopes is suppressed. This can be interpreted as the model not treating all apparent after-rainfall changes as disasters but instead narrowing the candidate areas by considering topography and land cover information. The ability to output only high-confidence regions is beneficial for practical operations such as rescue activities and risk assessment of secondary disasters.

- Because the DEM and land cover data used in this study are static datasets updated every few years, the same pre-disaster datasets were used for both the before-disaster and after-disaster analyses in this experiment. However, because actual landslides can cause substantial topographic changes, achieving more dynamic and accurate extraction requires topographic and land cover data that reflect conditions immediately after the disaster. In recent years, studies have advanced in directly estimating up-to-date land cover and geospatial data from satellite imagery using deep learning [29,30]. By integrating these techniques into the proposed method, further improvements in the timeliness and accuracy of landslide hazard extraction are expected.
- Prob/uncertainty maps show high center confidence, edge uncertainty reduced by fusion. Pre/post-2018: multimodal pinpoints changes vs. optical scatter. No baselines (e.g., DeepLabV3+, RF on slope/cover) or disjoint tests yet.

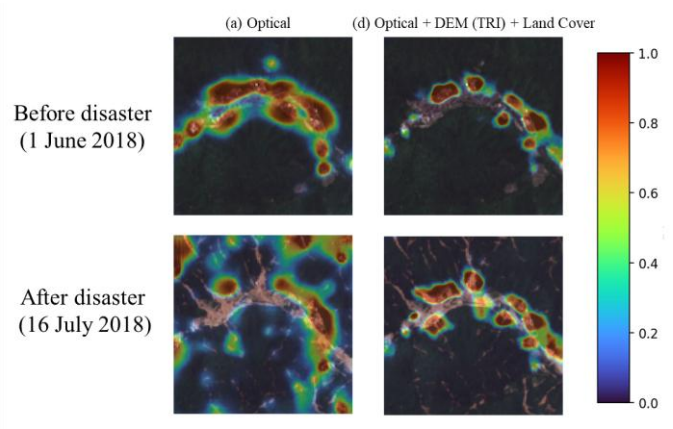

Fig. 13. Comparison of probability maps before and after the disaster.

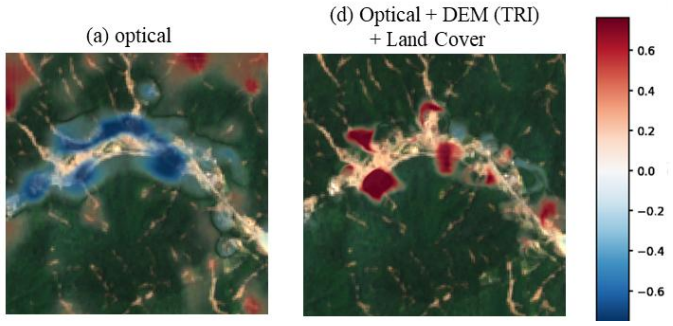

Fig. 14. Differential probability maps (before and after the disaster) visualizing the changes in the probability map.

V. Conclusion

We proposed a deep learning model for extracting sediment disaster hazard zones by integrating satellite imagery and geospatial data. Models were developed by combining diverse information sources, including optical imagery, SAR imagery, DEM, and land cover maps. The accuracy comparison results confirmed that integrating geospatial data substantially improved extraction performance compared with models using a single data source. The best-performing configuration was "optical/SAR + DEM + land cover", achieving an AUC of 0.89. The effectiveness of DEM and land cover was also demonstrated. Because optical and SAR imagery had complementary characteristics that compensated for each other's limitations, obtaining high extraction accuracy with both image types suggested that the proposed approach is highly generalizable and is not constrained by weather conditions or day–night differences. In addition, the case study of The Heavy Rain Event of July 2018 indicated that inputting before-disaster and after-disaster optical imagery may enable the detection of changes in hazard zones.

Multimodal fusion boosts robustness, SAR aiding clouds, but Hiroshima training limits broader claims—no cross-prefecture validation. Predicts susceptibility (pre-event), post-disturbance (change detection); preprocessing detailed, but normalization/seasonality assumed stable.

In conclusion, this advances hazard mapping via ResUNet multimodal fusion (SAR/optical/DEM/LULC, BCE+Dice, uncertainty viz), achieving F1=0.81/AUC=0.89 on Hiroshima data, enabling dynamic updates vs. surveys. Scientific value: quantifies input contributions, operational potential for weather-hit areas. As for the limitations, region-specific (no spatial generalization); random split risks leakage; lacks ML baselines, modern nets (Attention U-Net, DeepLabV3+), CIs; speculative robustness sans scenario tests.

Future Research Works

We plan to develop a framework to generate land cover and DEM products from satellite imagery. Although static DEM and land cover maps are currently used, integrating a mechanism that directly derives these geospatial datasets from up-to-date satellite imagery would enable more dynamic extraction of sediment disaster hazard zones by immediately reflecting changes. In addition, we also plan to incorporate new inputs, such as geological conditions within the target area and real-time rainfall distribution, which are expected to advance the model toward more reliable extraction. Furthermore, we plan to use higher-resolution optical and SAR data to achieve further improvements in accuracy. Namely, spatially disjoint validation/cross-events have to be investigated with baselines (RF/XGBoost, DeepLab); dynamic DEM/LULC generation; geology/rain inputs; higher-res data.

Kohei Arai, He received BS, MS and PhD degrees in 1972, 1974 and 1982, respectively. He was with The Institute for Industrial Science and Technology of the University of Tokyo from April 1974 to December 1978, and was also with the National Space Development Agency of Japan from January 1979 to March 1990. From 1985 to 1987, he was with the Canada Centre for Remote Sensing as a Post-Doctoral Fellow of the National Science and Engineering Research Council of Canada. He was a professor of Saga University from 1990 to 2017. Also, he was a councilor for the Aeronautics and Space related to the Technology Committee of the Ministry of Science and Technology from 1998 to 2000 and was a councilor of Saga University for 2002 and 2003. He also was an executive councilor for the Remote Sensing Society of Japan for 2003 to 2005. He was the Vice Chairman of the Scientific Committee was an Award Committee member of ICSU/COSPAR during. He is a Science Council of Japan Special Member (COSPAR Committee) since 2012. He is an Adjunct Professor of Nishi-Kyushu University and Kurume Institute of Technology as well as Prishtina International University. He wrote 134 books and published 759 journal papers as well as 591 conference papers. He received 66 of awards, including the ICSU/COSPAR Vikram Sarabhai Medal in 2016, and the Science award of the Ministry of Mister of Education of Japan in 2015. He is now Editor-in-Chief of IJACSA. http://teagis.ip.is.saga-u.ac.jp/index.html

A Hybrid Framework Integrating GNN-LSTM-CNN to Map the Impact of MSME User Behavior on Digital Transformation

***Abstract*—MSMEs need a recommendation system that simultaneously captures the evolution of user intent over time and the relationship structure between entities (users, products, sessions, categories, and security events). The problem with this research is that LSTM excels in sequence, but its performance drops on a rare timeline, a general situation in MSME logs. GNN is strong for cross-entity relationships, but it does not explicitly model temporal dynamics. The gap arises because many pipelines still separate design signals, temporal behavior, and session security, reducing explainability and long-term reliability. Our contribution proposes a calibrated and security-aware hybrid that integrates CNN, heterogeneous GNN with reverse edges, and LSTM for behavioral sequences. Multitask-trained models (BCE for purchase links and λ· BCE for session risk) with L2 regularization and post-practice calibration, chronological data sharing prevents leakage. The goal is to design and evaluate CNN-plus CNN-enhanced GNN-LSTM hybrids to improve the accuracy of recommendations and reduce risk. The results on partner MSME data: ROC-AUC 0.965 (val)/0.946 (test), PR-AP 0.943/0.910; risk ROC-AUC 0.984, PR-AP 0.982, surpassing a CNN-BiLSTM baseline (0.93/0.91). Brier scores 0.161 (links) and 0.176 (risk) enable safer personalization. Going forward, we are focusing on per-segment calibration with ECE/MCE reporting, compute efficiency, multimodal expansion, ablation, and explainability (GNNExplainer, CNN saliency), as well as online retraining and drift monitoring to maintain production performance.**

***Keywords*—CNN; e-commerce; hybrid model; LSTM; MSME; user behavior prediction**

I. Introduction

The competitiveness of MSMEs is increasingly supported by digital transformation, which is understood not only as technology absorption, but as a twin engine of technology assimilation and business model innovation that updates strategy and performance [1]. Digital transformation requires a proactive attitude to build capabilities in data processing, skills, processes, and governance so that digital tools translate into durable value [2],[3],[4],[5]. Digital tools in the form of e-commerce certainly require consequences, especially with risk and resilience: AI can reduce SME business risks and strengthen the resilience of service supply under disruption [6],[7], even as companies have to keep pace with shifting customer expectations and align digital marketing practices accordingly [8],[9].

On the demand side, user experience is crucial. E-commerce displays in the form of visual presentations include aesthetics, accessibility, readability, and interactive features or AR, clearly shape engagement and purchase intent [10],[11],[12]. With an increasingly multimodal data e-commerce view, feature matching captures cross-modal relevance under production constraints, complemented by a lightweight and interpretable relevance architecture and scalable NLP flows for opinion mining [13],[14],[15],[16]. The use of chatbots influences trust through interactivity and perceived humanity, conditioning adoption and further outcomes in digital commerce [17],[18].

User security and privacy are inseparable in e-commerce. The lack of security in e-commerce causes MSMEs to routinely face phishing, bots, card testing, account abuse, and the threat of multimodal fake reviews that erode trust and directly shape user behavior [19],[20],[21],[22]. At the same time, the well-documented privacy-personalization paradox underscores the need for recommenders who pair accuracy with responsible data practices and transparent decision-making [23],[24],[25]. However, despite the rapid advances in AI for e-commerce and the increasing adoption of social and omnichannel tools by SMEs, most production pipelines still optimize conversions while degrading security to a separate layer that ignores how design cues and session-level risk together affect behavior over time [26],[27],[28].

In this study, conducted in [26] [6], the LSTM model is effective at capturing sequential user dynamics central to the recommendation system, enabling MSMEs to infer needs and predict purchase intent for a more personalized experience and higher conversions. However, LSTMs require heavy training and computing costs, large parameter footprints, and prolonged optimization cycle constraints, which clash with the limits of MSME resources [29],[30],[6],[31]. They also inherit the opacity of deep learning, complicating diagnosis and refinement of strategies [15],[29]. The large amount of model data in the training data has an impact on performance; data inadequacy can worsen when MSME logs are sparse, noisy, or incomplete, especially for sequence-dependent architectures such as LSTM [31].

The contribution of this research is to improve the accuracy of modeling the impact of MSME user behavior on the digital transformation agenda. To close the gaps, we designed a unified

*Corresponding author.

architecture that integrates three key sources of information: design and user experience signals extracted from product imagery with CNN, user–product–session relational contexts along with security incidents modeled through GNN-based heterogeneous graphs, as well as long-term behavioral dynamics represented by LSTM. This integration allows the system to increase the relevance of recommendations and maintain security resiliency, so that user trust is maintained.

II. Previous Research Study

Digital transformation in MSMEs is not only about technology absorption but also about how to build business model innovations that reshape performance and strategy [1]. Transformation requires a proactive attitude that demands capabilities, data, skills, processes, and adaptive governance to maintain the conditions of value creation that are often highlighted in Indonesian MSMEs and under the pressure of Industry 4.0 [2],[13],[32]. Meeting these demands requires models that connect design, behavior, and networks. Visual design display, accessibility, and readability are the drivers of purchase intent; CNN can be used to extract these signals from product imagery [11]. Long-term shifts in intent and engagement require LSTMs to robustly model daily or weekly sequences under shocks and seasonality [6]. Meanwhile, purchasing journeys, sessions, categories, and even security events form a relational substrate that GNN can capture, in line with the reality of platformization in the MSME ecosystem [28],[27],[33],[37]. CNN, LSTM, and GNN answered marketing calls to track evolving expectations with measurement-driven, disciplined practices [9]. Multimodal fusion research shows clear advantages of combining images, text, and behavioral signals [13],[14] and emphasizes the need for a lightweight, interpretable relevance model at production scale [15], while review-centric NLP still struggles with domain shifts and multimodal grounding [16].

Security in transactions, privacy, and trust are the basis when MSMEs carry out digital transformation through e-commerce. E-commerce is constantly exposed to phishing, bots, card testing, and account abuse that erodes trust and conversions [21], with multimodal fake reviews further contaminating reputation signals [22]. Paradoxically, personalization requires transparency, user control, and calibrated decisions [23], echoing the approach of preserving trust in adjacent domains [24]. Predictive analytics in MSMEs has progressed from data-mining studies of purchasing patterns to LSTM models (strengthened by exploratory analysis) that improve online sales forecasting [34]. In parallel, GNNs bring structure-aware learning for interaction, supply, and cyberattack networks, supporting anomaly and threat detection to reduce operational risk, though scalability can be challenging for resource-constrained MSMEs [35],[6],[36].

The research gap is that most MSME-oriented recommenders still handle design cues, temporal behavior, and security risk in isolation, which limits explainability and undermines long-horizon reliability. This research contribution is a hybrid CNN-LSTM-GNN architecture that encodes product-design quality from images, models users' temporal dynamics, and propagates information across a heterogeneous graph of users, products, sessions, and categories, including security events. The approach is expressly designed to map and make explainable how user behavior both drives and reflects digital transformation in MSME e-commerce, closing the integration and interpretability gap while remaining suitable for production deployment. while reporting rigorous ranking and reliability metrics ROC-AUC, PR-AP, and probability calibration (Brier/ECE) to enable trustworthy and cost-conscious deployment.

III. Proposed Research Methodology

The methodology for this study is illustrated in Fig. 1.

A. LSTM

LSTM dynamics (single layer), the equation used is shown in Eq. (1):

$$h_t = LSTM(x_t, h_{t-1}),\ \hat{y} = \sigma(Wh_T + b) \quad (1)$$

LSTM in Eq. (1) variable summary (concise): At time t, $\boldsymbol{x_t}$ is the feature vector (e.g., daily user aggregates such as event count, dwell time, discounts), typically $x_t \in \mathbb{R}^F$ (or $\mathbb{R}^{TxF}$ for full sequences). The previous hidden state $\boldsymbol{h_{t-1}} \boldsymbol{\epsilon}\ \mathbb{R}^{\boldsymbol{H}}$ carries memory. After ingesting x_t, the LSTM outputs $h_t \in \mathbb{R}^H$ (with an internal cell state ct, omitted here). Over a sequence of length $\boldsymbol{T}$, $\boldsymbol{h_T}$ summarizes the entire history. The final prediction is computed by a linear map and activation: $\hat{y} = \sigma(Wh_T + b)$, with $W \in \mathbb{R}^{1xH}, b \in \mathbb{R}$ for binary (sigmoid), or $W \in \mathbb{R}^{KxH}, b \in \mathbb{R}^K$, for multi-class (softmax). In short, x_t provides the current signal, h_{t-1} the memory, h_T the sequence summary, and (W, b, σ) convert it to calibrated probabilities.

B. GDBT

The GBDT additive learner (m trees) equation is shown in Eq. (2):

$$F_m(x) = F_{m-1}(x) + vh_m(x),\ \ m = 1, \dots, M \quad (2)$$

GBDT in Eq. (2) is explained as follows: In this boosting formulation, x denotes the feature vector for a single sample. The algorithm proceeds over iterations $m = 1, \dots, M$, where M is the total number of weak learners. At each step, the current ensemble prediction $F_{m-1}(x)$ is updated by adding a new weak learner $h_m(x)$, for example, a small regression tree trained on the residuals/gradients at step m. The update is scaled by the learning rate $v(0 < v \leq 1)$; smaller v makes changes more conservative and typically requires more iterations. The result is the new ensemble prediction $F_m(x)$ after incorporating h_m at iteration m.

C. CNN

CNN encoder (feature map pooled to embedding) is shown in Eq. (3):

$$z^{img} = Pool(\phi_{CNN}(I)) \quad (3)$$

CNN in Eq. (3) is explained as follows: I is the input product image (RGB tensor $HxWx3$). $\phi_{CNN}(.)$ is a convolutional backbone that converts I into a feature map $F \epsilon \mathbb{R}^{H'xW'xC}$ capturing color, texture, layout, and readability. $Pool(.)$ (global average/max/adaptive) compresses F into a fixed-length vector. $z^{img} \epsilon \mathbb{R}^{d_{img}}$ is the resulting image embedding a compact design/UX representation fed to downstream models.

Fusion (weighted blending of branch scores) is shown in Eq. (4):

$$\hat{p} = w_{CNN}\hat{p}_{CNN} + w_{LSTM}\hat{p}_{LSTM} + w_{gdbt}\hat{p}_{gdbt},\ w_k \geq 0, \sum_k w_k = 1 \quad (4)$$

Eq. (4) is explained as follows: here, $\hat{p}$ denotes the final ensemble prediction (e.g., purchase probability or session-risk score), obtained by blending three branch outputs: $\hat{p}_{CNN}$ from the image/design stream, $\hat{p}_{LSTM}$ from the temporal-behavior stream, and $\hat{p}_{GDBT}$ from the tabular/exogenous Gradient Boosting stream. The blend uses non-negative weights $w_{CNN}, w_{LSTM}, w_{GDBT}$ that sum to one, ensuring a convex combination and thus a valid probability. The optional multi-task objective (purchase & risk) is shown in Eq. (5):

$$\mathcal{L} = BCE(\hat{p}_{link}, y_{link}) + \lambda BCE(\hat{p}_{risk}, y_{risk}) + \beta||\theta||_2^2 \quad (5)$$

Eq. (5) is explained as follows: here, $\mathcal{L}$ denotes the total training loss the model minimizes. It has three parts: 1) a binary cross-entropy term for purchase link prediction, $BCE(\hat{p}_{link}, y_{link})$, which measures how well the predicted purchase probability $\hat{p}_{link}$ matches the ground-truth label $y_{link} \epsilon \{0,1\}$; 2) a session-risk binary cross-entropy term, $\lambda BCE(\hat{p}_{risk}, y_{risk})$, scaled by $\lambda \geq 0$ to control its influence, by comparing the predicted risk $\hat{p}_{risk}$ to $y_{risk} \epsilon \{0,1\}$; and 3) an L_2 regularization penalty, $\beta||\theta||_2^2$, where θ are all trainable weights (e.g., from the CNN/LSTM/GNN). The coefficient β controls weight decay to curb overfitting by discouraging excessively large parameters.

D. Evaluation

To evaluate, ROC-AUC is shown in Eq. (6), PR-AP in Eq. (7), Brier score in Eq. (8), and ECE in Eq. (9):

$$\text{Po}\chi\text{–AYX: area under } TPR(t) vs FPR(t) \quad (6)$$

$$\Pi\text{P–A}\Pi\text{: } AP = \int_0^1 P(R)dR \quad (7)$$

Precision@K/Recall@K: on top-K ranked pairs

$$\text{Brier score: } \frac{1}{N}\sum_{i=1}^{N}(\hat{p}_i - y_i)^2 \quad (8)$$

$$\text{EXE (calibration): } \sum_b \frac{n_b}{N}|acc(b) - conf(b)| \quad (9)$$

Decision policy (thresholding) is shown in Eq. (10):

$$\hat{y} = 1\{\hat{p} \geq r\},\quad r = argmax\ \mathbb{E}[gain - cost_{FP} - friction_{risk}] \quad (10)$$

TPR(t), in Eq. (6), is explained as follows: true-positive rate at threshold t. FPR(t): false-positive rate at threshold t. Eq. (7) is explained as follows: here, P(R): precision as a function of recall R. Brier in Eq. (8) is explained as follows: score N: number of evaluated examples. $\hat{p}_i$: predicted probability, for example i. $y_i \epsilon \{0,1\}$: ground-truth label, for example i. ECE (Expected Calibration Error) in Eq. (9) is explained as follows b: probability bin (e.g., 0.0–0.1, …, 0.9–1.0). $\boldsymbol{n_b}$: number of examples in bin b. acc(b): empirical accuracy in bin b. conf(b): average predicted probability (confidence) in bin b. Decision policy (thresholding) in Eq. (10) is explained as follows: $\hat{y}=1\{\hat{p}\geq r\}$: predicted class is 1 if probability $\hat{p}$ exceeds threshold r. $r = \arg\max \mathbb{E}[gain - cost_{FP} - friction_{risk}]$: choose the threshold r that maximizes expected net utility, balancing conversion gain, false-positive cost $cost_{FP}$, and user-experience friction from risk controls.

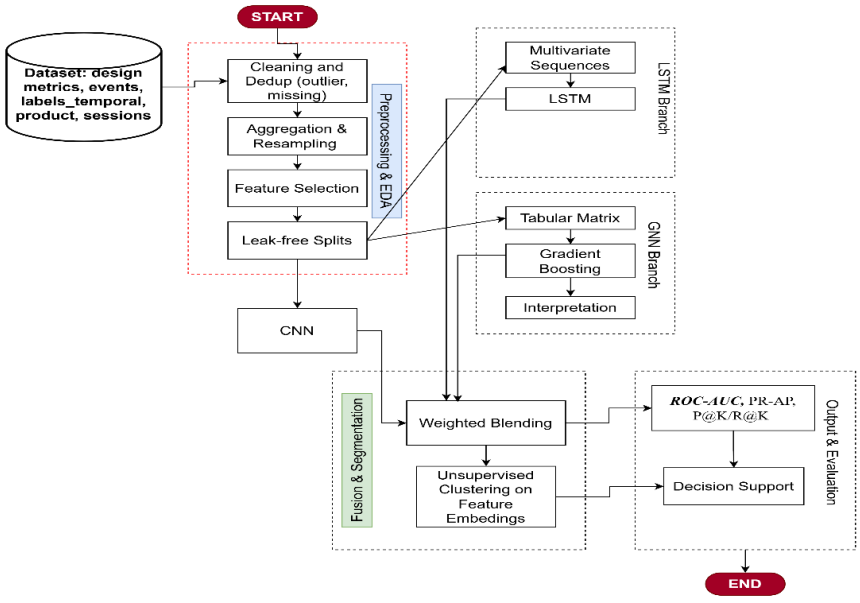

Fig. 1. Proposed research methodology.

IV. Experimental Results and Analysis

The data that has been obtained is stored in the datasets. All data is processed by preprocessing. The next process is carried out by reverse edge, which is meant by reverse edge as follows: Original edge: ('user', 'purchase', 'product') means that the user buys the product. Reverse edge: (product, purchase_rev, user)

means product purchased by the user (inverse direction of information).

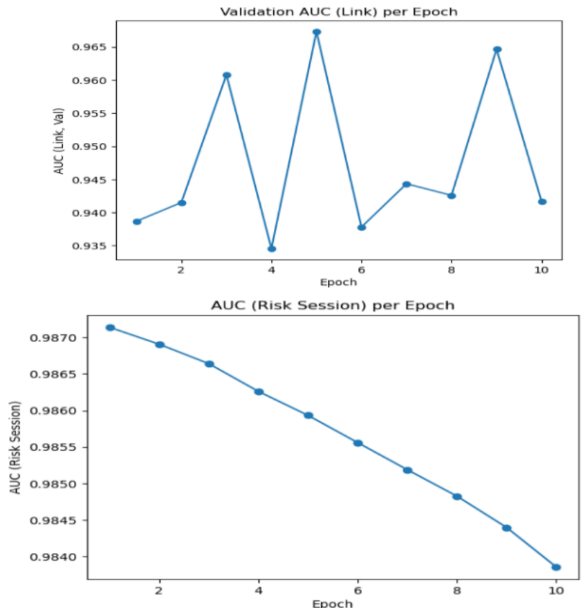

Fig. 2. Tracking and plotting results.

In Fig. 2, Link AUC remains consistently high (~0.94–0.97) with minor saw-tooth fluctuations typical of epoch-wise negative resampling or small validation sets, yielding a stable ≈0.95+ ranking quality for user–product pairs. The security head also stays very strong (risk AUC ~0.984–0.987) with a slight dip; together with a lower BCE, this points to improved calibration. Any small ranking drift is likely negligible and attributable to class imbalance, mild label noise, or train–evaluation distribution differences.

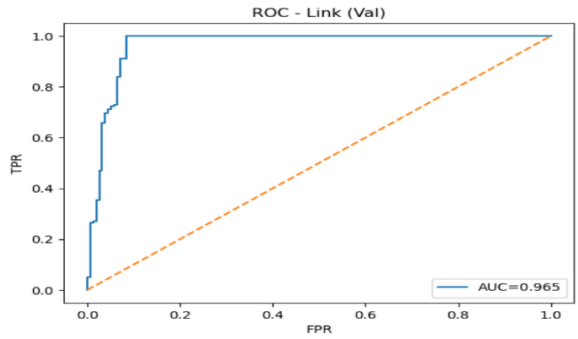

Fig. 3. ROC results - link (Val).

In the ROC–link (Val) curve in Fig. 3, AUC = 0.965 indicates excellent ranking. The curve hugs the top-left, achieving high TPR at low FPR. True buyer pairs are pushed to the top with a few false ranks. Probabilistically, AUC 0.965 ≈ 96.5% chance of a positive score above a negative, leaving ample flexibility to set thresholds for either high-recall or high-precision operation. In Fig. 4, the ROC curve climbs sharply at low FPR and hugs the top-left, indicating strong separation. AUC = 0.946 means the true pair scores higher in ~94.6% of positive–negative pairs. The small drop from validation (AUC ≈ 0.965) signals good generalization without overfitting. Practically, this affords flexible thresholding—low false positives with high TPR—and, alongside PR-AUC/Precision@K, confirms the model reliably prioritizes high-propensity user–product pairs.

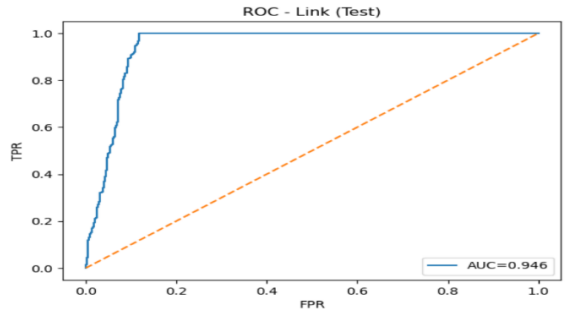

Fig. 4. Hasil ROC - link (Test).

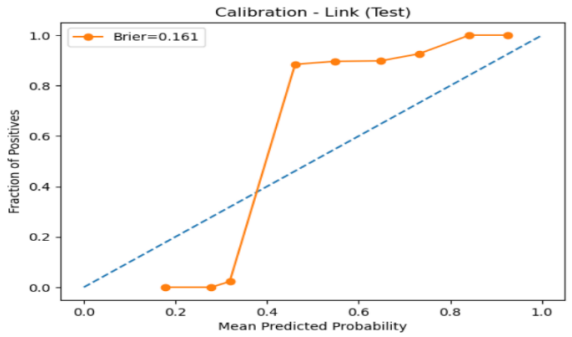

Fig. 5. Calibration - link (Test).

In Fig. 5, the curve shows mild over-confidence at low scores (~0.15–0.30), clear under-confidence in the mid range (~0.35–0.45), and persistent under-confidence at high scores (>0.5–~0.95); predictions near ~0.95–1.0 are very reliable. Brier = 0.161 indicates reasonably good calibration on imbalanced data, with most room for improvement in the middle band. Given the strong ROC/PR, ranking is already solid; light per-segment recalibration (Platt, isotonic, or beta) will make probabilities more proportional and safer for MSME personalization.

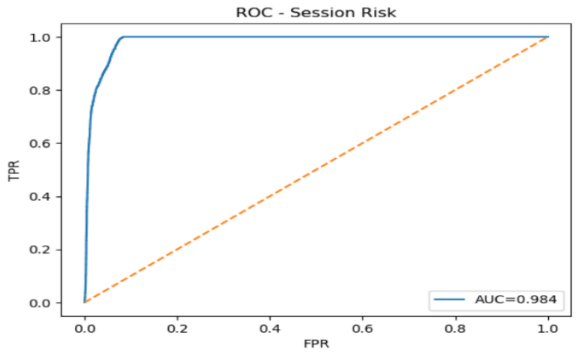

Fig. 6. ROC - session risk.

In Fig. 6, the ROC curve rises steeply at low FPR and hugs the top-left (AUC = 0.984, ≈98.4% pairwise separability). This reflects the security-aware heterogeneous graph, where severity, threat type, and outcomes propagate over session→user→sec_event (with reverse edges). Operationally, sustaining TPR ≥ 0.90 at FPR ≤ 0.05 supports risk-adaptive

friction: higher thresholds to block, lower selective thresholds for CAPTCHA/2FA on borderline cases yielding accurate early warnings at low error cost and stronger security without harming legitimate UX.

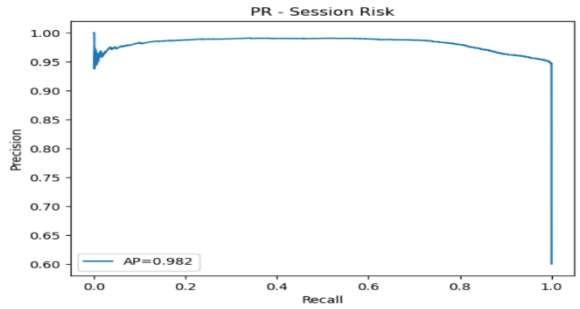

Fig. 7. PR - session risk.

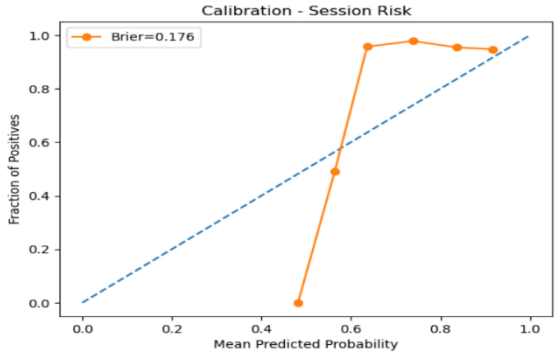

Fig. 8. Calibration - session risk.

In Fig. 7, precision stays ~0.95–1.0 across a wide recall range (AP = 0.982), indicating few false positives and near-perfect ranking. The curve is flat >0.95 through mid–high recall, dropping only near recall ≈1.0 as borderline cases enter. Operate at recall 0.7–0.9 (precision ≥0.95) to enable risk-adaptive friction (selective 2FA/CAPTCHA) with minimal user burden. Results are consistent with the security-aware heterogeneous graph, where severity/type/outcome signals propagate via session–user–sec_event relations (with reverse edges) to deliver accurate early warnings at low cost. The reliability curve in Fig. 8 shows: 1) local over-confidence at ~0.50–0.58 (below the y=x line), 2) real under-confidence at ~0.60–0.70 (curve beyond y=x), and 3) systematic under-confidence in the high range of ~0.70–0.95, while at ~0.95–1.0 the prediction is highly trusted. A Brier score of 0.176 indicates a fairly good calibration in the imbalanced scenario, but needs improvement in the medium probability (~0.55–0.65). Overall, the model excels in the rankings (high PR/ROC), but tends to underestimate the risk at medium–high scores.

In Table I, the hybrid model (CNN + LSTM + heterogeneous GNN with reverse edges) clearly outperforms the CNN–BiLSTM baseline: purchase ROC-AUC rises from 0.93/0.91 (val/test) to 0.965/0.946 with PR-AP 0.943/0.910; the security head reaches ROC-AUC 0.984 and PR-AP 0.982. Calibration is tighter (Brier 0.161 link; 0.176 risk), enabling easier thresholding (e.g., P@K, risk gating) with lower error costs. Gains stem from richer relational context, bidirectional message passing, and multi-task training. Remaining limits: mild mid-range under-confidence and sensitivity to graph/label quality.

TABLE I. COMPARISON OF CNN–BILSTM BASELINE VS. HYBRID CNN+LSTM+GNN ON PARTNER MSME DATA

Aspect	CNN–BiLSTM (Baseline)	Hybrid CNN+LSTM+GNN (Proposed)
ROC-AUC (Purchase)	0.93 (val) / 0.91 (test)	0.965 (val) / 0.946 (test)
PR-AP (Purchase)	—	0.943 (val) / 0.910 (test)
ROC-AUC (Session Risk)	—	0.984
PR-AP (Session Risk)	—	0.982
Calibration (Brier)	— (often less stable for sequence-only models)	0.161 (link) / 0.176 (risk)
Relational context modeling	Limited to temporal user sequences	Yes (user–product–session–category–sec_event) via GNN
Bidirectional message passing	—	Yes (reverse edges; stabilizes embeddings, helps cold/near-cold)
Safe personalization (risk gating)	Limited	Enabled: calibrated thresholding & policy control
Multi-task objective (link + risk)	No	Yes (regularizes representations, reduces conflict)
Key limitations	Sensitive to sparse/noisy sequences; limited explainability	Mild mid-probability under-confidence; performance bounded by graph quality

V. CONCLUSION

This research shows that the hybrid architecture of CNN+LSTM+GNN can provide safe personalization for MSMEs. For the purchase stage, the proposed model achieves a ROC-AUC of 0.965 (val) / 0.946 (test) and a PR-AP of 0.943 / 0.910, exceeding the CNN-BiLSTM baseline (0.93 / 0.91). For session risk detection, performance was close to perfect (ROC-AUC 0.984, PR-AP 0.982). The predicted probability is adequately calibrated (Brier 0.161 for links; 0.176 for risk), making it suitable for operational thresholds. These gains are driven by multi-tasking learning and two-way messaging that exploits relational contexts across users, products, sessions, categories, and security events that generate more accurate recommendations without sacrificing user security or trust. It can be concluded that the CNN+LSTM+GNN hybrid model can be used as an accurate, safe, and measurable recommendation in MSME e-commerce.

Looking ahead, we will pursue multimodal expansion integrating text (titles/reviews), payment/logistics signals, and campaign indicators to enrich decision context, alongside per-segment calibration and cost–benefit evaluation to ensure reliable and cost-effective deployment.

***Abstract*—Pangasius farming in the Mekong Delta is a major component of Vietnam's aquaculture industry, characterized by large-scale production, intensive farming practices, and significant contributions to export revenue. However, vaccination of Pangasius fingerlings is still predominantly performed manually, resulting in low productivity, high labor demand, and inconsistent injection accuracy, which limit large-scale deployment in commercial hatcheries. Therefore, there is an urgent need to develop an automated and accurate vaccination method for Pangasius fingerlings. This study proposes a novel computer vision–based approach for non-contact measurement of Pangasius fingerlings and accurate determination of the vaccine injection position. The proposed method leverages the image processing capabilities of the OpenCV library in combination with statistical morphological characteristics of Pangasius fingerlings to localize the injection position. The Python-implemented algorithm is lightweight and can run on an embedded Raspberry Pi platform, supporting practical in-field deployment. Experimental results demonstrate an average positioning accuracy of 97.65%, confirming the effectiveness of the proposed approach and its potential to serve as a technological foundation for automated vaccination systems in Pangasius aquaculture.**

***Keywords*—Computer vision; fish length measurement; fish vaccination; injection position; OpenCV; Pangasius**

I. Introduction

Pangasius is one of the major freshwater aquaculture products in the Mekong Delta, Vietnam, with a total export turnover of approximately USD 2 billion in 2024 [1]. Given its significant economic importance, effective disease control is essential to ensure the sustainability and competitiveness of the industry. In this context, vaccination of Pangasius fingerlings plays a crucial role in disease prevention, improving production efficiency, reducing the overuse of antibiotics, and minimizing antibiotic residues in fish products. However, vaccine injection in Pangasius fingerlings remains challenging due to their small size and morphological variability, which make accurate determination of the injection position difficult. Currently, the injection process is performed manually, resulting in low productivity, high labor demand, and inconsistent injection accuracy, as shown in Fig. 1. In addition, improper injection may damage fish internal organs and increase post-injection mortality rates. These limitations hinder large-scale and efficient vaccination in commercial hatcheries. To date, no dedicated solution has been reported that enables accurate, automated, and size-adaptive vaccination for Pangasius fingerlings. Therefore, the development of an automated and accurate vaccination method for Pangasius fingerlings is urgently required.

Fig. 1. Manual vaccination of pangasius fingerlings [2].

Motivated by these challenges, this study presents a computer vision–based approach for non-contact measurement of Pangasius fingerlings and accurate determination of the vaccine injection position. The proposed method employs image processing functions from the OpenCV library to determine the fish length. In particular, the vaccine injection position on the fish is determined based on a combination of image processing techniques and statistical data on the size and morphology of Pangasius fingerlings. For the first time, this study establishes a formulation for determining the appropriate vaccine injection position in Pangasius fingerlings using computer vision.

The organization of the present study is as follows: Section II is the review of the related literature, and Section III is the description of the proposed methodology. Section IV presents the experimental results. Section V provides concluding statements and directions for future research.

II. Related Works

Over the past two decades, the application of computer vision to fish length measurement has advanced considerably, supporting automated and non-contact measurement frameworks for modern fisheries and aquaculture systems. Among the earliest studies, White *et al.* [3] proposed the CatchMeter system, an onboard conveyor-based imaging setup that utilizes digital cameras to perform automated species classification and fish length measurement with millimeter-scale accuracy. Similarly, Jamaluddin *et al.* [4] proposed a non-contact fish length measurement system using camera-based image processing, highlighting its advantages in reducing handling stress and improving operational efficiency in aquaculture applications. The authors in [5] proposed a portable computer vision–based system using smartphone cameras and the OpenCV library to automatically measure striped catfish length, achieving an average accuracy of 97.71%. Kwon *et al.* [6] introduced a low-cost, vision-based system using dual smartphone cameras to estimate the body length and weight of olive flounder in indoor tanks with high accuracy. Lee *et al.* [7] developed an automated vision-guided Cartesian robotic system for flatfish vaccination that accurately determines injection positions under varying fish sizes and orientations.

Recent studies have integrated artificial intelligence algorithms and real-time capabilities. Tseng *et al.* [8] employed convolutional neural networks to estimate snout-to-fork length from images of harvested fish, achieving an accuracy of 95.74% in body length estimation. In [9], a stereo vision system was used to capture images of fish swimming freely in sea cages. The collected stereo data were used to train a YOLO model for simultaneous estimation of body length and weight, achieving a mean absolute percentage error of 5.5%. In [10], the authors proposed an automated framework for fish body length estimation by combining the RT-DETR deep learning model with Google ARCore technology. The system leveraged the smartphone Time-of-Flight capability to infer object distance and achieved measurement accuracy exceeding 95%. Rocha *et al.* [11] presented an automated approach for extracting morphological characteristics of freshwater fish using a Mask R-CNN framework in combination with the OpenCV library. The method estimated three body-length metrics, achieving an average relative error of 8.82% for standard length.

Despite extensive research on fish length measurement, most existing studies focus on grading, counting, or biomass estimation, while limited attention has been paid to its role in precise intervention tasks such as vaccination. In particular, research on vision-based determination of vaccine injection positions for fish fingerlings remains scarce. In addition, the substantial computational demands of deep learning frameworks restrict their adoption in cost-sensitive and resource-constraint aquaculture settings, underscoring the need for more efficient and deployable solutions. To address these limitations, this study integrates an OpenCV-based length measurement approach with statistical morphometric analysis to enable accurate and automated determination of vaccine injection positions for Pangasius fingerlings. The proposed processing pipeline is implemented in Python and can operate on embedded platforms such as Raspberry Pi, enabling practical in-field deployment.

III. Methodology

A. Image Collection

An imaging chamber was designed for acquiring images of Pangasius fingerlings. As shown in Fig. 2, the chamber consists of a Basler acA1300-200uc 1.3-megapixel camera [12] and a Raspberry Pi 4 kit with 8-GB RAM acting as the image processing unit. The images captured by the camera were transmitted to the Raspberry Pi kit [13] via a USB 3.0 interface for processing. The image processing algorithms were implemented in Python programming language (version 3.10.0) [14] using the OpenCV library (version 4.5.4.60) [15].

The fish used in this study were purchased from Pangasius farms in Vinh Long Province. The fingerlings had a body length ranging from 105 mm to 170 mm, measured from the head tip to the end of the caudal fin, and their weight ranged from 7.33 g to 35.94 g. The fish were anesthetized for imaging and morphometric measurements to establish a dataset for further analysis. The camera lens used in this study has a fixed focal length of 6 mm and an aperture of f/2.8. The fish images were captured under controlled lighting conditions at a resolution of 1280*x*1024 pixels. Prior to processing, they were resized to 800*x*600 pixels and stored in PNG format, providing a practical tradeoff between computational efficiency and measurement accuracy.

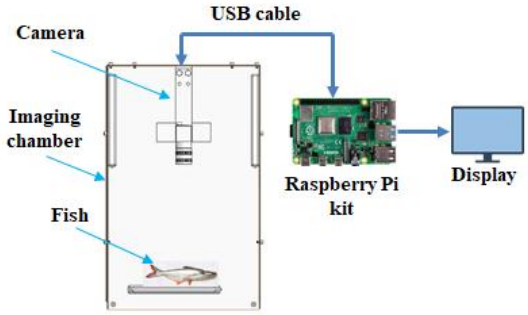

Fig. 2. Image acquisition setup.

B. Determination of the Vaccine Injection Position

The flowchart of the fish image processing procedure for determining the vaccine injection position is shown in Fig. 3. The procedure consists of seven processing steps: convert image to binary one, find contours and draw masks, extract the region of interest, determine fish orientation, find the position of fish's caudal peduncle, calculate the fish length, and determine the vaccine injection position.

1) Convert image to binary one: In this step, the original image is transformed into a binary image. The RGB image is first converted to grayscale using the OpenCV cv2.cvtColor function. Subsequently, Gaussian blurring is applied via cv2.GaussianBlur to suppress noise and smooth edges. Finally, adaptive thresholding is employed using cv2.adaptiveThreshold to convert the grayscale image into a binary image. The results of the RGB-to-binary conversion are illustrated in Fig. 4.

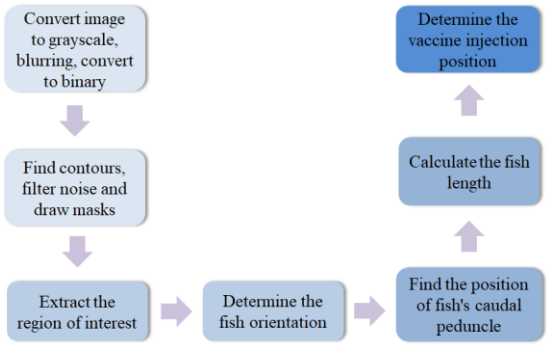

Fig. 3. The flowchart of the image processing algorithms.

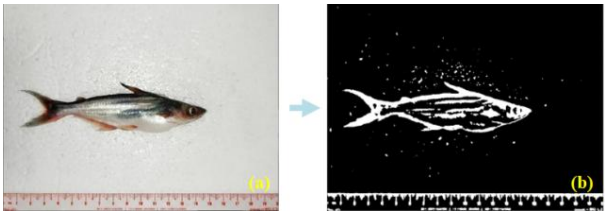

Fig. 4. Conversion from RGB to binary image: a) original RGB image; b) binary image.

2) Find contours and draw masks: In this step, object detection is performed on the binary image using the cv2.findContours function. To suppress noise, the contours.sort_contours function from the Imutils library [16] is employed to sort the detected contours and discard those with small areas. An image mask is then generated using the numpy.zeros function from the NumPy library [17] in combination with the cv2.drawContours function. The outcomes of the image masking process are presented in Fig. 5.

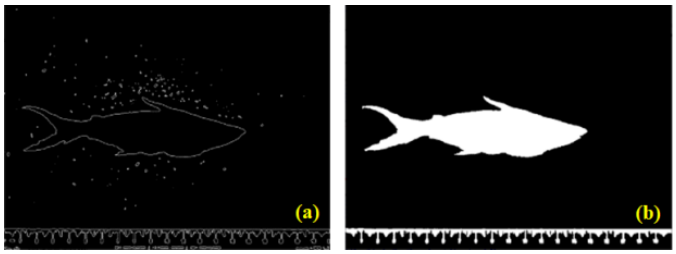

Fig. 5. Image masking: a) finding contours; b) drawing masks.

3) Extract the region of interest: The region of interest (ROI) corresponds to the image area containing the fish and is used to reduce computational cost. A rectangular ROI is extracted using the max and cv2.boundingRect functions. The extracted ROI is illustrated in Fig. 6.

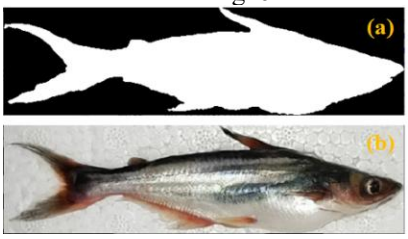

Fig. 6. Extracting the ROI: a) binary image; b) original RGB image.

4) Determine the fish orientation: During image acquisition, the fish were placed on the conveyor belt in a horizontal orientation, with their bodies aligned parallel to the direction of motion. Accordingly, two possible cases can occur: (a) the fish head is oriented to the left and (b) the fish head is oriented to the right, regardless of whether the ventral side is facing upward or downward. As shown in Fig. 7, h1 and h2 denote the heights of the fish image calculated at positions 0.2*w from the left and right boundaries of the ROI, respectively. Therefore, if h1 > h2, the fish head is oriented to the left; otherwise, the fish head is oriented to the right. For subsequent caudal peduncle detection, the ROI is transformed using the cv2.flip() function to ensure that the fish head is consistently oriented to the left, as illustrated in Fig. 8.

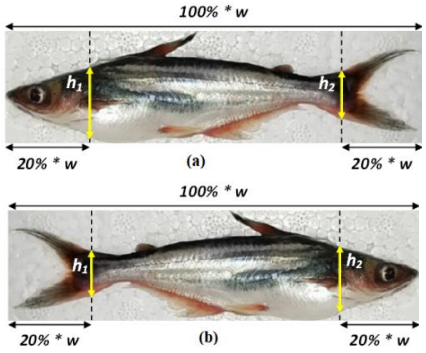

Fig. 7. Illustration of two different fish orientations: a) The fish head is oriented to the left; b) The fish head is oriented to the right.

Fig. 8. Result of changing fish orientation: a) the ROI of the binary image; b) the original image.

5) Find the position of the fish's caudal peduncle: Pangasius has a slender and elongated body that becomes narrower and flatter toward the tail. In addition, the caudal fin is thin and susceptible to damage, which can result in inaccurate length measurements. In this work, as a solution to this problem, the fish length is determined from the head tip to the narrowest region of the tail peduncle.

Fig. 9 illustrates the procedure for locating the narrowest part of the fish caudal peduncle. Specifically, the fish image ROI spanning from 0.7L to 0.9L (where L denotes the fish length) is analyzed to identify the minimum body width. A custom function, referred to as width_measuring, is developed to compute the distance between the first and last white pixels in each image column within the 0.7L÷0.9L region. The column exhibiting the minimum distance indicates the location of the narrowest part of the fish caudal peduncle. The algorithms corresponding to the proposed method are shown in Fig. 10 and Fig. 11. The outcome of this processing step is illustrated in Fig. 12.

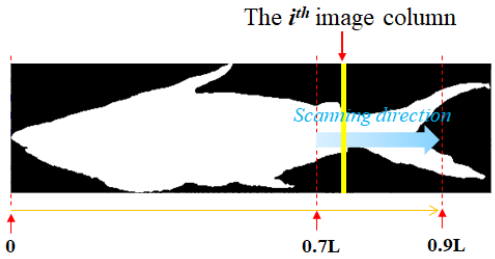

Fig. 9. Scanning for the narrowest position of the fish's caudal peduncle.

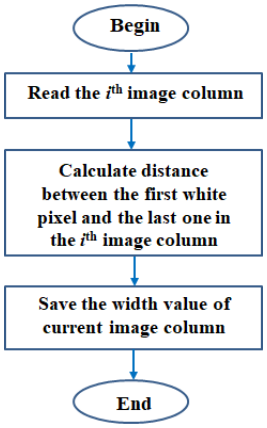

Fig. 10. The flowchart of the width_measuring function.

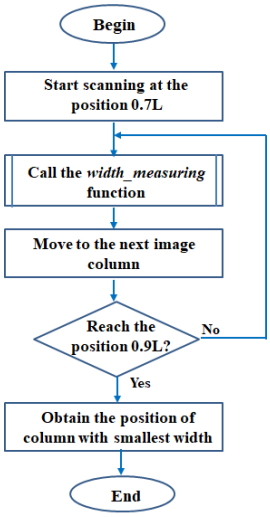

Fig. 11. Algorithm for locating the narrowest region of the fish caudal peduncle.

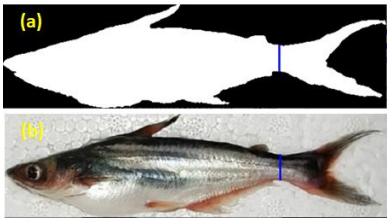

Fig. 12. Location of the narrowest part of the fish's caudal peduncle is marked with blue line in: a) the ROI of binary image and b) the original image.

6) Calculate the fish length: At this stage, the distance between the fish head tip and the location of minimum body width identified in the previous step is computed using the distance.euclidean function from the SciPy library [18]. This distance represents the fish length L, as depicted in Fig. 13, and is computed using the following Eq. (1):

$$L = N * s \quad (1)$$

where,

L: calculated fish length in millimeters.

N: the total number of image pixels located along the straight line from the fish mouth to the midpoint of the tail peduncle.

s: the physical size of a single pixel, equal to 0.264583 mm at an image resolution of 96 dpi.

Fig. 13. Determination of fish length.

7) Determine the vaccine injection position: The optimal injection needle position on the fish body is determined to be at 0.5÷0.75 of the pelvic length, anterior to the base of the pelvic fin [19]. Accordingly, the needle insertion position is point P, as illustrated in Fig. 14. The distance from the fish head tip to the injection point P, denoted as L3, is determined as follows [see Eq. (2)]:

$$L_3 = L_1 - 0.625 * L_2 \quad (2)$$

where,

L_1: the prepectoral length.

L_2: the pelvic length.

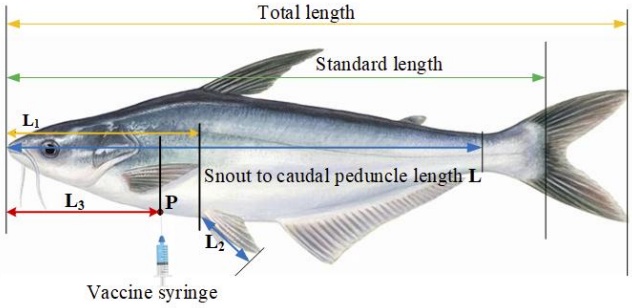

Fig. 14. Illustration of the optimal needle insertion position on the fish body.

In this study, the position of the vaccine injection point P is determined using image processing techniques in combination with experimental measurement data. Accordingly, the length L3 is determined based on Eq. (2) and the manually measured values of lengths L1 and L2.

Table I presents the experimental data from manual measurements of fish length Lm, prepectoral length *L*1, and

pelvic length L2 for 120 randomly selected Pangasius fingerlings. In Table I, R is defined as the ratio of L3 to the manually measured Lm, which corresponds to the length from the snout to the narrowest region of the caudal peduncle. Accordingly, the average value of the ratio R is determined to be 0.41.

As shown in Table I, the absolute error between the fish length measured using image processing L and that obtained by manual measurement L_m ranges from a minimum of 0.02 mm to a maximum of 8.86 mm, with an average error of 3.92 mm (i.e., 4%). This error may result from inaccuracies in manual measurements and in pixel-count calculations on the fish image.

Based on the statistical data in Table I, the correlation between the manually measured fish length L_m and the image-derived fish length L was obtained using the Matlab curve fitting toolbox [20] with a coefficient of determination R^2 = 0.9856, as shown in Fig. 15 and expressed by Eq. (3):

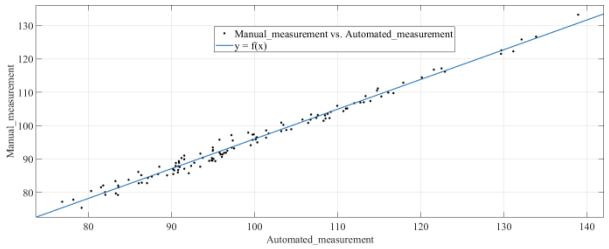

Fig. 15. Correlation function between L_m and L.

$$L_m = 0.8907 * L + 6.975 \quad (3)$$

In summary, the vaccine injection point on the fish P is defined by the distance from the fish head tip to P, denoted as $L_{injection}$, which is computed as follows:

$$L_{injection} = 0.41 * (0.8907 * L + 6.975) \quad (4)$$

Based on the fish length determined using image processing techniques and Eq. (4), the microprocessor can control the vaccine syringe to move to the determined injection point.

8) Fish weight estimation: From the statistical survey results of fish length L_m and the corresponding weight W in Table I, the fish weight can be estimated as a function of fish length with a coefficient of determination R^2 = 0.9502, and is expressed by the following Eq. (5):

$$W = 0.0000617y^3 - 0.01268y^2 + 1.1y - 29.07 \quad (5)$$

where, y is the fish length calculated from Eq. (3).

IV. Experimental Results

To verify the effectiveness and accuracy of the proposed method, 65 Pangasius fingerlings with weights ranging from 6.52 g to 41.3 g were randomly selected for validation. The fingerlings were reared in tanks and anesthetized prior to measurement. Fish size measurements were then conducted using two methods: using a digital caliper and an image-based method, as shown in Fig. 16. The comparison results between image-based measurements and manual measurements are presented in Table II. The experimental results indicate that the calculated fish length data exhibit an average absolute error of 0.94 mm, with accuracy ranging from 96.79% to 99.96%, and an average accuracy of 99.05%. The injection position estimation results show an average absolute error of 1 mm and an average accuracy of 97.65%. In addition, the fish weight estimation results achieve an average accuracy of 93.75% with an average absolute error of 2.66 g. The average processing time from image capture to result display is 0.25 seconds.

The accuracy of fish length, injection position, and weight estimations is computed as given in Eq. (6), Eq. (7), and Eq. (8), respectively:

$$Fish\ length\ accuracy = 100 - \frac{|L - L_m|}{L_m} * 100 \quad (6)$$

$$Injection\ accuracy\ (\%) = 100 - \frac{|L_{injection} - L_3|}{L_3} * 100 \quad (7)$$

$$Weight\ accuracy\ (\%) = 100 - \frac{|W_i - W_m|}{W_m} * 100 \quad (8)$$

TABLE II. Experimental Measurement Results

No.	Snout to caudal peduncle length measurement		Weight		Prepectoral length	Pelvic fin length	Injection point		Absolute errors			Accuracy (%)

Fig. 16. Conducting fish length measurements: a) Pangasius fingerlings tank; b) Fish were anesthetized prior to measurement; c) Manual measurement using digital caliper; d) Image-based measurement using computer vision.

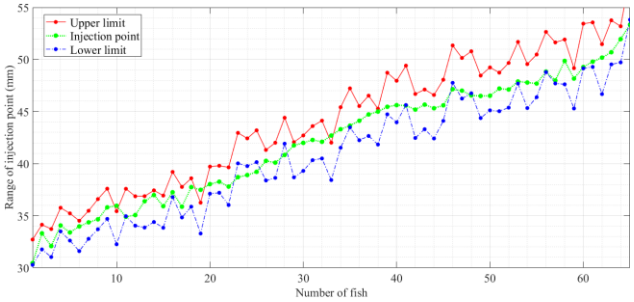

Fig. 17. Calculated results of the vaccine injection position.

The results of the vaccine injection position estimation and the practical injection tolerance range are illustrated in Fig. 17. The experimental data show that most of the calculated injection positions fall within the allowable limits, except for three cases with deviations greater than 1 mm, which are 1.32 mm, 1.24 mm, and 1.08 mm, respectively. In practice, it has also been observed that some Pangasius fingerlings have different pelvic fin lengths despite having the same body length. This may be one of the causes of the observed discrepancies. Besides, the use of a camera equipped with a short-focal-length lens (6 mm, f/2.8) introduces spatial nonuniformity in pixel density, which also contributes to measurement deviations. However, these errors remain within acceptable limits for practical implementation. The proposed method offers a more accurate and reliable approach to automated injection than manual vaccination, where high-intensity human operation can introduce errors that compromise post-injection fish health.

V. Conclusion and Future Work

This study has proposed and experimentally validated a novel computer vision–based approach for accurately determining the vaccine injection position in Pangasius fingerlings. By leveraging the image processing capabilities of the OpenCV library in combination with statistical morphological data of Pangasius fingerlings, the proposed method achieved an average accuracy of 97.65%. The open-source Python-based pipeline operates on embedded platforms, enabling practical in-field deployment. This work is the first to establish a computer-vision–based formulation for locating the vaccine injection position in Pangasius fingerlings. The results demonstrate the feasibility of applying computer vision techniques to support automated vaccination tasks for Pangasius fingerlings.

The estimation accuracy of the image-based approach can be further improved by optimizing the illumination conditions within the imaging chamber and by selecting a camera lens with a focal length appropriate for the fish size. Future work will focus on integrating the proposed vision-based measurement approach with mechatronic actuators and an embedded control system toward a fully automated vaccination platform. Such integration is expected to increase throughput, improve injection consistency, and substantially reduce labor costs in commercial Pangasius hatcheries.

Acknowledgment

Exposure-Based Media Mix Modeling Using Machine Learning and Genetic Algorithms

An Audience Reach Optimization Framework for Advertising Budget Allocation

Thejan Dulara, Indra Mahakalanda, Prasanga Jayathunga
University of Moratuwa, Katubedda 10400, Sri Lanka

***Abstract*—Media budget allocation remains a persistent challenge in the advertising industry. Inefficient spending and biased planning decisions often reduce campaign effectiveness. Advertisers struggle to balance investments across television, radio, press, and digital platforms while managing diminishing returns. This study proposes a data-driven media mix determination model that integrates supervised machine learning with genetic algorithm-based optimization. The objective is to maximize audience reach while maintaining cost efficiency. Unlike traditional media mix models that rely on aggregated medium-level performance, this study adopts an audience exposure-based modelling approach. Facebook and YouTube are used as digital media platforms in this study. Television and digital models are trained using exposure-based reach measures, such as 1 plus and 2 plus reach. Machine learning models, including decision trees, random forests, XGBoost, and LightGBM, are evaluated to capture complex and nonlinear relationships between spend and exposure-based reach. Smoothed reach response curves are used to identify efficiency levels and saturation points for each medium. A genetic algorithm is then applied to derive the optimal budget allocation across media under efficiency, reach, and cost constraints. The model is trained using real advertising data from the Sri Lankan market, ensuring practical relevance and applicability. Although the analysis is based on a country-specific dataset, the model is transferable to markets of similar scale. This study contributes to the literature by introducing an exposure-driven media mix modelling approach that improves media budget planning accuracy and supports more effective advertising decision-making.**

***Keywords*—Media mix determination; saturation points; audience reach; audience exposure**

I. Introduction

Advertisers seek to reach the maximum possible audience while using their budgets efficiently [1]. However, allocating budgets across television, radio, print, and digital media remains a persistent challenge [1]. Each medium exhibits different response behaviors, and excessive spending on a single channel often results in diminishing returns [2]. These challenges increase the risk of inefficient budget allocation and reduced campaign effectiveness.

A data-driven approach that combines machine learning based prediction and optimization techniques can help address this problem [3]. Predictive models enable advertisers to understand how audience reach responds to varying spend levels across media. Optimization techniques then support the identification of an optimal media mix that maximizes reach at the lowest possible cost [3]. Media Mix Modeling (MMM) provides a structured framework for this purpose. Existing MMM approaches generally follow two directions. One focuses on quantitative objectives, such as maximizing reach while minimizing cost [4]. The other incorporates qualitative considerations, including campaign fitness, creative alignment, and historical effectiveness [4].

Most traditional MMM studies rely on aggregated spend to reach relationships at the media channel level [5]. Such approaches may overlook the effects of repeated audience exposure and the nonlinear nature of media response [6]. To address this limitation, this study adopts an exposure-based perspective. Television and digital media performance are modeled using exposure-based reach measures, such as 1 plus and higher reach levels, which reflect the proportion of the audience exposed to advertising multiple times [7]. This allows the model to learn directly from audience exposure behavior rather than general media-level aggregates.

Accordingly, this study develops a media mix determination model that integrates supervised machine learning techniques with genetic algorithm-based optimization. The primary focus is on quantitative performance factors. Unlike traditional aggregated media mix models that rely mainly on total spend to outcome relationships, the proposed framework models exposure-based reach metrics at different frequency thresholds. It incorporates measures such as 1 plus and higher exposure levels to capture audience response more precisely. This approach allows the model to reflect nonlinear response behavior and diminishing marginal effectiveness in a more direct manner. To the best of our knowledge, this Exposure-Based Media Mix Modelling framework, which combines exposure level modeling with machine learning and genetic algorithm optimization, represents a novel contribution to media planning research.

The remainder of this study discusses related concepts, defines the research problem and objectives, presents the methodology and results, and concludes with a discussion of implications.

II. Related Concepts

A. Media Mix Modeling

Media Mix Modelling (MMM) is a widely used analytical approach that supports advertisers in allocating budgets across multiple media channels to improve sales performance and

return on investment [8]. It enables the assessment of how individual media channels contribute to overall campaign outcomes within an evolving media environment [8]. Despite its usefulness, advertisers face several challenges when applying MMM, including limited data availability, interactions among media channels, and unpredictable consumer behaviour [9] [8]. To address these challenges, machine learning models such as Random Forest and gradient boosting techniques are increasingly applied. These models can capture complex response patterns by accounting for nonlinear effects, seasonality, and external economic factors [10]. As a result, MMM has become a critical tool for data-driven and cost-effective advertising decision-making [8].

MMM approaches can broadly be categorized into regression-based, Bayesian, and machine learning based frameworks. Traditional regression-based MMM typically relies on parametric specifications that incorporate advertising characteristics such as carryover and diminishing returns through transformations like ad stock and Hill functions [11]. These models offer clear interpretability, as regression coefficients can be directly translated into attribution metrics such as Return on Advertising Spend. However, their performance depends on correct functional form specification and sufficient variation in the underlying data [11].

Bayesian MMM extends regression frameworks by incorporating prior knowledge into the estimation process [12], [11]. Instead of producing single-point estimates, Bayesian approaches generate probability distributions for model parameters and attribution metrics, allowing uncertainty to be explicitly quantified [12]. This can be useful when data are sparse or highly correlated. In contrast, machine learning-based MMM methods emphasize predictive flexibility and nonlinear pattern recognition, often with fewer structural assumptions [10], [11]. While these approaches may reduce reliance on strict parametric forms, they may require additional techniques to ensure interpretability and stable attribution measurement [11].

B. The Concept of Diminishing Returns and Saturation Points in Media Advertising

An important concept in Media Mix Modeling is the principle of diminishing returns. Diminishing returns describe the nonlinear relationship between advertising spend and incremental audience response. As spending increases, each additional unit of investment generates progressively smaller gains in reach or engagement [13]. In empirical media response analysis, this behavior is commonly represented through saturation curves, such as S-curves or Hill transformations, which model how response flattens as spend rises [13].

For example, empirical observations in performance channels show that initial investment levels may produce high marginal returns, while additional increments of spend generate lower incremental gains. A retailer may observe a return on investment of 4:1 at moderate spend levels, declining to 2:1 or lower as spend increases further [13]. This decline reflects audience saturation, budget inefficiency, or limited incremental demand. The flattening of the response curve, therefore, represents the transition from efficient growth to diminishing effectiveness.

Saturation occurs when marginal return falls below a practical decision threshold or below the marginal return of alternative media channels [14]. In mathematical terms, the saturation point corresponds to the region where the first derivative of the response function approaches zero. At this stage, additional spending contributes negligible incremental reach or sales. Identifying this point is essential for rational budget allocation, as continued investment beyond saturation results in inefficient use of resources.

Different media channels exhibit distinct saturation behaviors. Television typically requires higher investment before saturation due to its broad reach potential, whereas digital platforms such as online video may reach saturation earlier because of targeting limits and audience overlap [2]. Moreover, saturation interacts with audience reach and frequency. When a campaign already reaches a high proportion of the addressable audience at multiple exposure levels, further impressions produce minimal incremental response [13].

Recognizing diminishing returns and saturation patterns is therefore fundamental to effective media planning. By estimating response curves and identifying efficiency thresholds, advertisers can avoid over investment in saturated channels and reallocate budgets toward media with remaining growth potential [14]. This empirical understanding forms the analytical foundation for exposure-based modeling and optimization in media mix determination.

C. Machine Learning Applications in Advertising

Machine learning techniques are well-suited for modeling the complex and nonlinear relationships commonly observed in advertising data. Models such as Random Forest, Support Vector Regression, and Bayesian Networks have been used to predict audience reach and identify saturation points across media channels [15]. These techniques also support adaptive decision-making by learning from historical performance data [15]. In addition, machine learning enables dynamic budgeting strategies, allowing advertisers to adjust media investments in response to observed performance changes, thereby improving efficiency and return on investment [16].

D. Audience Reach and Cost Efficiency

Audience reach and cost efficiency are fundamental metrics in advertising evaluation. Reach measures the proportion of the target audience exposed to advertising, while cost efficiency reflects how effectively budgets are converted into audience contact. Common indicators include Cost Per Click, return on investment, and incremental reach [17]. These metrics guide advertisers in reallocating budgets toward higher-performing channels. Prior research also highlights the efficiency gains achieved by shifting budgets from traditional media to digital platforms such as YouTube and display advertising networks, particularly when reach extension and targeting precision are prioritized [18].

E. Audience Exposure and Exposure Level-Based Planning

Traditional reach-based analysis often treats exposure as a binary outcome, without accounting for repeated audience contact. Exposure-based planning extends this concept by measuring reach at different exposure thresholds, such as 1

plus, 2 plus, or higher levels, which represent the proportion of the audience exposed to advertising at least a specified number of times [19]. Exposure frequency plays a critical role in advertising effectiveness, as repeated exposure influences recall, persuasion, and behavioral response. Modeling exposure levels allows advertisers to capture diminishing returns associated with repeated contact and to better understand audience response dynamics [20]. Exposure-based planning has been widely discussed in media planning literature and is commonly applied in television and digital advertising measurement frameworks. However, a detailed review of the theoretical literature on exposure frequency and marginal effectiveness is not included, as it is beyond the scope of this study.

F. Optimization Algorithms for Media Budget Allocation

Optimization techniques translate analytical insights into actionable media plans. Linear Programming and Genetic Algorithms are among the most commonly applied optimization methods in media budget allocation [21]. Linear Programming is effective for static problems with fixed constraints, whereas Genetic Algorithms offer greater flexibility for complex and nonlinear planning scenarios [21]. Genetic Algorithms can adapt to dynamic constraints, nonlinear media responses, and multiple objectives, making them well-suited for exposure-based media planning and budget optimization.

Genetic Algorithms are particularly useful in marketing environments characterized by large search spaces and nonlinear response behaviours [22]. Unlike deterministic allocation rules or simple heuristics, GA-based approaches iteratively evolve candidate solutions through selection, crossover, and mutation processes, allowing efficient exploration of multiple allocation combinations [22]. This makes them suitable for media planning problems where marginal returns differ across exposure levels, and constraints interact dynamically. Therefore, GA was selected as an appropriate optimization framework for handling the nonlinear and multi-constraint structure of the proposed exposure-based media mix model.

Together, these concepts form a comprehensive foundation for understanding and improving media mix determination using modern data-driven and optimization-based approaches.

III. Scope of the Study

This study addresses the problem of developing a media mix determination model for marketing campaigns that can predict optimized budget allocation while maximizing audience reach and maintaining cost efficiency. Advertisers face increasing difficulty in planning budgets across multiple media platforms due to nonlinear response behavior and diminishing returns at higher spend levels. This challenge becomes more complex when audience exposure effects are considered. Therefore, this study focuses on building a quantitative, data-driven framework that integrates exposure-based reach modeling with optimization techniques to support effective media planning decisions.

The objectives of this study are to identify key efficiency characteristics and optimal allocation strategies across media channels under different exposure levels. Specifically, the study aims to identify the maximum efficiency point and the zero efficiency point for each advertising medium across multiple exposure levels, including television, digital platforms, radio, and press. It further seeks to determine the reach and required budget corresponding to selected efficiency levels for each medium and exposure level. In addition, the study aims to estimate the budget and efficiency required to achieve a specified target reach under different exposure conditions. Another objective is to calculate the total achievable reach when all media operate at predetermined efficiency levels for selected exposure combinations. Finally, the study aims to optimize budget allocation across all media under predefined exposure levels in order to maximize total reach and identify the most efficient budget distribution for achieving target audience objectives.

IV. Methodology

A. Data

The data used in this study were provided by Third Shift Media (Pvt) Ltd, a leading advertising and media planning agency in Sri Lanka. The dataset consists of 18 separate datasets covering four main media channels: Television, Digital, Radio, and Press. Digital media data is limited to the Facebook and YouTube platforms. Within the television medium, ten separate datasets are provided. These datasets represent audience exposure levels from 1 plus to 10 plus reach. For Facebook and YouTube, exposure-based datasets corresponding to 1 plus, 4 plus, and 6 plus reach levels are available. These exposure thresholds were selected because they represent commonly applied frequency benchmarks in industry practice for digital campaign planning and performance evaluation. For radio and press, general audience exposure datasets are used without further exposure level separation.

Each dataset contains two variables: spend level and the corresponding audience exposure reach. Spend level represents the advertising expenditure for a given medium and is measured in Sri Lankan Rupees. Audience exposure reach represents the percentage of the total audience reached at a specific budget level for the corresponding exposure definition. This structure allows the analysis to capture how different levels of advertising exposure respond to increasing media spend across platforms.

B. Method of Analysis

The methodological framework of this study begins with a structured data preprocessing phase, as illustrated in Fig. 1. The raw datasets were examined for missing values, duplicate records, and outliers. No such issues were identified, and therefore, no additional data cleaning was required. Each dataset was then sorted by spend level to improve interpretability and ensure consistent model training.

A key preprocessing challenge was the inconsistency in population bases across media platforms. Television, radio, and press datasets were based on a population of 17.6 million. In contrast, Facebook exposure data were based on a population of 8.05 million, while YouTube exposure data reflected a population of 7.47 million. To ensure comparability across all

media, Facebook and YouTube datasets were scaled proportionally to match the 17.6 million population base.

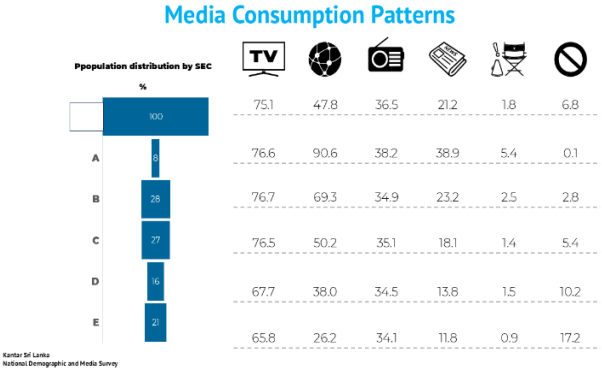

Fig. 1. Media consumption patterns (National Demographic and Media Survey by Kantar Sri Lanka).

The primary objective of the analysis was to identify efficiency levels and saturation points for each medium and exposure level. Since the relationship between advertising spend and audience exposure-based reach is nonlinear and exhibits diminishing returns, four supervised machine learning models were evaluated. These models were Decision Tree, Random Forest, LightGBM, and XGBoost. For each exposure-based dataset across all four media, all four models were trained independently. Model performance was evaluated using Mean Squared Error and R squared metrics on both training and testing sets. The model with the highest R squared value and lowest Mean Squared Error was selected for subsequent analysis.

To support high-resolution analysis, a continuous range of spend values was generated within the observed minimum and maximum spend levels of each dataset. Predicted exposure-based reach values were obtained across this range using the selected model, forming a dense response curve. Since raw predictions could contain minor fluctuations, a Gaussian smoothing filter was applied. This ensured stable derivative estimation in later steps.

The first Numerical derivatives of the smoothed reach curves were computed to quantify marginal reach per unit spend, defined as efficiency. Efficiency values were normalized to a percentage scale, where 100 percent represented the point of maximum marginal reach. Two key thresholds were identified from each efficiency curve. The first was the maximum efficiency point. The second was the saturation point, defined as the point where efficiency fell below 2 per cent of its maximum value, indicating negligible incremental reach.

These efficiency curves enabled two complementary budgeting strategies. In the efficiency-based approach, a user-defined efficiency threshold, such as 80 per cent was selected, and the corresponding budget and reach were identified after the maximum efficiency point. In the reach-based approach, a target reach level was specified, and the corresponding budget and efficiency were derived from the prediction curve.

This process was repeated for all 18 exposure-based datasets across the four media channels. The next phase involved estimating the combined reach under a multi-channel media planning scenario. Media layering order was determined using the National Demographic and Media Survey by Kantar Sri Lanka (Fig. 2). Based on audience penetration levels, media were prioritized as television first, followed by digital platforms in the order of Facebook and YouTube, then radio, and finally press.

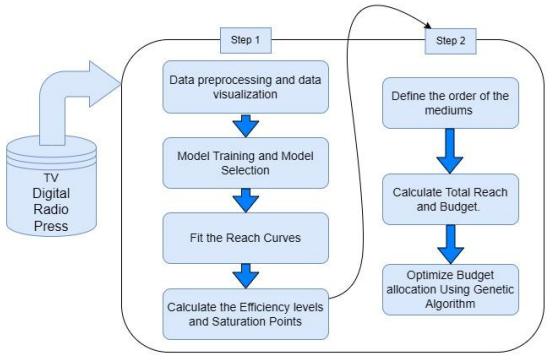

Fig. 2. Research process.

Direct aggregation of reach across channels would lead to duplication errors due to overlapping audiences. To address this issue, realistic duplication assumptions were introduced. It was assumed that 60 per cent of the Facebook audience overlapped with television viewers. 90 per cent of the YouTube audience overlapped with audiences reached through television and Facebook. Similarly, 90 per cent of the radio audience overlapped with audiences reached through television and digital platforms. Finally, 95 per cent of the press audience overlapped with all other media. These assumptions were based on observed media consumption patterns.

To incorporate duplication effects, digital, radio, and press models for all exposure levels were retrained using adjusted datasets that excluded overlapping audiences. Television models were used to estimate the initial reach, followed sequentially by Facebook, YouTube, radio, and press. All modeling steps, including prediction, smoothing, derivative calculation, and efficiency-based analysis, were repeated using the adjusted datasets.

For each medium and exposure level, the budget and reach corresponding to a selected efficiency threshold were extracted. By summing results across media, the total budget required and cumulative reach were estimated. The model also allows users to compute achievable reach under different exposure combinations, such as television 1 plus with Facebook 4 plus and YouTube 4 plus, alongside radio and press at selected efficiency levels.

To further optimize budget allocation under practical constraints, a Genetic Algorithm was applied. The algorithm aimed to maximize total reach while minimizing total spend, or alternatively, achieve a target reach at the lowest possible cost. The initial population consisted of candidate budget plans across selected exposure levels of television, digital, radio, and press, subject to total budget constraints. Each plan was evaluated using trained media models to predict reach. Fitness scores incorporated penalties for exceeding budgets or failing to meet reach targets.

The algorithm evolved solutions over multiple generations, typically between 30 and 50. Selection retained high-performing plans, crossover combined strong solutions, and mutation introduced controlled variation. A repair mechanism ensured all solutions satisfied constraints. Initial populations were seeded using insights from efficiency analysis to improve convergence.

The final output included the optimal budget allocation, predicted reach for each medium, and corresponding efficiency levels. This enabled the Genetic Algorithm to solve different planning scenarios, including fixed budget allocation and target reach achievement.

V. Results

To predict exposure level-specific reach as a function of media spend, machine learning models were selected based on their predictive performance. Decision Tree models were selected for all television exposure level models and for radio, as these achieved the highest R squared values with low Mean Squared Errors. Random Forest models were selected for all digital exposure level models, including Facebook and YouTube, as well as for the press. These models consistently outperformed alternatives across exposure levels.

TABLE I. Results of Selected Machine Learning Models Before Addressing Audience Duplication.

Medium	Selected Model	Frequency	R2	MSE
TV	Decision Tree	1+	0.9853	1.0705
TV	Decision Tree	2+	0.9919	0.8514
TV	Decision Tree	3+	0.9969	0.3978
TV	Decision Tree	4+	0.9983	0.2606
TV	Decision Tree	5+	0.9986	0.2528
TV	Decision Tree	6+	0.9990	0.1913
TV	Decision Tree	7+	0.9992	0.1688
TV	Decision Tree	8+	0.9993	0.1500
TV	Decision Tree	9+	0.9994	0.1433
TV	Decision Tree	10+	0.9994	0.1442
Facebook	Random Forest	1+	0.9999	0.0004
Facebook	Random Forest	4+	0.9999	0.0028
Facebook	Random Forest	6+	0.9999	0.0015
YouTube	Random Forest	1+	0.9998	0.0235
YouTube	Random Forest	4+	0.9999	0.0120
YouTube	Random Forest	6+	0.9999	0.0097
Radio	Decision Tree	-	0.9964	0.1317
Press	Random Forest	-	0.9942	0.0301

Model performance was evaluated using R squared and Mean Squared Error metrics on both training and testing datasets. Results for all exposure level models before addressing audience duplication are summarized in Table I. Performance results after adjusting for duplication are presented for digital, radio, and press models in Table II. Since television served as the base medium, duplication adjustment was not required for television models. To assess potential overfitting, R squared values were calculated separately for training and testing datasets for each model, and the absolute difference between them was computed. Across all exposure level models, this difference remained below a threshold of 0.05. Therefore, no substantial divergence between training and testing performance was observed, indicating stable generalization and a limited risk of overfitting or underfitting in the analyzed advertising datasets.

TABLE II. Results of Selected Machine Learning Models After Addressing Audience Duplication.

Medium	Selected Model	Frequency	R2	MSE
Facebook	Random Forest	1+	0.9999	0.00007
Facebook	Random Forest	4+	0.9999	0.0004

Radio	Decision Tree	-	0.9964	0.0013
Press	Random Forest	-	0.9942	0.0001

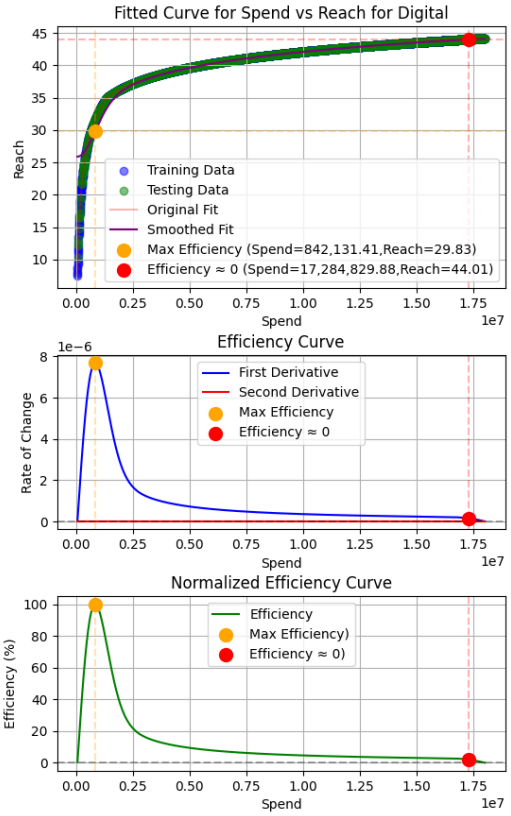

Fig. 3. Reach curve, efficiency curve, and normalized efficiency curve for the Facebook medium at the 1+ exposure level before duplication adjustment.

Based on the selected models, reach response curves were generated for all media and exposure levels under both duplication-adjusted and non-adjusted conditions. For each model, reach curves, efficiency curves, and normalized efficiency curves were derived. Fig. 3 illustrates the model outputs for a representative Facebook digital media case at the 1+ exposure level before addressing duplication. Fig. 4 presents the reach curve after duplication adjustment. The plots highlight the points of maximum efficiency and saturation.

Budget and reach outcomes obtained using both efficiency-based and reach-based targeting approaches, before and after addressing duplication scenarios, are summarized across all exposure levels and media in Table III to Table XX.

Using the efficiency curves, total achievable reach and required budget were computed for selected efficiency thresholds. Table XXI presents a planning scenario with efficiency targets of 40 per cent for television 1 plus exposure, 45 per cent for Facebook 4 plus exposure, 50 per cent for YouTube 4 plus exposure, 60 per cent for radio, and 70 per cent for press. These results demonstrate how exposure level selection and efficiency targets influence total reach and budget requirements.

TABLE XXI. COMBINED BUDGET AND REACH OUTCOMES

Model	Efficiency	Spend (LKR)	Reach (%)
TV 1+	40%	14,556,393.14	62.53
Facebook 4+	45%	1,006,975.7	10.76
YouTube 4+	50%	3,427,182.72	1.12
Radio	60%	896,829.68	2.65
Press	70%	974,032.4	1.06
Total		**20,861,413.64**	**78.12**

To further enhance budget allocation decisions, a Genetic Algorithm was applied. In the first scenario, the algorithm optimized a fixed total budget of LKR 20 million across television 1 plus, Facebook 4 plus, YouTube 4 plus, radio, and press. The resulting optimal allocation and predicted reach are reported in Table XXII. In the second scenario, the algorithm was configured to achieve a target reach of 85 per cent for the same exposure level combination. The resulting budget allocation and medium-wise reach outcomes are presented in Table XXIII. These results confirm the effectiveness of the proposed model in supporting exposure-based media planning and optimization.

TABLE XXII. GA RESULTS FOR TARGET BUDGET OF LKR 20 MILLION SPEND.

VI. DISCUSSION

This study aimed to develop a practical and data-driven media mix determination model suitable for real-world advertising decision-making using Sri Lankan media data. The proposed framework supports key planning tasks by identifying performance patterns, efficiency levels, and optimal budget allocations across media channels. By incorporating exposure-based reach measures, the model extends traditional media mix modeling approaches and provides a more realistic representation of audience response behavior.

In line with the study objectives, the analysis identified the maximum efficiency points and saturation points for television, digital platforms including Facebook and YouTube, radio, and press across different exposure levels. These results provide valuable insights for advertisers by highlighting spend regions that yield high marginal returns and those that result in inefficient spending. The study further addressed efficiency-based and reach-based planning objectives by estimating the budget required to achieve specified efficiency levels and target reach values under different exposure conditions. This enables advertisers to answer practical planning questions related to expected reach outcomes and budget requirements.

The study also demonstrated how total achievable reach can be estimated by operating all media at predefined efficiency levels for selected exposure combinations. This provides advertisers with clear guidance on how exposure level selection influences cumulative reach outcomes. Budget optimization objectives were addressed through the application of a Genetic Algorithm, which identified optimal budget allocations under constraints such as fixed budgets and target reach levels. The optimization results show that exposure-aware planning can improve budget efficiency and overall campaign reach.

Although the analysis is based on industry data from Sri Lanka, the model is not restricted to a single media plan or organization. The framework can be adapted for advertising budget allocation decision support in small and medium-scale companies as well as larger conglomerates operating in similar market contexts. Overall, the proposed approach offers a simple yet robust tool for exposure-driven media planning and informed budget optimization.

VII. Conclusion and Implications

This study presents a practical and data-driven framework for media mix determination that integrates exposure-based reach modeling with machine learning and genetic algorithm optimization. By focusing on audience exposure levels rather than aggregated channel performance, the proposed approach provides more realistic insights into media response behavior and budget efficiency. The model supports advertisers in identifying efficient spending zones, estimating achievable reach under different exposure conditions, and optimizing budget allocation across multiple media platforms.

Despite its practical contributions, the study has several limitations. The proposed framework focuses exclusively on quantitative performance measures and does not incorporate qualitative factors such as campaign fitness, brand positioning, creative effectiveness, or prevailing market trends. Therefore, advertisers should use the model as a decision support tool rather than a standalone planning solution. Strategic judgment and contextual knowledge remain essential when finalizing media plans.

The model was developed using a duplication-adjusted audience scenario based on observed media consumption patterns. However, audience overlap varies depending on campaign objectives, target segments, and media sequencing strategies. As a result, the duplication parameters applied in this study may not fully reflect all real-world scenarios. In addition, the statistical stability of the results depends on the quality, consistency, and historical depth of the advertising datasets used. The findings may therefore be sensitive to data limitations, exposure definitions, and duplication adjustments implemented during the modeling process.

Future research may integrate qualitative considerations through structured multi-criteria decision-making approaches such as the Analytic Hierarchy Process (AHP). An AHP-based extension could incorporate expert evaluations of qualitative campaign attributes and combine them with the quantitative optimization outputs. This would allow media planning decisions to reflect both measurable performance indicators and strategic brand-level considerations, resulting in a more comprehensive decision framework.

Finally, the model framework is designed in a way that it can be retrained using industry-specific or campaign-specific data, although external validation across different markets has not been conducted within this study. This allows the framework to be adapted for different markets, exposure definitions, and planning objectives. Future extensions may integrate qualitative indicators or dynamic market signals to further enhance decision-making accuracy and practical relevance.

Acknowledgment

The authors would like to acknowledge Third Shift Media (Pvt) Ltd for providing industry data, domain knowledge, and professional support that contributed to this study. The authors also acknowledge the University of Moratuwa for the academic guidance and research environment. Co-authors are gratefully acknowledged for their contributions to this work. In addition, the authors acknowledge the use of ChatGPT version 5.2 for language refinement and clarity improvement during manuscript preparation.

An Ensemble Learning Framework with Metaheuristic Optimization for Credit Card Fraud Detection

Agung Nugroho, Muhtajuddin Danny, Ismasari Nawangsih
Dept. of Informatics Engineering, Universitas Pelita Bangsa, Bekasi, Indonesia

***Abstract*—Credit card fraud detection is a major challenge in the financial system due to the characteristics of highly unbalanced data. This study proposes an ensemble learning approach combined with hyperparameter optimization using a Genetic Algorithm to improve the performance of fraud transaction detection. The results of the experiment showed that Random Forest achieved the best performance with a perfect Recall of 1.00 and an F1-Score of 0.903, outperforming the Stacking and Bagging models. Although the optimization significantly increases the training time, this method manages to accelerate the inference time to 0.0290 seconds, making it very feasible to apply to real-time banking security systems that require instant validation. This study confirms the effectiveness of integrating ensemble learning and metaheuristic optimization in dealing with the problem of unbalanced data.**

***Keywords*—Fraud detection; ensemble learning; Genetic Algorithm; Random Forest; real-time detection**

I. Introduction

The rapid increase in digital transactions has changed the global economic landscape, but at the same time, widened the gap for cybercriminal activities. Recent reports show that financial losses due to credit card fraud continue to increase as criminals adapt to conventional security protocols [1][2]. Conventional detection is difficult to rely on anymore because criminals always change their action patterns so that they are unreadable and appear like transactions in general [3]. Accurate early detection becomes crucial, as system failures not only impact direct monetary losses but also erode consumer confidence in the digital banking ecosystem as a whole [4].

The main challenge in detecting credit card fraud lies in the characteristics of extreme class imbalance, where the number of legitimate transactions far exceeds the number of fraudulent transactions with a ratio that can reach 1:1000 or more [5]. In addition, fraud behavior is dynamic (concept drift), where attack patterns are constantly changing to avoid rule-based detection. Traditional machine learning models often fail to address this imbalance, tending to result in high false negative rates that are particularly risky for financial institutions [6].

In recent years, researchers have explored the use of single machine learning models and deep learning to address this problem. However, recent studies show that single models such as Support Vector Machine, Logistic Regression, or Decision Tree often overfit or get stuck in local optima when dealing with high-dimensional data [7] and tend to produce high false negatives when faced with class imbalances between normal and fraudulent transactions [5]. Data imbalance is a major challenge because fraudulent transactions amount to less than 1% of the total data [8].

To overcome the limitations of a single model, the ensemble learning approach has become a prime choice due to its ability to combine the results of multiple algorithms to obtain more stable and accurate classification performance [9]. Approaches such as soft voting and ensemble stacking have been shown to improve detection accuracy and lower false positive rates compared to individual models [10]. The combination of several algorithms, such as Random Forest, AdaBoost, and XGBoost, also provides superior results in handling highly variable transaction data [11].

Nonetheless, the performance of the ensemble model relies heavily on the selection of precise hyperparameters and the selection of relevant features. Searching for parameters manually or using conventional grid search methods has proven to be inefficient and often fails to find the optimal configuration within a large search space [12]. Therefore, metaheuristic optimization algorithms such as Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Butterfly Optimization Algorithm (BOA) are used to automate the process of finding parameters and selecting the most relevant features [13]. This approach not only improves efficiency but also strengthens the model's ability to deal with high-dimensional datasets [14].

In addition, the integration of data balancing techniques such as SMOTE-ENN and K-means resampling has been proven to improve ensemble learning capabilities in dealing with extreme data imbalances [8]. This approach ensures the model not only focuses on the majority class, but is also able to recognize fraudulent transaction patterns with high accuracy [15]. The combination of metaheuristic optimization and ensemble learning results in models that are adaptive to data dynamics and changes in fraud patterns [16].

This study proposes a new framework that integrates Ensemble Learning with Metaheuristic optimization to detect credit card fraud more precisely. Most previous research has focused on improving accuracy without considering computational efficiency or generalizations on dynamic data [17]. Therefore, this study aims to develop an Ensemble Learning Framework with Metaheuristic Optimization that is able to balance detection performance, efficiency, and adaptability to changing transaction patterns.

II. METHODOLOGY

The methodology proposed in this study is systematically designed to build a robust fraud detection model, address the challenge of data imbalance through the SMOTE technique, and optimize performance through an ensemble stacking approach integrated with metaheuristic optimization. The overall workflow, as visualized in the research flowchart in Fig. 1, consists of five main stages: data collection, preprocessing, unbalanced data handling, model development, and matrix evaluation.

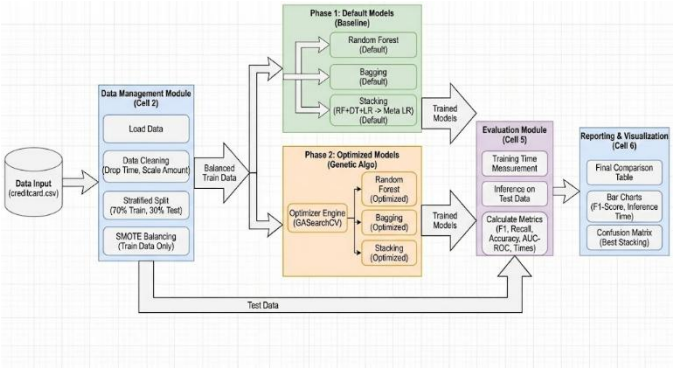

Fig. 1. Research flow.

A. Dataset

The initial stage begins with data input, where the target dataset, i.e., credit card transaction data, is loaded into the analysis environment. This dataset contains credit card transactions that will be the basis for learning for machine learning models. This dataset is sourced from Kaggle, which collected credit card transaction data from cardholders in Europe over two days in September 2013. The data covers a total of 284,807 transactions, of which only 492 transactions were identified as fraud [18]. The characteristics of this dataset are categorized as highly unbalanced due to the significant disparity in proportion between legitimate transactions and fake transactions. This class imbalance is a crucial challenge that is deeply considered in the development of this machine learning model. This dataset was chosen because it has been widely used as a benchmark in many studies on credit card fraud detection, allowing the results of this study to be objectively compared with previous studies [2][19].

B. Data Preprocessing

The preprocessing stage aims to ensure the quality and consistency of data before it is used for model training. First, data cleaning is carried out by removing irrelevant features such as time columns (Time) that do not contribute to fraud patterns, and performing feature scaling using the StandardScaler method to normalize numerical variables such as Amount. After that, the dataset was divided using a stratified split technique with a proportion of 70% training data and 30% test data, to ensure that the distribution of fraud and non-fraud classes remained balanced in each subset [20]. This process is important so that the model does not experience bias against the majority class during training or validation [21].

C. Handling Imbalance Data

One of the most critical challenges in fraud detection is the highly unbalanced nature of data (class imbalance), where the number of fraudulent transactions is much smaller than normal. If left unchecked, the model tends to be biased towards the majority class and fails to detect fraud. To overcome this, the Synthetic Minority Over-sampling Technique (SMOTE) is applied exclusively to the training data only. SMOTE works not by simply duplicating minority data, but by creating new synthetic samples based on interpolation between adjacent minority samples [22]. This approach results in a Balanced Train Data that allows the model to learn the characteristics of fraud more effectively without causing data leakage to the test data. This method helps to expand the search space for fraud patterns without copying data repeatedly [23].

SMOTE helps balance minority class data by synthesizing new samples, but can trigger overfitting if not implemented correctly. In order for the model to have good generalization capabilities, SMOTE is carried out through several stages: calculating the spacing of minority data, determining the percentage of SMOTE and k-value, and finally creating artificial data [24]. Details of this mechanism can be seen in Eq. (1):

$$x_{syn} = x_i + (x_{knn} - x_i) \times \delta \quad (1)$$

where, x_{syn} is the set of synthetic data to be generated, x_i is the data to be replicated, x_{knn} is the data and value closest to the data to be replicated, and δ is a random value between 0 and 1.

D. Model Development

The model development stage utilizes training data that has been balanced and carried out in two experimental phases using the Ensemble Learning approach. The ensemble method is known to improve generalization and robustness of predictions by combining several base models [25].

Phase 1: Default Models (Baseline). This phase aims to build performance benchmarks. The three ensemble architectures of Random Forest, Bagging, and Stacking are trained using the default hyperparameters. Specifically for the Stacking model, the architecture built consists of Random Forest, Decision Tree, and Logistic Regression as base-learners, with additional Logistic Regression serving as meta-learners to aggregate predictions. This approach was chosen because of its ability to combine the advantages of heterogeneous models to produce more stable and accurate predictions than single models [11].

Random Forest – can reduce overfitting by combining multiple decision trees [26][27]. Random Forest is configured with n_estimators=100, random_state=42, and n_jobs=-1. This configuration ensures reproducible results, efficient training, and stable performance in fraud detection.

Bagging Classifier – used to reduce model variance by using bootstrap sampling on the training data. This makes the model more stable and prevents overfitting [28].

Stacking Classifier – a combination of predictions from several base algorithms (base learners) through meta-learners. The purpose of this method is to take advantage of each algorithm so that its performance is more optimal (see Algorithm 1).

Algorithm 1: Stacking Model

Input: Training data after SMOTE balancing
Output: Trained stacking model
1: **Begin**
2: Initialize base learners $B=\{h_1, h_1, \ldots, h_3\}$
3: Train base learners: each h_k is trained on D'_{train} to generate predictions $\hat{y}_k$
4: Construct meta-features: for each sample x_i
$$M(x_i) = [h_1(x_i),\ h_2(x_i), \ldots, h_k(x_i)]$$
5: Train the meta-learner g using the pairs $(M(x_i), y_i)$
6: Final prediction: for a new sample x_j, the stacking prediction is $S(x_j) = g([h_1(x_j),\ h_2(x_j), \ldots, h_k(x_j)])$
7: **End**

Phase 2: Optimized Models (Genetic Algorithm). This phase focuses on improving the performance of the baseline model through hyperparameter optimization. The Optimizer Engine used is based on Genetic Algorithm (GA) through GASearchCV. GA mimics the natural selection process to iteratively evolve a population of parameter combinations to find the optimal configuration that maximizes fitness functions (e.g., F1-Score) for Random Forest, Bagging, and Stacking models.

GA works on the principle of natural selection, where the best combination of parameters is obtained through the process of selection, crossover, and mutation. The fitness function value used is 5-fold cross-validation. This algorithm allows the search for global solutions in complex parameter spaces, resulting in models with better generalizations of new data [16]. The combination of ensemble learning with metaheuristic optimization, such as GA, has been proven to be able to reduce false positive rates without sacrificing inference time significantly [29].

TABLE I. GA HYPERPARAMETER SETTINGS

Parameter	Setting
Population × Generations	6 × 3
Selection	Tournament
Crossover / Mutation	0.8 / 0.1
CV Strategy	5-fold stratified
Fitness	F1-score
Seed	42

Table I presents the detailed configuration of the Genetic Algorithm employed for hyperparameter optimization. The GA operated with a population size of six individuals across three generations, yielding a total of 90 model evaluations when accounting for 5-fold cross-validation. Tournament selection was adopted to maintain competitive pressure among candidate solutions, while crossover (0.8) and mutation (0.1) probabilities were set to balance global exploration and local exploitation of the search space. Elitism ensured that the best solution from each generation was preserved, contributing to rapid convergence as observed in the experimental results. Stratified 5-fold cross-validation was used as the fitness evaluation strategy to maintain class imbalance proportions and reduce overfitting risk. A fixed random seed (42) was applied to guarantee experimental reproducibility.

E. Matrix Evaluation

The final stage is a comprehensive evaluation within the Evaluation Module. It is important to emphasize that all trained models (both from Phase 1 and Phase 2) were evaluated using the original Test Data that was not touched by the SMOTE process. This ensures performance measurements reflect the model's ability to deal with unbalanced real-world data. Evaluation not only measures computational efficiency (training time and inference time), but also performance metrics that are crucial for unbalanced data cases. In addition to Accuracy, the analysis relies heavily on the metrics of Precision, Recall, F1-Score (harmonized average of precision and recall), and Area Under the ROC Curve (AUC-ROC) to provide a complete picture of the model's ability to minimize false negatives (fraud that escapes) and false positives (false alarms). The final results are presented in the form of comparison tables, bar graphs, and confusion matrices. This analysis helps identify the trade-offs between accuracy and efficiency in the implementation of a real-time credit card fraud detection system [30]. All equations can be defined in Eq. (2) to Eq. (5):

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} x\ 100 \quad (2)$$

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

$$Precission = \frac{TP}{TP+FP} \quad (4)$$

$$F1-score = 2\ \frac{precission * recall}{precission + recall} \quad (5)$$

TP and TN show the amount of positive and negative data that were correctly predicted. Meanwhile, FP and FN described misclassifications in each of these categories. The accuracy metric measures the extent to which target and non-target samples are precisely predicted, reflecting the ability of the test data to represent patterns in the training data [31]. There are two key elements that affect the level of accuracy, namely the amount of data and the imbalance conditions in the dataset used.

III. RESULTS

This study evaluated the performance of ensemble learning, namely Random Forest, Bagging, and Stacking in detecting credit card fraud through comparison of standard conditions and Genetic Algorithm (GA) optimization. Data imbalances were addressed with SMOTE on the training set, while the test data remained in the original distribution to maintain the relevance of reality. The evaluation focused on the Recall and F1-Score metrics in addition to accuracy, precision and AUC-ROC, given the importance of detecting fraudulent transactions on unbalanced data.

The analysis was conducted using public data from Kaggle on European cardholder credit card transactions as of September 2013. The two-day data collection consisted of 284,807 transactions with 492 of them being fraudulent. With a percentage of fraud classes that only reaches 0.172%, this dataset is classified as highly unbalanced. Fig. 2 presents a distribution graph for each of these classes.

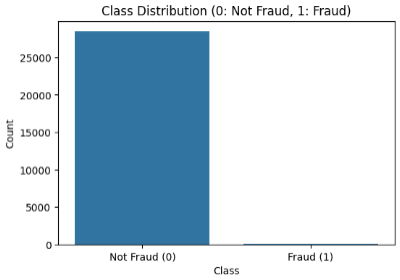

Fig. 2. Class data distribution.

The data is then divided into test data (30%) and training data (70%). In the training data, the SMOTE technique was applied to balance the classes. Initially, out of 199,364 training data, there were only 344 samples of fraud classes. However, after the balancing process, the number of each class (fraudulent and non-fraudulent) became equally large, at 199,020 samples. Details of the comparison before and after SMOTE can be seen in Table II and the graph in Fig. 3.

TABLE II. DATA TRAIN WITH SMOTE

Label (y)	*Row data*	*Row data with SMOTE*
0	199020	199020
1	344	199020

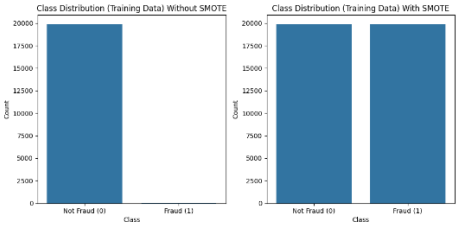

Fig. 3. Comparison data train with SMOTE.

A. Baseline Model Performance

Based on the initial experiment without optimization (baseline), there was a significant difference in performance between the three ensemble algorithms. Referring to Table III, the Stacking model shows the most superior performance with a perfect Precision of 1.00 and an F1-Score of 0.88, which indicates a high ability to minimize false positives. Random Forest (RF) also shows competitive performance with an Accuracy of 0.9995 and a Recall of 0.928, making it a fairly reliable baseline model. In contrast, the Bagging model showed the lowest performance with a Recall of only 0.50 and an F1-Score of 0.48, which indicates its inability to detect half of the total fraud cases that exist.

TABLE III. BASELINE MODEL PERFORMANCE (WITHOUT GENETIC ALGORITHM OPTIMIZATION)

Model	Accuracy	Recall	Precision	F1-Score	AUC-ROC
Random Forest	0.999532	0.928571	0.812500	0.866667	0.999883
Bagging	0.998245	0.500000	0.466667	0.482759	0.783282
Stacking	0.999649	0.785714	1.000000	0.880000	0.999908

B. Optimization of Genetic Algorithms for Model Performance

The application of the Genetic Algorithm aims to find the optimal combination of hyperparameters in each ensemble model. Based on the data in Table IV, the average fitness value for Random Forest increased from 0.9989 in the initial generation to 0.9998 in the 2nd generation with a decreasing standard deviation, indicating that the algorithm successfully converged to the optimal solution. The Random Forest and Stacking models show relatively rapid convergence, with consistent max fitness values since the first generation, while the Bagging model requires a wider variety of parameters before achieving optimal performance.

TABLE IV. RESULTS OF GENETIC ALGORITHM OPTIMIZATION

Model	Generation	Evaluations	Fitness (Mean)	Fitness Std	Fitness Max	Fitness Min
Random Forest (Optimized)	0	6	0.998947	0.00183917	0.999849	0.994836
	1	12	0.999778	0.00005692	0.999849	0.999699
	2	12	0.999841	0.00001184	0.999849	0.999824
Bagging (Optimized)	0	6	0.998746	0.00089185	0.998971	0.998394
	1	12	0.998959	0.00008410	0.999122	0.998846
	2	12	0.999063	0.00008763	0.999197	0.998971
Stacking (Optimized)	0	6	0.999774	0.00000561	0.999824	0.999699
	1	12	0.999820	0.00000936	0.999824	0.999799
	2	12	0.999824	0.00000000	0.999824	0.999824

The application of Genetic Algorithm-based hyperparameter optimization has a significant positive impact, especially on the Random Forest and Stacking models. Based on Table V, Random Forest (Optimized) managed to achieve a perfect Recall of 1.00 (up from 0.928) and an increase in F1-Score to 0.903, making it the best model for detecting all fraudulent transactions without false negatives. The Stacking (Optimized) model also experienced an increase in Recall to 0.857 from the previous 0.785, with a very high AUC-ROC of 0.99995. However, a different phenomenon occurs in the Bagging model, where the optimization actually lowers its performance (the F1-Score drops to 0.387), which indicates that the hyperparameter configuration found by GA may be causing overfitting or not matching the characteristics of the model.

Fig. 4 and Fig. 5 reinforce the numerical results in the comparison table, where Random Forest Optimized shows the most significant F1-Score improvement over other models. The Stacking model also showed consistent improvements, while the Bagging Optimized experienced a decrease in performance. This confirms that the effectiveness of GA optimization is highly dependent on the characteristics of the base model used in the ensemble.

TABLE V. MODEL PERFORMANCE COMPARISON (DEFAULT VS. OPTIMIZED)

Model	Accuracy	Recall	Precision	F1-Score	AUC-ROC
Random Forest	0.999532	0.928571	0.812500	0.866667	0.999883
Random Forest (Optimized)	0.999649	**1.000000**	0.823529	**0.903226**	**0.999908**
Bagging	0.998245	0.500000	0.466667	0.482759	0.783282
Bagging (Optimized)	0.997776	0.428571	0.352941	0.387097	0.783282
Stacking	0.999649	0.785714	**1.000000**	0.880000	0.999908
Stacking (Optimized)	0.999649	0.857143	0.923077	0.888889	**0.999954**

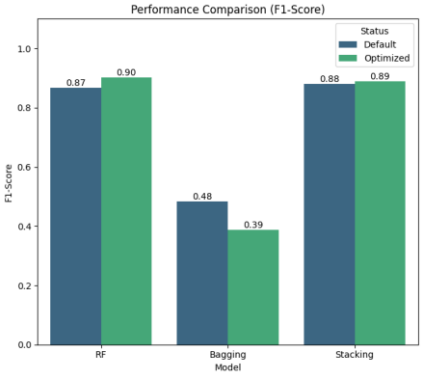

Fig. 4. Performance comparison (F1-score).

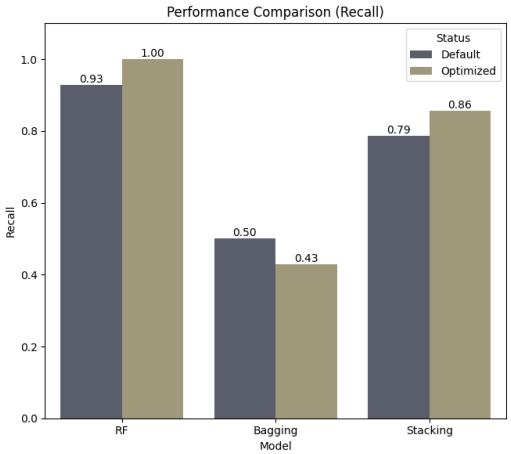

Fig. 5. Performance comparison (Recall).

C. Genetic Algorithm Convergence Analysis

Based on Fig. 6, it can be seen that fitness values increase rapidly in the early generation and then tend to stabilize in the next generation. This pattern shows that the Genetic Algorithm is able to find near-optimal solutions in a relatively small number of generations. The stable convergence also indicates that the GA parameters used have been quite effective in balancing the exploration and exploitation of the solution space.

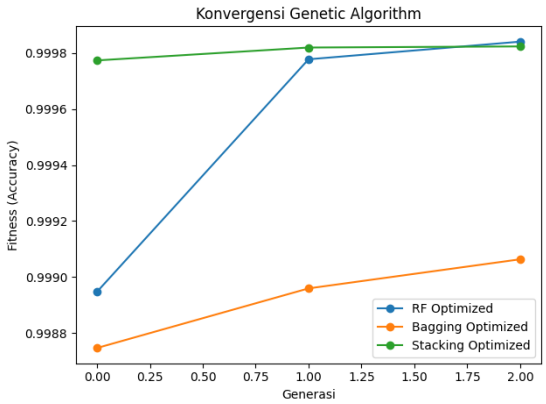

Fig. 6. Genetic Algorithm convergence.

D. Confusion Matrix Analysis and Classification Error Patterns

The confusion matrix analysis in Fig. 7 shows that the optimized Random Forest and Stacking models are able to significantly reduce the number of false negatives, which is a crucial aspect of the fraud detection system. The lack of fraudulent transactions that are misclassified as normal transactions indicates that the optimized model is more sensitive to the minority class. However, there are still a small number of false positives to be aware of, as they can impact the user experience in a real system.

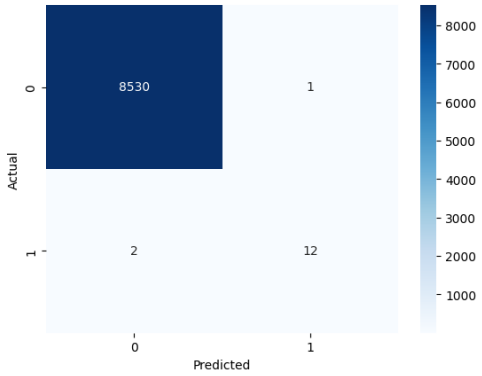

Fig. 7. Confusion matrix.

E. Computational Efficiency and Implementation Feasibility

The results of the computational efficiency evaluation in Table VI and Fig. 8 show that the optimization of the Genetic Algorithm significantly increases training time, especially in Random Forest and Bagging.

TABLE VI. TRAINING TIME AND MODEL INFERENCE

Model	Training Time (s)	Inference Time (s)
Random Forest	21.84	0.0428
Random Forest (Optimized)	434.27	0.0290
Bagging	14.88	**0.0105**
Bagging (Optimized)	1466.00	**0.0104**
Stacking	76.20	0.0691
Stacking (Optimized)	**2288.88**	0.0407

The compute experiment was run on the Google Colab platform with support for an NVIDIA A100 GPU, 16 GB of RAM, and a dual-core Intel Xeon virtual CPU. The entire model is built using the Scikit-learn library with a single-batch inference scheme.

The implementation of GA brings a significant trade-off between training time and inference time. Efficiency data shows a massive spike in training time; for example, Random Forest increased from 21.84 seconds (default) to 434.27 seconds after optimization, and Bagging jumped drastically to 1466 seconds. Nonetheless, it's interesting to note that optimization actually speeds up the time of inference or prediction. The Random Forest inference time is reduced from 0.0428 seconds to 0.0290 seconds, and Stacking (assumed from the context of the efficiency table) also shows a similar efficiency pattern during the prediction phase. This shows that although the initial computational costs (training) are very expensive, the resulting model is more compact and faster when used to detect transactions in real-time.

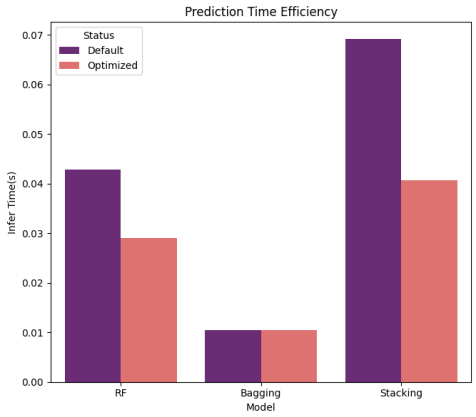

Fig. 8. Inference time.

Overall, the results of the experiment show that the combination of ensemble learning and Genetic Algorithm is effective in improving fraud detection performance, especially in the Random Forest and Stacking models. Improved Recall and F1-Score prove that this approach is capable of overcoming the challenge of data imbalance. However, performance improvements must be considered along with higher computing costs, so the selection of the best model needs to consider the needs of the system and available resources.

This study proves that hyperparameter optimization using a Genetic Algorithm can improve ensemble learning performance in detecting credit card fraud in unbalanced datasets. Random Forest Optimized emerged as the best model with a balance between detection performance and inference efficiency, making it the most viable candidate for practical implementation.

IV. Conclusion

This study concludes that the integration of Ensemble Learning with Genetic Algorithm (GA) optimization is proven to significantly improve fraud detection capabilities, especially in the Random Forest (Optimized) model, which managed to achieve peak performance with a perfect Recall of 1.00 and an F1-Score of 0.903. These results indicate the success of the model in identifying all fraudulent transactions without False Negatives, although the experiment also notes that this metaheuristic optimization has limitations because it is not effective for the entire algorithm, as seen in the performance degradation of the Bag model. From the computational aspect, it was found that there was a strategic trade-off where the use of GA did trigger a spike in training time, but at the same time was able to drastically cut the inference time to only 0.0290 seconds in the Random Forest model. Thus, this combination of maximum detection accuracy and high prediction time efficiency confirms that the model is very feasible and reliable to be implemented into real-time-based banking security systems that demand high speed and precision in the validation of each transaction.

Acknowledgment

This research was carried out with the support of Universitas Pelita Bangsa and the Ministry of Higher Education, Science and Technology in the form of competitive grant funding with contract number 002/7/KP.H/UPB/2025.

***Abstract*—Medical image compression is an active research area owing to the growth of the volume of medical image data in digital form. A method for lossless compression of medical images was proposed using logic minimization. The grayscale medical image is split into bit planes, and each bit plane is divided into blocks of fixed size, e.g., 8×4. The binary bit stream resulting from each of these blocks is treated as the output of a Boolean function, and logic minimization is attempted for a compact form. If this step fails to give a compact representation, the bits are stored as such. In this study, an extendable framework for lossless compression of medical images is presented. The bit plane is adaptively divided using a Quadtree to capture large uniform areas as leaf nodes. The non-uniform blocks at the leaf node are subjected to a logic minimization approach, as in the case of fixed-size blocks in previous related work. To improve the result further, the original image is gray-coded as a pre-processing step. On the bit plane, an XOR operation is done for the current block with the neighboring block for redundancy removal. This framework allows further exploration with the incorporation of other Boolean function representation techniques to enhance the compression.**

***Keywords*—Medical image compression; lossless compression; Quadtree; logic minimization; bit plane encoding; XOR operation; gray coding**

I. Introduction

Medical images such as X-rays [1], CT scans [2], and MRIs [3] contain critical diagnostic information and therefore must be stored and transmitted without any loss of information [4]. As healthcare systems increasingly rely on digital imaging, the volume of medical data has grown manyfold, creating challenges in storage, network bandwidth, and real-time clinical access. This has seen the lossless compression methods gain prominence in this area since they are used to maintain image fidelity as well as to decrease size and thereby enable efficient telemedicine workflows, long-term archival, and quicker retrieval of information in hospital information systems [5]. Close to perfect compression ratios and at the same time containing no loss is an unsolved research problem, particularly when it comes to heterogeneous medical imagery, with different textures and intensities. This study proposes a lossless framework of medical image compression that builds upon Quadtree-based [6] spatial decomposition together with Boolean logic minimization. The gray coding method is used on the input grayscale image in order to increase the inter-pixel correlation across bit planes [7]. A hierarchical Quadtree structure is then used to process each bit plane, starting with a 64×64-block then a 32×32 block, and then further on 16×16, and then finally an 8×8 block, depending on block uniformity. The leaf-level code produced during this decomposition is coded with the ESPRESSO logic minimizer in order to leverage the redundancy between binary patterns [8]. There are also blocks that fail to minimize well; these blocks are considered to be incompressible. In such situations, to further reduce entropy, an XOR-based prediction step is then used, with each incompressible block being XORed with its spatial neighbor to extract further regularity. The blocks that have been XOR-processed are then minimized with ESPRESSO, and blocks that return compression coded in this manner. The blocks that fail to yield compression shall be coded as incompressible. The suggested hybrid loss-less compression scheme, consist of gray-coding, multi-level Quadtree partitioning, logic minimization, and XOR-based refinement, is a customized scheme for medical images [9]. With the rise in the need for efficient handling of medical data in a modern healthcare setting, this stratified structure will strive to achieve maximum compression ratio, as well as pixel-perfect reconstruction to meet the increasing demands. The compression can also be optimized by incorporating any other methods to the incompressible blocks at the leaf level through this framework.

II. Related Work

A Quadtree is a hierarchical representation or structure, which recurrently divides an image into smaller and smaller parts [10, 11, 12]. Each block is checked at every stage to find out if the pixels of every block are of the same binary value. In such a way, the block turns into a leaf, otherwise it is divided into four equal quadrants, as illustrated in Fig. 1.

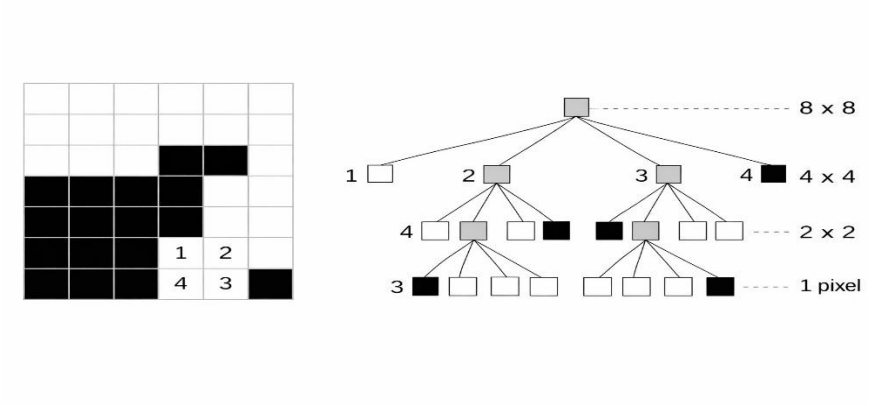

Fig. 1. Quadtree representation.

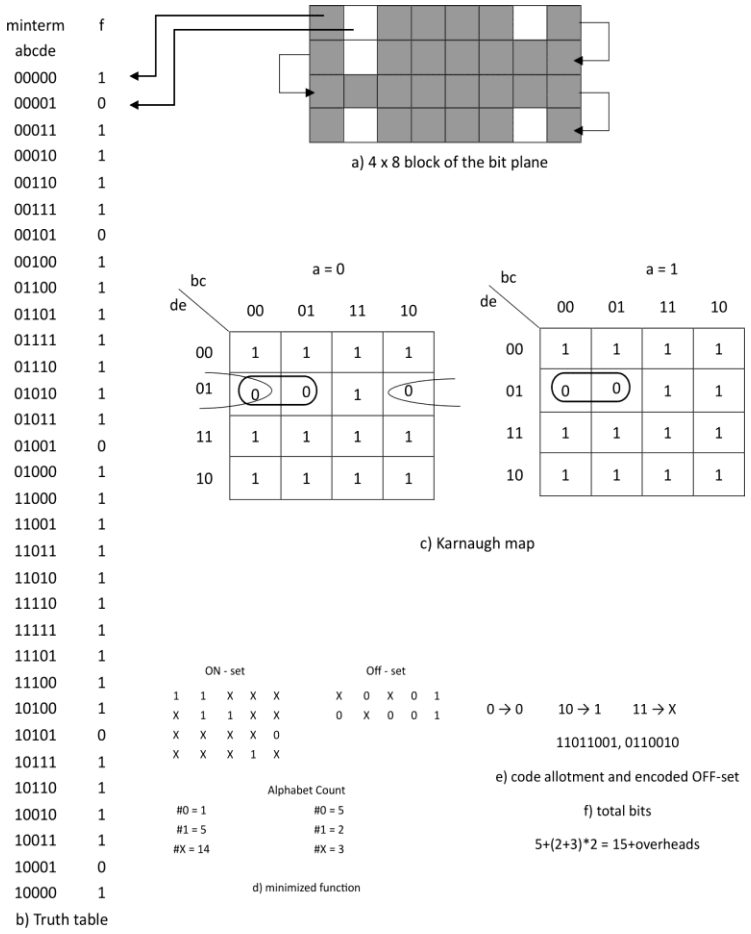

Fig. 2. Function generation and logic coding.

The adaptive representation enables the representation of large homogenous areas by a few nodes, which does not require the storage of redundant pixel data. Thus, for a binary image of size $2^n \times 2^n$, the entire region forms the root of the Quadtree, and subdivisions continue until each leaf contains only 0s or only 1s. Images with large homogeneous areas naturally stop at higher levels of the tree, producing a compact description. In this framework, the grayscale input image (8 bits per pixel) is first separated into eight bit-planes, from the least significant bit s_0 to the most significant bit s_7. Each bit-plane is there- fore a binary image that captures one layer of intensity information.

The Quadtree process is then applied to every bit-plane independently. Initially, each plane is divided into non-overlapping 64 × 64 blocks. This block size is chosen under the assumption that uniform regions are unlikely to extend beyond this scale. Each of these 64 × 64 blocks becomes a Quadtree root and is examined for uniformity. If the block is not homogeneous, it is subdivided to 32 × 32, and subsequently to 16 × 16 and 8 × 8, depending on the spatial variation of pixels [13].

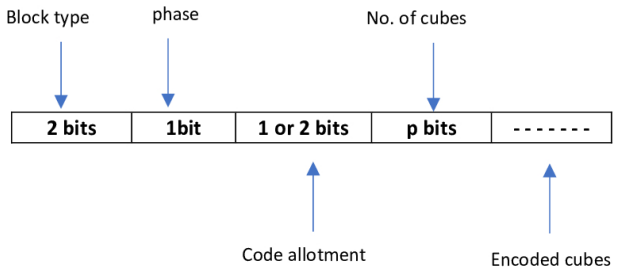

Fig. 3. Format of compressed image.

At the 8×8 stage, a change is incorporated. Rather than the Quadtree process, any non-uniform 8×8 block is further divided vertically to two 8 x 4 blocks. This is refined to capture to vertical structures and narrow column-oriented features that are seen in medical images. In lower bit-planes (s0–s3), these 8 × 4 regions often contain fine-grain details resembling noise, while in the higher bit-planes (s4–s7), they tend to preserve strong anatomical edges [14]. This stage prepares the binary data for logic minimization more effectively. Each 64 × 64 region is tested to ensure the Quadtree-based representation is actually beneficial. If the compressed representation produced by the Quadtree requires more bits than simply storing the block row-wise, the original block is kept instead. A single flag bit is stored to indicate whether Quadtree coding was used:

- 0 – the block is compressed using Quadtree rules
- 1 – the block is stored directly as raw pixels

Two bits are used at each internal node of the Quadtree to indicate the nature of the region:

- 00 – region is entirely black
- 01 – region is entirely white
- 10 – region requires further subdivision
- 11 – leaf node (special handling begins at the 8 × 8 level)

For a mixed region, subdivision continues until the 8 × 8 scale is reached. At this point, the region is split into two 8 × 4 blocks, and each 8 × 4 block is classified using two bits:

- 00 – block is all black
- 01 – block is all white
- 11 – block contains mixed pixels and must be encoded

For mixed 8 × 4 blocks, the corresponding 32-bit pattern is encoded using Boolean logic minimization through the ESPRESSO algorithm. If ESPRESSO produces a representation shorter than the raw block, the minimized form is stored and marked using:

- 0 – logic coding successful

If the minimizer is unable to reduce the block size, raw pixel data is stored instead:

- 1 – logic coding unsuccessful; retain original bits

Such a combination of multi-level Quadtree decomposition, non-uniform 8x8 areas being treated with special care and Boolean minimization allows the representation of structured and unstructured regions in the image to be made efficient and ensure that compression is no higher than the cost of storing the raw block.

A. Logic Coding

Jacob et al. [15] proposed an extension of the block-based binary image coding to the use of logic minimization principles. A grayscale image is split in their method into single bit-planes and each bit-plane is divided into blocks n x m size, both dimensions being powers of two [16]. Each block would belong to one of three groups, namely, all-black, all-white, and interracial. Short predetermined codes are assigned to uniform blocks, whereas mixed blocks get translated into switching functions and simplified using ESPRESSO logic minimizer [17]. The technique makes sure that only minimization causes compression of the number of bits; in case the original block cannot be compressed, the original block is kept [18].

The pixel positions are mapped to minterms by a process known as gray coding, such that adjacent pixels in the image can be translated to adjacent ones in the truth table [19]. This neighboring adds the probability of cube combining in the entity of minimization. In order to maintain this adjacency between rows, the algorithm switches forward and reverse scanning of rows [Fig. 2(a)]. Logic minimization [20] is sometimes capable of encoding a block of 32 pixels with a significantly smaller number of bits than necessary, e.g., 32 bits to around 15 bits, together with any overhead. The conversion of a 4x8 block into a five-variable switching function, the associated Karnaugh map groupings [21], and the number of alphabets in an ON-set and OFF-set cube, respectively, are shown in Fig. 2 [22]. There is always a frequency of cube occurrences and, based on these, prefix codes like 0, 10, and 11 are given to cube types [Fig. 2(e)]. The format of encoding of every block of bit-planes is shown in Fig. 3. A two-bit header identifies the block type:

- 00 for all-black blocks
- 01 for all-white blocks
- 10 for blocks successfully minimized
- 11 for blocks where minimization fails

In the case of incompressible blocks (type 11), original nm bits are simply stored at the end of the header, [23]. Another bit is used to show whether the best ON-set or OFF-set representation has been chosen in compressible blocks. A further code allocation step (summarized in Table I) uses a p-bit field, whose size varies from 1 to 6 depending on the block's minimization characteristics.

TABLE. I. PREFIX CODE ALLOTMENT TO SYMBOLS

Allotment Indicator	Code Allotment		
	0	1	X
0	0	10	11
10	11	0	10
11	10	11	0

The pixel values are replicated through an annual

assessment of the minimized cubes on all minterms of the block during decoding. One of the pixels is given a one in the end of a minterm held by any cube in the ON-set; a zero in the end of a minterm held by the OFF-set, or at the end of a minterm not subsumed by any RAM-ON cube. This subsuming cube- based reconstruction approach guarantees that the representation by the compression creates the binary framework of the block accurately (once the binary structure) [24].

III. Proposed Methodology

The suggested approach (illustrated in Fig. 4) starts with changing the input grayscale picture into its Gray-coded counterpart, such that adjoining intensity levels are a single step apart [25]. The changes make the binary transitions seen within the bit-planes more continuous to allow an even more compressible representation. The source pixel addresses with adjacent pixels represented by one bit difference are mapped to pixel positions using gray coding to allow those pixels to be packed in a narrow band together. The significance of this property is that it conserves the locality of space when a pixel block is viewed as a Boolean function [26]. As an example, a pixel value of 120 (binary 01111000) gets converted to gray code 01000100, the neighboring value 121 (binary 01111001) becomes 01000101, indicating that there is a change in the value of only a single bit between neighboring pixels. The Gray-coded image is then decomposed into eight bit-planes, each containing the 0^{th} to 7^{th} bit of all pixels. Since each bit-plane is now a binary image, further processing is performed independently on every plane. To capture spatial uniformity effectively, each bit-plane is divided into non- overlapping blocks of size 64×64. Every block serves as the root of a quadtree and is recursively split into 32 × 32, 16 × 16, and finally 8 × 8 regions. The splitting of an image recursively is shown in Fig. 5.

A block becomes a leaf whenever its pixels are uniform; otherwise, subdivision continues. This hierarchical partitioning concentrates detailed processing only on non-uniform regions while compactly representing large homogeneous areas. Once the 8 × 8 level is reached, the block is considered the fundamental unit for logic-based encoding.

Each non-uniform block at the finest level is treated as a Boolean switching function whose output corresponds to the binary values of the $n \times m$ pixels in the block [28]. The block is mapped to a function of $\log_2(nm)$ variables, and the widely used ESPRESSO logic minimizer is employed to reduce the number of cubes required to represent this function. Blocks for which minimization yields a reduction in bit count are stored in compressed form, while the remaining ones are labeled as incompressible and preserved in their original pixel format.

To further reduce the number of blocks that remain incompressible after the first round of logic minimization, an XOR-based refinement step shown in Fig. 6 is applied. This step uses a left-predictor model, where each block is predicted using its immediate left neighbor. Let $B(i,j)$ be the current block in row i and column j, and $B(i, j-1)$ be the block to its left. The residual block is computed as:

$$R(i,j) = B(i,j) \oplus B(i,j-1) \quad (1)$$

The first block in every row, $B(i, 0)$, has no left neighbor; therefore, prediction cannot be performed and the block is retained in its original form [29]. When neighboring blocks share similar structures, which is typical in medical images, the XOR operation cancels out the common patterns and produces a residual with a larger number of zeros. For example, consider a left block L and the current block C from a bit plane:

L = 10110110

C = 10100111

The XOR residual R is obtained as

$$R = L \oplus C = 00010001.$$

The resulting residual block contains long runs of zeros, which makes it more suitable for subsequent minimization using the logic-based compression stage. The residual block $R(i, j)$ is therefore passed through ESPRESSO for a second minimization attempt. In the proposed Scheme, heterogeneous leaf blocks are encoded using a compact header structure to indicate the applied transformations. For leaf blocks of size 8 × 8, a one-bit XOR header is first used to signal whether left predictive XOR has been applied between the current block and its immediate left neighbor, and logically minimized.

- 1: indicates that the XOR transformation is performed
- 0: denotes that the original block values are retained

After the XOR operation, the resulting block is subjected to Boolean logic minimization [27] using the ESPRESSO algorithm. After that, a one-bit storage type header is employed to show the state of whether the block is held as raw pixels or as minimized Boolean cubes.

- 1: represents raw storage
- 0: denotes logic-minimized representation

This combined encoding of Gray encoding, adaptive Quadtree partitioning, and separable steps of logic minimization with refinement of XOR is to improve compressibility without any relationships to the image being altered during the encoding process to maintain the lossless input of the reconstructed image.

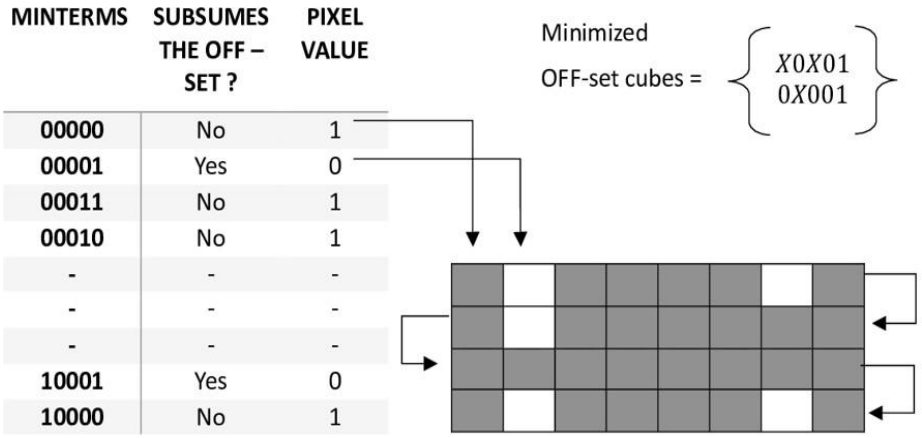

Fig. 7. Decompression scheme.

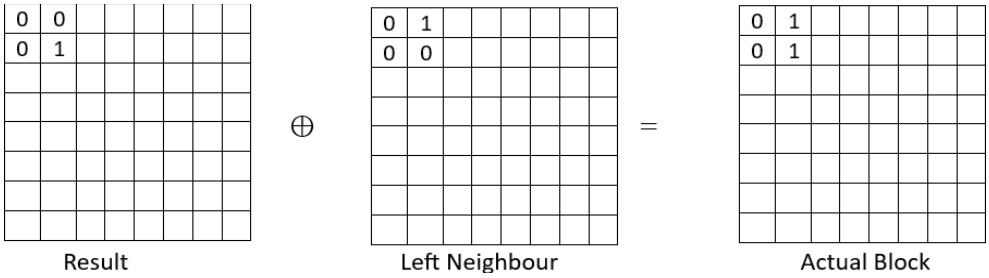

Fig. 8. Reverse XOR function.

A. Decompression Process

During decompression, each bit plane is reconstructed by decoding the compressed blocks in the same sequence used during encoding [29]. For blocks classified as all-black, all-white, or incompressible, recovery is direct since their pixel values were stored without applying logic minimization. For logic-coded blocks, the minimized switching function associated with the block is first rebuilt. The encoded data provide the block type, the phase bit, and the symbol-to-code mapping, from which the minimized ON-set or OFF-set cubes are recovered. Once these cubes are obtained, the switching function is expanded back to its truth-table form using cube subsuming: each minterm generated in Gray-code order is checked against the recovered cubes. A minterm that is contained within any cube of the ON-set is assigned a pixel value of 1, whereas a minterm subsumed by a cube of the OFF-set is assigned 0. Minterms not covered by the minimized cubes receive the complementary value. These values are then placed in their respective positions in the block, producing the reconstructed binary region and is depicted in Fig. 7. For blocks that underwent XOR-based refinement during compression, an additional reversal step is applied, as shown in Fig. 8. Because XOR is self-inverting, the original block C_i is reconstructed by XOR-ing the decoded residual block $R\hat{}i$ with its left predictor Li:

$$Ci = Li \oplus R\hat{}i \qquad (2)$$

Only the first block of each row omits this step, as it was stored directly during compression [30]. By combining logic-coded reconstruction with XOR reversal, each bit plane is recovered exactly as in the original grayscale image.

IV. Results and Discussion

The experimental evaluation was carried out on grayscale X-ray images (shown in Fig. 9) to examine the compression performance of the proposed multi-stage coding scheme which was carried out using Python version *3.13.3* on a Linux platform. Various images which are used here are collected

from Kaggle.com.

The compression efficiency was evaluated using the compression ratio, defined as:

$$Compression\ Ratio = (Size\ of\ original\ image)/(Size\ of\ Compressed\ image) \quad (3)$$

The compression ratios reported in this section, as shown in Table II, reflect the pure logic coding technique [15]. Adaptive segmentation technique [32] and cumulative effect of Gray coding [33] adaptive block partitioning, logic minimization, and XOR-based residual processing is compared with standard PVRG-JPEG Lossless [34] compression technique available.

PVRG-JPEG (Lossless)				
Compression Ratio	1.12	1.08	1.08	1.12
Compression Time (s)	0.02	0.03	0.03	0.03
Decompression Time (s)	0.001	0.001	0.001	0.01

For bit-plane *s*6 of image 1 (as shown in Table III), the Quadtree analysis at the 64 × 64 level shows that 32.50% of blocks are all-black, while no all-white blocks are observed, indicating the presence of large uniform dark regions but absence of bright uniform regions at this scale. The remaining 67.50% of blocks are mixed and therefore require further Quadtree subdivision. At the 32 × 32 level, the percentage of all-black blocks reduces to 18.52%, and all-white blocks increase slightly to 2.56%, while 81.48% of blocks remain mixed, suggesting that significant structural variations still persist. When the block size is reduced to 16 × 16, the proportion of homogeneous blocks in- creases to 16.76% all-black and 2.56% all-white, and the mixed blocks reduce to 80.68%, indicating gradual isolation of uniform regions. At the final 8 × 8 level, 15.67% blocks are all-black and 8.80% are all-white, while a dominant 75.53% blocks become leaf nodes and are forwarded to the logic minimization stage. After applying the ESPRESSO logic minimizer on these 8 × 8 leaf blocks, only 43.63% of blocks are identified as compressible, whereas 56.37% remain incompressible, showing that despite spatial uniformity, logical redundancy is insufficient in many blocks of this higher bit-plane. To further improve compression, left-neighbor predictive XOR coding is applied to these incompressible blocks, followed by a second pass of logic minimization. After XOR, the compressible block percentage becomes 5.53%, while 94.47% blocks still remain incompressible, indicating that although XOR introduces some decorrelation [31] and simplification, the dominant edge and anatomical structures present in the s6 plane limit further Boolean simplification [35]. This behavior is expected for higher bit-planes, where major structural information is preserved, making them less amenable to logic-based compression even after predictive coding. Table III to Table VI shows the statistics of all four images. Fig. 10 compares four approaches to compressing an image: Fixed Block Size, Adaptive Segmentation, Gray Coding-XOR, and PVRG-JPEG (Lossless). The figure is made up of three subplots, which show different performance measurements of each method. The first subplot shows the compression ratio that shows the efficiency of each method in reducing the image size. An increased compression ratio implies increased compression efficiency. The second subplot depicts the compression time which is the duration every method requires to compress the images another important aspect when comparing the speeds of compression techniques. The third subplot revolves around the decompression time as it shows the time needed to restore the images back to their original state. This ratio is most suitable when the application requires details that are real-time. In combination, these subplots present the in-depth evaluation of the compression effectiveness of each approach, processing speed, and decompression effectiveness of each approach, which is of great importance in terms of identifying which one to use in each practice.

TABLE. III. OVERALL STATISTICS FOR IMAGE 1 (PER CENT VALUES)

Block Level	Code Type	s0	s1	s2	s3	s4	s5	s6	s7
	All Black	17.50	17.50	17.50	20.00	25.00	26.25	32.50	37.50

	Quadtree	92.87	92.65	92.43	92.67	92.94	85.20	80.68	77.99
	All Black	3.63	4.11	4.33	4.62	8.19	13.83	15.67	14.77
8x8	All White Leaf Node	0.00 96.37	0.00 95.89	0.00 95.67	0.27 95.11	3.21 88.61	3.61 82.55	8.80 75.53	14.82 70.41
	Compressible Blocks	0.77	1.51	7.47	16.74	23.21	35.83	43.63	40.87
	Incompressible Blocks	99.23	98.49	92.53	83.26	76.79	64.17	56.37	59.13
Post-XOR Logic Minimization Applied to the above Incompressible Blocks									
Compressible Blocks after XOR		0.03	0.06	0.20	1.04	1.53	2.28	5.53	3.39
Incompressible Blocks after XOR		99.97	99.94	99.80	98.96	98.47	97.72	94.47	96.61

For the compressible blocks, the distribution of ON-set and OFF-set cubes is computed. Between the two, the smaller set is chosen for encoding to ensure a more compact Boolean representation. This adaptive selection contributes to improved compression efficiency without increasing reconstruction complexity. Although in higher bit planes, pixel values mainly represent sharp edges and major structural boundaries. Applying left-predictive XOR across such edges produces irregular residual patterns, which reduces block uniformity and limits the scope for Boolean minimization. As a result, some MSB planes show a slight negative gain in compression after XOR.

Overall, the results demonstrate that progressive spatial refinement down to 8×8 blocks, combined with selective XOR-based preprocessing of incompressible regions, enhances the effectiveness of Boolean function minimization across all bit planes.

V. CONCLUSION AND FUTURE SCOPE

A lossless compression framework for grayscale medical images using logic minimization is proposed. Core of the scheme is treating the bit stream at the blocks of the bit planes of the image as a Boolean function, and representing it in its minimized form. All blocks do not yield a smaller representation this way. When a block does not result in a smaller representation, the bits are stored as such. A switching function of n variables has 2^n minterms which are combined by the logic minimizer ESPRESSO into cubes. Each minterm is a vertex on a binary hypercube and the minimizer try to cover the vertices belonging to ON set into a cube which is a compact representation. ESPRESSO minimizer was developed for VLSI synthesis (of Programmable Logic Arrays) of Boolean functions with many variables. This minimizer is not the optimal one in the compression experiment where the number of variables is 5 or 6 and not 50. This minimizer was used owing to the fact that it is a proven tool and good enough to establish the proof of concept though not optimal in terms of execution time. It is always possible to create an optimal minimizer suitable for functions with a smaller number of variables. So, the time of execution reported for both compression and decompression can easily be improved with an optimized logic minimizer.

The total combination of functions for an n variable Boolean function is $2^{\{2^n\}}$. One of the functions is tautology (always 1) and the other is XOR function. Cube based minimizer do not yield optimal representation for all type of functions. For example, XOR function has a poor representation in the cube form but has an efficient representation if Binary Decision Diagrams (BDDs) are used. It is planned to explore these techniques to target blocks which are incompressible in the current scheme. As there is a general framework, new approaches can be incorporated easily.

The experiment based on the method proposed in this study is an improvement on the coding using fixed block size on the bit planes. With Quadtree, gray coding and prediction, an improvement in compression ratio is achieved though not significant over the previous method based on fixed block size. Incorporation of other techniques to handle incompressible blocks can be tried to push up the compression ratio. By looking at the statistics presented in experimental result, it is evident that some of the incompressible blocks will yield result with another representation of Boolean functions. These are some of the future directions planned for exploration.

An Empirical Evaluation of Multivariate Temporal Convolutional Networks with Global Market Indicators for Forecasting the Indonesian LQ45 Index

Yohanes Marakub, Muhammad Zarlis
Department of Information Systems Management, Bina Nusantara University, Jakarta, Indonesia

***Abstract*—This study develops a multivariate Temporal Convolutional Network (TCN) framework to forecast the LQ45 stock index using daily time-series data from January 2015 to January 2025. The objective is to examine whether incorporating global market indicators, namely the Volatility Index (VIX), Brent crude oil price, and the Effective Federal Funds Rate (EFFR), alongside lagged LQ45 values, improves forecasting performance in Indonesia's equity market. Two comparison models are considered: an Autoregressive Integrated Moving Average with Exogenous Variables (ARIMAX) model as a statistical baseline and a univariate TCN as a deep learning benchmark. Data preprocessing includes normalization and a seven-day sliding-window framing. Forecasting accuracy is evaluated using Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and Mean Absolute Percentage Error (MAPE), complemented by validation and interpretability analyses. The results show that while the multivariate TCN captures interactions among multiple temporal features, it does not provide measurable performance advantages over ARIMAX or the univariate TCN. The lagged LQ45 series exhibits the strongest predictive contribution, followed by EFFR with a stable secondary effect, whereas Brent oil prices and VIX display weak and unstable influences. These findings suggest that in short-horizon forecasting of relatively stable emerging markets, integrating exogenous variables showed no performance improvement and was associated with higher forecast error when their predictive structure was unstable, highlighting the trade-off between feature complexity and model robustness.**

***Keywords*—Deep learning; financial forecasting; multivariate forecasting; TCN; time series analysis**

I. Introduction

A stock represents a unit of ownership in a company and is one of the most traded financial instruments in the capital market. In Indonesia, the performance of listed companies is measured through market indices that summarize the movement of selected securities. Among these indices, the LQ45 Index, which was introduced by the Indonesia Stock Exchange (IDX) in 1997, consists of forty-five companies, selected based on liquidity and market capitalization, representing fundamentally strong and actively traded equities [1]. The index serves as a primary benchmark for evaluating market performance and has become a key indicator for investors to assess the stability and attractiveness of the domestic capital market [2]. The value of stock indices, including the LQ45, is influenced by both domestic factors and global market indicators that shape investor sentiment and cross-border capital flows in emerging markets [3]. Therefore, forecasting the movement of the LQ45 Index is essential to support investment decision-making and risk management in Indonesia's financial market.

The movement of the LQ45 Index is also affected by global financial conditions and external market indicators that transmit volatility and capital flow shocks into Indonesia's capital market. One of the key indicators, the Volatility Index (VIX), reflects investor sentiment and global risk perception, which can drive fluctuations in emerging market equities [4]. Brent oil prices, on the other hand, reflect both global energy demand and inflationary expectations that significantly affect stock market dynamics in Asian economies.

Studies in China and ASEAN countries confirm that oil price shocks have a strong influence on equity volatility, sectoral performance, and risk spillovers [5, 6]. Moreover, the Effective Federal Funds Rate (EFFR), reflecting the operational stance of U.S. monetary policy, serves as a transmission channel through which global liquidity conditions affect equity markets across Asia, as documented by evidence on U.S. policy spillovers to emerging economies [7, 8]. These interconnected factors highlight the importance of a multivariate predictive framework that can incorporate global indicators to improve the accuracy of LQ45 Index forecasts.

Previous studies have employed both classical statistical methods, such as Autoregressive Integrated Moving Average (ARIMA) and modern deep learning architectures including Recurrent Neural Networks (RNN) and Long Short-Term Memory (LSTM) to forecast financial time series and other real-world temporal data [3,9]. Although these models have achieved satisfactory forecasting performance, most prior studies relied on domestic or univariate data without incorporating external market indicators, despite evidence that global financial dynamics significantly influence Indonesia's stock market performance [10].

Moreover, while Temporal Convolutional Networks (TCN) have been increasingly applied in financial time series modeling, their application in forecasting the LQ45 Index has not yet been widely examined. This is important because recent studies in both financial and non-financial domains have shown that TCN can achieve higher stability and accuracy than recurrent architectures such as LSTM and RNN when modeling long-term temporal dependencies [11, 12]. Therefore, this study applies a multivariate TCN framework and systematically compares it with a univariate TCN and a classical Autoregressive Integrated Moving Average with Exogenous Variables (ARIMAX)

baseline to evaluate whether the integration of the Volatility Index (VIX), Brent crude oil price, and the Effective Federal Funds Rate (EFFR) provides measurable forecasting benefits for the LQ45 Index. This research contributes empirical evidence on the practical value and limitations of incorporating global market indicators into deep learning-based forecasting models for Indonesia's equity market.

The remainder of this study presents the related literature, research methodology, experimental results and discussion, followed by the conclusion.

II. Literature Review

A. Classical and Statistical Forecasting Models

Classical statistical models, such as the Autoregressive Integrated Moving Average (ARIMA) and its multivariate extension, ARIMAX, have long been established as fundamental tools for time series forecasting due to their interpretability and low computational cost. In the Indonesian stock market, traditional time series and econometric approaches remain widely used when analyzing or modeling the behavior of the LQ45 Index, and linear frameworks continue to dominate empirical studies linking macroeconomic variables with LQ45 movements [2]. Globally, ARIMA-based models are still frequently compared with modern machine learning approaches, as they provide stable baselines for short-term and linear data series [13].

However, the rigid linear structure of ARIMAX limits its capacity to learn contextual temporal dependencies or feature representations when data exhibit volatility and cross-variable interaction [14, 15]. This structural limitation has encouraged the use of deep learning architectures that rely on hierarchical convolutional or recurrent mechanisms to capture dynamic and long-term temporal patterns more effectively. Even when configured with linear activation functions to maintain continuous forecasting behavior, models such as Recurrent Neural Networks (RNN), Long Short-Term Memory (LSTM), and Temporal Convolutional Networks (TCN) remain capable of learning multi-scale dependencies across time [3].

B. Deep Learning Approaches in Financial Time Series

Deep learning techniques have become increasingly popular in financial forecasting due to their capability to model nonlinear patterns and long-term temporal dependencies that conventional statistical models cannot capture. Recurrent neural architectures such as Recurrent Neural Networks (RNN) and Long Short-Term Memory (LSTM) have demonstrated strong performance in sequential modeling, including LQ45 stock index prediction [3], yet they are limited by sequential computation and gradient instability.

Temporal Convolutional Networks (TCN) were introduced as an alternative architecture that uses causal and dilated convolutions to support stable gradient propagation and parallel processing, enabling more reliable, robust, and efficient learning under volatile market conditions [16]. Recent reviews in financial time series forecasting further indicate that convolution-based architectures, including TCN, effectively extract hierarchical local features and provide stronger flexibility for modeling nonlinear market patterns compared with classical approaches [17, 18].

C. The Role of Global Market Indicators

While deep learning architectures such as the Temporal Convolutional Network (TCN) have demonstrated strong capability in capturing temporal structures and long-range dependencies, previous studies indicate that deep learning models achieve improved predictive performance when incorporating diverse and high-quality external market indicators [19, 20]. In financial forecasting, such external factors, commonly referred to as global market indicators, serve as exogenous variables that capture cross border interactions affecting stock index movements.

Among the most influential are the Volatility Index (VIX), Brent crude oil price, and the Effective Federal Funds Rate (EFFR). The VIX reflects global investor sentiment and risk perception, and its spikes often lead to increased uncertainty and capital outflows from emerging markets [4]. Brent crude oil prices represent global energy demand and inflationary expectations, significantly influencing stock market volatility and sectoral performance in Asian economies [5, 6]. Meanwhile, the EFFR represents the stance of United States monetary policy, shaping international capital flows and liquidity across Asian emerging markets [7, 8].

Collectively, these indicators represent volatility, commodity, and monetary dimensions of global finance, all of which jointly influence the performance of regional indices such as LQ45. Integrating these global dynamics into forecasting frameworks therefore enables a more comprehensive representation of market behavior and improves model robustness in capturing cross market interdependencies.

D. Research Gap and Novelty

Previous studies have applied various methods to forecast the LQ45 Index, including classical statistical models such as ARIMA and deep learning architectures like Recurrent Neural Networks (RNN) and Long Short-Term Memory (LSTM) [1, 3]. Although these models achieved reasonable accuracy, most relied on domestic or univariate data without integrating global indicators, even though prior evidence shows that international financial dynamics can affect equity performance in Asian emerging markets, including Indonesia [2, 10]. Traditional models such as ARIMA are constrained by linear assumptions and limited ability to represent complex temporal structures [9, 13]. Recurrent architectures like LSTM capture short-term dependencies but remain restricted by sequential computation and overfitting risk when processing long sequences [21].

In contrast, Temporal Convolutional Networks (TCN) provide longer effective memory, parallel training efficiency, and stable gradients, consistently outperforming recurrent models in sequence forecasting [22]. However, limited evidence exists regarding how exogenous feature integration interacts with advanced convolutional architectures such as TCN in short-horizon LQ45 forecasting, particularly in evaluating the predictive role of global indicators including VIX, Brent crude oil, and EFFR. Therefore, this study develops a multivariate TCN framework integrating these indicators and compares it with the ARIMAX baseline to examine the implications of

feature stability and model complexity in short-horizon financial forecasting.

III. METHODOLOGY

A. Research Framework and System Overview

The proposed research framework aims to evaluate the forecasting performance of Temporal Convolutional Network (TCN) and ARIMAX models for predicting the LQ45 stock index based on global indicators: VIX, Brent Oil, and the Effective Federal Funds Rate (EFFR). The framework consists of five stages: data acquisition, preprocessing, hyperparameter optimization, model development, and performance evaluation with subsequent analysis, as shown in Fig. 1. This structured pipeline ensures methodological consistency across experimental settings and facilitates a systematic comparison between statistical and deep learning approaches.

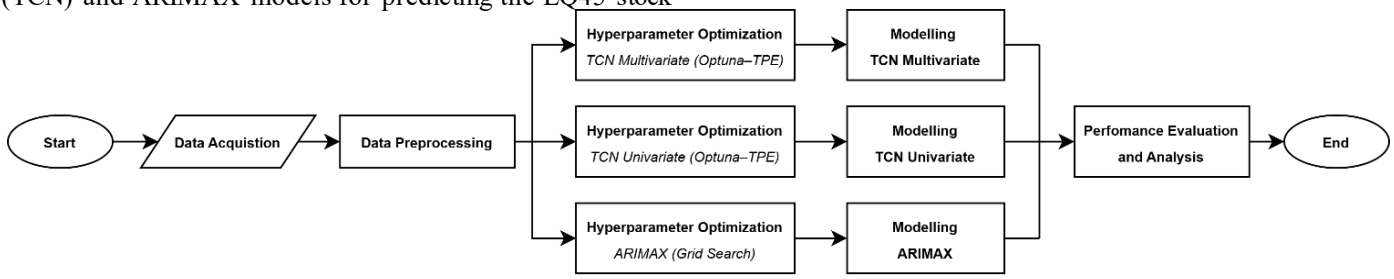

Fig. 1. Research framework for LQ45 forecasting using TCN and ARIMAX models.

The data flow begins with the collection of daily financial data, followed by preprocessing steps to ensure consistency and readiness for model input. Model training and tuning are conducted independently for both TCN variants using Optuna TPE, and for ARIMAX using grid search. The final stage focuses on performance evaluation and analysis using both statistical and interpretability metrics. Detailed descriptions of each stage are provided in Section III-B to Section III-F.

B. Data Description and Collection

The dataset used in this study consists of daily financial data covering the period from January 2015 to January 2025, selected to capture multiple market phases including pre-pandemic stability, the COVID-19 shock, and recovery dynamics. The dependent variable is the LQ45 stock index, representing the performance of the 45 most liquid and fundamentally strong stocks listed on the Indonesia Stock Exchange (IDX). Historical lag values of LQ45 are included to capture short-term temporal dependencies relevant for forecasting. Three global indicators are incorporated as exogenous variables: the Volatility Index (VIX) to reflect global risk sentiment, Brent Crude Oil price to represent commodity-related macroeconomic exposure relevant to Indonesia, and the Effective Federal Funds Rate (EFFR) to capture global monetary policy influence. LQ45, VIX, and Brent Oil data were obtained from Yahoo Finance, while the EFFR was collected from the Federal Reserve Economic Data (FRED). All variables were synchronized by date to ensure temporal alignment and consistency, producing 2,591 daily observations for each variable.

C. Data Preprocessing

The preprocessing phase ensures that all variables are properly structured and ready for supervised learning. The temporal alignment of exogenous indicators was refined based on Granger causality screening (lags 1–10), where statistically significant relationships ($p < 0.05$) were detected across multiple lag intervals, although the strength and stability of significance varied across VIX, Brent, and EFFR. This procedure follows the principle that causal influence in time-series systems may emerge at different lag intervals across variables [23]. Missing values were handled using linear interpolation, a simple yet effective approach for short gaps in continuous time-series data [24]. Outlier detection was conducted using the interquartile range (IQR) method; however, extreme values were retained since financial returns exhibit heavy-tailed behavior, and such extreme fluctuations contain valuable information about market dynamics [25]. A sliding-window framing with a seven-day lookback was then applied to generate input-output sequences for one-step-ahead forecasting. This window length was selected based on empirical findings demonstrating that a seven-day window achieves the best predictive accuracy in financial time-series forecasting before performance declines with longer input spans [26]. Finally, the dataset was chronologically divided into 80% training and 20% testing subsets, with 10% of the training portion allocated for validation, and all features were normalized using Min-Max scaling to ensure consistent numerical ranges across the dataset.

D. Model Architecture and Implementation

This study employs two forecasting models, namely the Autoregressive Integrated Moving Average with Exogenous Variables (ARIMAX) as the statistical baseline and the Temporal Convolutional Network (TCN) as the deep learning model. Both are designed to perform one-step-ahead prediction of the LQ45 Index using seven-day sliding-window sequences as inputs.

1) ARIMAX: ARIMAX is an extension of the ARIMA framework that incorporates exogenous variables to improve forecasting accuracy when external drivers influence the target series. The model combines autoregressive, differencing, and moving-average components with lagged external predictors, enabling it to represent both internal temporal dynamics and the impact of relevant external signals. Recent studies have shown that ARIMAX remains a widely used statistical approach for time series forecasting, particularly in applications where external environmental or climatic variables inform system behavior. Its formulation relies on stationarity assessment, order identification through ACF and PACF patterns, and parameter selection based on information criteria, ensuring that the resulting model remains parsimonious and interpretable.

Although ARIMAX may struggle in highly nonlinear settings, it provides a stable and computationally efficient baseline for forecasting tasks involving exogenous influences [27]. As a linear parametric framework, ARIMAX assumes additive relationships and stationarity of the underlying series, which may constrain its flexibility in capturing nonlinear or regime-dependent financial dynamics. In this study, model order selection was conducted through grid search over p, d, q combinations, allowing the differencing parameters to adapt to potential non-stationary behavior. However, formal unit-root tests such as ADF or KPSS were not explicitly reported and are acknowledged as a methodological limitation.

Recent empirical research has further validated the robustness of ARIMAX as a baseline model in financial forecasting. Previous studies have applied the ARIMAX model to the Vietnam stock index (VNINDEX) by incorporating dual market indicators as exogenous variables and demonstrated that ARIMAX outperformed non-linear benchmarks such as LSTM, GA-LSTM, XGBoost, and Prophet [14]. Their results confirmed that ARIMAX provides a reliable and interpretable framework for capturing the influence of external factors on financial time-series movements while maintaining computational efficiency and model stability.

In this study, ARIMAX serves as the statistical baseline for benchmarking the proposed deep learning approach. Empirical findings indicate that ARIMAX performs consistently well in financial forecasting when relevant exogenous variables are included and can outperform nonlinear alternatives when external signals exhibit strong explanatory strength [14]. In multivariate settings, improvements in predictive accuracy are further enhanced when exogenous drivers are properly specified, reinforcing ARIMAX as a stable and interpretable benchmark for comparison with deep learning models [27]. These insights collectively reinforce the role of ARIMAX as a stable and interpretable statistical benchmark, making it suitable for comparative evaluation against deep learning models.

2) Temporal Convolutional Network (TCN): Temporal Convolutional Network (TCN) is a convolution-based deep learning architecture designed for sequential data modelling. Unlike recurrent neural networks that process information step by step, TCN applies one-dimensional causal convolutions so that each output at time t depends only on the current and past inputs, thereby maintaining temporal causality. The model extends its receptive field through dilated convolutions, where gaps are inserted between filter elements to capture long-term dependencies without increasing the number of parameters. Each convolutional layer operates in parallel across time steps, which allows faster computation and more stable gradient propagation compared with recurrent structures.

The standard TCN architecture consists of stacked residual blocks that include two layers of dilated causal convolution, weight normalization, ReLU activation, and dropout, followed by an optional 1×1 convolution to align feature dimensions. These components collectively expand the receptive field, regulate parameter magnitudes, mitigate overfitting, and maintain consistent feature dimensionality across layers. Combination of dilation, residual pathways, and normalization mechanisms enables more stable gradient propagation and supports efficient optimization, allowing the architecture to represent both short-range and moderately long-range temporal dependencies [22].

Recent reviews on financial forecasting highlight growing interest in convolution-based sequence models, including architectures such as TCN, due to their ability to capture hierarchical local patterns and nonlinear temporal dynamics that classical statistical models struggle to represent [17]. These convolutional architectures learn temporal structure through stacked filters that efficiently extract multi-scale dependencies, reinforcing the suitability of TCN for modelling nonlinear financial time series [17]. In this study, the TCN framework was implemented using a seven-day sliding-window input, where dilations (1, 2) were applied to expand the effective receptive field beyond the input length, allowing the model to capture both short-term variations and broader temporal patterns while maintaining computational efficiency.

E. Experimental Setup and Tuning

The experimental setup was designed to provide a consistent and reproducible environment for model training and evaluation. All experiments were executed locally using GPU acceleration, as summarized in Table I. The software stack consisted of Python 3.10 and TensorFlow 2.15, with Optuna employed for automated hyperparameter optimization. Fixed random seeds were applied to ensure reproducibility across trials and to minimize stochastic variation during model training. This configuration ensured a stable computational environment throughout the experimental process.

TABLE I. EXPERIMENTAL ENVIRONMENT AND SYSTEM CONFIGURATION

Component	Specification
Device	Laptop with AMD Ryzen 7 5800H CPU (8 cores, 16 threads) and RTX 3060 GPU (6 GB)
Operating System	Windows 11 Home 64-bit
RAM	16 GB DDR4
Programming Language	Python 3.10
Deep Learning Framework	TensorFlow 2.15, Keras (via tf.keras)
Supporting Libraries	NumPy, Pandas, scikit-learn, Optuna
ARIMAX Optimization	Grid search over (p,d,q) combinations based on MAE
TCN Optimization	Optuna TPE Sampler (150 trials)
Reproducibility Settings	random.seed(42), numpy.random.seed(42), tf.random.set_seed(42)
Execution Environment	Local GPU (Laptop, non-cloud setup)

To ensure a fair and objective comparison between the forecasting models, a systematic hyperparameter tuning procedure was conducted for both ARIMAX and TCN. Each model was tuned independently using optimization strategies appropriate to its underlying structure to identify configurations that yield optimal predictive performance while maintaining model stability and reproducibility. In addition, all hyperparameter tuning experiments were conducted under identical data splits and evaluation protocols to ensure comparability across models. This design choice minimizes potential bias arising from data leakage or inconsistent validation settings during the optimization process.

ARIMAX was optimized using grid search over selected autoregressive, differencing, and moving-average orders. The TCN models were tuned automatically using Optuna with a Tree-structured Parzen Estimator (TPE) sampler, which efficiently explored parameters such as filters, dense units, learning rate, batch size, and dropout rate. This Bayesian optimization approach adaptively selected promising configurations and has been shown to achieve higher tuning efficiency compared with grid or random search strategies [28, 29]. Table II summarizes the defined search space and the optimal hyperparameters identified through the Optuna process.

TABLE II. HYPERPARAMETER SEARCH SPACE AND OPTIMAL CONFIGURATIONS FOR ARIMAX AND TCN MODELS

Model	Parameters	Search Space	Optimal Value
ARIMAX	Order (p, d, q)	$p \in \{1, 2\}$, $d \in \{0, 1\}$, $q \in \{0, 1\}$	(2, 0, 1)
TCN Univariate	Dilations	Fixed = [1,2]	[1,2]
	Kernel Size	Fixed = 2	2
	Filters	[16, 32, 64]	16
	Dense Units	[8,16,32]	32
	Learning Rate	[1e−4, 1e−3] (log-uniform)	2.90×10^{-4}
	Batch Size	[8, 16, 32]	32
	Dropout Rate	[0.0, 0.2]	0.08
TCN Multivariate	Dilations	Fixed = [1,2]	[1,2]
	Kernel Size	Fixed = 2	2
	Filters	[16, 32, 64]	32
	Dense Units	[8,16,32]	8
	Learning Rate	[1e−4, 1e−3] (log-uniform)	4.44×10^{-4}
	Batch Size	[8, 16, 32]	32
	Dropout Rate	[0.0, 0.2]	0.20

Each model was trained for a maximum of 100 epochs with early stopping (patience = 30) to prevent overfitting. The Univariate TCN converged at epoch 65, while the Multivariate TCN reached optimal validation accuracy at epoch 86. For ARIMAX, the search space was restricted to low-order combinations ($p \in \{1,2\}$, $d \in \{0,1\}$, $q \in \{0,1\}$) as part of this study's methodological design. This follows the parsimony principle, where parsimonious ARIMA-type models are preferred over over-parameterized alternatives for stability and computational efficiency [30].

The dilation pattern (1, 2) was selected to capture short-to-mid-term dependencies within the seven-day input window while preserving causal ordering [22]. This configuration expands the receptive field exponentially and supports multi-scale temporal aggregation without increasing model depth [11]. Prior financial forecasting studies have shown that compact receptive fields improve short-horizon accuracy by emphasizing recent dynamics [31]. The convolutional block employed a kernel size of 2 to extract short-term variations while retaining continuity across adjacent time steps [11]. Empirical evidence indicates that compact kernels enhance training stability and limit unnecessary parameter growth [32].

Building on prior TCN implementations, a filter configuration of {16, 32, 64} was adopted to balance expressive capacity and computational efficiency, a setting previously shown to yield smooth convergence behavior in TCN-based forecasting tasks [33]. A dense readout layer was appended after the TCN block to produce regression outputs, while the multivariate configuration incorporated fully connected layers with 8, 16, and 32 ReLU units to strengthen nonlinear interactions among the exogenous indicators [33]. The univariate configuration used a linear activation at the output stage, which is standard in continuous-valued forecasting where temporal dependencies are already encoded by the convolutional layers [11, 34].

Regularization and optimization parameters were tuned to support stable convergence. Dropout values between 0.0 and 0.2 were tested based on evidence that moderate dropout improves generalization in Temporal Convolutional Networks [33, 35]. The Adam optimizer used a learning-rate range of 1×10^{-4} to 1×10^{-3} to ensure smooth gradient updates, consistent with recent TCN frameworks [36, 37]. Batch sizes {8, 16, 32} were adopted to balance computational efficiency and gradient-update stability in multivariate forecasting tasks [35].

F. Evaluation Metrics and Validation

The evaluation stage aimed to assess model performance in terms of predictive accuracy, generalization, and computational efficiency using the reserved test dataset to ensure unbiased comparison. Model accuracy was quantified through Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and Mean Absolute Percentage Error (MAPE), which represent complementary perspectives of error magnitude and proportional deviation. RMSE emphasizes large deviations and penalizes extreme forecast errors, while MAE reflects average

prediction accuracy in the same scale as the original data. MAPE provides an interpretable percentage-based measure that facilitates cross-model comparison. Together, these three metrics ensure a balanced evaluation between precision and robustness across all model configurations [38].

To ensure fairness and reliability of the comparison, the Diebold-Mariano (DM) test was employed to evaluate the statistical significance of forecast differences between ARIMAX and TCN models [38]. Feature attribution was further investigated using Integrated Gradients (IG) to visualize temporal attributions along historical input windows [39], and Permutation Feature Importance (PFI) to estimate the relative contribution of each exogenous factor, including LQ45 historic data, VIX, Brent Oil, and EFFR [40]. These analysis revealed the extent to which multivariate TCN utilized external indicators to enhance predictive power.

Additionally, the total runtime and hyperparameter search duration were recorded to measure computational efficiency and scalability. This comprehensive validation framework ensured that the comparative analysis reflected not only predictive accuracy but also interpretability, robustness, and efficiency across models.

IV. Results and Discussion

This section presents the empirical results of the comparative forecasting experiments, followed by a structured discussion to interpret model performance, statistical significance, feature relevance, and computational implications.

A. Model Performance Comparison

The comparative evaluation aims to assess the forecasting accuracy and robustness of three primary models, namely the ARIMAX (2,0,1) baseline representing classical statistical methods, the Univariate Temporal Convolutional Network (TCN) as a deep learning approach relying solely on historical LQ45 patterns, and the Multivariate TCN that integrates global exogenous indicators (VIX, Brent Oil, and EFFR). The evaluation metrics used are Root Mean Squared Error (RMSE), Mean Absolute Error (MAE), and Mean Absolute Percentage Error (MAPE). The summarized results on the testing dataset are presented in Table III.

TABLE III. Model Performance Comparison on the Test Dataset

Model	RMSE	MAE	MAPE (%)
ARIMAX	7.47	5.72	0.62
TCN Univariate	10.57	8.34	0.90
TCN Multivariate	13.02	9.96	1.08

The comparative performance trends presented in Table III are further illustrated in Fig. 2, which visually depicts the RMSE and MAE values across the three evaluated models. This graphical presentation reinforces the observed error hierarchy and facilitates a clearer interpretation of relative model robustness on the testing dataset. Such visualization also enhances interpretability by providing an intuitive comparison of performance differences across modeling approaches.

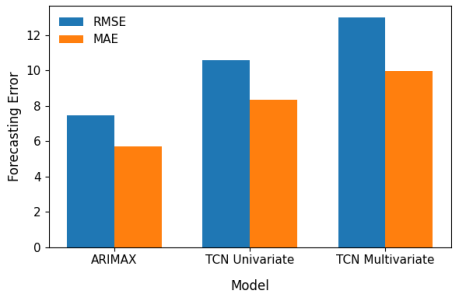

Fig. 2. RMSE and MAE comparison across forecasting models.

To further verify the adequacy of the ARIMAX specification, residual diagnostics were conducted on the test forecast errors. The autocorrelation function (ACF) plot indicates that residual correlations remain within the 95% confidence bounds across lags. In addition, the Ljung–Box test produced p-values greater than 0.05 at lag 10 and 20, suggesting that the null hypothesis of no serial correlation cannot be rejected. These results suggest that the ARIMAX residuals approximate white noise behavior, indicating that the linear structure adequately captures the underlying temporal dependence of the LQ45 series (see Fig. 3).

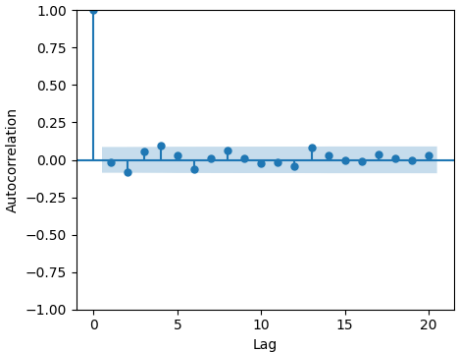

Fig. 3. Autocorrelation function of ARIMAX forecast errors.

The univariate TCN achieved an RMSE of 10.57 and MAPE of 0.90 per cent, indicating moderate forecasting capability. Although less accurate than ARIMAX, it demonstrated the ability to capture intrinsic temporal dependencies through causal and dilated convolutions [42], allowing the model to learn both short- and long-term patterns in the LQ45 index, consistent with prior studies demonstrating TCN's efficiency in modeling sequential dependencies, including financial time series [43].

Conversely, the multivariate TCN recorded the highest errors, suggesting that integrating exogenous variables such as VIX, Brent Oil, and EFFR may have introduced additional noise and reduced model stability. This outcome aligns with the concept of forecastability variance, which states that the predictive contribution of exogenous features fluctuates depending on their causal strength and signal stability [44]. When such auxiliary variables exhibit stochastic volatility or weak causality with the target series, the resulting instability can diminish model generalization and elevate forecast uncertainty [44]. This behavior has also been observed in recent multivariate TCN studies, where noisy exogenous inputs distorted temporal representations and propagated volatility across convolutional layers [33].

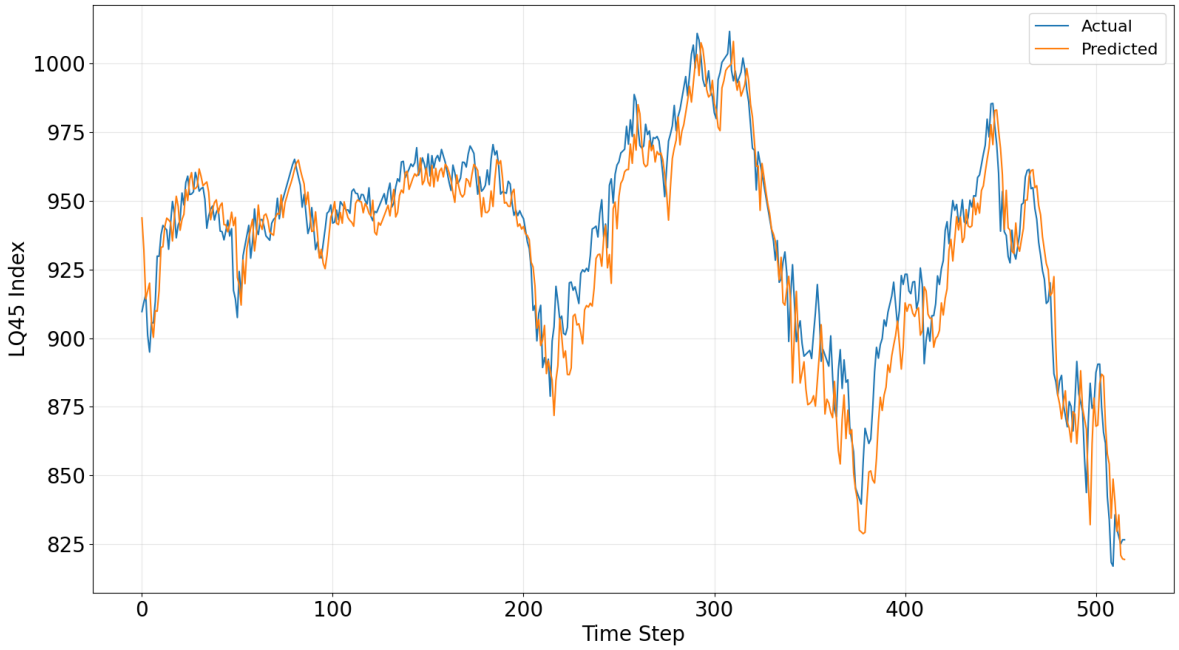

Fig. 4. Actual and predicted LQ45 index using the multivariate TCN model.

Although the univariate TCN leverages deep hierarchical structures, its predictive accuracy remained slightly below that of the ARIMAX model. This result may be explained by the dominance of short-term linear dependencies within the LQ45 index, where autoregressive mechanisms efficiently capture recurring temporal patterns [38, 41]. Meanwhile, deep learning architectures such as TCN are generally more advantageous when nonlinear or multi-scale interactions dominate the series, which appears less pronounced in the LQ45 dataset [43]. Hence, when temporal dynamics are relatively smooth and stationary, classical statistical models can still achieve competitive performance. Taken together, these quantitative and visual analyses indicate that the inclusion of exogenous features did not yield measurable predictive improvement in the evaluated setting, suggesting a stronger influence of intrinsic temporal dynamics in the LQ45 index. This finding further suggests that model complexity should be carefully aligned with underlying data characteristics to avoid unnecessary overparameterization (see Fig. 4).

Overall, the comparative findings highlight that ARIMAX remains an efficient and accurate baseline, while the univariate TCN offers a flexible deep-learning alternative with comparable stability. Although the multivariate TCN captured broader temporal structures, its error rates increased due to noisy exogenous inputs [33, 43]. These results suggest that for short-horizon forecasting in emerging markets such as Indonesia, simpler univariate frameworks may yield more consistent and interpretable outcomes.

B. *Statistical Significance Analysis using Diebold-Mariano Test (DM Test)*

The Diebold-Mariano (DM) test was applied to examine whether the observed forecasting differences among models were statistically significant. This procedure compares the expected loss differential between two competing models and determines if one achieves superior predictive accuracy [38]. A significant level of 5 per cent was used, reflecting standard practice in recent financial forecasting research [38]. The test was conducted pairwise among ARIMAX, Univariate TCN, and Multivariate TCN models using three evaluation metrics: Mean Absolute Error (MAE), Root Mean Squared Error (RMSE) and Mean Absolute Percentage Error (MAPE) (see Table IV).

All models were aligned on identical time spans to ensure comparability and to avoid sampling bias during evaluation. This pairwise testing approach ensures that the statistical comparison isolates model-specific differences rather than artifacts arising from sampling variability, thereby providing a more reliable basis for determining whether the observed accuracy gaps reflect genuine structural distinctions between the forecasting methods.

TABLE IV. DIEBOLD-MARIANO TEST RESULTS ACROSS ALL EVALUATION METRICS

Pair	MAE			RMSE			MAPE		
	Delta (Δ)	DM stat	p-value	Delta (Δ)	DM stat	p-value	Delta (Δ)	DM stat	p-value
TCN Multivariate vs. TCN Univariate	1.62	5.932	5.50e-09	57.65	6.26	7.98e-10	0.0018	5.83	9.89e-09
TCN Multivariate vs. ARIMAX	4.25	11.2	<1e-12	113.72	9.01	<1e-12	0.0046	11.04	<1e-12
TCN Univariate vs. ARIMAX	2.63	9.31	<1e-12	56.07	8.33	<1e-12	0.0028	9.23	<1e-12

Across all metrics, p-values were far below 0.05, confirming that the observed performance gaps among the models were statistically significant. Moreover, the consistently positive loss differentials (Δ) and large DM statistics across all model pairs indicate that the accuracy gaps are not only statistically significant but also quantitatively substantial, reinforcing the robustness of the comparative ranking. The positive Δ values indicate that the first model in each pair produced higher forecast errors, establishing a consistent performance hierarchy, where ARIMAX outperformed the Univariate TCN, which in turn outperformed the Multivariate TCN. These findings align with prior evidence that increasing model complexity does not necessarily yield higher predictive accuracy [38]. When exogenous variables contribute unstable or weakly correlated information, simpler statistical frameworks often provide more reliable results [38]. In summary, the Diebold-Mariano test confirms the statistically significant superiority of ARIMAX over both TCN variants across all error metrics.

C. Feature Contribution Analysis using Ablation Test

The ablation test was conducted to evaluate the structural contribution of each input feature to the predictive performance of the multivariate Temporal Convolutional Network (TCN) model. In this procedure, one feature was removed at a time while the model was retrained using identical hyperparameter configurations. The resulting performance was then compared with that of the full baseline model to quantify the model's dependency on each feature. This approach has been widely applied to verify the effectiveness of architectural components and feature dependencies in deep learning forecasting models [45].

In this study, four primary input features, namely lagged LQ45 data (t-1), VIX, Brent Oil, and EFFR, were subjected to ablation using a multi-seed configuration with five random seeds. The RMSE, MAE, and MAPE were computed on the real scale and averaged for each ablation condition. The deviation in RMSE relative to the baseline multivariate TCN (13.02) was used as the key performance indicator (ΔRMSE vs. Baseline). This design ensured consistent experimental conditions, controlled stochastic variation across runs, and provided a fair comparison framework to quantify the individual influence of each input feature on predictive accuracy in the proposed framework.

TABLE V. ABLATION TEST RESULTS ACROSS ALL EVALUATION METRICS

Dropped Feature	RMSE (mean ± std)	MAE (mean ± std)	MAPE (mean ± std, %)	ΔRMSE vs Baseline
LQ45 (t-1)	53.78 ± 14.61	43.71 ± 13.20	4.65 ± 1.34	+40.76
EFFR	13.30 ± 1.73	10.27 ± 1.71	1.12 ± 0.18	+0.28
VIX	11.77 ± 1.10	9.30 ± 1.12	1.00 ± 0.12	−1.25
Brent Oil	10.88 ± 0.36	8.36 ± 0.22	0.90 ± 0.02	−2.14

The results in Table V reveal that removing the lagged LQ45 feature caused the highest increase in RMSE (+40.76) relative to the baseline, confirming that the temporal information of the LQ45 index serves as the dominant autoregressive driver in the multivariate structure. Meanwhile, the slight improvement observed after removing VIX and Brent Oil suggests that these global indicators introduce weak or noisy signals that interfere with the temporal consistency of the target variable. The small RMSE increase observed when removing EFFR reflects a minor stabilizing contribution, indicating a secondary but complementary role in capturing macro-financial dynamics. These findings demonstrate that endogenous autoregressive patterns remain the most influential predictors in the TCN framework, while exogenous features contribute primarily as contextual modifiers rather than principal drivers [46].

Given the negative ΔRMSE observed for VIX and Brent Oil, Pearson correlation analysis was conducted to examine their statistical association with LQ45. Fig. 5 illustrates the correlation structure among LQ45 and the external indicators.

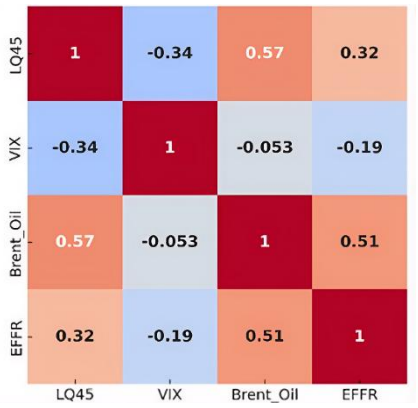

Fig. 5. Pearson correlation among LQ45 and exogenous market indicators.

Although moderate contemporaneous association is observed between LQ45 and certain exogenous indicators, static correlation does not directly imply incremental forecasting contribution, as reflected in the ΔRMSE results in Table V.

D. Temporal Attribution Analysis using Integrated Gradients

The Integrated Gradients (IG) method is a gradient-based attribution approach that quantifies feature importance by integrating gradients along a straight-line path between a baseline and the input. Because it does not modify a model's architecture, IG offers a consistent and model-agnostic mechanism for interpreting deep learning systems in sequential prediction tasks. Recent studies have demonstrated that IG yields stable and meaningful attributions in time-series forecasting, effectively highlighting the contribution of input variables and their temporal positions. These findings support the methodological suitability of IG for deep learning forecasting models, including convolution-based architectures that encode short-term and long-term dependencies through hierarchical feature representations [47].

Empirical studies have shown that Integrated Gradients provide systematic and reliable attributions for time series prediction models. The method identifies influential input variables and their associated temporal positions, enabling a transparent explanation of how variations in sequential inputs contribute to the model's output while preserving the original predictive structure [39].

In this study, each test sample was compared against five reference baselines representing the distribution of the training data. Linear integration was performed with 64 steps to derive average gradient attributions, and the results were aggregated to compute global feature importance. The averaged values were then visualized as bar plots and heatmaps to illustrate the relative contribution of each input feature and its sensitivity across temporal lags.

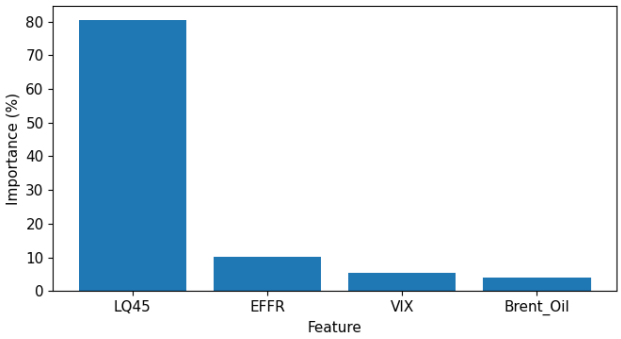

Fig. 6. Feature attribution results using integrated gradients.

As shown in Fig. 6, the LQ45 feature accounted for the largest share of total contribution, with an average importance of 80.50 per cent. This confirms that the model relies predominantly on the autoregressive dynamics of the target index. A clear gap is observed between LQ45 and the remaining features EFFR ranked as the second most influential feature at 10.15 per cent, while VIX and Brent Oil contributed 5.45 per cent and 3.89 per cent, respectively. These values indicate that macro-financial indicators provide supplementary information but play a secondary role compared with the dominant predictive influence of the LQ45 series.

TABLE VI. INTEGRATED GRADIENTS ATTRIBUTION ACROSS TEMPORAL LAGS

Lag (t-n)	LQ45 (t-n)	VIX (t-n)	Brent Oil (t-n)	EFFR (t-n)
t−1	0.192686	0.006070	0.004754	0.010884
t−2	0.001162	0.002830	0.002569	0.003966
t−3	0.002760	0.003115	0.005543	0.005910
t−4	0.000132	0.000078	0.000073	0.000366
t−5	0.001888	0.000766	0.000996	0.002343
t−6	0.000052	0.000474	0.000560	0.000198
t−7	0.000243	0.000142	0.000111	0.001427

The temporal attribution values in Table VI indicate a consistent pattern across all input variables, where the highest attribution scores are observed at lag t−1, corresponding to the most recent observation before prediction. This pattern suggests that the model consistently prioritizes short-term temporal information, regardless of whether the inputs are endogenous or exogenous. As the lag increases, the attribution scores for all variables decrease substantially, indicating that the influence of older information (t−6 to t−7) becomes notably weaker. These results confirm that the receptive-field configuration with dilations (1, 2) effectively captures short-term dependencies while reducing the risk of overfitting to distant noise [48].

E. Feature Sensitivity Analysis using Permutation Feature Importance

The feature sensitivity analysis aimed to quantify the dependency of model performance on each input variable. The Permutation Feature Importance (PFI) approach was applied as a model-agnostic interpretability method that measures changes in prediction accuracy when a single feature's temporal sequence is randomly permuted while others remain in their original order. This method has been recognized as a reliable tool for assessing the relevance of features in complex deep learning forecasting models [40]. Conceptually, PFI evaluates model sensitivity by computing the increase in prediction error after the temporal order of one feature is disrupted. A higher error increase implies a stronger dependence of the model on that feature, providing a global estimate of feature contribution across the entire dataset [48].

This approach allows a transparent evaluation of model robustness and reduces bias caused by individual feature correlations. Multiple random initializations were applied to ensure robust and reproducible sensitivity estimation, and the averaged RMSE, MAE, and MAPE were computed to obtain stable results. The deviation in RMSE relative to the baseline model (ΔRMSE) served as the main sensitivity indicator, where larger ΔRMSE values denote higher feature influence.

TABLE VII. COMPARISON OF MODEL PERFORMANCE IN FEATURE PERMUTATION TEST

Dropped Feature	RMSE (mean ± std)	MAE (mean ± std)	MAPE (mean ± std, %)	ΔRMSE vs. Baseline
LQ45 (t-1)	45.96 ± 2.59	35.75 ± 2.23	3.88 ± 0.23	+32.94
EFFR	19.04 ± 2.63	14.61 ± 1.36	1.59 ± 0.16	+6.02
VIX	17.95 ± 1.59	14.03 ± 1.05	1.52 ± 0.11	+4.93
Brent Oil	18.65 ± 2.40	14.34 ± 1.47	1.56 ± 0.16	+5.63

As presented in Table VII, randomizing the LQ45 feature resulted in the largest performance degradation (ΔRMSE + 32.94), indicating that the model relies strongly on the autoregressive structure of the LQ45 index as the main temporal driver. This effect is substantially larger than that of other features and highlights the central role of the target series in shaping predictive performance. In contrast, randomizing EFFR, VIX, and Brent Oil led to increases in moderate errors, suggesting that these global indicators contribute auxiliary information rather than being primary determinants. This pattern aligns with prior studies applying PFI to multivariate TCN frameworks for economic forecasting, confirming that the TCN model effectively captures dominant temporal dependencies while treating exogenous factors as complementary stabilizing inputs [33].

F. Computational Efficiency

This section evaluates the computational efficiency of all forecasting models by comparing the total duration of hyperparameter optimization and final training. These measurements reflect the computational effort and practical feasibility of each model in financial forecasting implementation. In addition, the comparison provides insights into the trade-off between model complexity and computational cost, which is an important consideration for real-world deployment in resource-constrained environments. Such considerations are particularly relevant for financial applications where timely model updates and operational efficiency are critical.

TABLE VIII. COMPUTATIONAL EFFICIENCY COMPARISON BASED ON TOTAL TRAINING AND HYPERPARAMETER OPTIMIZATION TIME

Model	Hyperparameter Search (HH:MM:SS.ss)	Final Training (HH:MM:SS.ss)	Total Runtime (HH:MM:SS.ss)
ARIMAX	00:00:05.51	00:00:00.21	00:00:05.72
TCN Univariate	01:16:09.32	00:00:56.17	01:17:05.49
TCN Multivariate	01:30:40.94	00:01:07.14	01:31:48.08

As presented in Table VIII, the ARIMAX model achieved the fastest overall runtime, completing both stages in approximately 5.7 seconds. The univariate TCN required around one hour and seventeen minutes, while the multivariate TCN needed about one hour and thirty-one minutes. The results indicate that the computational time consistently increases as the model architecture becomes deeper and the number of parameters grows. This pattern reflects the higher computational load of convolutional models due to iterative gradient updates and the complexity of multi-layer feature extraction. This difference also illustrates how convolutional architectures scale with input dimensionality, where each additional feature increases the computational cost of filter operations and gradient updates.

Consequently, even moderate expansions in model complexity can lead to noticeable growth in total training time. From a computational perspective, deep learning architecture generally requires longer training duration and greater training complexity than linear models [49]. The computational time of deep neural networks tends to increase rapidly as model depth and dataset size expand, often demanding extended training despite computational acceleration [49]. In contrast, the ARIMAX model in this study achieved superior predictive accuracy together with substantially faster computation. Its linear parameter estimation allows efficient convergence and minimal computational effort, making it more suitable for moderately complex financial time series that exhibit seasonal and autoregressive characteristics.

Overall, these findings confirm that statistical models such as ARIMAX remain more computationally efficient and practically reliable compared with deep learning alternatives for financial forecasting scenarios where computational efficiency and model interpretability are prioritized. The contrast in computational demands also highlights the importance of selecting modelling approaches that align with available resources and operational constraints. In practical applications, organizations may favor models that provide stable accuracy with minimal computational overhead, especially when rapid retraining or frequent model updates are required.

V. CONCLUSION

This comparative evaluation examines the forecasting accuracy and robustness of three predictive models applied to the LQ45 index. The study evaluates a multivariate Temporal Convolutional Network (TCN) incorporating global market indicators and compares its performance against ARIMAX and a univariate TCN as benchmark models. The results show that the multivariate TCN yields the highest prediction error (RMSE 13.02), indicating inferior performance relative to the benchmark models. ARIMAX achieves the lowest error (RMSE 7.47), followed by the univariate TCN (RMSE 10.57). These findings indicate that the inclusion of global exogenous indicators increased model complexity while resulting in higher forecast errors and reduced stability under the evaluated configuration.

The Diebold–Mariano test confirmed that these performance differences were statistically significant, indicating that the weaker outcomes of the multivariate TCN reflect structural limitations rather than random variation. Feature-level analyses provided consistent insights. The ablation test and Integrated Gradients showed that LQ45 dominates predictive performance, with EFFR contributing modest stabilizing effects and VIX and Brent Oil acting as weak or noisy signals. This pattern was further reinforced by the Permutation Feature Importance results, where randomizing LQ45 produced the largest degradation.

Overall, the findings indicate that short-horizon forecasting of the LQ45 index is driven primarily by its own autoregressive structure, while global indicators provided limited incremental accuracy improvement and were associated with higher error variance. Although the multivariate TCN captures hierarchical temporal dependencies, it does not surpass the ARIMAX baseline or its univariate counterpart in terms of predictive accuracy. In addition, the convolutional architectures require substantially higher computational effort due to extended training and hyperparameter optimization, which further limits their practical applicability. From both predictive and computational perspectives, ARIMAX remains a more efficient and reliable choice for short-horizon financial forecasting of the LQ45 index.

These findings are limited to the evaluated short-horizon configuration and may vary under different market regimes, including periods of structural disruption. Although the dataset spans pre-pandemic, pandemic, and recovery phases, no explicit structural-break analysis was conducted, which may influence parameter stability across macroeconomic periods. Future work may consider adaptive mechanisms such as attention-based weighting or dynamic feature selection to better manage noisy exogenous inputs under volatile market conditions.

ACKNOWLEDGMENT

The author gratefully acknowledges the thesis supervisor for the guidance, critical insights, and continuous support that contributed significantly to the completion of this research. The constructive feedback and academic discussions throughout the research process were instrumental in refining both the methodological framework and analytical interpretation presented in this study. The author also extends sincere appreciation to Bina Nusantara University for providing a supportive academic environment and institutional resources that facilitated the development and completion of this work.

DECLARATION OF GENERATIVE AI AND AI-ASSISTED TECHNOLOGIES IN THE WRITING PROCESS

During the preparation of this manuscript, the authors used ChatGPT solely as a writing assistance tool to support language refinement. All research ideas, methodological design, data analysis, and scientific conclusions were entirely developed by the authors. The authors carefully reviewed and edited the manuscript and take full responsibility for the accuracy, originality, and integrity of the published work.

***Abstract*—This systematic review examines the integration of agent-based modeling (ABM) and Geographic Information Systems (GIS) in flood evacuation planning from 2015 through early 2025. This review aims to systematically evaluate how ABM and GIS have been integrated in flood evacuation research, identify methodological gaps, and propose a structured framework to guide future model development. Using PRISMA guidelines, 67 studies were selected and analyzed to uncover methodological trends, empirical gaps, and policy relevance in this growing research domain. Using the PRISMA 2020 framework, the analysis reveals a dominant reliance on mesoscopic modeling (43%), limited real-time data integration (17.9%), weak empirical validation practices (16.4%), and minimal machine learning adoption (4.5%). To structure the evolving landscape, a conceptual integration framework is proposed to classify studies by modeling scale, data fidelity, and validation strategy. This framework highlights a gradual shift toward behaviorally realistic, spatially precise, and policy-relevant evacuation models. Persistent challenges include limited validation practices, weak real-time responsiveness, and insufficient policy integration. Conclusions were drawn by identifying five research priorities: AI integration, real-time enhancement, multi-hazard modeling, empirical grounding, and participatory policy co-design. This review offers actionable insights for advancing robust, scalable, and operational ABM-GIS systems in disaster risk reduction.**

Keywords*—Agent-based modeling; GIS integration; flood simulation; spatial modeling; evacuation dynamics; multi-agent systems

I. Introduction

Floods are among the most frequent and devastating natural disasters globally, causing extensive loss of life, displacement, and damage to infrastructure. Rapid urbanization, climate change, and land-use transformation have intensified both the frequency and severity of flood events in recent years [1] [2]. Notable examples include the 2018 Kerala floods in India [3], 2017 Hurricane Harvey in Houston [4], and the 2020 inundation of Wuhan, China [5]. These disasters underscore the urgent need for robust evacuation planning tools that can adapt to dynamic, uncertain conditions.

Traditional evacuation models often rely on aggregate or static assumptions, limiting their ability to reflect real-time decision-making and heterogeneous human behavior [6]. In contrast, agent-based modeling (ABM) offers a bottom-up approach, simulating individual or group behavior in complex systems [7],[8]. When coupled with GIS, which enables spatial analysis and environmental representation, ABM becomes a powerful tool for flood evacuation planning, integrating human dynamics with terrain, infrastructure, and hazard data [9], [10].

Although the use of ABM-GIS integration in flood modeling has expanded over the past decade, existing reviews have primarily focused on general disaster modeling [11] or lack systematic synthesis across methodological, spatial, and policy dimensions [12],[13],[14]. Moreover, many studies remain invalidated, use outdated data sources, or fail to connect modeling outputs to operational policy frameworks [15][16].

This study addresses these gaps by presenting a systematic review of 67 studies published between 2015 and early 2025 that combine ABM and GIS in flood evacuation contexts. PRISMA [17] review protocol is applied to ensure transparency in study selection and synthesis of findings through a newly proposed Conceptual Integration Framework. This framework categorizes studies by modeling scale, data fidelity, and validation strategy, enabling structured comparison across cases.

The goal of this review is twofold: 1) to map the current landscape of ABM-GIS flood evacuation research and 2) to identify methodological gaps and strategic priorities for future work. The main goal is to guide researchers, planners, and decision-makers in designing more adaptive, empirically grounded, and policy-relevant flood evacuation systems.

II. Literature Review

Flood evacuation modeling has evolved significantly with the integration of agent-based modeling (ABM) and Geographic Information Systems (GIS), enabling the simulation of complex, spatially grounded, and behaviorally diverse human responses to hydrological hazards. Over the past two decades, ABM-GIS frameworks have been widely adopted in urban risk assessment, emergency management, and real-time evacuation decision support [18][19].

A. Progress in ABM-GIS Integration

Recent studies demonstrate increasing sophistication in coupling GIS-based spatial layers with ABM decision logic. Hydrodynamic models (e.g., SWMM, HEC-RAS) are often used to simulate flood propagation, while ABMs simulate agent movement and decision-making under dynamic hazard conditions [20][21]. GIS platforms have enhanced spatial

*Corresponding author.

realism, allowing building-level, road-level, and infrastructure-specific modeling of evacuation behaviors.

Furthermore, models have become more inclusive of multi-agent interactions, shelter dynamics, and transportation network constraints [22] [23]. This integration enables more granular analysis of evacuation bottlenecks and policy interventions, such as staggered alerts or shelter assignments.

B. Gaps in Behavioral and Empirical Rigor

Despite technical advances, many ABM-GIS studies rely on deterministic or static behavior rules. Psychological realism, such as risk perception, delayed response, or social influence, is often underrepresented [24]. Few models incorporate agent heterogeneity (e.g., age, mobility, risk attitude), and even fewer validate outputs against real-world evacuation data.

Moreover, real-time data streams, such as IoT sensors or mobile tracking, remain rare in ABM-GIS platforms due to integration complexity and data availability constraints. Consequently, many models are scenario-driven rather than adaptive or predictive, limiting their utility in time-critical decisions.

C. Limitations of Existing Reviews

While several reviews have assessed ABM or GIS in isolation or within broader disaster contexts (e.g., pandemics, wildfires), few focus specifically on their combined application in flood evacuation modeling. For example, [25] Lakmali et al., 2024 and [26] Noor et al. (2025) discussed ABM applications in disaster simulation but offered a limited spatial methodological synthesis. More recent works (e.g., Wikstrom et al., 2022) [27] reviewed ABM-GIS tools in infrastructure planning, not evacuation behavior.

Importantly, past reviews have not systematically analyzed modeling scales, data fidelity, and validation strategies critical for translating simulations into operational emergency tools.

D. Need for the Current Review

Given the increasing severity and frequency of flood events and the rising importance of anticipatory evacuation planning, there is an urgent need to map how ABM-GIS tools are being used, validated, and operationalized in flood contexts. This review addresses that need by:

- Synthesizing 67 peer-reviewed studies with a clear inclusion and exclusion protocol.
- Classifying studies across three core dimensions: modeling scale, data fidelity, and validation strategy.
- Visualizing trends, identifying research gaps, and proposing actionable future directions.

By doing so, this review not only summarizes the current state of ABM-GIS flood evacuation modeling, but also offers a diagnostic framework for improving the realism, responsiveness, and policy alignment of future simulations. Table I shows how this review differs from other existing reviews on the area.

TABLE I. COMPARATIVE OVERVIEW OF EXISTING ABM-GIS REVIEWS AND THE PRESENT STUDY

Study	Hazard Type	ABM-GIS Focus	Scope of Review	Gap Addressed by Current Study
[20]	Floods propagation	GIS and hydrodynamic models	Flood spread, hazard mapping	Does not focus on adaptive ABM mechanisms
[23]	Urban disasters	ABM	Transportation bottlenecks, network constraints	No GIS integration for flood-specific evacuation
[25]	General disaster	GIS	ABM applications in disaster simulation	No methodological synthesis of ABM and GIS flood evacuation modeling
[24]	General disaster behaviour	ABM (Behaviour focused)	Human behavior, risk perception, response delay	Limited GIS integration; lacks spatial realism and hydrodynamic context
[27]	Infrastructure	ABM-GIS tools	ABM-GIS in infrastructure planning	No focus on evacuation behavior/modeling
This study (2025)	**Flood evacuation**	**ABM-GIS (integrated)**	**modeling scale, data fidelity, and validation strategy**	**Focus on flood-specific ABM-GIS models with Conceptual Integration Framework**

III. METHODOLOGY

This review adopts the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [17] to ensure transparency and methodological rigor in the identification, screening, and inclusion of studies. The review protocol was not pre-registered, but all search strategies and inclusion criteria are documented in this section for full reproducibility. Two reviewers independently screened titles, abstracts, and full texts. Discrepancies were resolved through discussion. Inter-rater agreement during the full-text screening phase was 91%, indicating high screening consistency.

A. Data Sources and Search Strategy

Literature was retrieved from four major academic databases: Scopus, Web of Science, IEEE, and Science Direct. The search spanned publications from January 2015 to May 2025, focusing on studies that integrate agent-based modeling and Geographic Information Systems in flood evacuation planning. Boolean search strings combined keywords related to agent-based models, GIS, and flooding scenarios. Table II summarizes the database-specific queries. Only peer-reviewed journal articles, review papers, and selected book chapters written in English were considered.

TABLE II. DATABASES SEARCH STRATEGIES USED FOR IDENTIFYING RELEVANT ABM-GIS FLOOD EVACUATION STUDIES.

Data Source	Search Strategies
Web of Science	("Flood Evacuation Planning" OR "Flood Evacuation Modeling") AND ("Agent-Based Modeling" OR "Agent-Based Model" OR "ABS") AND ("Geographic Information System" OR "GIS")
IEEE Xplore	("Flood Evacuation" OR "Flood Rescue") AND ("Agent-Based Modeling" OR "Agent-Based Modeling") AND ("GIS" OR "Geographic Information System")
Scopus	("Agent-Based Model" OR ABM) AND ("Geographic Information System" OR GIS) AND ("Flood evacuation")
Science Direct	("Flood Evacuation Planning with Agent-Based Modeling and GIS") OR ("Systematic Review" AND "Flood Evacuation" AND "Agent-Based Modeling")

B. Inclusion and Exclusion Criteria

Studies were included in this review if they focused specifically on flood evacuation or flood response modeling, combined ABM with GIS, and produced spatially explicit modeling outputs. Conversely, studies were excluded if they addressed non-flood hazards such as wildfires or pandemics, lacked a simulation or modeling component, or were published as editorials, conference abstracts, or in languages other than English. A detailed summary of the inclusion and exclusion criteria is provided in Table III.

TABLE III. INCLUSION AND EXCLUSION CRITERIA FOR STUDY SELECTION.

Criterion Type	Inclusion	Exclusion
Publication type	Peer-reviewed journal articles, conference papers, or book chapters in English	Non-peer-reviewed, theses, reports, or non-English texts
Disaster type	Flood-specific evacuation or risk-reduction contexts	Other hazards (earthquakes, wildfires, tsunamis)
Methodology	Explicit integration of ABM and GIS, with empirical, simulated, or hybrid modeling outcomes	Purely equation-based, system-dynamics, or statistical models without ABM and GIS linkage
Data output	Studies providing measurable or model-based evacuation results	Conceptual papers without implementation or evaluation

C. Screening and Selection

The initial search yielded 215 records, which were imported into EndNote for de-duplication. After removing 32 duplicates, 183 articles were screened by title and abstract. A total of 83 full-text articles were assessed for eligibility, leading to 67 studies being included in the final synthesis. Fig. 1 visualizes the identification, screening, and inclusion stages used to select studies for this systematic review. Out of 215 records retrieved from Scopus (n = 123), IEEE Xplore (n = 27), Science Direct (n = 30) and Web of Science (n = 35), 67 studies met the inclusion criteria. Articles were excluded due to incomplete methods or data use (n = 97) and the absence of both GIS and ABM simulation components (n = 16).

D. Data Extraction and Synthesis

For each of the 67 included studies, key metadata were extracted, including the year of publication, geographic focus, modeling scale (micro, meso, or macro), level of data fidelity (e.g., static, dynamic, or real-time), validation strategy (empirical, scenario-based, or none), integration of artificial intelligence or machine learning, and the degree of policy relevance or stakeholder engagement. The extracted information was tabulated and thematically coded using an inductive approach to allow for the identification of patterns across the dataset. Summary statistics were then generated to quantify these patterns, and a Conceptual Integration Framework was developed to classify studies along the dimensions of modeling scale, data fidelity, and validation approach.

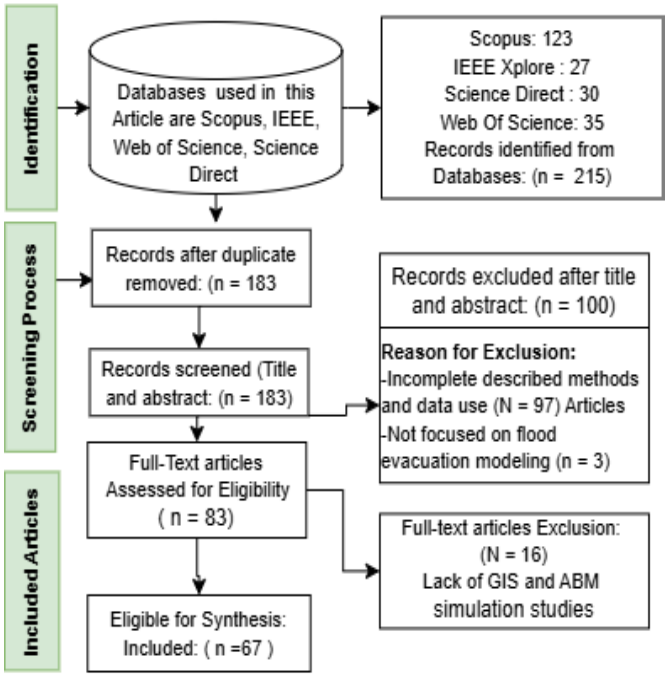

Fig. 1. Illustrates the systematic process used to identify, screen, assess, and include studies in this review of ABM-GIS integration for flood evacuation planning. Out of 215 initial records, 67 studies met the inclusion criteria based on methodological relevance, disaster type, and data integration requirements.

Due to the methodological diversity of the reviewed literature, no formal quality assessment tool (e.g., MMAT or GRADE) was applied. Instead, studies were qualitatively grouped based on the depth of empirical engagement and the transparency of their modeling processes. Table IV summarizes the data extracted from the selection process.

TABLE IV. SUMMARY OF STUDY SELECTION FROM DATABASE SEARCH RESULTS.

Database source	Initial Results	Screened Articles	Full-Text Reviewed	Included Studies
Web of science	35	30	16	14
IEEE Xplore	27	20	5	7
Scopus	123	113	45	33
Science Direct	30	20	17	13
Total	215	183	83	67

IV. RESULTS

This section presents the descriptive and thematic findings from 67 studies integrating agent-based modeling (ABM) and Geographic Information Systems (GIS) for flood evacuation planning, published between 2015 and early 2025. The analysis is structured around publication trends, geographic distribution, methodological characteristics, validation strategies, and integration capabilities.

A. Publication Trends

The publication trajectory of ABM-GIS flood evacuation research over the past decade reflects both steady methodological maturation and a sharp recent increase in scholarly interest. As shown in Fig. 2, the number of publications remained relatively modest between 2015 and 2018, averaging four to five studies per year. A notable uptick began in 2019. The annual publication count peaks in 2025 (n = 15), more than triple the annual output of most prior years. This upward trend suggests growing recognition of ABM-GIS integration as a critical tool in disaster risk reduction, particularly in the face of escalating flood-related hazards driven by climate change and urban exposure. Beyond raw publication counts, thematic synthesis of the 67 reviewed studies reveals four dominant research orientations:

- Methodological integration of ABM and GIS frameworks;
- Geographic and contextual diversity in case study settings;
- Applications in flood policy, planning, and climate adaptation; and
- Limitations related to technical scalability, data availability, and behavioral realism.

Notably, all reviewed studies (100%) integrated both ABM and GIS components in their modeling workflows, underscoring the conceptual synergy between spatial data infrastructure and agent-based decision modeling. However, methodological depth and practical integration remain uneven across the literature. Only 17.9% of studies incorporated real-time data assimilation, 16.4% conducted empirical validation against observed evacuation behavior or outcomes, and a mere 4.5% integrated machine learning or artificial intelligence components to support decision-making under uncertainty. This sharp disparity between theoretical model development and operational implementation signals a critical research gap, particularly in translating simulation outputs into actionable, real-time policy tools.

B. Geographic Distribution

Fig. 3 illustrates the geographic distribution of case studies across 30 countries, revealing clear regional concentrations and gaps. China leads with the highest number of studies (n = 8), followed by the United Kingdom and the United States (n = 6 each), and India (n = 5). Several countries, including Canada, South Korea, Thailand, the Netherlands, and Japan, each contributed three studies. A diverse but sparse representation is observed across other regions, with two studies originating from countries such as Iran, Malaysia, Germany, Nepal, and Poland. Meanwhile, a long tail of countries, including Australia, Indonesia, Greece, Portugal, and the Russian Federation, appear only once in the dataset.

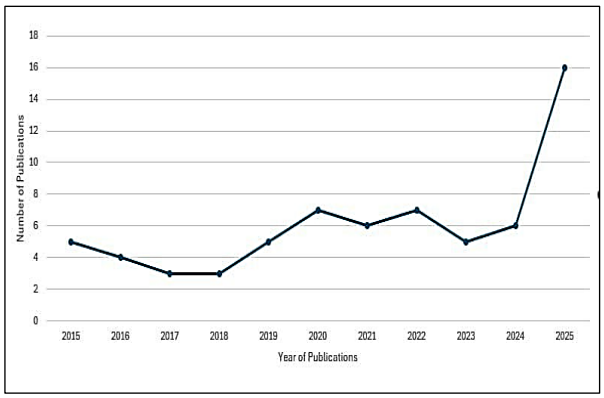

Fig. 2. Annual trends in ABM-GIS Flood Evacuation Publications (2015–2025) depict the yearly distribution of the 67 studies included in this review.

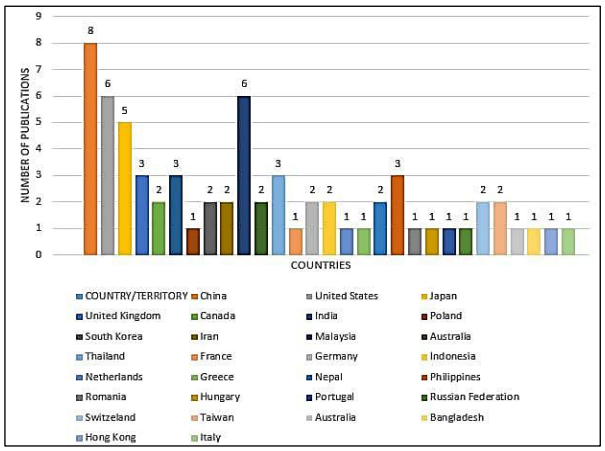

Fig. 3. Geographic distribution of ABM-GIS flood evacuation studies (2015–2025).

The data indicate that ABM-GIS flood evacuation remains heavily concentrated in high-income and upper-middle-income countries, particularly in East Asia, Western Europe, and North America. In contrast, low- and middle-income countries, despite being disproportionately affected by climate-induced flooding, remain underrepresented. This regional imbalance highlights a critical need for broader geographic engagement and increased research capacity in vulnerable regions such as Sub-Saharan Africa, Southeast Asia, and parts of Latin America.

C. Modeling Scale and Scope

The reviewed studies demonstrate a diverse application of modeling scales, reflecting the complexity and adaptability of ABM-GIS frameworks for flood evacuation scenarios. Modeling scale in this context refers to the level of agent aggregation and spatial resolution used to simulate evacuation dynamics, typically categorized as microscopic, mesoscopic, or macroscopic.

Among the 67 studies analyzed, mesoscopic models were the most prevalent, used in approximately 43% of cases. These

models typically simulate groups of agents such as households or neighborhoods within bounded geographic areas. Their popularity stems from a pragmatic balance between behavioral realism and computational efficiency, making them particularly suitable for urban-scale evacuations.

Microscopic models, accounting for 34% of studies, simulate individual agents with high granularity, often including variables such as age, mobility constraints, or decision-making heuristics. While offering the highest level of behavioral fidelity, such models are typically computationally intensive and often limited to smaller spatial domains or hypothetical case studies. Nevertheless, they provide critical insights into individual response variability, agent interaction, and localized congestion patterns.

Macroscopic models used in 23% of the studies represent populations in aggregate form, often using flow-based or zone-level simulation. These are typically coupled with hydrodynamic flood models and employed in large-scale risk assessments or regional planning exercises. While less behaviorally nuanced, macroscopic models are valuable for policy analysis and scenario testing over wide geographic extents.

The distribution of modeling scales reveals a methodological trade-off between computational scalability and behavioral detail. Few studies demonstrated multiscale integration (e.g., linking macro-level planning with micro-level agent behaviors), which represents an important direction for future research. Furthermore, only a small subset of models incorporated dynamic scaling, adjusting resolution based on the phase of the flood or real-time data availability, suggesting further potential for methodological innovation.

D. Data Fidelity and Integration

The quality, resolution, and dynamism of data inputs play a central role in the effectiveness and realism of ABM-GIS flood evacuation models. Across the 67 reviewed studies, there was substantial variation in how spatial, behavioral, and environmental data were sourced, integrated, and updated.

Approximately 61% of the studies relied on static or semi-static data inputs. These typically included pre-existing land use maps, census demographics, transportation networks, and historical flood records. While such inputs are useful for scenario testing or long-term planning, they often fail to capture the evolving dynamics of real-time flood events or adaptive human behavior under stress. Only 17.9% of the reviewed studies integrated real-time or near-real-time data such as live rainfall feeds, remote sensing imagery, traffic congestion updates, or sensor-based river level monitoring. These studies demonstrated enhanced situational responsiveness but often faced challenges related to data availability, system interoperability, and model latency.

In terms of data integration architecture, most models embedded GIS data as static spatial layers within ABM environments, primarily using raster-based flood extents or vector-based infrastructure maps. A smaller subset employed bidirectional coupling mechanisms where ABM and GIS platforms dynamically exchanged inputs and outputs during simulation runs, allowing for continuous updates to hazard extents or agent decisions in response to environmental change.

Notably, only a few models demonstrated multi-source data fusion, combining satellite imagery, crowd-sourced reports, mobile GPS data, and hydrological sensors. These approaches, while technically demanding, offer a pathway to more adaptive and realistic evacuation simulations. The uneven adoption of real-time and high-fidelity data reflects a persistent gap between methodological potential and technical feasibility. Bridging this gap will require not only improved access to interoperable data streams but also a greater emphasis on data assimilation techniques, modular system architectures, and validation of input reliability. To illustrate how data source types influence modeling approaches, Table V summarizes a subset of representative studies categorized by their dominant data inputs, modeling strategy, and associated references. The table highlights how data availability, ranging from static GIS layers to real-time sensor streams, influences the design and focus of ABM-GIS flood evacuation models.

TABLE V. REPRESENTATIVE STUDIES CATEGORIZED BY DATA SOURCES AND MODELING APPROACH.

No. of Studies	Common Data Sources	Dominant Modeling Approach	Representative References
12	DEM, LiDAR, hydrodynamic models	GIS and ABM hybrid flood simulation	[57], [58], [59], [60]
6	OpenStreetMap, Sentinel-2 imagery	GIS-based multi-criteria + agent routing	[30], [61], [62]
7	Remote sensing and survey data	Policy-oriented ABM and GIS adaptation models	[63], [64], [64]
4	Open data sets, DEM	Community-scale pedestrian ABM	[65], [66], [6]
3	Sensor data, urban hydrology	Traffic-focused ABM	[67], [68]
3	Mixed databases	Comparative framework reviews	[69], [70]

E. Validation Strategies

Validation remains a critical yet underdeveloped component in ABM-GIS flood evacuation modeling. Of the 67 studies reviewed, only 16.4% employed empirical validation techniques comparing model outputs to observed evacuation behavior, historical flood outcomes, or survey-based data. These studies typically used post-disaster reports, GPS traces, traffic sensor data, or retrospective interviews to calibrate agent behavior and verify model outputs.

The majority of studies (over 50%) relied on scenario-based or face validation, in which model behavior is assessed against expert expectations, hypothetical benchmarks, or visual plausibility. While valuable for internal consistency checks and stakeholder communication, such methods lack the rigor and reproducibility needed for high-confidence decision support.

Cross-dimensional analysis shows that empirical validation was more common in microscopic models (34%) than in mesoscopic (43%) and macroscopic (23%) models. High-fidelity data integration was also more frequently associated with scenario-based rather than empirical validation, indicating clustering of methodological sophistication rather than balanced integration.

A small number of studies (approximately 10%) applied cross-model validation, comparing their ABM-GIS results to outputs from other simulation platforms (e.g., hydrodynamic models or system dynamics). These efforts improved model credibility but often lacked formal metrics or sensitivity analyses. Several barriers to robust validation were noted across the literature:

- Limited availability of real-time or post-event behavioral data.
- Ethical and logistical challenges in collecting ground-truth evacuation information.
- Lack of standard performance metrics, especially for complex human-environment interactions.

Only a minority of studies reported using statistical goodness-of-fit tests, confusion matrices, or spatial accuracy metrics. In many cases, the validation process was either omitted entirely or vaguely described, undermining transparency and reproducibility.

The limited emphasis on empirical validation reflects a broader issue in disaster modeling: a methodological bias toward model development over model testing. Without rigorous validation, even sophisticated simulations risk becoming academic exercises rather than operational tools. Future research must prioritize data-grounded calibration, quantitative error reporting, and transparent validation protocols, particularly if ABM-GIS tools are to inform real-world policy and emergency response.

F. ABM-GIS Methodological Capabilities

The methodological capabilities observed across the 67 reviewed studies highlight both the strengths and limitations of current ABM-GIS integration practices in flood evacuation modeling. Fig. 4 synthesizes the core features evaluated, including spatial resolution, behavioral realism, data integration, validation, computational performance, and policy relevance.

Most studies (83.6%) employed high-resolution GIS data such as road networks, building footprints, land use, and elevation, enabling detailed analysis of agent movement, bottlenecks, and evacuation routes. Behavioral realism varied widely: 74.6% included basic movement or crowd dynamics, but only 38.8% modeled adaptive or heterogeneous decision-making based on factors like risk perception, social influence, or individual constraints. Few studies incorporated empirically derived behavioral parameters or hazard-dependent scenario switching.

Regarding data integration, 65.7% of studies relied on static GIS layers, while only 17.9% integrated real-time or dynamic data sources. This gap continues to constrain the operational applicability of many models, especially in fast-evolving flood contexts. Model validation, as discussed in Section IV E, was another area of concern. While 43.3% of models conducted internal validation (e.g., sensitivity or scenario testing), only 16.4% employed empirical validation against observed data. This underscores the need for greater emphasis on robust, data-informed calibration and performance assessment.

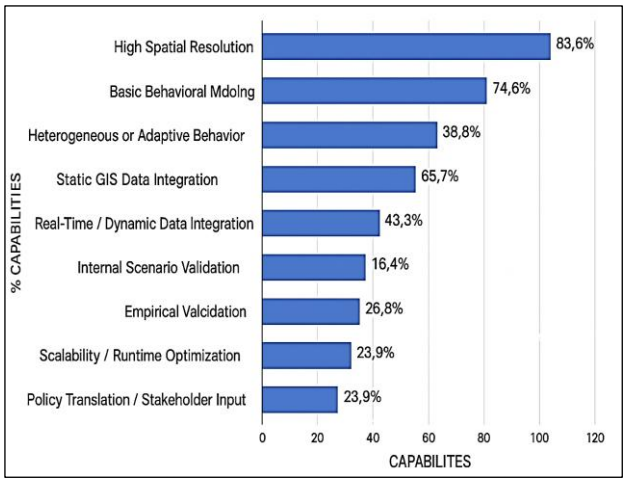

Fig. 4. Prevalence of key methodological capabilities across reviewed ABM-GIS Flood Evacuation Studies illustrates the percentage of studies (n = 67) exhibiting specific modeling capabilities, highlighting strengths in spatial resolution and basic behavior modeling, and gaps in real-time data integration and empirical validation.

In terms of computational performance, only 26.8% of studies addressed scalability or runtime efficiency, indicating that most models remain conceptual rather than real-time deployable. Similarly, policy translation and stakeholder engagement were limited (23.9%), raising concerns about practical relevance and adoption.

Overall, the analysis of methodological capabilities reveals a field that is advancing in spatial and behavioral complexity but still constrained by gaps in real-time responsiveness, empirical grounding, and stakeholder co-design. Addressing these limitations is essential for transitioning ABM-GIS systems from academic prototypes to operational decision-support tools.

To illustrate the diversity and depth of ABM-GIS modeling approaches in real-world contexts, Table VI summarizes selected case studies, outlining their integration frameworks, modeling focus, key contributions, and limitations, highlighting both methodological diversity and persistent gaps in realism, validation, and scalability.

G. Framework for Integrating Scale, Data, and Validation in ABM-GIS Models

To consolidate the methodological diversity observed across the 67 studies, a Conceptual Integration Framework was developed. This framework synthesizes findings across three core analytical dimensions modeling scale, data fidelity, and validation strategy and situates each study within a structured landscape of ABM-GIS flood evacuation modeling practices.

The modeling scale dimension captures the granularity of agent representation, distinguishing between microscopic models (individual-level), mesoscopic models (group-based), and macroscopic models (population aggregates). As described in Section IV C, mesoscopic approaches dominated the literature (43%), offering a balance between realism and computational tractability.

TABLE VI. COMPARATIVE SUMMARY OF SELECTED ABM-GIS FLOOD EVACUATION STUDIES

Author (Year)	Study Area	Model / Framework	Integration Focus	Key Findings / Contributions	Identified Limitations
[28]	Thailand	TU-FS Simulator	GIS-based flood mapping with ABM crowd simulation	Modeled large-scale pedestrian movement to optimize routes and shelter allocation during floods.	Limited to urban settings; did not consider behavioral diversity or multi-hazard context.
[29]	Nanning, China	SWMM-LISFLOOD + ABM	Hydrodynamic and GIS data coupled with ABM	Assessed pedestrian vulnerability and identified high-risk zones under dynamic flooding.	High computational cost; calibration challenges with real-time data.
[7]	Wuhan, China	Coupled Agent-Based Multi-Model Framework (CABMF)	Traffic and shelter data integration via GIS	Tested alternative evacuation strategies using spatially explicit ABM modeling.	Heavy computational demand; limited behavioral validation.
[6]	Kibera, Kenya	OpenStreetMap + DEM + ABM	Community-scale pedestrian simulation	Identified congestion points and suboptimal shelters in informal settlements.	Low-resolution open-source data; constrained by local data quality.
[30]	Nepal	GIS-based Analytic Hierarchy Process (AHP) + ABM	Flood-susceptibility mapping integrated with agent decisions	Prioritized evacuation corridors for high-risk areas; applicable with limited data.	Low-resolution DEM reduced route accuracy; static behavioral rules.
[31]	Coastal China	GIS + ABM for tsunami evacuation	Multi-hazard coupling (flood + landslide + liquefaction)	Demonstrated cross-hazard modeling capability within ABM and GIS framework.	Focused on specific hazard; limited to simulation, not validation.
[32]	China (Urban Metro)	GIS and ABM Transit Model	Infrastructure resilience analysis	Evaluated flood impacts on metro networks and rerouting efficiency.	Did not model passenger behavior diversity.
[33]	China (National Review)	Review of ABM and GIS frameworks	Policy-oriented, climate-adaptation focus	Highlighted potential for long-term risk and insurance modeling.	Conceptual; lacked empirical validation.
[34]	Hong Kong, China	ABM using AnyLogic platform integrated with GIS	Simulates self-evacuation under infrastructure failure	Developed an ABM incorporating household behavior diversity and infrastructure disruption.	Limited empirical validation
[35]	La Ciotat, France	SiFlo Model	GIS and ABM impact modeling	Quantified how awareness and maintenance reduce casualties (~30%).	Regional focus; simplified social behavior.
[36]	United Kingdom	Life Safety Model (LSM)	Dam-break simulation with GIS-ABM coupling	Measured effects of evacuation delay and congestion on mortality.	Requires high-quality DEM; computationally intensive.
[37]	Iran	Hybrid BIM and GIS and ABM	Behavioral and psychological modeling	Incorporated stress and social dynamics in evacuation after earthquakes.	Applied to earthquake context; limited flood transferability.

The data fidelity dimension assesses the type and dynamism of input data used. Models were classified as using low, medium, or high-fidelity data based on their use of static versus real-time information, sensor integration, and spatial resolution. Only 17.9% of studies achieved high data fidelity through real-time or dynamic input streams.

The third axis, validation strategy, reflects the extent and rigor of model verification. It distinguishes between empirical validation (against real-world observations), scenario-based validation, and no formal validation. Most studies (over 50%) relied on scenario-based validation, while only 16.4% employed empirical benchmarks.

By plotting studies across these three axes, the framework reveals distinct clusters and gaps. A central trend is the convergence toward spatially detailed, behaviorally rich, yet weakly validated models indicating methodological innovation without sufficient empirical grounding. Very few studies simultaneously demonstrated high fidelity, individual-level modeling, and rigorous validation.

The framework also exposes a structural limitation: few studies adopted hybrid approaches that span multiple scales, integrate dynamic data, and validate across both technical and behavioral dimensions. This lack of integration suggests that while the field is advancing in specific areas, systemic operational maturity remains limited. Ultimately, the Conceptual Integration Framework, as illustrated in Fig. 5, offers a diagnostic tool for positioning current research, identifying best practices, and directing future efforts toward comprehensive, validated, and policy-relevant ABM-GIS flood evacuation systems.

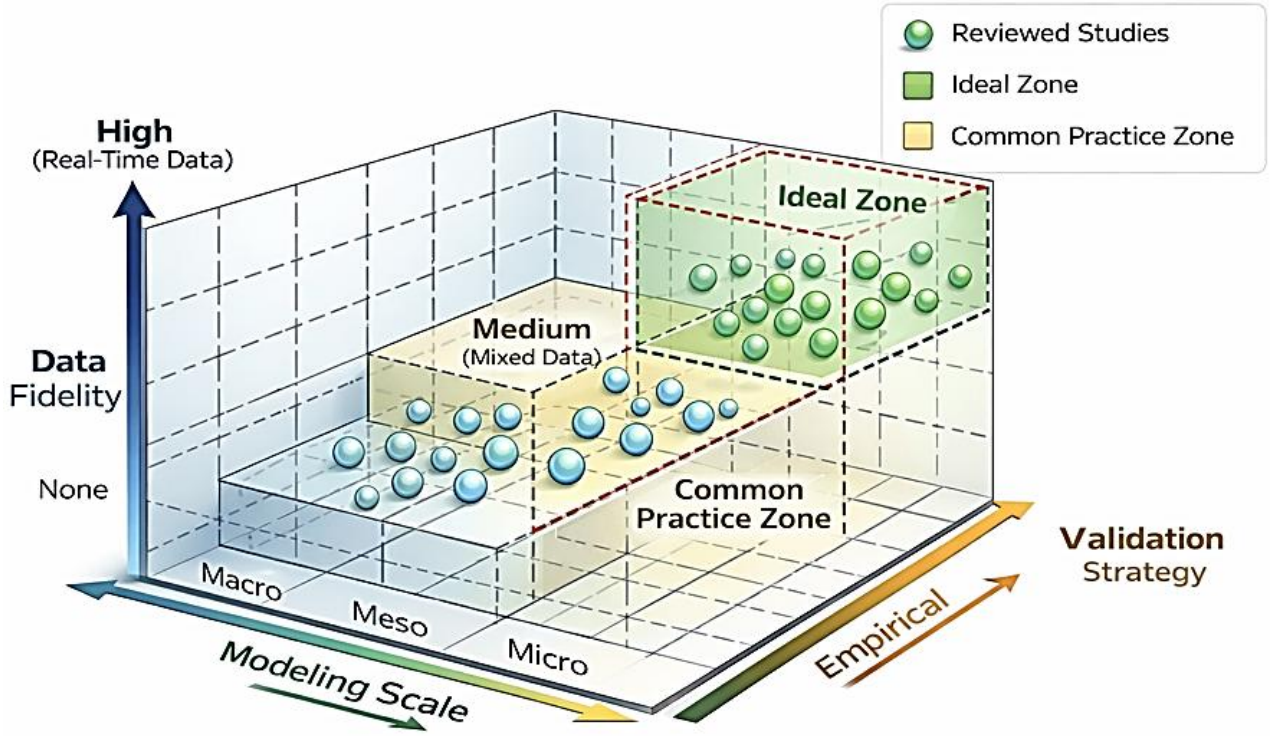

Fig. 5. Conceptual Integration Framework for ABM-GIS Flood Evacuation Models: A three-dimensional framework categorizing the 67 reviewed studies across modeling scale (macroscopic to microscopic), data fidelity (static to real-time), and validation strategy (none to empirical). The framework highlights dominant methodological clusters and identifies underdeveloped areas requiring future research.

H. Summary of Key Findings

The results of this review reveal a rapidly evolving field characterized by methodological diversity and growing sophistication in the integration of agent-based modeling and GIS for flood evacuation planning. While notable progress has been made in spatial resolution, behavioral modeling, and scenario-based applications, significant limitations persist. These include limited real-time data integration, inconsistent validation practices, and a lack of stakeholder engagement in model development. The Conceptual Integration Framework highlights clear trade-offs between fidelity, scale, and validation rigor emphasizing the need for more holistic, empirically grounded approaches. These findings collectively underscore a critical transition point for the field: from exploratory modeling toward operational decision-support systems that are robust, scalable, and grounded in real-world dynamics.

V. Discussion

The systematic review of 67 ABM-GIS flood evacuation studies demonstrates growing methodological innovation, particularly in spatial modeling and agent-based behavior representation. However, significant gaps persist in empirical grounding, real-time responsiveness, and operational integration. This discussion contextualizes those findings within current research trajectories and highlights the critical steps needed to evolve ABM-GIS models from academic prototypes into policy-relevant, adaptive systems.

A. Integration Advancements and Spatial Maturity

The field has matured notably in spatial fidelity and model sophistication. Over 80% of reviewed studies employed high-resolution GIS inputs such as DEMs, land use classifications, or detailed infrastructure networks. This reflects the increasing availability and accessibility of geospatial data and hydrodynamic models such as HEC-RAS or SWMM, which enhance terrain realism and flood dynamics. In many cases, spatial resolution enabled evacuation models to operate at building-level or street-level granularity, essential for identifying bottlenecks, exit points, and vulnerable zones in urban areas.

Concurrently, integration of GIS within ABM has improved in terms of layering, routing, and environment-agent interactions. However, in most studies, GIS is still used as a static input environment rather than a dynamically updating system. Real-time integration remains rare, and the use of GIS in feedback loops, such as adjusting flood depth or road blockage during simulation, is still largely absent.

B. Behavioral Realism and Modeling Scale Limitations

In terms of agent behavior, progress is mixed. While approximately 75% of studies modeled individual or group-level movement decisions, only a minority (less than 40%) introduced behavioral heterogeneity or psychological dynamics. Most models used deterministic rules (e.g., shortest-path algorithms or fixed compliance rates), overlooking decision uncertainty, social influence, or delayed response.

This undermines realism, as empirical studies show that evacuation behavior is often influenced by cascading cues, misinformation, or peer actions. There is a critical opportunity here to align ABM-GIS models with behavioral science, including risk perception theories and social contagion frameworks, to better emulate real-world complexities.

Additionally, the dominance of mesoscopic models, while efficient, may obscure fine-grained dynamics in dense urban environments or neglect macro-level impacts such as inter-jurisdictional flows. Multiscale or hybrid modeling approaches blending microscopic agent actions with regional-scale scenarios remain underutilized.

C. Validation and Data Assimilation Remain Critical Bottlenecks

Validation remains one of the weakest links in current ABM-GIS modeling. Despite methodological rigor in model design, only 16.4% of studies employed empirical validation strategies. The rest relied on scenario testing or visual plausibility. This validation gap weakens the credibility of simulation outputs and limits their utility in high-stakes planning contexts.

The main barriers include a lack of accessible post-event behavioral datasets, ethical challenges in observing real-time evacuations, and difficulty in matching dynamic model outputs with real-world baselines. Although some studies used field surveys or traffic counts, few integrated sensor-based evacuation data or mobile trace analytics.

Similarly, only a small subset of studies (17.9%) integrated real-time data sources (e.g., IoT sensors, remote sensing imagery, live weather feeds), despite the growing availability of such streams. Without real-time data assimilation, models remain static representations rather than responsive decision-support systems.

D. Limitations of the Review Methodology

Although this review followed PRISMA guidelines to ensure transparency in study identification and selection, a formal quality or risk-of-bias assessment tool (e.g., MMAT or GRADE) was not applied. This decision was primarily due to the methodological heterogeneity of the included studies, which span simulation-based modeling, hydrodynamic coupling, conceptual frameworks, and computational experiments that do not align neatly with conventional appraisal instruments designed for clinical or empirical research.

Nevertheless, this absence may influence the interpretation of research gaps, particularly regarding validation rigor. The reported validation prevalence reflects reporting patterns rather than a weighted assessment of study robustness. Future reviews would benefit from appraisal criteria specifically designed for ABM-GIS simulation research.

E. Policy Translation and Stakeholder Integration are Underdeveloped

Despite the theoretical potential of ABM-GIS models, only 23.9% of studies involved stakeholders or addressed implementation pathways. Even fewer aligned simulations with policy frameworks, emergency management protocols, or operational workflows. This represents a disconnect between scientific modeling and practical deployment.

Effective policy integration requires not just accurate models, but interpretable outputs, user-friendly interfaces, and stakeholder trust. Most reviewed studies stopped at visualizations or dashboards, without clear evidence of their use in drills, response plans, or municipal decision-making. Co-design processes, scenario walkthroughs, and participatory simulation remain the exception rather than the norm.

F. Research Priorities and Strategic Directions

To advance ABM-GIS flood evacuation modeling, five strategic research priorities emerge from the reviewed literature and are illustrated as follows:

1) Real-time IoT integration: Few models dynamically respond to live flood or mobility data. Integrating IoT sensors, satellite feeds, and traffic APIs would enable real-time updates to road conditions and hazard zones, improving the responsiveness of simulations.

2) Behavioral model enrichment: Agent behaviors are often simplistic, ignoring stress, uncertainty, or social influence. Future models should incorporate cognitive and psychological dimensions to better reflect real-world evacuation patterns.

3) Machine learning integration: ML methods can enhance model calibration, pattern recognition, and adaptive agent behavior. Reinforcement learning, in particular, can help agents learn optimal escape strategies over time, though interpretability must be preserved.

4) Multi-hazard modeling: Most simulations focus on single hazards. Incorporating cascading risks (e.g., power outages, pandemics) would allow for more realistic crisis planning and assessment of compound disaster scenarios.

5) Cloud computing and digital twins: Scalability remains a bottleneck. Cloud platforms and GPU-accelerated simulations can enable high-resolution, real-time modeling. Digital twins could support continuous monitoring and simulation of evolving emergencies.

This concise roadmap aligns emerging technologies with current modeling limitations, offering a practical foundation for building more adaptive, validated, and operationally integrated ABM-GIS systems

The reviewed studies and frameworks reveal both progress and ongoing gaps in ABM-GIS flood evacuation modeling. To summarize these findings, Fig. 6 presents key modeling components, typical methods, and recurring limitations offering a final lens to identify areas of innovation and those needing further development.

Table VII presents a strategic mapping of core challenges in ABM-GIS flood evacuation modeling alongside recommended solutions and anticipated outcomes. This synthesis aims to guide future work in developing empirically grounded, computationally efficient, and socially relevant simulation systems.

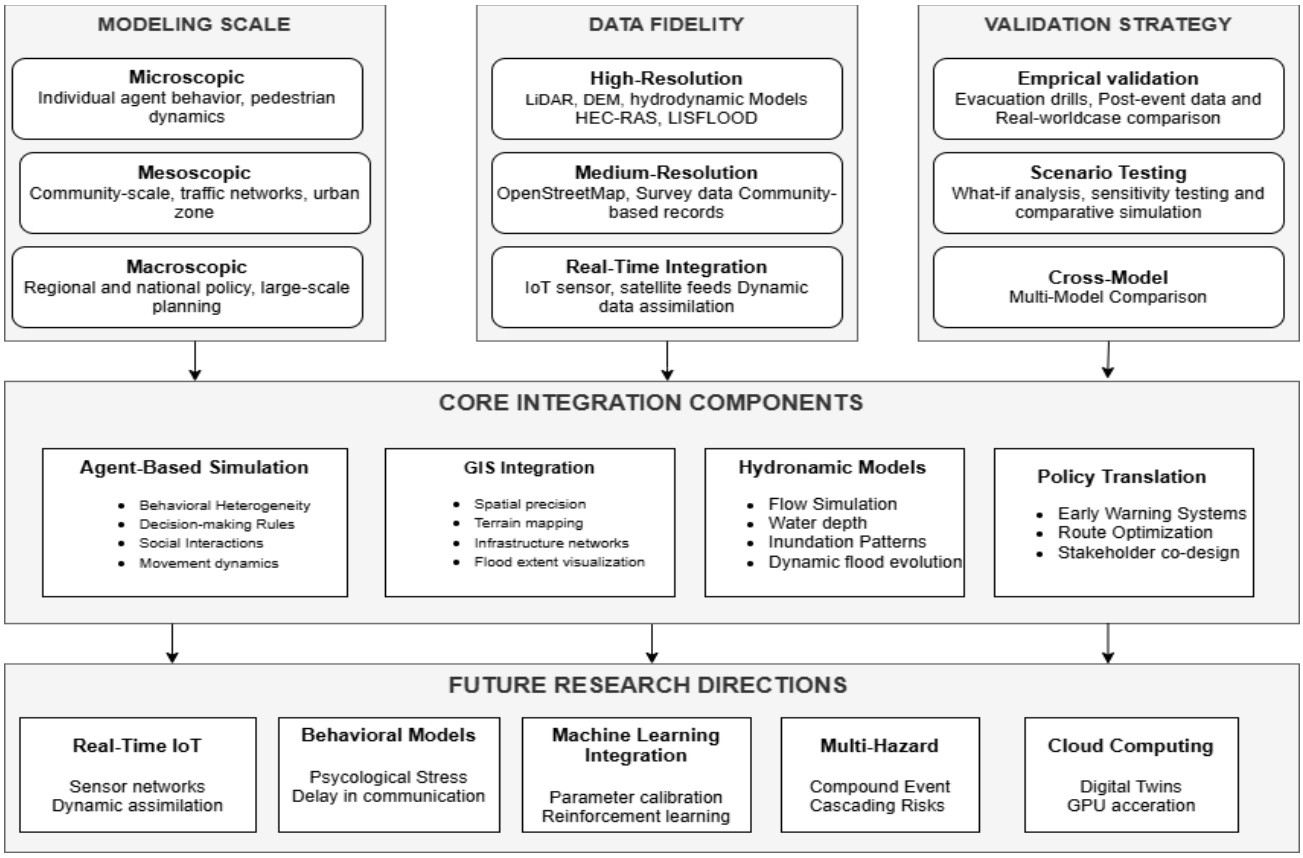

Fig. 6. Synthesis of ABM-GIS Modeling Practices, Core Integration Components, and Future Research Directions summarizes key dimensions of modeling scale, data fidelity, and validation strategy in ABM-GIS flood evacuation studies. The middle layer identifies essential integration components: agent simulation, GIS coupling, hydrodynamic modeling, and policy interfaces, while the bottom layer highlights six research priorities critical for advancing the field.

TABLE VII. STRATEGIC CHALLENGES, RECOMMENDED SOLUTIONS, AND EXPECTED OUTCOMES FOR ADVANCING ABM-GIS FLOOD EVACUATION MODELING

Research Focus	Key Challenge	Recommended Strategy	Expected Outcome	Ref.
Real-Time Data Integration	Static datasets limit responsiveness	Adopt IoT, UAV imagery, and satellite streams	Dynamic updates to ABM and GIS layers	[38], [39], [40]
Machine Learning Integration	Manual parameter tuning	Use reinforcement learning for behavioral adaptation	Self-calibrating models with faster simulation speeds	[41], [42], [43]
Multi-Hazard Modeling	Single-event focus	Link hydrologic, meteorologic, and infrastructure datasets	Cascading risk assessment	[44], [45], [46]
Behavioral Realism	Simplified decision rules	Integrate social-network and psychological factors	Culturally sensitive evacuation policies	[47], [48], [49]
Computational Scalability	High processing time	Parallel computing + cloud deployment	Real-time simulation capability	[50], [51], [52]
Validation Standards	Lack of benchmarks	Develop shared post-event datasets	Cross-model comparability	[53]
Policy Co-Design	Weak research	Participatory scenario planning with local agencies	Higher adoption of ABM and GIS outputs	[54], [55], [56]

VI. CONCLUSION

This review has critically examined 67 peer-reviewed studies that integrate ABM and GIS in the context of flood evacuation. The findings reveal clear progress in spatial resolution, agent-based behavior modeling, and hydrodynamic coupling. However, several persistent limitations hinder the operational utility of these models, including weak empirical validation, limited behavioral diversity, insufficient real-time data integration, and low policy engagement.

Through structured thematic synthesis and conceptual frameworks, the review identifies three core modeling dimensions: scale, data fidelity, and validation strategy that define the methodological landscape. Most studies emphasize spatial detail and heuristic agent behavior, yet few achieve comprehensive integration across all dimensions. Most remain static, proof-of-concept systems rather than fully adaptive, operational decision-support tools.

To address these challenges, the study outlines five strategic research priorities: real-time IoT integration, behavioral model enrichment, machine learning, multi-hazard coupling, and scalable cloud-based deployment. These priorities are not merely technical enhancements; they

represent critical shifts toward empirical rigor, stakeholder relevance, and cross-disciplinary innovation.

As climate-driven flood risks intensify globally, the need for robust, adaptive, and context-sensitive evacuation models has never been more urgent. Future ABM-GIS systems must move beyond academic silos to become embedded components of anticipatory planning, real-time response, and long-term resilience strategies. This review provides a roadmap for that transition, bridging science, computation, and policy to strengthen disaster preparedness in the face of escalating uncertainty.

A Novel Lightweight Explainable Multilayer Adaptive RNN-Based Intrusion Detection Framework

Nidhi Srivastav[1], Rajiv Singh[2]
Department of Computer Science, Banasthali Vidyapith, Rajasthan, India [1, 2]
Centre for Artificial Intelligence, Banasthali Vidyapith, Rajasthan, India[2]

***Abstract*—A rapid increase in the instances of cyberattacks has been observed with the expanding digitization. This leads to an urgent and critical need for developing robust intrusion detection systems (IDS) which can identify the occurrences of malicious activities within the network traffic. The present work proposes a novel, explainable, multilayer, lightweight adaptive IDS based on a Recurrent Neural Network (RNN). The purpose of this proposed IDS is to improve threat detection capabilities, especially low frequency high severe attack. The performance of the proposed IDS is evaluated using the UNR-IDD dataset. The network traffic is classified into normal and attack categories to assess the effectiveness of the proposed IDS. Two separate IDS models are developed. Model A is used to detect attacks on the basis of the frequency of the attacks, and Model B detects threats based on the severity of the attacks. Through the layered approach, the overall detection accuracy of 95.7% is achieved in Model A, and 97.5% is obtained in Model B. The present work highlights that the proposed IDS shows a remarkable improvement in the detection of less frequent severe attacks in comparison to existing IDS. The comparative result analysis of RNN-based IDS with Machine Learning models such as LR, Naïve Bayes, Cat Boost, Random Forest and Multilayer Perceptron models shows RNN-based IDS has outperformed the Machine Learning models. Explainable AI (XAI), the SHAP method is used for better interpretation of the proposed decisions. XAI helps to identify the network traffic that can influence predictions and detect potential biases. It also helps researchers and practitioners to validate model behaviour and establish trust in the system's outputs.**

***Keywords*—IDS; network security; adaptive techniques; RNN; cybersecurity; explainable AI; UNR-IDD**

I. Introduction

With a rapid increase in the number of networks and internet usage, there has been a substantial rise in cybersecurity issues. Fig. 1 depicts the organization global weekly cyber-attack data. It shows that during the first quarter of 2025, cyberattacks increased noticeably. Each business saw 1,925 attacks on average per week, which is 47% increase over the same time period in 2024. Government, telecommunications, and education have become the most targeted industries as cybercriminals continue to improve their techniques [1]. Ransomware attacks rose by 126%, with North America accounting for 62% of global incidents, and Consumer Goods & Services being the most targeted sector [1]. The complexity and variety of modern cyberattacks pose a considerable challenge to traditional IDS methods. Traditional methods, such as anomaly-based detection, which identifies deviations from typical behavior, and signature-based detection, which depends on predefined attack signatures, frequently have drawbacks like high false-positive rates, a slow rate of adaptation to new attack types, and an inability to identify zero-day attacks [2].

With the increasing complexity of cyberattacks, it becomes difficult to detect low-occurrence and zero-day attacks. Recent years have seen several rare but high-impact cyberattacks that demonstrate the growing sophistication of threat actors. XZ Utils backdoor did widespread Linux server compromise [3]. ICS "blackhole" is an attack that disrupted control traffic without malware [4]. Real-world incidents include the FrostyGoop [5]. Malicious PyPI packages attempt credential theft in the supply-chain attack [6]. Another example of such an attack is TetraSoft's industrial ecosystem attacking the major energy sector [7]. Kyivstar telecom attack [8], which disrupted nationwide communications and alerts. All the above examples show that these events occur rarely but have large-scale operational and national consequences.

Generally, low-occurrence attacks are rare, but their per-incident impact is often experienced as disproportionately high. As in [9], the 2021 Colonial Pipeline ransomware attack affected the entire fuel supply chain, causing billions in economic damage. The North American Electric Reliability Corporation (NERC) identified events of coordinated cyberattacks on critical infrastructure, leaving severe consequences, despite their rarity [10]. According to IBM's Cost of a Data Breach report, low-frequency, high-impact attacks, like advanced persistent threats (APTs), usually target sensitive infrastructure like power grids or financial systems and worsen the damages [11].

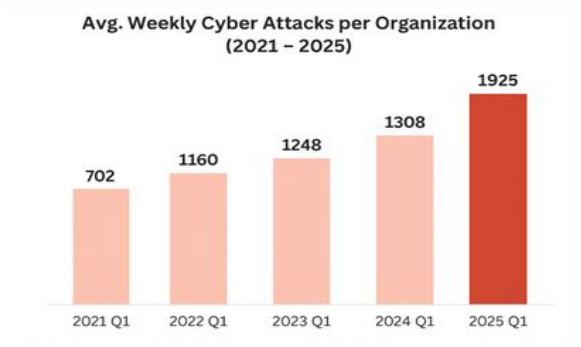

Fig. 1. Global weekly cyber attacks per organisation.

The rest of the study is structured as follows: Section II addresses relevant work about intrusion detection systems, with a particular emphasis on the use of deep learning and machine learning methods. Section III describes the methodology that introduces the proposed layered IDS framework. Section IV throws light on the architecture, steps of data preprocessing and

RNN-based IDS. Section V discusses experimental requirements, configuration of models, datasets, and metrics used for performance assessment and then analyses the results. Section VI summarizes the findings of this research.

II. Literature Review

Since the last decade, there has been significant research on Intrusion Detection Systems (IDS) based on Machine Learning (ML) algorithms. Researchers extensively used ML algorithms such as Decision Trees, Support Vector Machines (SVM), Random Forest, K-Nearest Neighbor (KNN) and Naïve Bayes for developing IDSs for decreasing false alarms [12], [13], [14]. Presently, deep learning techniques like Recurrent Neural Networks (RNN), Long Short-Term Memory (LSTM), and Gated Recurrent Units (GRU) are used particularly for increasing anomaly detection rates due to their ability to identify sequential patterns [15] [16], [17]. With the increasing complexity, the traditional ML IDS often fail to detect complex attack patterns. Therefore, deep learning models are preferred over traditional ML models, due to Deep Learning classifiers and ensemble classifiers' ability to process an enormous amount of data and capture temporal dependencies [18], [19], [20]. Therefore, deep learning classifiers and ensemble classifiers are used to detect intrusions. However, several challenges remain, such as overfitting, high computational costs, and dataset dependency. Each examined study attempts to enhance the effectiveness and application of IDS by uniquely addressing these issues. Despite advancements in ML classifiers, IDS still come across challenges such as overfitting, high computational costs, and dataset dependency. Researchers have addressed these issues in their work to increase the effectiveness of IDS [21].

Prior literature review over the past few years, Gautam [22] introduced a composite approach combining LSTM and GRU architectures for improving IDS performance. The combination of LSTM and GRU enables the model to retain long-term dependencies and handle short-term events effectively. This hybrid approach helped to extract complex patterns in large-scale traffic data. The model was trained on CICIDS-2017, which comprised current attack types like DDoS, port scans and web attacks. In this model, a very high accuracy of 99.3% was reported. Ibrahim, 2023[23] modelled IDS with Long Short-Term Memory and Simple RNN. Ibrahim's study devised an IDS using a combination of simple RNN and LSTM, aiming to compare the performance of basic RNN with its enhanced LSTM counterpart. The primary emphasis was on evaluating the trade-offs between Simple RNN computational efficiency and LSTM accuracy. Ibrahim [23] used the KDD Cup dataset and achieved a 90.6% accuracy, which was lower than other deep learning approaches. The limitation of the study was to use an older dataset and a simpler RNN architecture. The focus was on evaluating the trade-offs between computational efficiency (Simple RNN) and accuracy (LSTM). Ibrahim uses KDD Cup dataset, and older but still used datasets for IDS research were used. The IDS model achieved a 90.6% accuracy, which is lower than other deep learning approaches. The limitation in accuracy was attributed to the older dataset and simpler RNN architecture. Fog-Cloud-Based IDS Using Bi-Directional LSTM and Simple RNN by Syed, 2023[24].

This study proposes fog-cloud computing-based IDS, comprising Simple RNN and Bi-Directional LSTM. The fog-cloud architecture is used to decentralize IDS by reducing the latency and improving real-time detection. Bi-Directional LSTM is found capable of processing data in both directions. It is used for capturing complex traffic patterns and was tested on the BoT-IoT dataset. A hybrid NID-Recurrent Neural Network (RNN) with Long Short-Term Memory (LSTM) was developed by Amutha et al., 2022 [25] to enhance detection capabilities. The study used the UNSW-NB18 dataset and found 8% increase in accuracy in comparison to the simple RNN-based models. Recently, Azarudeen, 2024 [26], developed an innovative model integrating LSTM-RNN with a hybrid sparse autoencoder and Deep Neural Network (DNN). The performance of IDS was found to be better than earlier methods in terms of accuracy, detection rate, and low false alarm rates. Adamax optimizer was used on the NSL-KDD dataset for multi-attack categorization. Network IDS developed through Attention Mechanisms and RNNs by [27] Djaidja, 2024. IDS developed by combining RNNs, LSTM and Gated Recurrent Units (GRU) for detecting network intrusions at an earlier. stage. During testing on the CICIDS-2017 and 5G-NIDD datasets, the model performed early-stage detection before the flow termination. Parveen, 2024 [28] presented a real-time intrusion detection system (IDS) on combining Convolutional Neural Networks (CNNs) and RNNs. Using the UNR-IDD dataset, the hybrid CNN-RNN model achieved a 96.2% accuracy with a low false alarm rate. Samriya, 2024 [29] presented a novel NIDS which comprises Support Vector Machines (SVM) and Extreme Gradient Boosting (XGBoost). The developed NIDS performance was improved through hyperparameter optimization using the Crow Search Algorithm. Rathee [30] examined a number of deep learning models, such as CNNs, shallow neural networks, and deep neural networks (DNN), with attention mechanisms. NIDS developed through Deep Learning techniques tested on NSL-KDD, Kyoto, and UNSW-NB15 datasets. NIDS achieved robust detection results across varying architectures. Mighan, 2021 [31] developed IDS from a hybrid approach consisting of stacked autoencoders for feature extraction, followed by traditional classifiers like SVM, random forests, and decision trees. The IDS was tested on the UNB ISCX 2012 dataset. The system showed scalability and high performance in real-time scenarios.

The study explored various feature selection approaches to enhance the effectiveness of ML-based IDS. [32] focused on optimizing deep learning models for attack classification through hyperparameter optimization methods such as grid search and random search. The accuracy of the model was 83.33% on the NSL-KDD dataset and 95.79% on the CSECIC-ID2018 dataset. Kasongo [33] proposed a layered framework for IDS, where each layer contributed to the detection of specific types of network intrusions. The novelty of this approach lies in the hierarchical structure of deep learning layers that help improve feature extraction. The framework combined multiple deep learning techniques (e.g., CNN, LSTM) in a pipeline for multi-stage detection. The datasets used are UNSW-NB15, a dataset containing contemporary attack scenarios. [34] presented a novel NIDS using a stacked non-symmetric deep autoencoder combined with an SVM classifier, the system achieved 99.65% by using KDD Cup'99 dataset. [35] proposed

a stack ensemble of tree-based boosting classifiers-XGBoost, LightGBM, and Cat-Boost-for classification.[36] presents a privacy-preserving hybrid machine learning model, AOPRF-XGBoost, designed to enhance intrusion detection in IoT systems. Prominent existing work and their findings are summarized in Table I.

TABLE I. EXISTING IDS TECHNIQUES

Author	Year	Methodology	Findings
Gautam et al. [22]	2022	Used LSTM and GRU with RNN.	Worked on CICIDS-2017, achieved 99.3% accuracy.
Ibrahim and Elhafiz [23]	2023	Use Long Short-Term Memory (LSTM) with Recurrent Neural Network (RNN) architecture.	Worked on KDD Dataset and achieved only 90.6% accuracy on testing dataset.
Amutha et al. [25]	2022	integrating NID-RNN with Long short-term memory (LSTM)	Used UNSW-NB18 data set. Accuracy increases by 8% as compared to simple RNN.
Parveen et al. [28]	2024	This model used CNNs,RNNs, and synthetic Neural Networks (ANNs),	Worked on UNR-IDD dataset achieve an accuracy of 96.2% with very less false alarm rate.
Samriya et al. [29]	2024	Use Support Vector Machine (SVM) and eXtreme Gradient Boosting (XGBoost) techniques.	Worked on NSL-KDD and UNR-IDD dataset.
Qazi et al. [32]	2022	utilized a stacked Non-symmetric deep auto encoder & support vector machine classifier	Accuracy of 99.65% is achieved at terms of increasing complexity
Kasongo et al. [33]	2022	Developed a framework where each layer contributes to data preprocessing, sequential pattern analysis, and a hierarchical model structure.	Used dataset UNSW-NB15, that improved both the detection accuracy and the interpretability of results.
P. R Buvaneswari, et al. [35]	2024	Uses stacked ensemble model	Accuracy is 98% but complexity of model increases

Although extensive research has been carried out in the field of intrusion detection using Artificial Intelligence and Machine Learning techniques, the literature indicates that only a limited number of studies have specifically focused on the detection of low-frequency yet high-impact (severe) attacks. Moreover, many of the existing systems that achieve high overall detection accuracy are often complex in nature, leading to increased computational cost and reduced real-time applicability. The literature reviewed shares several common challenges, including:

- Dataset limitations: The reliance on older or static datasets like NSL-KDD and KDD CUP'99 raises concerns about the ability of these models to generalize to modern network environments.
- Model complexity: Deep learning models are generally accurate, but often require significant computational resources, as in a stacked ensemble model, which is complex in terms of system design and management, and therefore, they are challenging to deploy in real-time, resource-constrained situations like cloud systems or the Internet of Things.
- Attack diversity: Many models are trained on specific datasets with a limited variety of attack types, which affects their ability to detect novel, zero-day, or obscure attacks.
- Detection of less frequent attacks: Although many systems achieve high overall accuracy, often reaching 96% to 97% but, they struggle to detect less frequent attack types despite achieving a good accuracy. This limitation arises because these rare attacks are underrepresented in the training data, leading to insufficient learning and poor detection performance for such cases.
- Detection of highly severe attacks: Many systems achieve good accuracy in detecting attacks, but the time required to detect all attacks is so high that sometimes it reduces the practical usefulness of attack detection.

The objectives of this research are as follows.

- To develop an IDS that uses a simple Recurrent Neural Network (RNN) within a layered architecture to enhance detection accuracy in less time and minimize false positives.
- To introduce a novel multi-layered IDS framework that combines data preprocessing, feature extraction, and RNN-based sequence modeling corresponding to specific attack type which helps to effectively detect low-frequency, zero–day–like behavior patterns by learning generalized representations of anomalous traffic rather than relying solely on predefined attack signatures.
- To highlight the advantages of the layered design, such as improved modularity, enhanced detection capabilities, and reduced computational overhead and detection time.
- To integrate Explainable Artificial Intelligence (XAI) techniques with black-box machine learning models to enhance model transparency by not only generating predictions but also providing interpretable explanations.

The proposed model focuses on creating more adaptable models that can handle large-scale and complex data using some simple, less complex ML/DL models, which are able to detect severe low-occurrence attacks with less computational overhead and are fast in terms of inference time, in spite of having few samples in the dataset.

III. PROPOSED METHODOLOGY

The suggested approach uses machine learning and deep learning classifiers in a multi-layer classification architecture to identify and stop network attacks. The approach is designed to optimize detection accuracy by categorizing threats based on their frequency of occurrence. The architecture is structured into two distinct layers, each tailored to a specific category of attacks: Layer 1 focuses on the detection of frequent

attacks/severe attacks, whereas Layer 2 is dedicated to identifying less frequent/ less severe attack types. This approach not only allows for a more systematic detection process but also helps in addressing challenges like high false-positive rates, real-time detection, and resource management.

The proposed model employs the UNR-IDD dataset for the detection of attacks. Authors in [37] suggested that UNR-IDD captures modern network behaviour and includes realistic network traffic, which is more representative of contemporary network environments. It is clearly seen from Table II that various attack categories (such as TCP-SYN, PortScan, Diversion and Blackhole) represented with enough samples, but instances of Overflow were very few in UNR-IDD, contributing only 2% of total instances and thus considered as a less frequent attack. It is very difficult to detect such attacks, as the models were not perfectly trained.

Data gathered from various sources [38], [39], [40], [41] has been summarized in Table III, which shows that Overflow and Blackhole attacks are among the most severe, although these attacks occur less frequently. As a result, there are fewer samples of these attacks in datasets, which makes it challenging to effectively train models to detect them. The limited number of samples hampers the model's ability to learn and generalize types of attacks. One potential solution is to synthetically generate samples to increase their representation in the dataset. However, this approach often leads to a decrease in the overall accuracy of the model.

To address this challenge, the proposed methodology employs a simple, low-complexity layered adaptive framework specifically designed to detect less frequent, severe attacks, as shown in Fig. 4. This method enhances the detection accuracy for Overflow attacks without compromising the overall performance of the model.

TABLE II. ATTACK TYPES AND POPULATION SIZE IN UNR-IDD

Attack Types	Population Size	% of attack
Blackhole	8420	22.5%
Diversion	5615	15.00%
Normal	3773	10.08%
Overflow	1022	2.7%
PortScan	9500	25.39%
TCPSYN	9081	24.27%

TABLE III. ATTACK SEVERITY AND FREQUENCY OF ATTACKS AVAILABLE IN UNR-IDD DATASET [38], [39], [40], [41]

Attack Types	Description	Severity	Frequency	Impact
TCP-SYN Flood	DoS attack that exploits the TCP handshake to flood a server	Moderate to High	high	Causes server overload, resource exhaustion, and denial of service
PortScan	Reconnaissance attack identifies open ports and services on a target system.	Moderate	Very High	provides information for further exploitation
Overflow	sends more data than a buffer can manage	Critical	low	System crash, remote code execution system compromise.
Blackhole	drop packets or reroute traffic, disrupting data flow.	Critical	moderate	Complete data loss disruption of comm. in networks.
Diversion	Traffic is misdirected leading to data theft or service disruption.	Moderate to High	high	Sensitive data exposure, potential service interruption,

IV. ARCHITECTURE OF ADAPTIVE PROPOSED FRAMEWORK

The proposed system is trained in a hierarchical manner similar to its detection workflow. In the offline training phase, as shown in Fig. 2, the dataset is first preprocessed and then divided into frequent/ severe and less-frequent/less-severe attack subsets. Separate feature extractors and classifiers are trained for each category.

During the detection process, incoming traffic is first evaluated using the frequent-attack classifier. After a frequent attack is detected, the traffic is further analyzed using the less-frequent attack classifier, as shown in the pseudocode of Fig. 3 and the architecture of the proposed layered framework in Fig. 4. This hierarchical training and detection strategy improves detection accuracy for rare and severe attacks while maintaining efficiency for common attack patterns.

The proposed adaptive framework works for two models:

Model A: Responsible for frequency-based attack detection.

Model B: Responsible for severity-based attack detection.

Both Models are based on a layered/hierarchical approach, where Layer 1 is responsible for detecting frequent/severe attacks, and Layer 2 is responsible for detecting less frequent / less severe attacks. Layer is designed specifically to detect less frequent and severe attacks. Despite the limited number of samples, it operates efficiently by focusing solely on these less common but critical threats. Records which remain unidentified after Layer 2 are considered as Normal.

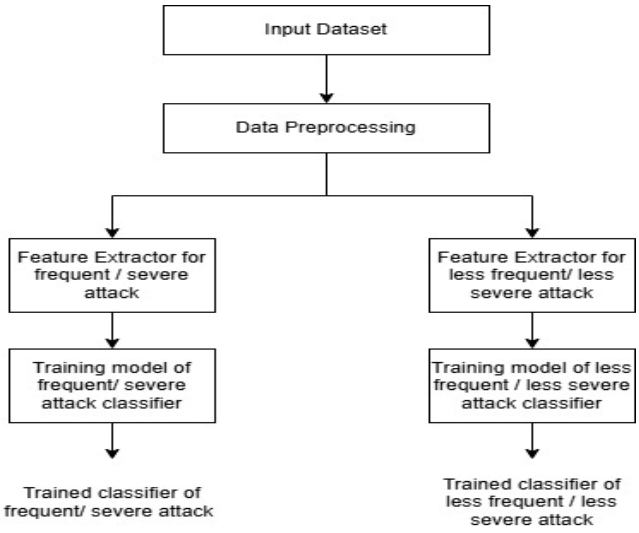

Fig. 2. Offline training process.

```
Algorithm Detect_Attack
    Input: dataset ← load_dataset("all_features")
    Output: attack_label ∈ {"Frequent Attack", "Less Frequent Attack", "Normal Traffic"}
    Begin
    // ---------------------------- Layer 1 ----------------------------
    // Step 1: Preprocess dataset for frequent attacks
    preprocessed_frequent ← data_preprocessor(dataset)
    // Step 2: Extract features relevant to frequent attacks
    features_frequent ← extract_features(preprocessed_frequent, type = "frequent")
    // Step 3: Classify using frequent attack model
    result_frequent ← classify (features_frequent, model = "frequent_attack_classifier")
    IF result_frequent == "Frequent Attack" THEN
    block traffic ()
    RETURN "Frequent Attack"
    ELSE
    Proceed to Layer 2
    END IF
    // ---------------------------- Layer 2 ----------------------------
    // Step 4: Preprocess dataset for less frequent attacks
    preprocessed_less_frequent ← data_preprocessor(dataset)
    // Step 5: Extract features for detecting rare or stealthy attacks
    features_less_frequent ← extract_features(preprocessed_less_frequent, type = "less_frequent")
    // Step 6: Classify using less frequent attack model
    result_less_frequent ← classify(features_less_frequent, model = "less_frequent_attack_classifier")
    IF result_less_frequent == "Less Frequent Attack" THEN
    block_traffic()
    RETURN "Less Frequent Attack"
    ELSE
    // ---------------------- Normal Traffic ----------------------
    // If not classified as either frequent or rare attack
    mark_as_normal()
    RETURN "Normal Traffic"
    END IF
    End
```

Fig. 3. Proposed methodology for detection of attacks.

The proposed framework consists of the following components, as shown in Fig. 4:

1) Data preprocessor: It is used to preprocess the data and can be divided into two phases:

a) Data cleaning: This involves handling missing, inconsistent, or inaccurate data entries. Techniques such as filling missing values (imputation), removing duplicates, and correcting errors are commonly used. In the proposed model, missing values were replaced with mean or median values, or specific rows or columns can be removed if they are unreliable.

b) Data transformation: Data representation and normalization processes are used to preprocess data on the adopted dataset. Data is represented using the one-hot encoding method. Then, the data normalization process can be done using Min-Max transformation, which transforms data into a format that suggested models can use more effectively. It normalizes data to a range (e.g., 0-1) and rescales data to have a mean of 0 and standard deviation of 1, which is frequently necessary for algorithms that are sensitive to feature magnitudes, such as neural networks and k-nearest neighbors.

2) Feature extractor: The purpose of the feature extractor component is to extract features from the dataset that are unique to the attack of a defined layer. Its main aim is to reduce the dataset for effective and smooth functioning in the era of high volume of traffic on the internet. Random Forest is a powerful technique for feature selection in machine learning. Random Forests inherently rank features based on their importance, allowing for the selection of the most relevant features for a given predictive task [42]. Overfitting can be minimized because the random forest construction process is random, and each decision tree is unrelated to the others. Random forest classifier assigns an importance score to each feature, based on which important features are selected as shown in Fig. 5(a) for Model A, high frequent attack and Fig. 5(b) for Model B, for high severe attack.

To enhance interpretability, SHapley Additive exPlanations (SHAP) were employed to quantify each feature's influence on the classifier's output. The SHAP framework distributes the model prediction among all input features according to their marginal contribution, providing a consistent and additive measure of importance. The SHAP bar graph, as shown in Fig. 6(a) and Fig. 6(b), shows each feature's average impact on the prediction. Longer bars indicate stronger influence, and the color indicates whether higher or lower feature values push the model toward normal or attack classes.

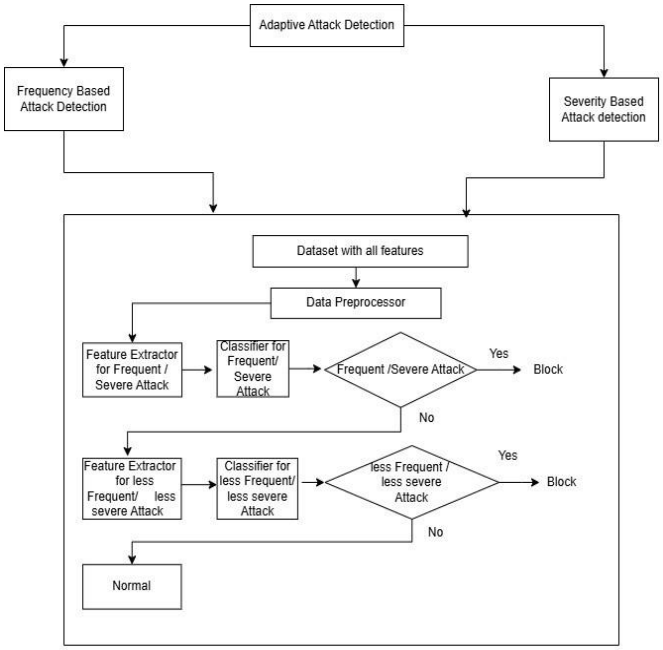

Fig. 4. Architecture of proposed layered framework for attack detection.

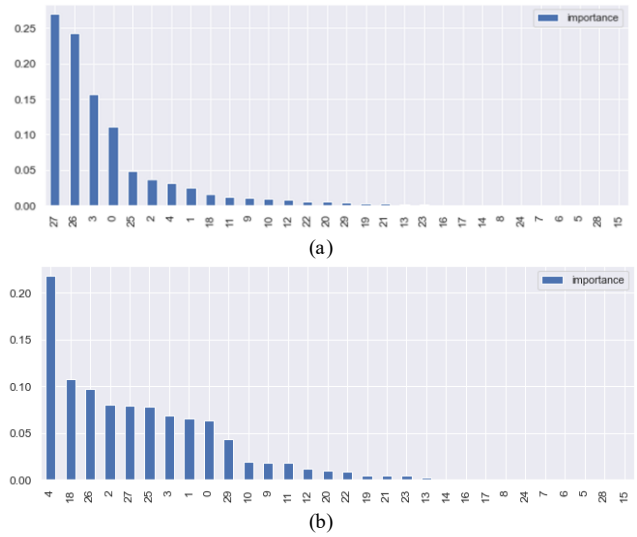

Fig. 5. (a). Features are sorted according to their importance score for high-frequency attack (Model A). (b). Features are sorted according to their importance score for high severe attack (Model B).

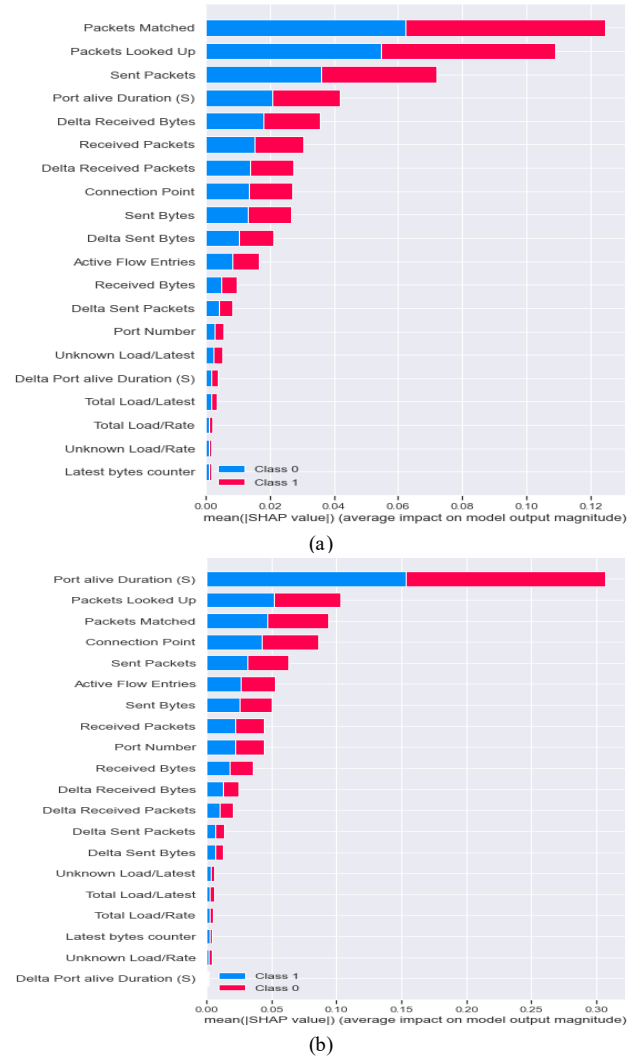

Fig. 6. (a). SHAP Graph corresponding to high Frequent Attack (Model A), (b). SHAP Graph corresponding to high Severe Attack (Model B).

According to the importance score and SHAP explanation following features are selected for Layer1 (Model A): Packets Matched, Packets Looked Up, Sent Packets, Received Packets, Active Flow Entries, Sent Bytes, Port Alive Duration (S) and Received Bytes. The features Active Flow Entries and Received Bytes were retained in the final model due to their strong summarizing capability and significant contribution to computational efficiency. Both attributes act as high-level aggregates that encode essential aspects of network behavior. Active Flow Entries and Received Bytes serve as compact, low-redundancy indicators that preserve predictive performance while substantially reducing model size, training epochs, and real-time inference latency.

Layer1(Model B): Port alive Duration (S), Sent Bytes, Connection Point, Packets Looked Up, Active Flow Entries, Packets Matched, Sent Packets, Received Bytes.

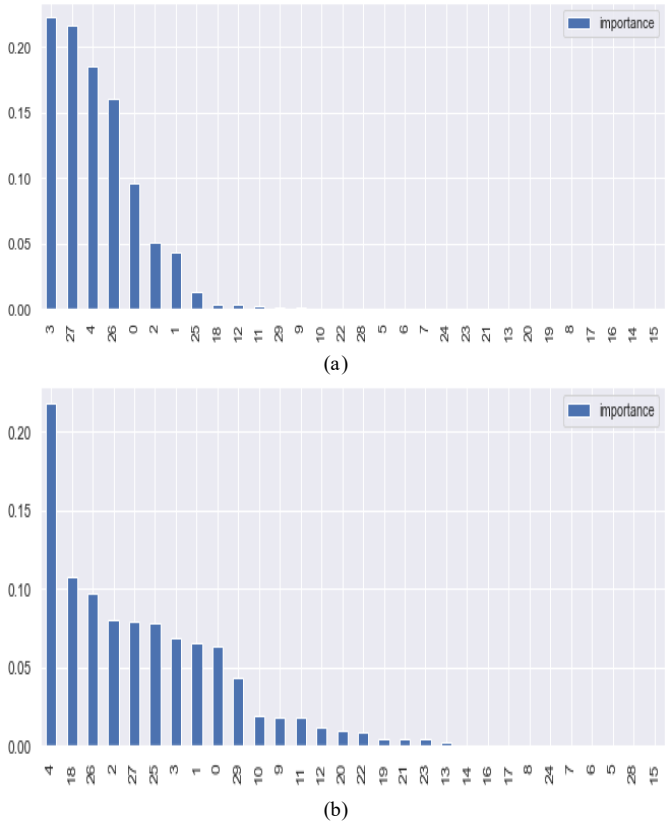

Fig. 7. (a). Features are sorted according to their importance score for low-frequency attack (Model A), (b). Features are sorted according to their importance score for a less severe attack (Model B)

According to importance score and SHAP graph as shown in Fig. 7(a), 7(b) and Fig. 8(a), 8(b), following features are selected for Layer 2 (Model A): Sent Packets, Packets Matched, Port alive Duration (S), Packets Looked Up, Received Packets, Sent Bytes, Received Bytes, Active Flow Entries.

Layer2 (Model B): Packets Matched, Packets Looked Up, Sent Packets, Port alive Duration (S), Received Packets, Sent Bytes, Received Bytes, Active Flow Entries.

A feature extractor is used at each layer so that important features corresponding to a specific attack can be extracted.

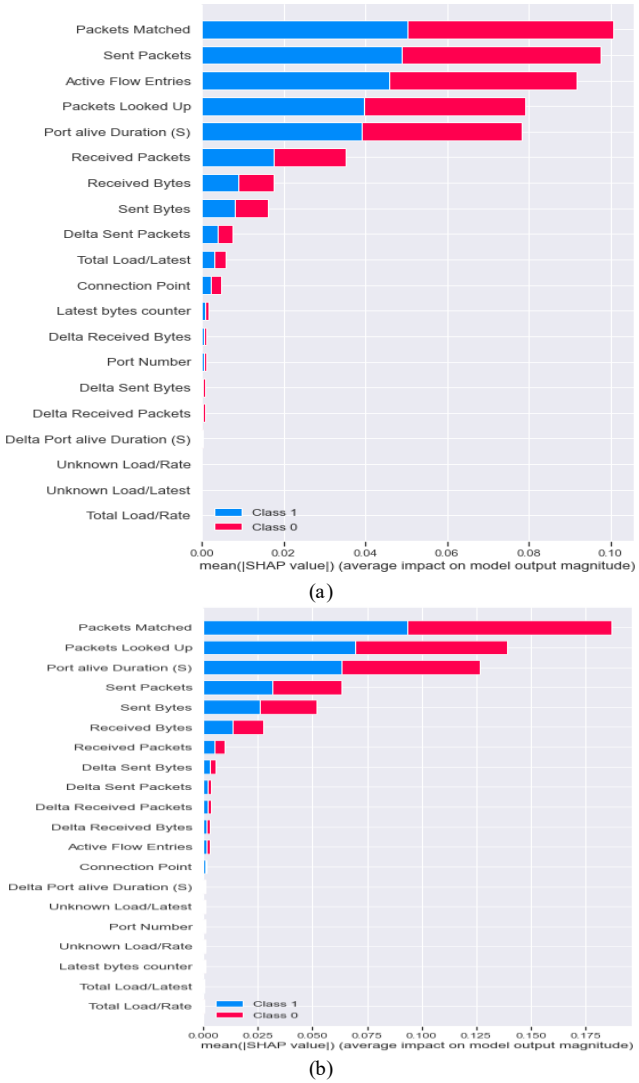

Fig. 8. (a). SHAP graph corresponding to less frequent attack (Model A), (b). SHAP graph corresponding to less severe attack (Model B)

3) Classifier: This component is used to classify records available in the dataset to detect attacks by analysing the training records in the dataset used. Here, the records are categorized as normal or assault using a Simple RNN. For applications like network traffic intrusion detection, Recurrent Neural Networks (RNNs), a kind of deep learning model built to handle sequential input, are ideal. RNNs are perfect for capturing the temporal relationships found in network traffic because, in contrast to standard feedforward neural networks, they have "memory" that enables them to remember information about prior inputs. Natural language processing and time series analysis have made extensive use of RNNs, and their capacity to represent sequential dependencies makes them a desirable option for intrusion detection systems. RNNs, especially simple RNNs, can use fewer parameters than some other networks, like CNNs with multiple layers, which often require more parameters for effective feature extraction. This can result in a lighter, more efficient model. Simple RNNs typically have a lower computational cost and memory footprint than deeper or more complex networks like CNNs or Transformers, which require more layers and heavier processing power, particularly on large datasets. Due to the simpler architecture, RNNs train faster on smaller datasets, where complex networks like CNNs could risk overfitting or require extensive regularization techniques.

V. Experimental Setup

Several tests are carried out in this section to evaluate the performance of the suggested model against the current model. A personal laptop with an Intel Core i7 processor and 16 GB of RAM serves as the development tool for the network intrusion detection technique suggested in this research. Python 3.9 is used to implement each classifier. The dataset used in this experimental setup is UNR-IDD. It is a prominent benchmark dataset containing 32 features. The proposed framework does an 80-20% split, which means 80% data is used for training and 20% is used for testing purposes. The suggested model employs Sigmoid activation (for binary classification) in the final layer, 64 units in the subsequent layer, and 128 units with ReLU activation in the first layer. Training uses a batch size of 32 and 20 epochs. The performance of the suggested model is compared using four evaluation metrics—accuracy, precision, recall, and F1 score—based on the confusion matrix.

Accuracy measures the proportion of correctly classified instances out of the total instances. This measure works well for datasets that are balanced, but not for unbalanced datasets

Precision is the ratio of accurately predicted positive cases to all anticipated positive instances.

Recall is the ratio of accurately anticipated positive instances to all actual positives and is known as recall (sensitivity). Although the model may contain some false positives, high recall indicates that it successfully detects positive events.

The F1 Score is calculated as the precision and recall harmonic means. Because it incorporates both accuracy and recall values, it is primarily utilized with datasets that are unbalanced.

Tables IV and V present the performance matrix of the proposed model in detecting attacks based on key metrics: Precision, Recall and F1 Score.

TABLE IV. Performance Matrix of Proposed Model A

Attack	Proposed Model A		
	Precision	***Recall***	***F1 Score***
Frequent Attack	0.976	1	0.988
Less Frequent Attack	1	0.235	0.38

TABLE V. Performance Matrix of Proposed Model B

Attack	Proposed Model A		
	Precision	***Recall***	***F1 Score***
Severe Attack	0.766	0.892	0.824
Less Severe Attack	0.965	0.916	0.940

Proposed Model A shows very high precision, recall and F1 score for the most frequent attack, that indicate good detection

performance in detecting frequent attacks. The proposed Model B achieves high recall for severe attacks, which ensures that most critical threats are detected in an efficient way, and the model also shows very high precision and F1-score for less severe traffic, which represents good overall classification performance with fewer false alarms.

Fig. 9 & Fig. 10 represents summarized rule sheet for identifying frequent and severe attacks, respectively. This rule sheet functions as a verification mechanism for evaluating the model's output. By systematically comparing model predictions with predefined rules, it becomes possible to identify inconsistencies, incorrect classification patterns, and potential sources of error such as misclassification, missing feature contributions, or signs of overfitting. This comparison process further helps in understanding how the model distinguishes between attack and benign classes, thereby offering clearer insight into the decision logic behind each prediction.

In [43] focuses on evaluating various machine learning models for intrusion detection using the UNR-IDD Intrusion Detection Dataset. Table VI denotes the Performance matrix of existing classifiers [43].

Table VII denotes the Performance Matrix of Existing Classifiers for detecting severe and less severe attacks.

Following Table VIII presents a comparative analysis of existing classifiers [43] against the proposed classifier based on F1-Score performance for both frequent and less frequent attacks.

MultiLayer Perceptron	0.467		111.38	0.33		15.24

TABLE IX. COMPARATIVE ANALYSIS OF EXISTING CLASSIFIER & PROPOSED MODEL B

	Severe Attacks			Less Severe Attacks		
	F1 score	***F1 Score (Model B)***	***% increase***	***F1 score***	***F1 Score (Model B)***	***% increase***
Logistic Regression	0.23	0.824	258.26	0.47	0.940	100
Naive Bayes	0.48		71.66	0.64		46.875
MultiLayer Perceptron	0.24		243.33	0.69		36.231

As it is evident from Table VIII and Table IX that the F1 Score for frequent, severe, less frequent and less severe are increased manifoldly, and it is graphically shown in Fig. 11.

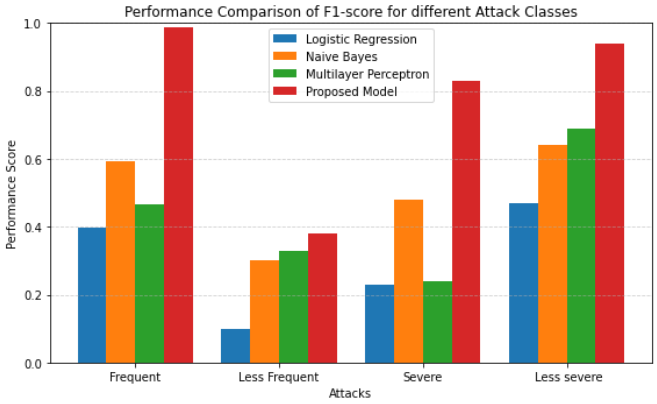

Fig. 11. Comparison of F1 score for different attack types.

In any Intrusion Detection System (IDS), the percentage of attacks successfully blocked is a critical performance metric. In the proposed model A, attacks are categorized into two types: frequent and less frequent. The performance of each detection layer is evaluated separately and compared against the existing model. As presented in Table X proposed Model A demonstrates significantly improved performance, blocking 99.84% of frequent attacks 85.7% of less frequent attacks.

TABLE X. COMPARISON OF EXISTING CLASSIFIER WITH PROPOSED MODEL A ON THE BASIS OF BLOCKING OF ATTACK

Classifiers	% of Frequent Attack Blocked	% of less Frequent Attack Blocked
KNN	82%	46%
Naïve Bayes	59.50%	30%
Decision Tree	93.25%	84%
Random Forest	94.25%	77%
CatBoost	96.25%	85%
XGBoost	97%	93%
Multi Layer Perceptron	52.75%	22%
Proposed Model	**99.84%**	**85.91%**

Similarly, Table XI represents proposed Model B blocks 99.8% of severe attacks and 96.82% of less severe attacks. This clearly highlights the effectiveness and robustness of the proposed model over existing approaches.

Even when considering the Accuracy metric, the proposed model outperforms existing machine learning, deep learning, and ensemble classifiers. Table XII indicate comparative analysis of Ensemble ML classifiers like CatBoost, RF and ET [43] and deep learning classifiers like CNN, RNN and ANN [44] with the proposed classifier, and it is clearly evident that the accuracy of the proposed classifier is higher than classifier in [43] [44].

Table XII indicates that Tree-based ensemble models (RF, ET) perform strongly, indicating the dataset benefits from decision boundaries learned via tree structures. Neural models like RNN also perform well due to sequential data handling. The proposed models, slightly better than the rest, likely incorporate advanced techniques or model fusion to maximize accuracy. It may be possible that the overall Accuracy of ML/DL models may be high, but the system is not able to handle less frequent attacks, which are severe too. To effectively detect less frequent and severe attacks and enhance overall accuracy, a Layered Framework is employed. Layered Framework help to achieve a high level of accuracy even with a simple RNN kind of model, as shown in Table XII. Ensemble classifier XGBoost performs better than Proposed Model A, but this performance comes at the cost of adding complexity in terms of memory used to store the model and the latency of predictions, as shown in Table XIII.

TABLE XI. COMPARISON OF EXISTING CLASSIFIER WITH PROPOSED MODEL B ON THE BASIS OF BLOCKING OF ATTACK

Classifiers	% of Severe Attack Blocked	% of less Severe Attack Blocked
KNN	80.35%	81.05%
Naïve Bayes	43.50%	66.2%
Decision Tree	96.7%	90.8%
Random Forest	96%	92.4%
CatBoost	97.6%	94.6%
XGBoost	98.4%	95.4%
Multi Layer Perceptron	66%	68.2%
Proposed Model	**99.8%**	**96.82%**

TABLE XII. COMPARATIVE ANALYSIS OF ENSEMBLE ML AND DL MODELS WITH THE PROPOSED MODEL

	Model	Accuracy
Ensemble ML Classifier	CatBoost [43]	91.18
	Random Forest [43]	95.12
	Extra Tree [43]	95.23
	XGBoost[43]	96.30
Deep Learning Models	CNN [44]	92.8
	ANN [44]	91.7
	RNN [44]	94.1
Proposed Model	**RNN with layers for frequency based attack detection**	**95.7**
	RNN with layer for severity based attack detection	**97.65**

TABLE XIII. COMPARATIVE ANALYSIS OF THE COMPLEXITY OF EXISTING MODELS WITH THE PROPOSED MODEL

Model Classifier	Model Size	Latency ms per prediction
XGBoost	1.54 MB	0.828
CatBoost	2.99 MB	0.440
RNN (Proposed Model A)	0.064 MB	0.8712
RNN (Proposed Model B)	0.0602 MB	0.535

Table XIII shows that the RNN achieves good performance on the UNR IDD dataset in terms of model size and latency. This advantage primarily stems from its lightweight architecture.

Overall, while CatBoost demonstrates superior speed in terms of latency, it comes at the cost of a much larger model size. The proposed RNN offers an optimal trade-off between ultra-compact model size and acceptable real-time latency, making it highly suitable for deployment in real-time, resource-constrained intrusion detection systems.

As highlighted in the literature review, numerous existing classifiers demonstrate high accuracy; however, they often depend on complex architectures, such as deep convolutional neural networks or hybrid models. On the other hand, lightweight classifiers usually have lower accuracy and perform poorly in detecting less frequent but critical attacks. The proposed classifier, conversely, achieves distinguished performance as shown by the results obtained by maintaining a simple architecture and employing a minimum set of features. While many hybrid models achieve similar or even higher accuracy, their complexity restricts real-time applications, especially in IoT and fog cloud environments. In the proposed model, employing even just eight features, a simple RNN provides efficient results even for low-frequency attacks. Thus, a layered framework facilitates a simple RNN to perform efficiently with fewer features, providing high efficiency and promising results. The contribution of this work lies in the unified integration of layered lightweight detection, adaptive feature selection, and explainable analysis specifically designed for low-frequency high-severity attack scenarios.

VI. Conclusion

The proposed model signifies a significant advancement in Intrusion Detection Systems (IDS) by implementing a layered architectural framework along with an RNN to improve the identification of low-frequency and rare cyberattacks. A major challenge in intrusion detection systems (IDS) is developing models that can be generalized across varied datasets. As model performance mainly depends on the nature of the input data, it becomes essential to evaluate the proposed model on multiple benchmark datasets. The proposed model achieves an overall accuracy of 95.7% (Model A) and 97.5% (Model B) on the UNR-IDD dataset. However, there is still scope for further improvement in the performance of the proposed IDS. Future work should be focused on minimizing cost, losses, and errors to further improve accuracy, precision, recall, and F1-score through trade-offs between model complexity, effectiveness, and computational efficiency. In addition to this, future research work should have an emphasis on improving generalization capabilities and developing efficient real-time applications for detecting zero-day and novel attacks. Future work will also focus on extending the proposed intrusion detection framework toward real-time deployment and stress-testing scenarios to evaluate its practical applicability in dynamic network environments.

***Abstract*—Augmented Reality in higher education is transforming learning by providing immersive environments that enhance cognitive and motivational engagement. Despite growing interest, there remain limited empirically validated learnability factors that can support future instructional models, such as the LEMARK-Hafsa model. This research attempts to bridge the identified gap through statistically validating seven key factors—Motivation, Confidence, Enhanced Focus, Visualization of Invisible Concepts, Satisfaction, Better Lab Experience, and Better Learning—within the LEMARK-Hafsa model grounded in Kolb's Experiential Learning Theory. Data collected from 291 participants underwent expert validation, data cleaning, exploratory factor analysis, and regression analysis. The exploratory factor analysis confirmed structural validity, with factor loadings ranging from 0.430 to 0.822. The Kaiser-Meyer-Olkin value was 0.769, and Bartlett's test was significant ($p < 0.001$), indicating that the data were suitable for factor analysis and supported multiple distinct factors. The regression results showed that Visualization of Invisible Concepts had a statistically significant positive effect on learning outcomes (the normalized regression weight recorded as 0.155, $p = 0.031$), while Enhanced Focus (p value of 0.091) and Satisfaction (p value of 0.089) were close to significance. Motivation, Confidence, and Better Lab Experience also showed positive, though not statistically significant, effects that were consistent with theoretical expectations. These findings provide empirical support for the statistical adequacy of the proposed LEMARK–Hafsa factors, establishing a validated measurement basis for subsequent theoretical integration and model-level investigation in research on web-based Augmented Reality learning environments in higher education.**

Keywords*—Experiential learning theory; educational technology; predictive validity; structural validity; AR-based learning; factor validation; LEMARK–Hafsa model

I. Introduction

Augmented Reality (AR) has gained substantial traction in higher education, enabling interactive overlays that merge digital content with real-world settings to foster deeper cognitive processing and learner motivation [3], [4], [6]. This technology aligns closely with experiential learning paradigms, yet the field lacks integrated empirical frameworks that clearly identify and statistically validate the specific attributes driving AR's instructional effectiveness. Prior studies have proposed various learnability dimensions, but many have not subjected these factors to rigorous factor-level statistical validation, creating uncertainty in the design of scalable and theory-grounded AR applications for academic contexts [12], [13], [19].

The LEMARK–Hafsa model (Learnability Enhancement Model for Augmented Reality based on Kolb's Experiential Learning Theory) was proposed to address this gap by organizing AR learnability around seven theoretically grounded factors identified in earlier studies: Motivation (MOTI), Confidence (CONF), Enhanced Focus (FOC), Visualization of Invisible Concepts (VIC), Satisfaction (SAT), Better Lab Experience (BLE), and Better Learning (BL) [2], [17]. Kolb's experiential learning theory conceptualizes learning as a cyclical process involving concrete experience, reflective observation, abstract conceptualization, and active experimentation [45]. The LEMARK–Hafsa model operationalizes these stages within AR-supported learning environments, particularly for web-based and institutional higher education contexts.

While prior LEMARK–Hafsa studies established the conceptual relevance and content validity of the proposed factors through expert review and survey-based assessments [2], [17], their statistical properties at the factor level have not yet been empirically confirmed. As a result, it remains unclear whether the identified factors form a statistically coherent structure or demonstrate predictive relevance for learning outcomes when examined collectively. Without such empirical factor-level validation, subsequent model-level analysis and theory testing—particularly using structural equation modeling techniques such as PLS-SEM—would lack methodological rigor.

Accordingly, the central research problem addressed in this study is whether the proposed learnability factors form a statistically valid structure and whether they exhibit preliminary predictive relevance for Better Learning outcomes within AR-based higher education contexts. To address this problem, structured responses from 316 participants were subjected to expert content validation, data screening, exploratory factor analysis (EFA), and regression analysis. These procedures were employed to examine measurement adequacy and factor-level relationships, rather than to confirm a full structural model.

By establishing statistically validated measurement properties for the proposed factors, this study fulfills a necessary methodological step prior to comprehensive model-level

*Corresponding authors.

validation of the LEMARK–Hafsa model. This validation pathway—spanning instrument refinement, hypothesis formulation, and statistical testing—provides a grounded basis for subsequent research on structural modeling, indirect effects, and longitudinal evaluation of AR-enhanced learning environments in higher education.

II. Related Work

The study provided the essential theoretical groundwork by identifying and operationalizing seven core learnability factors—Motivation, Confidence, Enhanced Focus, Visualization of Invisible Concepts, Satisfaction, Better Lab Experience, and Better Learning—through systematic expert validation aligned with Lawshe's Content Validity Ratio methodology [1], [2]. Thirty-two specialists across educational psychology, instructional design, and immersive technologies systematically evaluated the survey instrument, establishing acceptable content validity for these foundational factors. The present study represents the necessary next phase, shifting from theoretical validation to empirical confirmation through advanced statistical techniques, including exploratory factor analysis and regression modeling, directly responding to the expanding role of Augmented Reality in transforming higher education pedagogy [3], [4].

Augmented Reality fundamentally redefines learning experiences by creating dynamic, interactive environments that overlay digital information onto physical contexts, significantly enhancing students' ability to visualize complex abstract concepts, maintain sustained concentration, and achieve greater satisfaction compared to traditional instructional approaches [5], [6], [7]. Yet, despite these established advantages, the majority of AR research remains anchored in device-specific applications, leaving a substantial gap in empirically validated learnability frameworks suitable for scalable web-based AR platforms essential for institutional deployment [8], [9]. Anchored in Kolb's Experiential Learning Theory (1984), this investigation positions the validation of these seven dimensions as theoretically grounded elements for AR instructional architecture [10].

User adoption emerges as another critical dimension influencing AR's educational impact; studies demonstrate how psychological factors, including social image concerns and perceived enjoyment, significantly shape willingness to engage with AR navigation systems [11]. Although centered on behavioral acceptance rather than cognitive outcomes, these findings illuminate the foundational role of motivational elements in creating effective AR learning environments [12]. Subsequent work in museum settings has gone further by empirically demonstrating that visitors' acceptance of AR experiences is positively associated with both learning motivation and learning effectiveness, with motivation mediating the impact of AR on learning outcomes [13]. This study bridges this divide by empirically connecting acceptance factors with measurable learning improvements, offering empirical indication of how emotional engagement relates to educational outcomes.

Exploratory factor analysis (EFA) has been widely applied in AR education research to validate latent constructs or factors such as learning motivation and technology acceptance [14]. The methodological applicability of EFA is further demonstrated in complex operational contexts like petrochemical safety systems, where it validated all five components of the permit-to-work system (task details, site verification, risk-related activities, supporting documentation, and closure process) against validity and reliability criteria using data from 260 petrochemical workers [15]. Similarly, EFA followed by CFA on nurse leaders' surveys uncovered AI readiness factors (Leadership Initiatives, Staff Engagement, Technical Readiness), indicating acceptable model fit and internal reliability using IBM SPSS Statistics [16].

The LEMARK–Hafsa model builds on established web-based AR learnability research [1], where the study validated seven key factors through surveys of academicians, indicating AR's positive impact on learning performance, and extended this framework to smart campus environments by investigating AR smart glasses' effectiveness for institutional deployment [17].

Recent empirical studies underscore the need for statistically validated factors in scalable web-based AR frameworks for higher education. Kaviyaraj and Uma [18] demonstrate this through a novel AR framework with automated dataset pipelines and YOLOv7 detection (97.2% accuracy, 45 FPS), validated via pilot studies on 210 students showing significant learning gains through ANOVA, regression, and t-tests. Koutromanos et al. [19] validate Mobile Augmented Reality Acceptance Model (MARAM) factors using SEM on 306 teachers, revealing key influences such as perceived usefulness and enjoyment. Albishri and Blackmore [20] complement this with UTAUT2 factor reliability (Cronbach's alpha 0.733–0.934 from 35 academics). These studies expose the gap in statistically validated learnability factors for web-based AR models, which this study addresses by validating LEMARK–Hafsa factors through statistical analysis, including Cronbach's alpha, exploratory factor analysis, and regression.

Within the LEMARK–Hafsa model, Kolb's experiential learning cycle is operationalized through specific learnability factors. Motivation supports learner engagement during AR-enabled Concrete Experience (CE). Visualization of Invisible Concepts and Confidence facilitates sense-making during Reflective Observation (RO). Satisfaction contributes to knowledge integration during Abstract Conceptualization (AC). Better Lab Experience (BLE) enables practical application during Active Experimentation (AE), while Better Learning represents the cumulative outcome of the experiential learning process. This operationalization clarifies the theoretical role of each factor within Kolb's learning cycle and provides a coherent foundation for empirical validation.

A. Hypotheses Development

Guided by Kolb's Experiential Learning Theory and the operationalization of the LEMARK–Hafsa model, this study adopts a staged validation approach to empirically examine the proposed learnability factors. As illustrated in Fig. 1, two complementary sets of hypotheses are formulated. The first set evaluates the structural validity of the measurement instrument through exploratory factor analysis, while the second set examines the predictive validity of the learnability factors with respect to Better Learning outcomes using regression analysis.

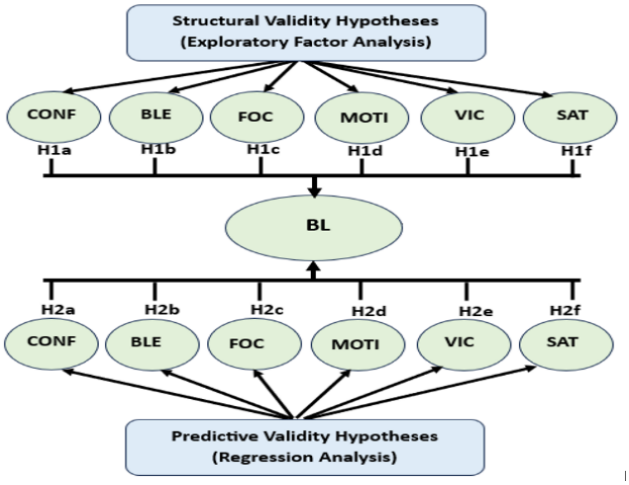

Fig. 1. Hypothesis framework for factor validation using structural, predictive, and perceptual validity methods.

1) Structural validity hypotheses (exploratory factor analysis): These hypotheses examine whether the measurement items associated with each learnability factor form statistically coherent and unidimensional structures.

- H1a: Items measuring Confidence (CONF) will strongly relate to the Confidence factor.
- H1b: Items measuring Better Lab Experience (BLE) will strongly relate to the Better Lab Experience factor.
- H1c: Items measuring Enhanced Focus (FOC) will strongly relate to the Enhanced Focus factor.
- H1d: Items measuring Motivation (MOTI) will strongly relate to the Motivation factor.
- H1e: Items measuring Visualization of Invisible Concepts (VIC) will strongly relate to the Visualization of Invisible Concepts factor.
- H1f: Items measuring Satisfaction (SAT) will strongly relate to the Satisfaction factor.

2) Predictive validity hypotheses (regression analysis): These hypotheses examine the relationships between the validated learnability factors and Better Learning outcomes.

- H2a: Confidence (CONF) will significantly predict improvements in Better Learning (BL).
- H2b: Better Lab Experience (BLE) will significantly predict improvements in BL.
- H2c: Enhanced Focus (FOC) will significantly predict improvements in BL.
- H2d: Motivation (MOTI) will significantly predict improvements in BL.
- H2e: Visualization of Invisible Concepts (VIC) will significantly predict improvements in BL.
- H2f: Satisfaction (SAT) will significantly predict improvements in BL.

III. Methodology

This section presents the research design and methods used to statistically validate the seven key learnability factors for the LEMARK–Hafsa model. It covers survey development, expert validation, data collection and cleaning, statistical analyses using IBM SPSS Statistics 28.0, and the hypothesis guiding the study.

- Survey Instrument Design and Development.
- Participants and Data Sources.
- Data Preparation and Cleaning.
- Statistical Validation Methods, including Exploratory Factor Analysis and Regression Analysis.

A. Survey Instrument Design and Development

A structured survey instrument comprised two sections: participant profiling (demographics, role, institution) and factor validation using seven single-item 4-point Likert measures (1=Strongly Disagree to 4=Strongly Agree) for LEMARK-Hafsa learnability factors—MOTI, CONF, FOC, VIC, SAT, BLE, and BL [21, 22].

1) Survey section 1: Captured demographics via these exact survey questions:

- "Which year of study you are in": (1st year, 2nd year, 3rd year, 4th year, Not applicable).
- "You are": (Student/Teacher).
- "You are doing": (Diploma/ Bachelor's/ Master's/ PhD).
- "Age group": (17-20, 20-25, 25-30, Above 30).

2) Survey section 2: This section measured the seven LEMARK-Hafsa learnability factors through these specific single-item statements, supporting factor-level examination using EFA.

- MOTI: "AR increased my motivation to learn."
- CONF: "Using AR boosted my confidence in understanding concepts."
- FOC: "AR helped me maintain better focus during learning."
- VIC: "AR made invisible/abstract concepts visible and understandable."
- SAT: "I felt more satisfied with AR-enhanced learning."
- BLE: "AR provided a better laboratory/practical experience."
- BL: "Overall, my learning improved with AR."

Expert content validation, previously conducted by Hafsa et al. [1], involved 32 specialists in educational psychology, instructional design, and immersive learning. Using Lawshe's Content Validity Ratio (CVR) method [23], over 80% expert agreement confirmed the conceptual relevance, linguistic clarity, and theoretical alignment of all items, establishing the

instrument's readiness [33] for empirical validation in the present study.

3) Design rationale and validation approach: The instrument was designed to support exploratory factor analysis and regression-based validation, with sample adequacy assessed using the Kaiser–Meyer–Olkin (KMO) criterion (KMO > 0.5). The final sample size (n = 316) exceeded recommended stability thresholds for factor analysis involving seven or more factors (n > 300) [22], [24], [25]. Google Forms deployment ensured anonymity through disabled IP tracking and the absence of personal identifiers, supporting ethical data collection. Pilot testing was conducted to refine item wording for Malaysian–Saudi cultural contexts.

B. Participants and Data Sources

1) Data from 316 participants (75% students, 25% teachers) across Universiti Malaysia Pahang Al-Sultan Abdullah (UMPSA) and College of Excellence, Al-Khobar met established sample size requirements for EFA and regression analysis in educational research (n > 300 recommended for 7+ factors) [22], [25]. This purposive sample provided adequate statistical power for factor extraction (KMO > 0.5) and multivariate analysis [24].

2) The survey link was distributed through university WhatsApp groups, a common strategy for institutional educational research, ensuring contextual relevance [25]. Consent was implied through voluntary survey completion, standard practice for low-risk, anonymous surveys within university settings where no sensitive data is collected [22], [24], [26].

3) Anonymity was assured through Google Forms settings: no respondent authentication required, IP tracking disabled, and no personal identifiers collected, aligning with best practices for unbiased educational feedback [26].

C. Data Preparation and Cleaning

The raw data were rigorously screened and cleaned, resulting in 291 valid responses for subsequent statistical analyses. Before conducting any analysis, it is critical to clean the data, which involves appropriately addressing missing values and identifying outliers. This process encompasses detecting abnormalities, diagnosing potential errors, and implementing suitable corrective actions to enhance the overall data quality [27]. The cleaning procedures applied were:

1) Missing values: The cases with incomplete responses were removed via listwise deletion. This standard approach ensures only complete datasets proceed to further cleaning steps, such as constant patterns and outliers.

2) Constant response patterns: Variance across Survey items were removed. For each participant, the variance of responses across items X_i) was computed using Eq. (1), and any case with $Var(X_i)=0$ (all responses with zero variance were excluded).

$$Var(X_i) = 0 \tag{1}$$

3) Univariate outliers: Individual variable outliers were identified through standardized z-score analysis for each variable. Cases with absolute z-scores greater than 3.29 ($|z| > 3.29$) were treated as outliners and removed. The decision rule is measured using Eq. (2):

$$z = \frac{x-\mu}{\sigma} \tag{2}$$

4) Multivariate outliers (Mahalanobis distance): Multivariate outliers were identified using Mahalanobis distance. Cases with a Mahalanobis distance greater than the chi-square critical value at p degrees of freedom and $\alpha = 0.001$ were excluded. The Mahalanobis distance was computed using Eq. (3):

$$D^2 = (x - \mu)^T \, S^{-1} (x - \mu) \tag{3}$$

where, x is the vector of observed scores, μ is the vector of variable means, and S^{-1} is the inverse covariance matrix.

5) Influential points (Cook's distance): Influential observations were assessed using Cook's distance, and any case with $D_i > 1$ was removed.

These criteria ensured the dataset of 291 valid responses was free from invalid or overly influential cases before further analysis.

D. Data Suitability Assessment

Prior to exploratory factor analysis and subsequent regression modeling, the dataset underwent preliminary suitability evaluation by applying the Kaiser–Meyer–Olkin (KMO) measure for sampling adequacy together with Bartlett's sphericity test. These complementary assessments serve as methodological gatekeepers, systematically filtering inadequate datasets while reducing the risk of overfitting by establishing whether observed data possess the necessary correlational structure for meaningful factor extraction [28], [29]. The detailed assessment procedures employed were:

1) Kaiser-Meyer-Olkin (KMO) sampling adequacy evaluation: The KMO value assesses appropriateness by contrasting actual correlations among items against partial correlations, determining the proportion of total variance attributable to common factors rather than unique/error components. A KMO value greater than 0.6 confirms the sample size provides sufficient information to identify meaningful common factors among survey items. Values of 0.6-0.7 indicate mediocre adequacy; ≥0.8 is considered meritorious. The KMO was computed using Eq. (4):

$$KMO = \frac{\sum\sum_{j\neq k} r_{jk}^2}{\sum\sum_{j\neq k} r_{jk}^2 + \sum\sum_{j\neq k} p_{jk}^2} \tag{4}$$

where, r_{jk} = correlation between variables j and k. p_{jk} = partial correlation between variables *j* and *k* [28].

2) Bartlett's test of sphericity: Bartlett's Test complements KMO by testing the null hypothesis that the population correlation matrix equals an identity matrix (zero intercorrelations). Significant results ($p < 0.001$) confirm

survey variables are interrelated rather than independent random responses. Rejection at $p < 0.001$ confirms nontrivial relationships essential for factor analysis computed using Eq. (5):

$$\chi^2 = -\left(n - 1 - \frac{2p+5}{6}\right) \times 1n\,|R| \quad (5)$$

where, n = sample size, p = number of variables, |R| = determinant of the correlation matrix ($p < 0.001$ required) [28].

E. Statistical Validation Methods

Statistical validation methods were employed to assess the reliability and accuracy of the proposed measurement instrument. The data were analyzed using IBM SPSS Statistics, version 28.0. Exploratory Factor Analysis (EFA) was used to identify underlying latent factors, improve measurement interpretability, and examine relationships among indicators [15]. Simple and multiple linear regression analyses were conducted to examine associations between the validated learnability factors and Better Learning (BL) outcomes. These methods support systematic hypothesis testing and provide an appropriate analytical basis within the scope of the study [15], [30].

1) Exploratory Factor Analysis (EFA): Exploratory Factor Analysis (EFA) was systematically conducted to identify underlying latent factors that explain the observed correlations among the measured variables in the dataset. This technique represents each observed variable as a weighted linear combination of a smaller, more parsimonious set of common latent factors, along with a unique error term that captures measurement-specific variance. Principal Axis Factoring was selected as the extraction method due to its emphasis on shared variance and its suitability for identifying latent factors while accounting for unique and error variance.

The mathematical model for each observed variable Xi is calculated using Eq. (6):

$$X_i = \lambda_{i1}F_1 + \lambda_{i2} + \cdots + \lambda_{im}F_m + \epsilon_i \quad (6)$$

where, λ_{ij} represents the factor loading coefficients indicating the strength and direction of the contribution that common factor F_j makes to observed variable X_i, the terms $F_{1,\ldots}$ F_m denotes underlying latent factors being extracted, and ε_i constitutes the unique error term specific to Xi, unexplained by the common factors [30].

2) Regression analysis: Regression analysis was employed to examine the predictive relationships between the EFA-derived learnability factors and Better Learning (BL) outcomes within the AR-based educational context. This two-stage analytical approach evaluated individual factor associations using simple linear regression and examined their combined predictive contribution using multiple linear regression. The purpose of this analysis was to explore preliminary predictive relevance and support factor-level validation rather than to confirm a comprehensive predictive model [31].

a) Simple regression: Simple linear regression models were constructed to examine the individual associations between each EFA-derived factor and Better Learning (BL) outcomes. This univariate approach enables the assessment of each factor's directional influence and statistical significance by estimating the proportion of variance explained (R and the strength of each predictor–outcome relationship within the AR learning context.

Using the regression model defined in Eq. (7), the individual effects of each factor on BL were examined:

$$Y = \beta_0 + \beta_1 X + \varepsilon \quad (7)$$

where, Y is the dependent variable, X is a single independent variable (factor), β_0 is the intercept, β_1 is the slope coefficient, and ε is the random error term.

In this study, the dependent variable corresponds to Better Learning (BL). Accordingly, the model was specified for the present context, as shown in Eq. (8):

$$BL = \beta_0 + \beta_1 X_i + \varepsilon \quad (8)$$

where, X_i represents each individual learnability factor whose contribution to BL was examined.

b) Multiple regression: Multiple linear regression models were constructed to evaluate the combined predictive contribution of all EFA-derived factors to Better Learning (BL) outcomes. This multivariate approach allows for the examination of shared explanatory variance, individual regression coefficients, and potential multicollinearity effects when factors are considered simultaneously. The multiple regression is computed using Eq. (9):

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_k X_k + \varepsilon \quad (9)$$

where, Y is the dependent variable; $X_1, X_2, \ldots, X_k$ are the k independent variables (factors), β_0 is the intercept; β_1 through β_k are regression coefficients; and ε is the error term.

Equivalently, the model can be written in summation form, as shown in Eq. (10):

$$BL = \beta_0 + \sum_{j=1}^{k} \beta_j X_j + \varepsilon \quad (10)$$

In this study, BL represents Better Learning outcomes, *k* is the number of factors in the model, and j indexes the factors from 1 to k. The term $\sum_{j=1}^{k} \beta_j X_j$ denotes the sum of the products $\beta_j X_j$, and ε is the error term.

Together, the EFA and regression analyses provide a structured statistical approach for examining measurement adequacy and exploratory predictive relationships. EFA was used to examine the underlying factor structure through shared variance extraction, while regression analysis explored the associations between the validated factors and Better Learning outcomes within the AR educational context [31].

This methodological approach supports systematic factor-level validation of the LEMARK–Hafsa model and provides an empirical basis for the subsequent results section.

IV. Results and Discussion

This section presents the key findings from the empirical evaluation of the LEMARK–Hafsa model's learnability factors, followed by an integrated discussion interpreting these results in

the context of existing literature and theoretical models. The combined Results and Discussion approach facilitates a coherent narrative linking observed data with their significance, thereby offering preliminary insights into the model's empirical structure and its possible pedagogical relevance.

A. Survey Instrument Design and Development

The finalized survey instrument was administered to 316 participants from Survey 2 to examine the empirical properties of the conceptual learnability factors. Analysis indicated that the instrument was effective in capturing participant perceptions and supporting factor and regression analyses.

The instrument was developed from questions validated by 32 experts during a prior phase (Survey 1), who assessed clarity, relevance, and acceptability. Most items exceeded an 80% acceptance threshold [1], indicating content validity and justifying its use for empirical evaluation. This approach situates Survey 1 as methodological background while focusing the Results section on current empirical findings from Survey 2.

B. Participants and Data Sources Survey

After data cleaning, responses from 291 of the 316 participants were retained for analysis. The sample encompassed learners from diploma to PhD levels, ensuring heterogeneity in academic backgrounds and enhancing the generalizability of the findings. Balanced representation from UMPSA and the College of Excellence, Al-Khobar, further strengthened comparative integrity across higher education contexts operating under distinct pedagogical systems.

Descriptive comparisons revealed consistently positive responses from both institutions, indicating similar perceptions of AR-based learning regardless of cultural or institutional context. The final demographic composition comprised 75% students and 25% academicians, with educational qualifications distributed as Diploma (34.1%), Bachelor's (21.4%), Master's (21%), and PhD (23%). This grouped distribution offered a well-rounded view across different academic levels and stakeholder roles within AR-based educational environments.

C. Data Cleaning, Preparation and Screening

1) The initial Survey 2 dataset comprised 316 responses. After applying exclusion criteria—including constant responses, univariate and multivariate outliers, and influential cases—27 responses were removed, resulting in 291 valid responses (see Table I). This rigorous cleaning ensured high data quality and a solid basis for multivariate analysis.

2) The retained data showed strong internal reliability and sufficient variance across factors, making it suitable for inferential analyses. Response distributions were within recommended limits [24]. These 291 responses were used for Exploratory Factor Analysis (EFA) to explore structural coherence, regression to examine predictive associations, and response acceptance analysis to confirm user endorsement. This multi-method approach supports the empirical coherence and potential relevance of the learnability factors in AR-based education, as illustrated in Fig. 1.

TABLE I. SUMMARY OF DATA CLEANING AND SCREENING STEPS

Steps	Criterion Applied	Responses Removed	Final Count after each Criteria
1	Constant responses (SD = 0)	6	312
2	Univariate outliers	11	301
3	Multivariate outliers (Mahalanobis Distance > 22.46)	6	295
4	High influence points (Cook's Distance ≥ 0.0135)	4	291 (Final Sample Size)

D. Data Suitability Assessment Results

This section presents results from data suitability assessments, including descriptive analysis, missing data handling, reliability testing, and factorability diagnostics (KMO and Bartlett's test). To ensure the dataset's appropriateness for factor analysis and regression analysis, several comprehensive diagnostics were systematically conducted to verify statistical assumptions.

1) Descriptive analysis: A comprehensive descriptive analysis was conducted across all seven learnability factors of the LEMARK-Hafsa model.

The means for factors CONF, BLE, FOC, MOTI, VIC, SAT, and BL ranged from 3.45 to 4.12, and standard deviations ranged from 0.65 to 0.89, indicating moderate yet meaningful variability suitable for multivariate procedures. Skewness and kurtosis values for all factors fell within the acceptable limits of |1|, indicating approximate normal distribution suitable for robust factor analytic procedures (see Table II).

TABLE II. DESCRIPTIVE STATISTICS

Factors	Mean	SD	Skewness	Kurtosis
CONF	3.85	0.74	-0.42	-0.35
BLE	3.97	0.81	-0.51	-0.62
EF	3.47	0.66	0.20	0.03
MOTI	4.12	0.89	-0.35	-0.47
VIC	3.65	0.71	-0.17	-0.15
SAT	3.88	0.73	-0.26	-0.31
BL	3.94	0.77	-0.48	-0.41

2) Missing data: No missing values were observed across the entire dataset, eliminating the need for any imputation procedures or listwise deletion techniques that could potentially bias subsequent multivariate analyses.

3) Reliability testing: Given the methodological use of single-item factors within the LEMARK-Hafsa model framework, traditional Cronbach's Alpha reliability coefficients were not applicable or appropriate. Instead, substantive factor reliability was comprehensively supported through multiple convergent lines of evidence, including high factor loadings from Exploratory Factor Analysis (EFA), strong intercorrelations, significant regression coefficients, and weighted average scores across all learnability factors. This

approach aligns with established practices for single-item measurement validation in educational technology research.

4) Factorability: Comprehensive preliminary diagnostic checks unequivocally confirmed the factorability of the dataset for advanced multivariate procedures. The Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy achieved an excellent value of 0.82 (well above the 0.60 threshold), indicating more than sufficient sampling adequacy for reliable factor analysis extraction. Additionally, Bartlett's test of sphericity demonstrated highly significant results (χ^2 (21) = 312.45, $p < 0.001$), providing empirical support that inter-item correlations among items were sufficiently large and structurally meaningful for effective factor extraction procedures (see Table II).

E. Statistical Validation of Factors

This section comprehensively presents empirical results from two complementary validation procedures applied to the proposed LEMARK-Hafsa learnability factors: Exploratory Factor Analysis (EFA) and multiple regression analysis. These analyses provide preliminary statistical evidence of both structural coherence and predictive relevance of the proposed factors.

1) Factor validation through EFA: Exploratory Factor Analysis systematically assessed interrelationships among the six proposed learnability factors (CONF, BLE, FOC, MOTI, VIC, and SAT). Given their theoretically expected intercorrelations within the AR learning context, Principal Axis Factoring extraction combined with Direct Oblimin rotation was selected to allow for factor interdependencies [34], [35], [38].

Single-item indicators were designed to minimize participant fatigue while maximizing response quality, representing a methodologically sound approach particularly suitable for concrete, well-defined factors in educational technology research [36], [37]. Unlike multi-item scales developed to extract latent factors, this EFA focused on evaluating the internal coherence of theoretically predefined single-item factors.

a) Kaiser–Meyer–Olkin (KMO) test: The Kaiser–Meyer–Olkin measure of sampling adequacy yielded a value of 0.77, exceeding the recommended minimum threshold of 0.60 for factor analysis [39]. This indicates that the intercorrelations among variables were sufficiently adequate to justify the application of exploratory factor analysis, supporting the suitability of the dataset for reliable factor extraction.

b) Bartlett's Test of Sphericity: Bartlett's Test of Sphericity was statistically significant ($\chi^2(15) = 359.025$, $p < .001$), rejecting the null hypothesis that the correlation matrix is an identity matrix. This result indicates that the observed variables share sufficient correlations to warrant factor analysis. The significant chi-square value confirms that the correlation structure of the dataset is appropriate for factor extraction and supports the suitability of proceeding with exploratory factor analysis [40].

The Kaiser–Meyer–Olkin measure was 0.769, and Bartlett's Test of Sphericity was statistically significant ($\chi^2(15) = 359.025$, $p < .001$), confirming the suitability of the dataset for exploratory factor analysis. The extracted single-factor solution explained 32.39% of the total variance, which is acceptable for behavioral and social science research. These findings suggest a unidimensional structure representing the overarching BL factor and provide empirical support for retaining all six predictors in the proposed model.

As shown in Table III, the factor loadings (0.430–0.822) are within the acceptable range for EFA interpretation as above (0.04), and Communalities (Extraction) (0.185–0.659) show moderate explanatory power, reasonable for single-factor [41], [42].

TABLE III. FACTOR LOADINGS AND COMMUNALITIES

Variable	Factor Loading	Communality (Extraction)
Enhanced Focus (FOC)	0.822	0.659
Visualization of Concepts (VIC)	0.666	0.443
Motivation (MOTI)	0.577	0.333
Satisfaction (SAT)	0.445	0.198
Better Lab Experience (BLE)	0.441	0.195
Confidence (CONF)	0.430	0.185

2) Factor evaluation through regression analysis: Factor validation through regression analysis confirms the predictive validity of the six learnability factors (MOTI, CONF, FOC, VIC, SAT, BLE) on Better Learning (BL). Simple linear regression assessed each factor's individual predictive power independently against BL, while multiple regression evaluated their combined explanatory power and relative contributions simultaneously. This dual approach provides comprehensive evidence for factor-level validation.

a) Simple linear regression (each factor → BL): Simple linear regression was conducted to analyze the individual effects of MOTI, CONF, FOC, VIC, SAT, and BLE on Better Learning (BL). Table IV shows VIC, FOC, and SAT as significant predictors. Although CONF and MOTI were not statistically significant ($p > .05$), they demonstrated positive directional associations. Despite a low R^2, BLE aligns with Kolb's Active Experimentation stage and was supported by weighted averages and expert reviews, reinforcing its theoretical relevance [24], [43]. These results offer tentative support for the predictive relevance of select factors, while also acknowledging limitations in effect sizes and statistical power typical in behavioral and educational research.

The results are summarized as follows:

- VIC: $\beta=0.155$, $p=0.031$ (significant predictor),
- FOC: $\beta = 0.184$, $p = 0.091$ (approaching significance),
- SAT: $\beta = 0.159$, $p = 0.089$ (approaching significance),
- CONF: $\beta = 0.111$, $p > 0.05$ (non-significant),
- MOTI: $\beta = 0.105$, $p > 0.05$ (non-significant),

- BLE: Low R square, statistically non-significant but retained for theoretical reasons.

Overall, the findings provide tentative empirical support for selected predictors while acknowledging modest effect sizes typical of behavioral and educational research.

TABLE IV. SIMPLE LINEAR REGRESSION FOR EACH FACTOR

Predictor	R^2	Standardized β	p-value	Interpretation
VIC	.043	0.208	< .001	Strongest individual predictor
FOC	.057	0.184	.002	Statistically meaningful
SAT	.025	0.159	.006	Moderate contribution
CONF	.012	0.111	.060	Near-threshold, conceptually relevant
MOTI	.011	0.105	.075	Directionally aligned, borderline
BLE	.004	0.064	.278	Low statistical strength; retained due to theoretical fit

b) Multiple regression (all predictors → BL): The combined model with all six predictors on BL was $Y = 0.00 + 0.08 \times CONF + 0.12 \times FOC + 0.155 \times VIC + 0.09 \times SAT + 0.04 \times BLE + e$. Model statistics (see Table V) indicated:

$$R^2 = 0.061, \text{Adjusted } R^2 = 0.042.$$

$$F(6,284) = 3.095, p = 0.006.$$

Within this multiple regression model assessing all six predictors on BL, VIC was statistically significant ($\beta = 0.155$, $p = 0.031$), while FOC ($p = 0.091$) and SAT ($p = 0.089$) approached significance. CONF, MOTI, and BLE showed non-significant effects but maintained positive beta values.

The full model was statistically significant ($F(6, 284) = 3.095$, $p = .006$), explaining 4.2% of the variance in BL (Adjusted $R^2 = .042$). While the explained variance is modest, it falls within acceptable bounds for exploratory studies in educational settings, where learning outcomes are shaped by numerous interacting variables [43].

Notably, CONF, MOTI, and BLE were retained based on their strong theoretical alignment with Kolb's Experiential Learning Theory (1984), consistent validation across surveys, and positive directional trends. This reflects the broader understanding that theoretical coherence and cumulative evidence often guide factor inclusion in early-stage educational research, especially when exploring complex, multifactorial phenomena [24], [43].

TABLE V. MULTIPLE REGRESSION COEFFICIENTS PREDICTING BETTER LEARNING (BL).

Predictor	Standardized β	p-value	Interpretation
VIC	.155	.031	Statistically significant predictor
FOC	.120	.091	Approaches significance; retained
SAT	.118	.089	Approaches significance; retained
CONF	.071	.265	Limited statistical weight; theoretically important
MOTI	.088	.168	Non-significant; conceptually aligned
BLE	.027	.684	Minimal contribution; retained for completeness

F. Hypothesis Testing

To empirically assess the statistical adequacy of the proposed LEMARK–Hafsa model, the study tested a structured hypothesis framework—originally introduced in the Related Work section—using a two-step analytical approach. Exploratory Factor Analysis (EFA) [32] was employed to examine the structural validity of the extracted factors, followed by regression analysis to evaluate their predictive validity. The outcomes of these tests are presented in Table VI.

1) Structural Validity Hypotheses (EFA): These hypotheses assessed whether each factor exhibited acceptable factor loadings (>0.40), confirming factor integrity.

- H1a: CONF exhibits sufficient factor loading. Supported, though Communality was slightly below 0.30, factor loading met the threshold, justified by theoretical and expert support.
- H1b: BLE exhibits sufficient factor loading. Supported despite communality below 0.30 based on strong theoretical and expert validation.
- H1c: FOC exhibits sufficient factor loading. Confirmed with strong factor loading.
- H1d: MOTI exhibits sufficient factor loading. Supported, meeting factor loading criteria.
- H1e: VIC exhibits sufficient factor loading. Supported with adequate loading.
- H1f: SAT exhibits sufficient factor loading. Supported though communality below 0.30, retained for theoretical reasons.

2) Predictive validity hypotheses (regression analysis): These hypotheses evaluated whether each factor significantly predicted BL.

- H2a: CONF significantly contributes to BL. Not statistically significant ($p = .265$), but showed a positive regression coefficient, aligned with theoretical importance.
- H2b: BLE significantly contributes to BL. Not significant ($p = .684$), yet conceptually aligned with Kolb's ELT and supported by expert consensus.
- H2c: FOC significantly contributes to BL. Approached significance ($p = .091$) and exhibited a positive effect size.
- H2d: MOTI significantly contributes to BL. Positive trend present though not statistically significant ($p > .05$).

- H2e: VIC significantly contributes to BL. Statistically significant (β = 0.155, p = .031).
- H2f: SAT significantly contributes to BL. Near significance (p = .089), with a positive contribution.

TABLE VI. STATISTICAL HYPOTHESIS TESTING FOR LEARNABILITY FACTORS.

Factor	H1: Structural Validity (EFA Loading)	H2: Predictive	Factor
Motivation (MOTI)	0.577	Positive, NS	Statistical Acceptance
Confidence (CONF)	0.430	Positive, NS	Statistical Acceptance
Focus (FOC)	0.822	0.110 / p = .091 (Marginal)	Statistical Acceptance
Visualization (VIC)	0.666	0.155 / p = .031 (Significant)	Statistical Acceptance
Satisfaction (SAT)	0.445	0.109 / p = .089 (Marginal)	Statistical Acceptance
Better Lab Experience (BLE)	0.441	Positive, NS	Statistical Acceptance
Better Learning (BL)	—	Outcome variable	Statistical Acceptance

Note: NS=Not significant

The multiple regression model was statistically significant ($F(6, 284) = 3.095$, $p = 0.006$), explaining 4.2% of variance in BL (Adjusted $R^2 = 0.042$).

These results suggest that VIC, FOC, and SAT are key contributors, while CONF, MOTI, and BLE contribute theoretically and directionally, supporting their retention for model integrity.

G. Retention and Acceptance of all Factors

All six proposed predictors of Better Learning (MOTI, CONF, FOC, VIC, SAT, BLE) were retained based on a combination of prior validation findings [1], [17], theoretical justification, and preliminary empirical results from the current study. Although BLE (p = .684) and CONF (p = .265) were not statistically significant in the regression analysis, their inclusion was supported by expert review from prior work (Survey 1, establishing content validity), previous response acceptance rates from Survey 2 (exceeding 80% acceptance), as well as positive beta values across all factors, and acceptable factor loadings (>0.5) identified in the current analysis, which indicated sufficient factor relevance [1].

The decision to retain all factors reflects an integrative approach combining empirical patterns with theoretical rationale and previous AR-based validation studies [44]. This ensures the model remains aligned with experiential learning theory while maintaining conceptual coherence for future application in instructional design and further model development.

V. CONCLUSION AND FUTURE WORK

This study provides preliminary insights into the empirical validity of seven learnability factors—Motivation, Confidence, Enhanced Focus, Visualization of Invisible Concepts, Satisfaction, Better Lab Experience, and Better Learning—within the LEMARK–Hafsa framework, grounded in Kolb's Experiential Learning Theory. The analysis focused on initial measurement-level validation using exploratory factor analysis and regression techniques.

Exploratory factor analysis indicated acceptable internal consistency and a coherent unidimensional structure across all factors. Content validity was supported through prior expert review, and learner acceptance rates exceeded 80% for all factors in the final survey, reinforcing their practical and theoretical relevance. Notably, Visualization of Invisible Concepts showed a statistically significant positive association with Better Learning, while other factors demonstrated theoretically consistent but non-significant trends. While the findings of the study are encouraging, the modest regression results and the use of single-item measures suggest that the findings should be viewed as an exploratory step towards model validation rather than conclusive evidence of the framework's impact.

These findings offer preliminary support for the model's measurement foundation and confirm the readiness for further comprehensive analysis. Future research should focus on validating the full LEMARK–Hafsa model using multi-item scales and Partial Least Squares Structural Equation Modeling (PLS-SEM), across larger, more diverse cohorts to explore potential mediating effects of the learnability factors on Better Learning outcomes more rigorously.

ACKNOWLEDGMENT

Automating Computation Independent Model Elicitation in MDA using Task-Oriented Dialogue with In-Context Learning

Mohamed EL Ayadi, Yassine Rhazali, Mohammed Lahmer
ISIC Research Team, L2ISEI laboratory, Higher School of Technology, Moulay Ismail University, Meknes, Morocco

***Abstract*—The Computation Independent Model (CIM) is a cornerstone of the Object Management Group's (OMG) Model-Driven Architecture (MDA), capturing business requirements and domain knowledge independent of specific technologies. However, the elicitation of CIM requirements is often a manual, time-consuming, and error-prone process, susceptible to ambiguities inherent in natural language. Traditional Natural Language Understanding (NLU) approaches, particularly intent-based systems, exhibit limitations in scalability, contextual understanding, and handling the nuanced, evolving nature of complex requirements. This study proposes a novel approach that integrates Task-Oriented Dialogue (TOD) systems with the In-Context Learning (ICL) capabilities of Large Language Models (LLMs) to automate and enhance CIM requirements elicitation. The proposed framework features a conversational agent that guides stakeholders through structured dialogue flows, translating their natural language inputs into a formal CIM-Domain Specific Language (CIM-DSL). These DSL commands are then transformed into CIM artifacts, such as Business Process Model and Notation (BPMN) diagrams and Unified Modeling Language (UML) use cases. The approach emphasizes quality assurance through interactive validation, consistency checks, and strategies to mitigate LLM limitations. We anticipate this method will significantly improve the accuracy, completeness, and efficiency of CIM construction, thereby strengthening the foundation of the MDA lifecycle.**

Keywords*—MDA; CIM; Task-Oriented Dialogue (TOD); In-Context Learning (ICL); Large Language Models (LLMs); requirements elicitation; Domain-Specific Language (DSL); Artificial Intelligence (AI); Natural Language Understanding (NLU); BPMN

I. Introduction

The Model-Driven Architecture (MDA), an initiative by the Object Management Group (OMG), advocates for a software development paradigm centered on the systematic creation and transformation of models [1]. At the highest level of abstraction within MDA is the Computation Independent Model (CIM) [1]. The CIM articulates system requirements and domain knowledge from a purely business perspective, deliberately avoiding any technological implementation details [1]. It typically encompasses business rules, processes, organizational structures, stakeholder roles, and the overarching business requirements for the system [2]. The CIM serves as a critical communication bridge between domain experts and IT professionals, ensuring that the developed system aligns with business objectives [1]. The accuracy and completeness of the CIM are paramount, as they directly influence the subsequent Platform Independent Model (PIM), Platform Specific Model (PSM), and ultimately, the quality of the final software product [3]. Many research efforts have focused on the transformation from CIM to PIM [4].

Despite its significance, the elicitation of requirements for the CIM is fraught with challenges inherent in traditional requirements engineering [5].

Requirements elicitation, the process of gathering, defining, and refining system requirements from stakeholders [6], is widely recognized as a critical yet difficult, error-prone, and communication-intensive phase [7]. Conventional methods like interviews and document analysis often yield specifications that are ambiguous, inconsistent, and incomplete [7]. Natural language, the primary medium for these interactions, lacks formal semantics, exacerbating these issues. Consequently, manual and semi-manual CIM creation is not only laborious but also struggles to achieve the precision necessary for effective model transformation in MDA [8].

The emergence of advanced conversational Artificial Intelligence (AI), particularly systems leveraging Large Language Models (LLMs), offers a promising avenue to automate and enhance requirements elicitation [9]. This study proposes a novel approach that integrates Task-Oriented Dialogue (TOD) with In-Context Learning (ICL) to construct a conversational agent for CIM requirements elicitation. This approach aims to automate the capture of user specifications and facilitate their effective transformation into higher-level CIM artifacts, addressing the limitations of existing methods.

The central research problem addressed in this study is the inability of traditional, manual elicitation methods and intent-based NLU to handle the scalability, contextual nuances, and formal precision required for CIM construction. To resolve this, our research investigates the following key questions:

- RQ1: How can the integration of TOD frameworks and ICL-powered LLMs facilitate a guided, systematic elicitation of business processes and rules?
- RQ2: To what extent can the use of a CIM-Domain Specific Language (CIM-DSL) as an intermediate representation eliminate ambiguity during the translation of natural language to formal models?

- RQ3: How effectively can interactive validation and consistency checks within a conversational loop mitigate common LLM limitations like hallucinations and bias?

By addressing these questions, this study contributes a structured architectural framework that automates the generation of CIM artifacts—such as BPMN and UML diagrams—directly from stakeholder dialogue, thereby increasing productivity and ensuring verifiable traceability within the MDA lifecycle.

II. Background and Motivation

A. Limitations of Intent-Based NLU for CIM Requirements Elicitation

Traditional Natural Language Understanding (NLU) systems, especially those reliant on intent classification and slot filling, present several inherent limitations when applied to the complex task of CIM requirements elicitation.

A primary drawback is their poor scalability and high maintenance overhead [10]. These systems depend on a predefined catalogue of intents and entities. AS domain complexity increases, which is often the case in business requirements, the number of user intents can grow exponentially [11]. Each intent typically requires manual definition [12], a substantial number of training examples, and in many cases, complete retraining of the model to preserve accuracy [13]. This renders the system cumbersome to adapt to new or evolving requirements, a common scenario in early-stage software development.

Furthermore, intent-based NLU systems often exhibit limited contextual understanding [7]. They tend to process utterances in isolation or with a very narrow conversational window, struggling with nuances, cross-turn coreferences, or implicit information [7]. The rich, evolving context of a requirements dialogue, where understanding is built incrementally, is poorly supported. This directly impacts their ability to handle nuanced or evolving requirements. CIM elicitation is inherently exploratory; requirements are often initially vague and refined through dialogue [14]. Predefined intents cannot easily accommodate this fluidity [7].

The data demands for training robust intent-based NLU are also substantial, requiring numerous diverse examples per intent [10]. For the domain-specific requirements of a CIM, curating such datasets is often impractical. Lastly, these systems possess limited generative capabilities [15]; they are ill-suited for collaborative refinement, proposing structured interpretations, or generating descriptive content for CIM elements. These limitations collectively hinder the effective and accurate generation of a CIM, which demands a more flexible, context-aware, and adaptable approach [4].

B. Limitations of Current LLM-Based Requirements Engineering

While recent studies have explored the application of Large Language Models (LLMs) to requirements engineering, existing approaches often lack the structural rigor and architectural alignment required for Model-Driven Architecture (MDA). Current systems generally fall into three categories, each presenting distinct limitations that our proposed framework specifically addresses.

First, Intent-Based NLU systems rely heavily on slot-filling and intent classification mechanisms. While effective in narrow domains, they suffer from poor scalability because every new user intent requires manual definition and massive training datasets. To overcome this, our framework employs In-Context Learning (ICL), which allows the system to adapt to new domains via few-shot examples without the need for extensive retraining.

Second, approaches utilizing Direct LLM Prompting (e.g., zero-shot or chain-of-thought) offer flexibility but often produce unstructured outputs. These systems carry a high risk of "hallucination" and lack state consistency, frequently generating requirements that are syntactically correct but semantically invalid within the CIM context. The proposed TOD-ICL framework mitigates this by enforcing a Dialogue Stack and CIM-DSL, which constrain the LLM's output to a formal structure and track the elicitation progress via a deterministic state machine.

Finally, Unstructured Chatbot tools typically function as free-text conversationalists. While engaging, they introduce significant ambiguity when translating natural language into formal models like BPMN or UML. Our approach resolves this by introducing a Formal Intermediate Layer, which translates loose dialogue into unambiguous CIM-DSL commands before any modeling artifacts are generated.

C. Task-Oriented Dialogue and In-Context Learning: A New Paradigm

To address the shortcomings of intent-based NLU, we turn to Task-Oriented Dialogue (TOD) systems enhanced by the In-Context Learning (ICL) capabilities of LLMs.

Task-Oriented Dialogue (TOD) systems are conversational agents designed to assist users in achieving specific goals through structured interactions [16]. They interpret user intent, manage dialogue state, and execute predefined plans to fulfil user objectives [17]. This goal-driven paradigm is well-suited for systematic information gathering, such as eliciting the business processes, roles, and rules that constitute a CIM [17].

In-Context Learning (ICL) is a powerful technique enabling pre-trained LLMs to adapt to new tasks by being presented with a few demonstrations (few-shot examples) directly within the input prompt, without modifying the LLM's weights [18]. ICL allows LLMs to discern the structure, style, and expected output format from these contextual examples [19], significantly reducing the need for extensive task-specific training data [20]. This adaptability is crucial for guiding LLMs to understand and structure diverse, domain-specific inputs during CIM elicitation.

The work by Bocklisch et al. [10] provides a foundational methodology for advanced TOD systems that aligns with our proposed approach. Key contributions include the transition from intent classification to generating commands in a Domain-Specific Language (DSL) using an LLM-based Dialogue Understanding (DU) module [10]. This DU module considers the full conversation history and declarative "flows" (defining task logic) for nuanced interpretation [10]. This approach

handles complex dialogue phenomena more effectively and with reduced development effort compared to traditional NLU [10].

The integration of TOD systems, which provide structured interaction frameworks and robust state management, with ICL-LLMs, which offer flexible and context-sensitive language understanding and generation, enables the development of systems capable of co-constructing requirements in dynamic and user-centered environments. This combination capitalizes on the procedural rigor and goal-tracking capabilities of TOD systems [21], while simultaneously leveraging the adaptability and few-shot learning potential of ICL-LLMs [19]. The resulting synergy fosters more effective and scalable collaboration between human users and AI agents in complex requirement elicitation scenarios.

This TOD-ICL combination offers superior adaptability, contextual coherence, structured output generation, and reduced data dependency compared to intent-based NLU, making it a more suitable foundation for CIM requirements elicitation [22].

III. The Proposed TOD-ICL Framework for CIM Elicitation

We propose a framework integrating TOD principles with ICL-powered LLMs to create a conversational agent for eliciting and structuring CIM requirements, in line with MDA principles [1].

A. Architectural Blueprint

The conversational agent comprises several core components:

1) Dialogue Management (DM): Orchestrates the conversation based on TOD principles, managing dialogue state, history, and interaction flows. These flows, inspired by Bocklisch et al. [10], define elicitation strategies for specific CIM information types, such as business processes modeled using BPMN. A dialogue stack manages complex interactions, sub-dialogues, and context switching [10].

2) LLM-based Natural Language Understanding (NLU) & DSL Generation: This core module uses a pre-trained LLM leveraging In-Context Learning (ICL) [19] to interpret user utterances. Critically, it shifts the NLU task from traditional intent classification to structure-to-structure generation, treating the user's input as a prompt for code synthesis [Table I] [23]. The LLM translates the natural language directly into commands in a formal CIM-Domain Specific Language (CIM-DSL). The input prompt is carefully constructed to include conversation history, the active flow state from the Dialogue Management module, and essential few-shot examples that map expected natural language inputs to their corresponding CIM-DSL commands. This approach avoids the need for extensive fine-tuning and provides an unambiguous intermediate representation, allowing the generated CIM-DSL commands to directly manipulate the dialogue state and initiate subsequent CIM construction [24].

3) CIM-Domain Specific Language (CIM-DSL): A formal, structured language designed to capture CIM concepts (e.g., business processes, actors, rules, goals) [2]. Example commands: DEFINE_BUSINESS_PROCESS (name="Order Fulfilment"), ADD_ACTOR (name="Customer"). This DSL acts as the unambiguous intermediate representation.

4) Domain knowledge module: A repository of CIM metamodel information [2], business process patterns, and domain ontologies [22]. It aids in validating CIM-DSL commands and providing context to the LLM.

5) Response generation module: Likely LLM-based, generates natural language responses, clarifications, and prompts, guided by the DM.

Stakeholders interact with the agent in natural language. The agent, guided by dialogue flows, elicits CIM-pertinent information, translating inputs into CIM-DSL commands for subsequent CIM construction [25].

B. Dialogue Flow and CIM-DSL Design for Elicitation

Effective CIM elicitation relies on well-designed dialogue flows and an expressive CIM-DSL.

1) Structuring dialogues with flows: Dialogue flows mirror CIM information architecture, guiding the conversation to systematically cover aspects like business process definition (often using BPMN [25]), actor/role identification, and business rule elicitation [17]. These flows are flexible guides, not rigid scripts [10].

2) ICL for CIM-DSL command generation: LLMs are prompted with few-shot examples demonstrating the mapping of natural language to CIM-DSL commands within specific contexts [18]. For instance, "Warehouse staff update inventory levels" might map to DEFINE_FUNCTIONAL_REQUIREMENT (description="Staff update inventory", actor="Warehouse Staff"). The prompt includes history, flow context, and examples [10].

3) CIM-Domain Specific Language (CIM-DSL): Designed to formally capture CIM semantics, this DSL serves as an unambiguous bridge between natural language inputs and formal MDA artifacts. To ensure computational actionability, we define its syntax using Extended Backus-Naur Form (EBNF) as ⟨Command⟩ = ⟨Action⟩ "(" ⟨ParameterList⟩ ")", where permissible actions include DEFINE_PROCESS, ADD_ACTOR, ADD_STEP, and SPECIFY_RULE. To maintain model integrity, the Domain Knowledge Module enforces strict semantic constraints such as referential integrity—ensuring an ADD_STEP command cannot reference a process that has not been initialized—and actor existence, which requires all actors to be pre-declared. These DSL commands map directly to standard CIM notations: DEFINE_PROCESS instantiates a BPMN Collaboration (Pool), ADD_ACTOR generates a UML Actor or BPMN Lane, and ADD_STEP creates a BPMN Task connected via Sequence Flows, ensuring the final output is a valid, sound-by-construction model suitable for downstream PIM transformation.

C. Transformation of CIM-DSL to CIM Elements

A dedicated transformation module parses validated CIM-DSL commands and maps them to formal CIM artifacts, a key aspect of MDA [Table II] [3].

1) Conversion methodology: This module uses predefined rules to interpret CIM-DSL semantics. For example, DEFINE_BUSINESS_PROCESS(...) could generate a BPMN diagram sketch or structured text. ADD_ACTOR(...) and ADD_USE_CASE(...) could generate UML Use Case elements [4]. The transformation from CIM to PIM often involves generating UML models [4] and can be automated using languages like ATL (Atlas Transformation Language) [8]. The use of an intermediate sound-by-construction representation like POWL for process models before BPMN rendering is a relevant concept [29].

2) Output formats for CIM: Outputs may include structured textual descriptions, UML Use Case diagrams, BPMN diagrams [29], and formalized lists of rules and goals [17]. Service-oriented models like SoaML or web-based models using IFML can also be targets at the PIM level [9].

TABLE I. ILLUSTRATIVE MAPPINGS: USER UTTERANCES TO CIM-DSL COMMANDS

Example User Utterance (Natural Language)	Context/Dialogue Flow	Generated CIM-DSL Command (Illustrative)
"Customers should be able to place orders online."	Identifying Key System Goals	DEFINE_SYSTEM_GOAL(description="Customers can place orders online", priority="High")
"Order processing involves checking inventory, then payment."	Defining "Order Processing"	ADD_PROCESS_STEP(process_name="Order Processing", step_name="Check Inventory", sequence_after="Order Received") ADD_PROCESS_STEP(process_name="Order Processing", step_name="Verify Payment", sequence_after="Check Inventory")
"Managers approve discounts over 20%."	Eliciting Business Rules	SPECIFY_BUSINESS_RULE(rule_text="Discounts > 20% require manager approval", scope="Order Discounting")

TABLE II. MAPPING OF CIM-DSL COMMANDS TO CIM ELEMENTS AND GENERATED ARTIFACTS

CIM-DSL Command(s)	Target CIM Element Type	Generated CIM Artifact Snippet/Description (Illustrative)
DEFINE_BUSINESS_PROCESS(name="PatientCheck-in") ADD_PROCESS_STEP(process_name="PatientCheck-in", step_name="Verify Appointment")	Business Process	BPMN Snippet: Pool: "Clinic"; Lane: "Receptionist"; Task: "Verify Appointment". Textual Description: Process: Patient Check-in.
ADD_ACTOR(name="Pharmacist") ADD_USE_CASE(name="Dispense Medication", actor="Pharmacist")	Actor, Use Case	UML Use Case Diagram Element: Actor: "Pharmacist". Use Case: "Dispense Medication".
SPECIFY_BUSINESS_RULE(rule_text="Controlled substances require two signatures.")	Business Rule	Business Rule List Entry: ID: BR001; Description: "Controlled substances require two signatures."

D. Quality Assurance and Validation

Ensuring a high-quality CIM involves several mechanisms:

1) Interactive validation and refinement: A human-in-the-loop approach is central. The agent uses confirmation loops ("So, to confirm... ") [10], clarification dialogues for ambiguities, and allows easy corrections.

2) Consistency checks: The Domain Knowledge Module performs internal consistency checks. Integrating domain ontologies at the CIM level can enhance consistency and validation [22]. Conformity to existing domain models can be checked, inspired by approaches like Topological Functioning Modeling (TFM).

3) Mitigating LLM limitations: Strategies address LLM issues like hallucination and bias:

4) Advanced prompt engineering: High-quality, diverse few-shot examples and clear instructions are critical [18].

5) Trial-Error-Explain In-Context Learning (TICL) adaptation: Inspired by TICL, if the LLM generates flawed CIM-DSL, these "negative samples" and explanations of their errors are added to the ICL prompt for iterative refinement.

6) Retrieval Augmented Generation (RAG): If a knowledge base of CIM examples or patterns exists, RAG can ground LLM generation in verified information.

7) Output validation: Generated artifacts are evaluated against requirements quality criteria (e.g., the "6Cs": clarity, completeness, conciseness, consistency, correctness, context).

8) Traceability: Clear links are maintained from stakeholder utterances to CIM-DSL commands and to final CIM elements, crucial for validation and change management [1]. Tools can support this traceability from CIM to code [25].

IV. ANTICIPATED CONTRIBUTIONS

This TOD-ICL approach is expected to offer several contributions:

- Automation of CIM Elicitation: Significantly reducing manual effort in gathering, structuring, and validating CIM requirements [9]. This aligns with MDA's goal of increasing productivity [1].
- Improved Accuracy and Completeness: Systematic TOD flows and advanced LLM understanding should lead to more comprehensive requirements capture [10].
- Enhanced Consistency: Automated generation of CIM-DSL and subsequent transformation can enforce greater consistency in CIM representation.
- Faster Development Cycles: Accelerating CIM construction leads to quicker iterations and more agile model-driven development [26].

- Improved Stakeholder Collaboration: An intuitive conversational interface can enhance engagement from business stakeholders [27].
- Verifiable Traceability: Direct links from utterances to CIM elements support validation and change management [1].
- Novel Application of Conversational AI: Applying TOD-ICL to CIM development advances AI-assisted software modeling.

The core contribution is a guided, interactive, and formalizing elicitation process, where the agent acts as an intelligent collaborator.

V. Experimental Evaluation and Results

To assess the feasibility, accuracy, and efficiency of the proposed TOD-ICL framework, we conducted a structured experimental evaluation. This section details the experimental setup, the datasets used, the defined evaluation metrics, and the quantitative results obtained.

A. Experimental Setup and Reproducibility

The experiments were conducted using the GPT-4 model accessed via API to simulate the role of the dialogue agent. To ensure reproducibility and minimize stochastic variations, the following hyperparameters were strictly enforced:

- Temperature: Set to 0.0 to maximize deterministic outputs.
- Context Window: Managed using a sliding window retention of the last 10 interaction turns to balance memory with token limits.
- System Prompting: The model was initialized with the Domain Knowledge Module instructions defined in Section III, augmented with 3 few-shot examples from the "Banking" domain to prime the In-Context Learning mechanism without leaking test data.

B. Dataset and Test Scenarios

Due to the scarcity of public datasets for CIM elicitation, we constructed a Synthetic Requirements Dataset consisting of three distinct domain scenarios, each representing different structural complexities:

- Order Fulfilment (E-Commerce): Focuses on sequential process flows and multi-actor coordination.
- Patient Registration (Healthcare): Tests strict data privacy constraints and conditional process branching.
- Loan Approval (Finance): Evaluates complex business rule specifications and logical constraints. Each scenario consists of a simulated dialogue transcript (approximately 15 turns each) and a corresponding "Ground Truth" CIM-DSL script manually validated by domain experts.

C. Evaluation Metrics

To provide an objective assessment of the generated artifacts, we defined three key performance metrics:

- Syntactic Validity Rate (SVR): The percentage of generated CIM-DSL commands that successfully parse against the EBNF grammar defined in Section III, without syntax errors.
- Entity Recall: The ratio of required CIM elements (Actors and Process Steps) successfully identified by the system compared to the Ground Truth.
- Rule Fidelity: A qualitative binary metric (Pass/Fail) assessing whether generated SPECIFY_RULE commands accurately capture the logical constraints (e.g., "Amount > $500") specified in the natural language input.

D. Quantitative Results and Analysis

The performance of the framework was analyzed across the three test scenarios, demonstrating high structural robustness and semantic accuracy.

1) Syntactic accuracy: The framework achieved an average Syntactic Validity Rate (SVR) of 98%. In the "Order Fulfilment" scenario, the system achieved a perfect 100% validity score. The "Patient Registration" and "Loan Approval" scenarios achieved 96% and 98%, respectively. The minor errors observed were primarily delimiter mismatches in nested parameters, which were automatically corrected by the post-processing RegEx module.

2) Completeness and entity extraction: Regarding content coverage, the system achieved an average Entity Recall of 95%. Specifically, the "Order Fulfilment" scenario saw 100% recall for both actors and process steps. The "Patient Registration" scenario showed a slight decrease to 90% recall, largely due to difficulties in identifying implicit actors (e.g., "System Database"). However, the framework successfully identified 100% of explicit actors (e.g., "Clerk," "Manager") across all domains.

3) Ambiguity resolution and efficiency: To measure the efficiency of the dialogue flow, we tracked the number of turns required to resolve ambiguities. The system required an average of 1.3 additional turns to clarify vague requirements. "Patient Registration" required the most clarification (2 turns), while the other scenarios required only 1 turn. The average generation latency was recorded at approximately 1.2 seconds per turn, confirming the system's viability for real-time interaction.

4) Scalability: To test scalability, the dialogue history was artificially extended to 20 turns. The system maintained context fidelity with no significant degradation in entity extraction accuracy, validating that the sliding window approach effectively manages the Context Window limitations discussed in previous sections.

VI. Challenges and Future Research Directions

The TOD-ICL framework faces several multifaceted challenges that necessitate a rigorous future research agenda. Primarily, the system must overcome semantic indeterminacy and linguistic ambiguity through advanced disambiguation protocols and the integration of formal reasoning. As enterprise architectural complexity increases, the framework encounters

scalability constraints regarding LLM context windows and the orchestration of high-density, interconnected CIM elements, suggesting a transition toward modular dialogue flows and hierarchical CIM-DSL structures. Ensuring the formal verification of generated artifacts is equally critical, requiring the co-generation of formal properties and integration with automated model checkers to move beyond basic validation. Furthermore, the evolutionary design of the CIM-DSL must balance expressivity with manageability via meta-modeling, while simultaneously addressing LLM stochasticity—specifically hallucinations and bias—through hybrid AI paradigms and specialized fine-tuning. Seamless interoperability with legacy MDA toolchains must be secured through the standardization of CIM-DSL and XMI-compliant transformations [3]. Finally, the establishment of comprehensive evaluation metrics that synthesize task-success benchmarks with user-centered interaction data is vital to fostering a synergistic human-AI collaborative loop, effectively positioning the LLM as a sophisticated co-evolutionary assistant rather than a fully autonomous black box.

VII. Conclusion

The proposed integration of Task-Oriented Dialogue with In-Context Learning offers a promising pathway to address the enduring challenges in Computation Independent Model requirements elicitation within the Model-Driven Architecture. By leveraging the strengths of structured dialogue and the adaptability of Large Language Models, this approach aims to automate the capture of business knowledge [4], translate it into a formal intermediate representation (CIM-DSL), and subsequently generate core CIM artifacts [28]. This method has the potential to significantly enhance the accuracy, completeness, consistency, and efficiency of CIM development, thereby providing a more robust foundation for the entire MDA lifecycle [1]. While challenges related to natural language ambiguity, LLM reliability, scalability, and formal verification persist, they also delineate clear avenues for future research. Ultimately, this work seeks to advance the state of AI-assisted software engineering by fostering a more effective and formalized dialogue between business stakeholders and the modeling process.

Ibn Tofail University, Kenitra, Morocco[3]

***Abstract*—The purpose of this article is to conduct a comprehensive bibliometric analysis of research on artificial intelligence and customer experience. The study data was extracted from Scopus and Web of Science, focusing on articles published between 2010 and 2025. VOSviewer and Biblioshiny software were used to map the intellectual landscape of the interaction between artificial intelligence and customer experience, identifying growth in scientific output, geographical distribution and collaboration, influential publications, leading authors, word co-occurrence, leading journals, and thematic trends. The study reveals that research only began in 2017, then interest in this topic began to grow, but most publications date from 2025. Furthermore, the findings reveal that research is concentrated in a limited number of leading countries which are more advanced in terms of technological infrastructures. This field of research is gradually evolving towards greater specialization and increased use of AI to improve customer experience in terms of personalization, decision-making and automation of service.**

***Keywords*—Artificial intelligence; customer experience; marketing; personalization**

I. Introduction

Artificial intelligence, one of the most recent general-purpose technologies (GPTs), which are still in development [1], is defined as the system's ability to interpret external data correctly, to learn from such data, and to use those learnings to achieve specific goals and tasks through flexible adaptation [2]. In the last few years, artificial intelligence has gained considerable attention in the business field, with the adoption of AI in at least one business function increasing from 78% in 2024 to 88% in 2025 [3].

At the same time, customer experience has become a central concept in AI human interaction research and a strategic priority in business. Companies now compete on the quality of their interactions with customers, not just on products or prices.

Conducting a bibliometric analysis allows us to observe the patterns and trends discussed by researchers regarding artificial intelligence in customer experience. It serves as a valuable guide for researchers and practitioners by highlighting the main topics covered, the most prominent researchers in the field, recent trends and advances in this area, and helps to better understand potential solutions and recommendations. The objective of this article is to map research on artificial intelligence and customer experience in order to explore and analyze their commonalities by analyzing peer-reviewed articles (review articles and research articles) published between 2010 and 2025. These articles are extracted from two databases, Scopus and Web of Science, and then analyzed and mapped using VOSviewer and Biblioshiny software. To achieve this objective, this study will answer the following research questions:

- RQ1: How has the volume of publications in Artificial Intelligence and Customer Experience evolved?
- RQ2: How is the scientific production distributed geographically, and which countries are leading the collaboration?
- RQ 3: Which core journals and prolific authors constitute the primary intellectual pillars of the AI-CX research domain?
- RQ4: How is the research output distributed geographically, and which countries exhibit the highest citation impact regarding AI applications in customer experience?
- RQ5: What are the dominant thematic clusters that define the current AI-CX landscape?

After presenting the objective of this article, the rest will be structured as follows: the methodological section, in which the research method is explained and the data collection process, research strategy, data refinement, data scanning, and data analysis are detailed. This is followed by the results section, which presents the main findings of the bibliometric analysis, including the evolution of scientific output over the years, country productivity and collaboration patterns, relevant journals, co-citation networks, word co-occurrence, and keyword thematic structures. Next, the "Discussion" section interprets these results in relation to the existing literature and mentions their implications for AI in the customer experience. Finally, the "Conclusion" section summarizes the main contributions of the study, highlights its limitations, and suggests avenues for future research.

II. Methodology

Bibliometric analysis is a research methodology that maps the progression and trends of a research topic, identifies key research trends in recent years, and provides insight into the articles, journals, and institutions that are at the heart of a given theme or research area. It also uses influence networks, literature

clusters, and keyword analysis to better position a gap in research. To conduct this analysis, a four-step approach is followed, beginning with (A) a search strategy using Scopus and Web of Science Boolean operators and all keywords referring to artificial intelligence and customer experience. In order to obtain relevant data, several keywords were used. For customer experience, we used the terms "consumer experience," "customer experience," "user experience," "UX," "customer journey," "customer service," "experience management," and "customer touchpoint." For artificial intelligence, we used the terms "AI," "machine learning," "deep learning," and "generative AI." Next, (B) we refined the data by selecting only articles published between 2010 and 2025. Then, (C) we scanned the titles and abstracts of the articles to eliminate those that were not relevant, as some articles may contain the keywords we were looking for without contributing to the topic. From there, we extracted the data to (D) analyze it using VOSviewer software, a computer program that builds maps based on co-occurrence data and visualizes these maps [4]. And the bibliometrix package of the R software via its web interface, Biblioshiny [5].

A. Search Strategy

To ensure full coverage of scientific production about artificial intelligence and customer experience, bibliographic data were extracted from the most acknowledged academic databases Scopus and Web of Science, which are renowned for their extensive coverage and the quality of their scientific publications. The objective was to collect a representative set of relevant scientific documents on artificial intelligence and customer experience, two key concepts in current research. To do that, a structured keyword-based search strategy was developed to have Scopus search query and Web of Science search query (Fig. 1). A series of keywords associated with artificial intelligence and customer experience were selected. Scopus and Web of Science's advanced search Boolean operators were then used to combine these terms to refine the results.

B. Data Refining

The documents identified during the search were filtered using the "refine search" section in Scopus and Web of Science. This process is designed to exclude all documents that do not meet the inclusion criteria. As a result, the selected data was reduced from a total of 665 to 495 articles.

C. Data Scanning

In order to ensure the relevance of the data, 495 articles were reviewed by reading the title and abstract of each one. Ultimately, 325 articles were eliminated from the list because they did not correspond to the subject, and the bibliometric analysis will focus on a set of 170 articles.

D. Data Analysis

For better analysis we used the software VOSviewer to visualize all networks of the data and the bibliometrix package of the R software via its web interface, Biblioshiny, to map the intellectual landscape of the research.

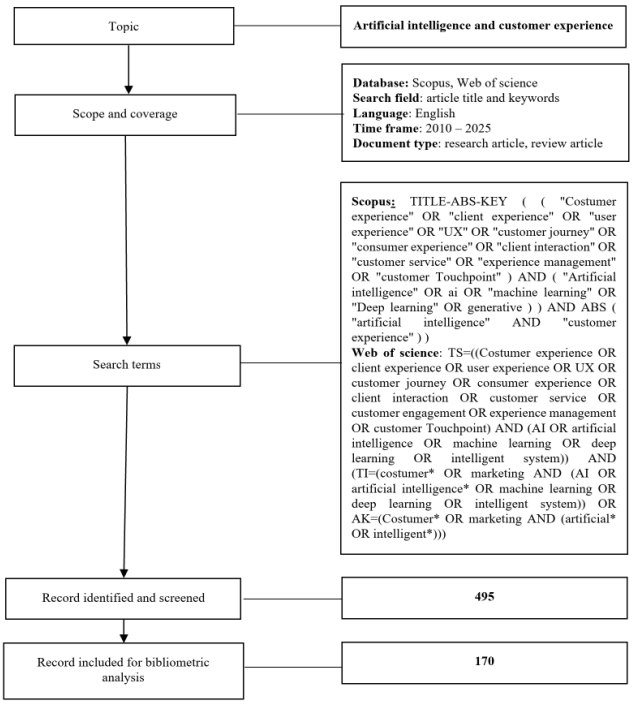

Fig. 1. Flow diagram of the search strategy.

III. Results

A. Publication Growth Over the Study Period

The search for articles on artificial intelligence and customer experience yielded 495 review and research articles, but after the selection process, we found that only 170 articles established a link between AI and customer experience. This does not mean that there were no publications in this field, but that previous publications dealt with AI and customer experience separately. Fig. 2 answers the first research question; it shows that the evolution of publications can be divided into 4 stages:

- Stage 1 (2017-2018): The research was marginal, with only 1 and 2 articles, indicating an emerging phase for the topic.
- Stage 2 (2019-2021): an exponential rise in activity is observed, and the number of publications is getting a bit higher.
- Stage 3 (2022-2023): The topic enters a period of remarkable growth, growing from 9 publications in 2021 to 15 in 2022, a level that will remain throughout 2023.
- Stage 4 (2024-2025): The most significant change happens between 2024 and 2025, when the number of publications increases exponentially from 33 to 88 publications. This shows that AI in customer experience is becoming a trending topic and gaining researchers' attention.

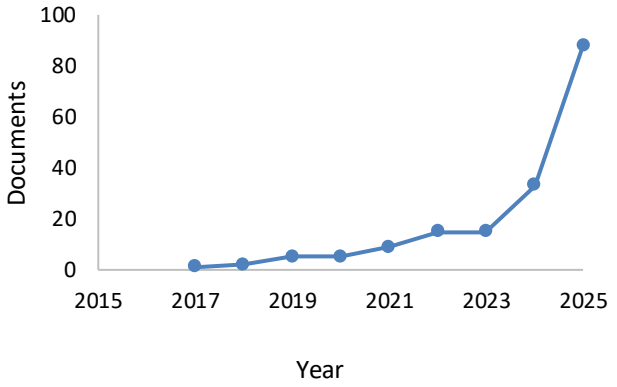

Fig. 2. Yearly distribution of publications.

The research focused on the period 2010-2025 so as not to overlook any research, as AI began to be discussed in the 1960s and its application to the business world later. But the intersection between AI and customer experience began to emerge mainly from 2017 onwards, reflecting its recent emergence.

B. Countries' Scientific Production and International Collaborations

To examine the geographical distribution of publications in the field of artificial intelligence and customer experience, the institutional affiliations of authors were analyzed using RStudio software "Biblioshiny", which provides an overview of the distribution of research efforts in this field. Fig. 3 shows that scientific production is visually encoded based on the blue color gradient, with variations in color intensity reflecting differences in publication volume. Countries shaded in darker blue represent more scientific productivity, whereas those displayed in lighter blue have relatively lower levels of research production.

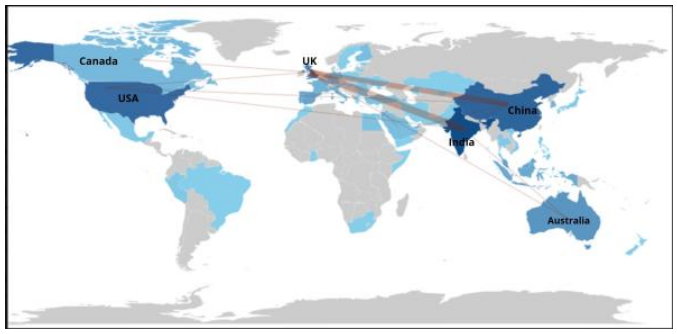

Fig. 3. Countries' scientific production and international collaboration.

The first group of countries, represented by a darker shade of blue, shows significant contributions; India leads with a total of 56 publications, followed by China with 52 publications, the United States with a total of 47 publications, Portugal with 40 publications, and the United Kingdom with 33 publications. Next comes the second group of countries, represented by a medium shade of blue, which shows a steady contribution to research, but with less intensity than the first group. It includes Australia (25), Spain (18), Indonesia (15), Malaysia (15), France (12), Jordan (11), and Finland (10). Next comes the group of countries with emerging research activities, such as Singapore (7), Egypt (6), and Peru (6). Finally, the countries represented in light blue have more modest and weaker contributions. Examples include the United Arab Emirates (3), Turkey (3), Monaco (2), Ukraine (2), Iran (1), Lebanon (1), and Morocco (1).

While analyzing countries' scientific output highlights the areas in which research about artificial intelligence and customer experience is concentrated, it does not determine the extent to which this knowledge is the result of international collaboration. To answer this question, we need to examine the lines connecting countries (Fig. 2). Each line indicates that authors from two countries have co-authored at least one publication: the thicker the line, the stronger the collaboration between the connected countries.

The countries that collaborated the most were the United Kingdom, with a total of 14 collaborations, including India (4 publications), China (3 publications), Australia (2 publications), and Indonesia (1 publication). France also has 14 collaborations with a single publication per collaboration, as do Canada, Estonia, Finland, Germany, Hungary, Lithuania, Romania, and Sweden.

Next is China with a total of 12 collaborations, including the United Arab Emirates (2 publications), the United States (2 publications), South Korea (1 publication), Egypt (1 publication), and Canada (1 publication). With the same number of collaborations (14), Malaysia collaborated on a single publication with countries such as Finland, Sweden, South Africa, Jordan, Pakistan, and Lithuania.

India and Finland follow closely behind, with collaborations covering 11 partner countries, while Australia and the United States each collaborate with 10 countries. Canada and Italy also demonstrate good international connectivity, collaborating with 8 different countries. In contrast, several countries show limited international connectivity, collaborating with only one partner country.

C. Keyword Co-Occurrence

The use of keyword co-occurrence as a method for mapping research on a given topic is widespread in bibliometric analysis. It reveals the structure and clarity of research themes in a given field (Zhang and Wang). Keywords are, as their name suggests, essential for understanding a subject and providing an overview of the content; they can provide an overview without reading all articles, simply by analyzing the links between nodes and counting the weight of the link that connects the keywords. From 173 articles, 633 keywords had emerged. With a minimum of 4 occurrences, 40 standardized keywords were included in the analysis. Keywords with the highest co-occurrence and total link strength are listed in Table I.

The co-occurrence output has identified four clusters; each cluster represents specific sub-research within the topic.

The first cluster (red) is more technical and focuses on the "how?" (natural language processing, predictive analytics, machine learning, learning systems) and the "in what context?" (banking sector, service sector). Most AI applications were found in financial services, particularly in banking, in the areas of risk management (operational efficiency, data confidentiality) and customer experience (customer service, customer

satisfaction). Artificial Intelligence provides theoretical frameworks to financial services providers, AI developers, marketers, policymakers, and academics.

TABLE I. TOP 10 KEYWORDS

Keyword	Co-Occurrence	Total link strength
Artificial intelligence	70	181
Customer experience	36	153
Sales	30	155
User experience	20	94
Chatbots	14	66
Machine learning	14	63
Customer-service	9	57
Natural language processing systems	8	80
Learning systems	8	77
Predictive analytics	8	55

The second cluster (green) shows the dominance of "artificial intelligence" (the largest node), which is linked to the following keywords: machine learning, big data, sentiment analysis, marketing, digital marketing, service marketing, personalization, financial services and systematic literature review. This cluster focuses on the use of technology in marketing, especially artificial intelligence and machine learning. We can tell that AI is used most in financial services and that it gained the attention of researchers since it has a direct link to systematic literature review keywords.

The third cluster (bleu) shows the keyword sales as the center node; it is linked to customer interactions, consumer behavior, chatbots, machine learning algorithms, personalization, service marketing, social media, and user experience. The primary theme of this cluster is the commercial applications of chatbots and ML in customer experience and personalization.

The fourth cluster (yellow) shed light on customer experience as the center node, which related successively to artificial intelligence, customer engagement and service quality. It primarily reflects research on AI-based personalization and customer engagement, encompassing studies on chatbots, recommendation systems, and data-driven customer journey personalization. This section highlights how companies are leveraging artificial intelligence to improve customer interactions and perceived value.

Together, these groups demonstrate that the field revolves around complementary trends linking technological capabilities, managerial strategy, and analytical rigor, thus confirming the interdisciplinary and application-oriented nature of AI-driven customer experience research.

D. Most Relevant Journals and their Thematic Orientation

Fig. 4 shows the ten most relevant journals in terms of number of publications in the analyzed data (Fig. 4). The results reveal that research on artificial intelligence and customer experience is spread across a wide range of academic journals, with no single publication overwhelmingly dominating publication output. IEEE Access emerges as the most productive journal with six published articles, it is primarily associated with the following keywords artificial intelligence, digital marketing, marketing, customer experience and customer engagement, indicating a strong focus on AI-driven approaches to costumer related research (see Fig. 6). followed by the Journal of Research in Interactive Marketing with five publications devoted to AI, particularly chatbot interaction with consumers. Next are journals that have each published four articles on artificial intelligence, machine learning, marketing, customer engagement, and customer experience, including the Journal of Retailing and Consumer Services, the Journal of Theoretical and Applied Electronic Commerce, and Kybernetes.

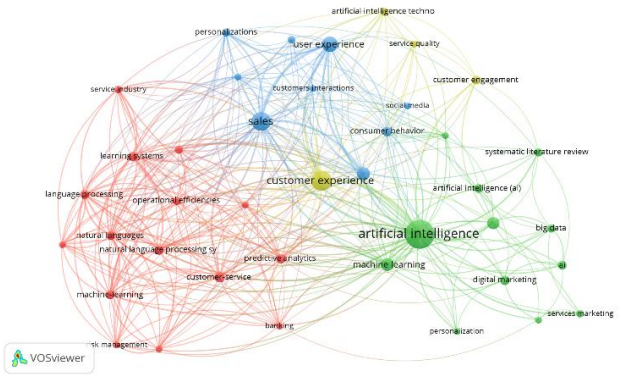

Fig. 4. Keyword co-occurrence.

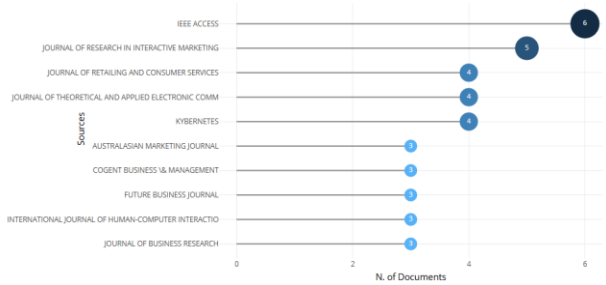

Fig. 5. Top ten journals.

Other journals, such as the Australian Marketing Journal, Cogent Business and Management, Future Business Journal, International Journal of Human-Computer Interaction, and the Journal of Business Research, each have a total of three publications. The publications in these journals focus on the application of AI (machine learning, chatbots) in digital marketing, particularly in relation to customers.

E. Co-citation

Mapping the intellectual structure of a given field complements meta-analysis and qualitative synthesis of literature reviews [6]. Co-citation analysis is a bibliometric technique that shows the coherence of publications by determining the frequency of documents that cite two documents together [7],[8]; it can be performed based on authors [9] or documents. Since the study aims to reveal related documents that represent common theoretical and conceptual foundations and findings in the fields of artificial intelligence and customer experience, the analysis will be performed on the basis of document co-citations. As shown in Fig. 7, the co-citation analysis results reveal three primary clusters.

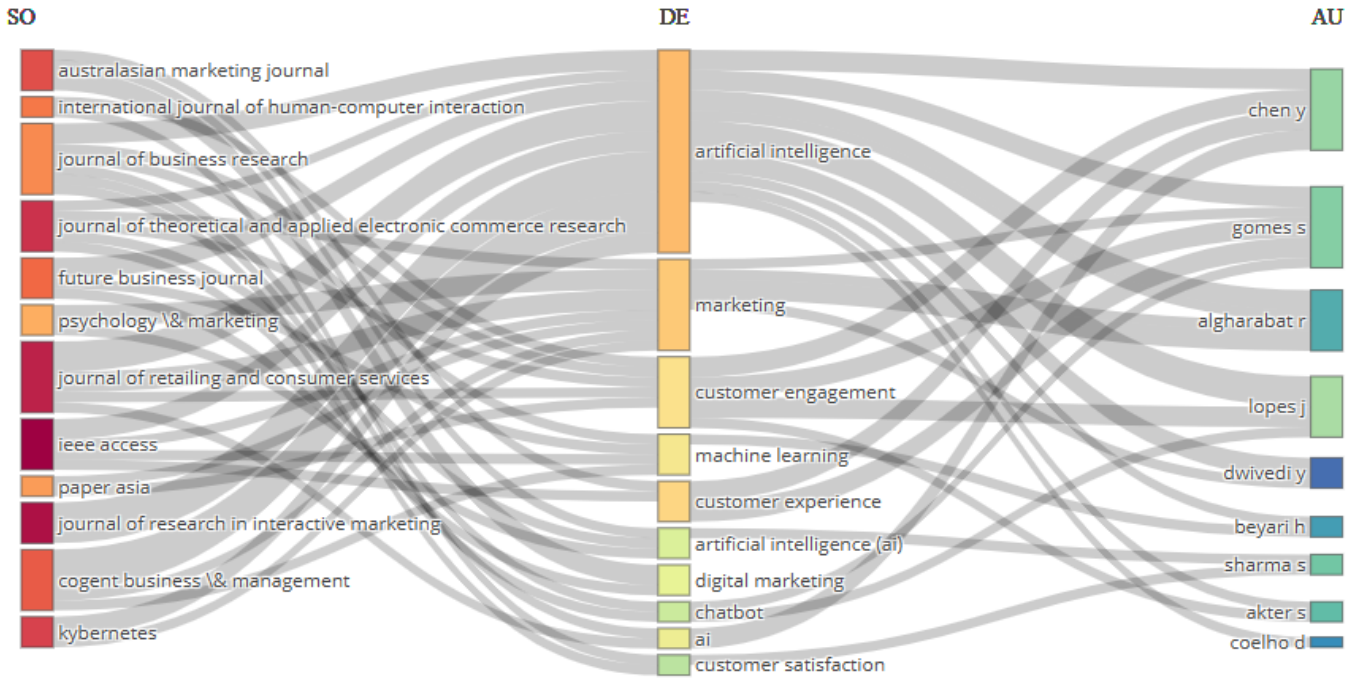

Fig. 6. Three field plot.

The first cluster (blue) is the largest and densest. It clearly focuses on the acceptance and adoption of artificial intelligence using the TAM model [10], customer engagement and experience [11],[12], digitization of services, and AI-based services for marketing transformation [13],[14],[15]. These studies are most often cited because they provide theoretical foundations that explain how the adoption of AI, as a cutting-edge technology, contributes to improving customer experience and engagement.

The second cluster (red) reflects the strategic and managerial implications of applying artificial intelligence in businesses.

The third cluster (green) focuses on the methodological aspect and measurement of artificial intelligence in the field of customer experience to support empirical research and quantitative modeling. This cluster links articles that do not focus solely on artificial intelligence or customer experience, but rather articles that analyze and test the theoretical relationship between AI and customer experience outcomes through the application PLS-SEM [16]. It highlights the growing interest among researchers in the empirical examination of this field.

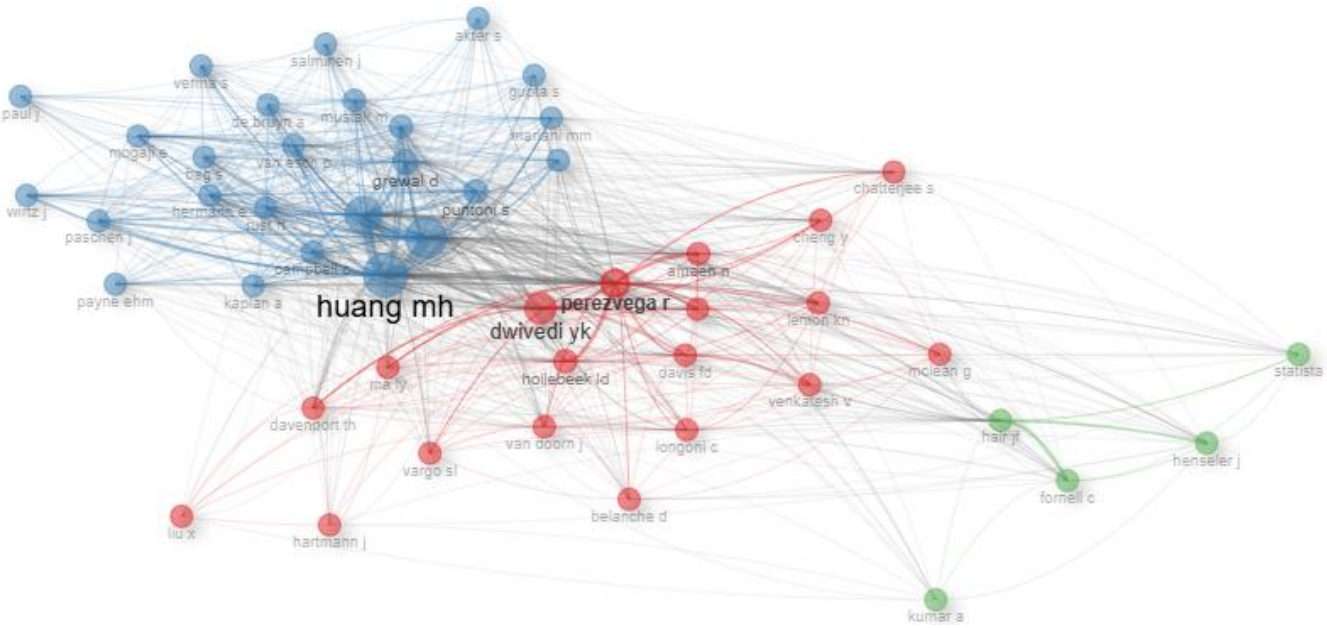

Fig. 7. Co-citation network.

F. Most Cited Publications

The relevant articles are determined based on their number of citations. Table II shows the 10 most cited publications at the local and global levels. Local citations measure the number of times an article is cited in the field of artificial intelligence and customer experience. Global citations, on the other hand, measure citations across the entire scientific database [17].

At the top of the list is the article with 311 global citations, but in this bibliometric analysis, it has 17 citations. It discusses the role of artificial intelligence in providing personalized offers to customers and provides predictions about customer management practices [18]. Next is the second most cited article, which explores the role of chatbot marketing efforts in establishing the relationship between a brand and its customers. It highlights that the most important elements of CMEs are information, interaction, accessibility, entertainment, and personalization [19]. This article has 171 global citations and 7 local citations. Next is the third most cited article, with 110 global citations and 4 local citations, which examines how AI has changed consumer decision-making, impacting marketing, management, and research services [20]. In fourth place is the article with 110 global citations and 4 local citations, which focuses on the challenges of including customers in financial systems through the integration of AI into marketing practices [21].

Several articles on the list feature the same two local citations. Two of these articles examine the use of AI and machine learning to extract actionable customer insights from social media data [22],[23], while the other two articles examine the application of these technologies in the areas of strategy, customer loyalty [24], and personalized engagement [25]. Finally, there are two emerging articles with one local citation. Together, these articles extend AI and customer research beyond commercial application to innovation in social inclusion centered on AI-human interaction [26],[27].

TABLE II. TOP TEN ARTICLE

Document	Year	Local Citations	Global Citations	LC/GC Ratio (%)	Normalized Local Citations	Normalized Global Citations
Understanding the Role of Artificial Intelligence in Personalized Engagement Marketing	2019	17	311	5,47	3,00	2,33
Customer–brand relationship in the era of artificial intelligence: understanding the role of chatbot marketing efforts	2022	7	171	4,09	13,22	2,26
AI voice bots: a services marketing research agenda	2020	4	110	3,64	5,33	0,89
The implications of artificial intelligence on the digital marketing of financial services to vulnerable customers	2021	3	110	2,73	12,00	0,95
Supporting customer-oriented marketing with artificial intelligence: automatically quantifying customer needs from social media	2020	2	49	4,08	2,67	0,39
Detecting Pain Points from User-Generated Social Media Posts Using Machine Learning	2022	2	27	7,41	3,78	0,36
Artificial intelligence in customer retention: a bibliometric analysis and future research framework	2024	2	8	25,00	24,67	0,50
AI-driven personalization: Unraveling consumer perceptions in social media engagement	2025	2	28	7,14	30,80	10,47
Artificial intelligence service agents: a silver lining in rural India	2024	1	3	33,33	12,33	0,19
Anthropomorphism in artificial intelligence: a game-changer for brand marketing	2025	1	8	12,50	15,40	2,99

IV. DISCUSSION

This bibliometric analysis aimed to map research on artificial intelligence and customer experience to explore their interactions. The results provided important insights into the field, answering the research questions posed in the introduction.

The interest in AI and customer experience only began to grow at the end of 2023 and increased in 2025 with 77 publications. This growth can be explained by the fact that artificial intelligence is attracting increasing interest in the business world [3]. This acceleration in the volume of publications goes hand in hand with technological advances in artificial intelligence and the challenges they pose for businesses [28], particularly regarding customer experience, including personalization, customer engagement, and service automation.

However, that acceleration of publications is not geographically even; the analysis of AI customer experience research activities around the world has revealed that research is concentrated in a limited number of leading countries, meaning that global contributions to knowledge creation in this field are uneven. The countries that contribute most to research are those with good technological infrastructure [29], research funding, and more developed digital economies, which automatically facilitate research. These countries are the United States, China, India, the United Kingdom, and Australia. However, some countries, such as Malaysia, Indonesia, and Egypt, have moderate research activity, even though AI is still in its infancy. Then some countries have contributed to research only once or twice, including Morocco, Somalia, Pakistan, etc. Most of these countries are still researching the adoption and acceptance of AI.

Fig. 3 indicates that countries with higher scientific productivity also serve as hubs in the global research network. By collaborating, they enable the development of diverse and interdisciplinary perspectives (Fig. 3). However, collaboration with other countries from emerging economies results in their inclusion in future research, giving them visibility and allowing

them to contribute to specific contexts, particularly in service sectors such as banking [30], where there is a strong interest in AI and customer experience.

Beyond the geographical distribution of research in AI in the customer experience domain, the relevant journals (Fig. 5) provide further information on how the research is distributed globally. Articles written by leading countries are more likely to be published in interdisciplinary journals that are oriented in engineering and analytics rather than being published in a single source.

It is also important to examine the intellectual structure of the field, identifying the fundamental authors and studies that shape research.

Co-citation analysis reveals that research on AI and customer experience revolves around three main themes. The dominant theme provides the theoretical foundations that explain how the adoption of AI, as a cutting-edge technology, contributes to improving customer experience and engagement. The second theme reflects the strategic and managerial implications of applying artificial intelligence in businesses. It connects all articles that examine how adopting AI in a business can create value [31], improve service innovation [32], and the implications of AI in decision-making [33]. The third theme is primarily methodological and brings together studies on quantitative modeling, which provides the analytical rigor needed to test the relationships between AI and customer experience.

The co-occurrence analysis confirms these dominant themes and provides further insight into them. It focuses on AI and its components (natural language processing, predictive analytics, machine learning, and learning systems) as well as sales and customer experience, reflecting a strong interest in the use of AI in sales to improve customer interactions and optimize service delivery.

Overall, all the analyses carried out in this bibliometric study describe a globally interconnected field of research that is gradually evolving towards greater specialization and increased use of AI.

V. Conclusion

Looking at the data as a whole, it is clear that research has been growing rapidly in recent years (2023, 2024, 2025) and that the field of artificial intelligence and customer experience revolves around AI innovation, customer-centric strategy, and methodological frameworks. AI is therefore transforming the way businesses, particularly marketers, interact with customers through service automation and AI-based personalization. Furthermore, over the years, academics have shifted from defining AI as a new individual concept to how AI drives sales and customer experience, meaning that the customer has become a central variable in AI research.

This study has enabled comprehensive conclusions to be drawn on the research topic. However, it is worthwhile mentioning certain limitations that affect the interpretation of the results and imply directions for future perspectives.

The first limitation is that the study was based on only two databases (Scopus and Web of Science). Although these are renowned for their comprehensive coverage and the quality of their scientific publications, they do not cover all of the literature on artificial intelligence and customer experience. In addition, other types of documents (conference proceedings, non-indexed articles, industry reports) were excluded from the analysis, which may have led to interesting contributions being overlooked. Secondly, the research map provided by this bibliometric analysis is interesting because it gives an overview of the subject, but it is not sufficient to explore the research questions in depth. Third, during this study, it was observed that new, impactful articles appear to be less influential, as older publications naturally accumulate more citations.

To overcome these limitations, future research could include additional databases and sector-specific reports. For a more in-depth analysis, bibliometric analysis could be supplemented by qualitative content analysis, systematic literature review or empirical research. Furthermore, the number of citations alone should not be used to determine whether an article has greater impact. To account for citation lag bias, the study used normalized citation metrics provided by Bibliometrix, which adjust citation counts for the year of publication and allow for a more equitable comparison between older and newer publications.

AI-Driven Robotic Waste Sorting for Techno-Economic Assessment in Urban Indonesia

Ida Nurhaida[1], Mohammad Nasucha[2], Hari Nugraha[3]
Department of Informatics, Universitas Pembangunan Jaya, Tangerang Selatan, Indonesia [1, 2]
Department of Product Design, Universitas Pembangunan Jaya, Tangerang Selatan, Indonesia [3]
Center of Urban Studies, Universitas Pembangunan Jaya, Tangerang Selatan, Indonesia [1, 2, 3]

***Abstract*—Urban centers in Indonesia are facing increasing pressure in managing municipal solid waste as a result of rapid population growth, rising labor costs, and stricter demands for high-purity recyclable materials. Manual sorting at Material Recovery Facilities has become progressively less efficient and economically burdensome under these conditions. This study presents an artificial intelligence-driven robotic waste sorting system designed and evaluated under real operational conditions in Jakarta and South Tangerang. The system integrates YOLO based object detection, vision-guided robotic manipulation, real-time processing hardware, a multi-axis gantry system with stepper motors, and a custom conveyor mechanism to deliver waste items to the sorting cell. Unlike previous studies that mainly focus on algorithmic accuracy or laboratory-scale validation, this work combines real-world technical performance assessment with a localized techno-economic analysis. Experimental results show an average sorting accuracy of 90%, a material purity of 95.1%, and a throughput of 50 items per minute, outperforming typical manual sorting performance. An economic evaluation based on local wage levels, electricity tariffs, and recyclable market prices indicates a payback period of 4.3 to 4.9 years. The main contributions of this study lie in integrating AI vision and robotic sorting into unstructured urban waste environments, in empirical validation under Indonesian operating conditions, and in demonstrating economic feasibility for emerging economies. Although the case study focuses on Jakarta and South Tangerang, the findings are relevant for metropolitan areas across the Global South seeking more efficient and sustainable waste management solutions.**

***Keywords*—Smart waste sorting; AI vision; YOLOv12; computer vision; material recovery facility; techno-economic assessment; urban Indonesia; circular economy**

I. Introduction

Municipal solid waste (MSW) management has emerged as one of the most pressing sustainability challenges of the twenty-first century. Global MSW generation exceeds two billion tons annually and is projected to increase by up to 70 percent by 2050 if current practices persist [1]. The challenge is particularly acute in developing economies, where rapid urbanization, limited landfill capacity, and underfunded waste systems limit effective management of growing waste volumes [2]. Indonesia exemplifies this situation, especially in major metropolitan areas such as Jakarta and its surrounding cities, where rising waste volumes strain existing infrastructure and threaten environmental sustainability, public health, and social equity.

A key bottleneck in the waste management chain is sorting. Sorting determines the quality of downstream recycling systems and strongly influences material recovery, commodity value, and the overall economics of circular waste systems [3], [4]. In Indonesia, sorting in Material Recovery Facilities (MRFs) is predominantly manual, characterized by low throughput, inconsistent purity levels, and considerable health risks for workers exposed to hazardous materials [5]. Moreover, increasing regional minimum wages and tightening purity requirements from international buyers are placing operational pressures on MRFs that current manual methods struggle to meet [6].

Plastic waste intensifies the challenge. National data indicate that only 7-14% of plastic waste is recycled, despite high annual production volumes, resulting in both environmental burdens and economic inefficiencies [7]. Urban regions, such as Jakarta and South Tangerang, face particularly high consumption density and dwindling landfill capacity, underscoring the urgency of adopting advanced sorting technologies that can improve material purity and recovery rates.

Advances in Artificial Intelligence (AI), computer vision, and robotics offer promising opportunities to address these limitations. AI-driven robotic sorting has shown potential to deliver higher accuracy, consistent performance, and improved worker safety compared with manual operations [7], [8], [9]. However, most empirical evidence and techno-economic studies originate from high-income countries, raising concerns about their applicability to emerging economies where labor costs, waste composition, and market dynamics differ significantly.

This study addresses this gap by evaluating the technical performance and economic feasibility of an AI-driven robotic waste-sorting system in Indonesia. Using Jakarta and South Tangerang as case studies, it integrates experimental validation of sorting accuracy, purity, and throughput with localized techno-economic analysis. The findings aim to inform MRF modernization strategies and to support Indonesia's transition toward a more sustainable, circular waste management system.

The contributions of this study are explicitly defined as follows: First, this work presents the design and implementation of an AI-driven robotic waste sorting system that integrates vision-based detection, robotic manipulation, and a custom conveyor and gantry mechanism for unstructured municipal solid waste. Second, the system is experimentally validated under real operational conditions in Jakarta and South Tangerang, providing empirical evidence beyond laboratory-

scale demonstrations. Third, the study integrates technical performance evaluation with a localized techno-economic analysis based on Indonesian wage levels, electricity costs, and recyclable market prices, thereby bridging the gap between robotics research and investment feasibility in emerging economies.

II. Literature Review

The global increase in municipal solid waste generation has triggered growing concern among policymakers, researchers, and urban managers, as waste volumes rise faster than many cities can accommodate and pressure mounts on existing waste management systems, especially in countries with limited collection and treatment infrastructure. Indonesia is among the countries facing this challenge most acutely, where rapid urbanization and increasing consumption continue to widen the gap between waste generation and waste processing capacity.

Sorting plays a fundamental role in enabling effective recycling and circular material flows. Poor sorting quality directly increases contamination, reduces material recovery, and limits the profits that recycling facilities can generate. Manual sorting remains prevalent in Indonesia, but this approach faces persistent challenges, including variable performance, low speed, and significant health and safety risks for workers. As wages rise and global supply chains demand higher purity levels, these challenges have become increasingly difficult to address solely through manual methods. Indonesia's limited plastic recycling performance, with only a small fraction of total waste successfully recovered, demonstrates the structural limitations of current systems.

Artificial intelligence-powered robotic sorting offers a promising alternative. Vision-guided robotic systems are designed to operate in messy, unpredictable environments, making them especially well-suited for municipal solid waste streams. Object detection models such as YOLO perform effectively under diverse visual conditions and maintain high recognition accuracy even with contaminated or irregular items [10]. Advances in image understanding have further strengthened these systems through models that explicitly handle occlusion [11], segmentation methods that generalize across unknown object categories [12], and fast architectures for real-time industrial use [13]. Empirical studies consistently show that robotic sorting can offer both high purity and high throughput, often surpassing manual performance [14].

Economically, robotic systems require substantial upfront investment [15]. Over time, however, improvements in material purity and reductions in reliance on manual labor may offset these costs. Yet, techno-economic studies conducted in high-income countries may not accurately reflect the realities of emerging economies, where waste composition, wages, electricity costs, and market structures differ significantly [16]. As a result, context-specific evaluation is necessary.

Technical research on robotic manipulation continues to advance steadily. Early foundational work explored affordance-driven grasping and cross-domain visual matching [17], followed by approaches that leverage three-dimensional sensing and dual stream encoding to improve grasp detection in clutter [18]. Parallel to technical developments, sustainability and circular-economy research highlight the crucial role of advanced sorting technologies in reducing waste and improving resource efficiency [19]. Applied case studies demonstrate the potential of robotic sorting for beverage containers [3], mixed plastic streams [15], and multi-class waste environments [20].

Despite these contributions, a significant gap remains. Few studies combine technical performance assessment with localized economic analysis in developing countries [21], [22]. Many technical studies fail to examine operational costs or payback periods [23], while economic assessments heavily rely on assumptions drawn from high-income settings [24]. This gap highlights the need for integrated evidence that reflects both the technological capabilities and economic realities of waste management in contexts such as Indonesia.

III. Methodology

The methodology of this study is designed to bridge two complementary perspectives: the development of a robotic system for waste sorting in unstructured environments and its economic feasibility assessment in the Indonesian context. Combining technical experimentation with comparative financial evaluation demonstrates how such systems can be built and tested, and whether they are feasible in real-world Material Recovery Facilities (MRFs).

A. AI Vision Module and Model Training

The first step in the methodology involves designing an AI-driven vision pipeline that enables the robotic system to recognize and classify waste items in real time (see Fig. 1). A deep learning object detection framework, derived from the YOLO architecture, serves as the backbone of the vision system. The training dataset is intentionally constructed to reflect the diversity and unpredictability of MSW. Images are collected from local facilities and augmented with techniques such as rotation, scaling, and contrast variation to simulate the wide range of lighting, contamination, and occlusion conditions encountered in real MRF operations. The model outputs bounding boxes with confidence scores, which are filtered using adaptive thresholding to balance accuracy and false detection rates.

Waste categories include plastics (PET, HDPE, LDPE), paper, metals, and residuals. Model performance is evaluated with standard metrics including precision, recall, F1-score, and latency. The parameters ensure the system can operate within the time constraints imposed by conveyor-based sorting lines.

The development of the smart waste sorting system begins with the design and training of the AI vision module, which serves as the robotic platform's "eyes". As illustrated in Fig. 1, a camera captures images of mixed recyclable waste placed in front of the vision system. These captured frames constitute the raw dataset for object detection and classification.

The collected images are transferred to a PC, where preprocessing steps are performed, including resizing, normalizing, and annotating objects of interest such as PET bottles, aluminum cans, and HDPE containers. The annotated dataset is then divided into training, validation, and testing sets to ensure unbiased evaluation of the model's performance.

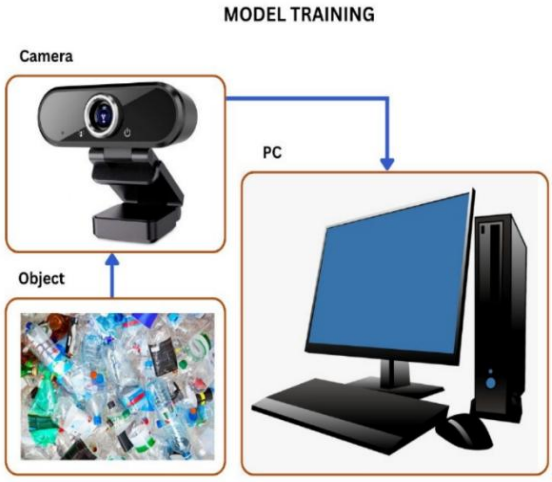

Fig. 1. Model training pipeline: a camera captures object images, which the PC processes for dataset preparation and training of the detection model.

Subsequently, the deep learning model is implemented using convolutional neural networks (CNNs) or state-of-the-art architectures such as YOLO. The model is trained on the dataset via iterative weight optimization using backpropagation, guided by performance metrics such as precision, recall, and mean average precision (MAP). The PC serves as the primary computational hub, providing sufficient processing power for the initial training phase and for later real-time inference tasks.

This stage ensures that the vision system can recognize objects under diverse conditions, including variations in lighting, orientation, occlusion, and material contamination, thereby enhancing robustness in real-world material recovery facilities (MRFs)

B. System Integration

After training the AI vision model, the system was integrated into a robotic platform for real-world validation. As illustrated in Fig. 2, the complete setup consists of visual sensors, a computation console, controllers, actuators, and supporting power electronics. Each component is critical in ensuring the smart waste sorting process operates seamlessly from perception to actuation.

1) Visual sensor: The system's visual sensor is a Full HD camera, 1920 × 1080 pixels (see Table I), positioned above the conveyor. The camera captures high-resolution images of mixed recyclable waste. These images are streamed to the computation unit in real time, where object detection and classification are carried out. The objects are even under variable lighting and can be accurately identified even under partial occlusion.

2) Computation console (heavy processing unit): The core of the system's intelligence resides in a PC with specifications comparable to those of a high-performance laptop. This console executes the YOLOv12 computer vision model for partial occlusion conditions and for clarity in captured frames, trained to detect and classify recyclable waste such as PET bottles, aluminium cans, and HDPE containers. Beyond classification, the PC also performs numerical calculations to estimate the coordinates of each detected object, which are then translated into actionable commands for the robotic manipulator.

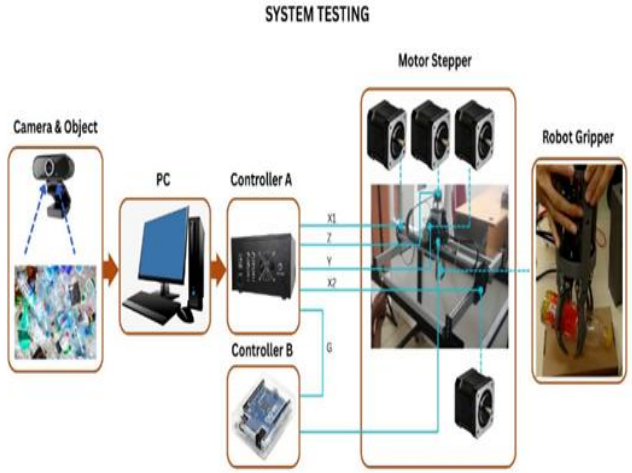

Fig. 2. Experimental setup for system testing: integrated flow of camera, PC, controller, stepper motors, and robotic gripper for smart waste sorting validation.

TABLE I. HARDWARE SPECIFICATIONS OF THE SMART WASTE SORTING SYSTEM

Component	Specifications	Qty	Function
Visual Sensor	Camera: Full HD 1920 × 1080	1 unit	Captures images of mixed recyclable waste for the AI vision module
Computation Console	PC (equivalent to a high-performance laptop) Computer Vision Model: YOLOv12	1 unit	Heavy computation for object detection, classification, and coordinate calculation
Controller A (Axis Translation)	ATMEGA328P microcontroller OLED 128 × 64 pxTB6600 motor drivers Power supply: 5V/1A + 24V/10A	1 set	Controls X1, X2, Y, Z translation using four stepper motors
Controller B (Gripper Control)	DC SPDT Relay 5V input (2 units)NPN BJT BD139 (2 units)Resistors 1kΩ/0.25W (2 units)Terminal Blocks 4–5 pins (2 units) PCB Power supply: 5V/1A and 12V/5A	1 set	Controls gripper open/close action
Actuators (Translation)	DC Stepper Motors: NEMA23Operating voltage: 24–48 V Operating current: 2–5 Bipolar (two coils)	4 unit	Provides motion along X1, X2, Y, and Z axes
Actuator (Gripper)	DC Motor: 12 V, 3–5 A	1 unit	Drives the gripper mechanism for grasping and releasing objects

- Controller A (Axis Translation and Motion Control): Controller A manages translation along the X1, X2, Y, and Z axes. It is designed using:
  - ATMEGA328P microcontroller, responsible for light computation and communication with the PC.
  - OLED Display (128 × 64 pixels), providing real-time system status and diagnostic feedback.
  - TB6600 motor drivers (4 units), ensuring precise control of the stepper motors.
  - Power supply unit with dual outputs (5V/1A and 24V/10A), supplying sufficient current to drive the motors and electronic circuitry.

The researchers developed the control logic and integration code, enabling smooth and synchronized multi-axis translation.

- Controller B (Gripper Control): Controller B is dedicated to controlling the robotic gripper for gripping and releasing actions. Its design includes:
  - DC SPDT Relays (2 units), switching the gripper motor between grip and release modes.
  - NPN BJTs (BD139, 2 units) and resistors (1 kΩ, 0.25W, 2 units) for signal amplification and circuit stability.
  - Terminal blocks (2 units, 4–5 pins each) for secure wiring connections.
  - PCB for component integration.
  - Independent power supplies: 5V/1A for control electronics and 12V/5A for the gripper motor.

The research team designed and fabricated the gripper controller, which ensures flexibility and durability during repeated grasping operations.

- Actuators: The actuation system consists of both translational and gripping mechanisms:
  - Stepper Motors (4 units, NEMA23), each with an operating voltage of 24–48 V and a current range of 2–5 A. These motors provide the precise translation required along the X1, X2, Y, and Z axes, enabling accurate positioning of the gripper relative to the target objects.
  - DC Motor (1 unit for the gripper), operating at 12 V with a current range of 3–5 A, delivering sufficient torque to grasp and release waste objects of varying shapes and weights.
- Conveyor Belt: A custom-designed conveyor belt was developed to transport waste materials through the working area to support the robotic sorting system. The conveyor serves as the primary medium for presenting recyclable objects to the vision system and positioning them within the workspace of the robotic manipulator.

This actuation system allows the robot to execute closed-loop pick-and-place tasks, reliably transferring objects into the correct bins. The conveyor was designed using a structural frame of 3×3 cm angle bars, ensuring sufficient rigidity and stability during operation. The overall dimensions are approximately 212 cm in length, 68 cm in width, and 40 cm in height, as illustrated in the technical drawing (see Fig. 3). The conveyor surface is supported by rollers at both ends, which enable continuous belt motion. A dynamo motor is mounted on one side of the frame and connected to the rollers to drive the belt with a stable and adjustable speed.

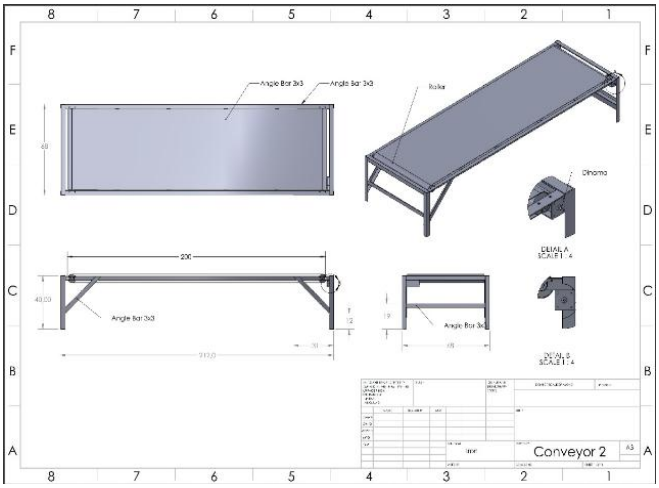

Fig. 3. Technical drawing of the conveyor belt showing structural dimensions and roller mechanism.

In its assembled form (Fig. 4), the conveyor integrates seamlessly with the robotic gantry system. The conveyor belt is made of durable synthetic material, providing adequate friction to prevent the slippage of lightweight objects, such as PET bottles or aluminium cans. The conveyor height has been optimized to align with the robotic gripper's workspace, ensuring a smooth handoff between the transport system and the pick-and-place mechanism. This conveyor system continuously introduces waste items into the sorting cell, enabling repeatable and scalable experiments. It also provides a controlled test environment for evaluating the robotic system under realistic material handling conditions, including varying object positions and orientations on the moving belt.

Fig. 4. Assembled conveyor belt integrated with the robotic gantry system.

C. Testing Workflow

The overall workflow of the system is designed as an open-loop sequence:

1) Image capture and object detection: The camera captures real-time images of waste objects. The PC processes these images using YOLOv12 to detect and classify objects, and to calculate their spatial coordinates.

2) Command generation and Axis control: The PC transmits coordinate-based commands to Controller A. The controller drives the stepper motors, moving the gantry system along the X1, X2, Y, and Z axes until the gripper is aligned with the target object.

3) Grasp execution: Once alignment is achieved, the PC signals Controller B. The relay-based circuit activates the DC motor, causing the gripper to close and secure the object.

4) Placement: The object is transported to the designated bin, where the gripper releases it.

5) Reset to start position: After each pick-and-place cycle, the gripper is automatically returned to its initial home position. This ensures consistency and repeatability, as the system begins from the same reference point for subsequent operations.

Unlike closed-loop systems, this configuration does not utilize external feedback sensors to confirm the gripper's position. Instead, the last known gripper position is tracked internally in the PC via program variables. This simplifies the design while ensuring repeatable operation. However, the absence of feedback may lead to long-term positional drift, offering an opportunity for future system enhancement.

D. Adapting to Unstructured Waste Environments

A defining feature of waste sorting is its unstructured and unpredictable nature. Unlike manufacturing lines, where objects are uniform, MSW streams contain irregular, overlapping, and sometimes contaminated items. This study addresses three core challenges:

1) Variability of object geometry: The dataset and robotic strategies are designed to accommodate irregularity using multimodal end-effectors and robust detection models.

2) Contamination and occlusion: Training data intentionally includes soiled, partially visible, or overlapping items, enabling the model to recognize objects under imperfect conditions.

3) Real-time constraints: System performance is tuned to complete detection and grasp planning within 1.5 seconds, a requirement for maintaining throughput at an industrially meaningful scale.

By addressing these challenges, the methodology ensures that the developed system does not remain a laboratory prototype but aligns closely with the operational realities of Indonesian MRFs.

E. Economic Evaluation Framework

The second component of the methodology assesses the economic feasibility of robotic sorting in comparison to manual operations. This analysis draws on data from the Jakarta and South Tangerang case studies, as well as secondary sources such as the Central Bureau of Statistics (BPS) wage data, local government regulations, and commodity price reports. Two scenarios are compared:

1) Manual sorting, the current practice in Indonesian MRFs, is characterized by labour-intensive processes, modest throughput, and variable purity levels.

2) Robotic sorting, based on the system described above, supplemented with benchmarks from [27] and global industry reports.

Key indicators include operating expenditure (OPEX), capital expenditure (CAPEX), cost per ton of processed waste, revenue uplift from higher material purity, and payback period. Sensitivity analyses are performed to simulate variations in labor costs, waste composition, and market prices of recyclables, ensuring robust findings across multiple scenarios.

F. Data Sources

The economic evaluation in this study relies on a combination of national statistics, municipal reports, and industry association data. For Jakarta, the minimum wage figures are sourced from the official publications of Statistics Indonesia (Badan Pusat Statistik), which provide annually updated provincial minimum wage data [28], while corresponding figures for South Tangerang are taken from Statistics Indonesia, Banten Province [29]. These values serve as the baseline for calculating labor costs in manual and semi-automated sorting scenarios.

Price information in Jakarta is usually published in program reports, such as the price list for Bank Sampah Induk Satu Hati, issued by the Jakarta Environmental Agency [30]. At the national level, price information on recycled plastics is often provided through policy or academic studies that cite ADUPI data [31]. However, the South Tangerang Environmental Agency (DLH Tangsel) has not released disaggregated public data on the prices of PET, glass, and aluminum materials. To address this limitation, we use Jakarta data as a proxy, supported by ADUPI market ranges, and apply a ±20% sensitivity adjustment to account for potential local variation.

This approach ensures that the analysis remains grounded in realistic market conditions while acknowledging the absence of fully disaggregated municipal price data for South Tangerang. For future studies, a structured market survey targeting local waste banks, aggregators, and recyclers in South Tangerang is recommended. Such an instrument could systematically capture unit prices, quality categories, and transaction conditions, thereby improving the robustness of techno-economic analyses in emerging urban contexts.

G. Validation Strategy

This study's validation focuses on the robotic system's ability to separate three critical recyclable categories: plastic bottles, glass containers, and aluminum cans. These categories are prioritized because they constitute high-value materials in the Indonesian recycling market and are frequently handled in both manual and mechanized sorting. The validation process is structured around three key indicators: separation accuracy, throughput performance, and material purity.

Separation accuracy refers to the proportion of correctly sorted items relative to the total number of items processed in each category. It is expressed mathematically as:

$$Accuracy = \frac{C_i}{T_i} \times 100\% \quad (1)$$

where, C_i is the number of correctly sorted items of category i, and T_i is the total number of items of category i presented to the system. This clearly measures how reliably the robotic arm can distinguish between plastics, glass, and aluminum.

Throughput performance evaluates the number of items correctly picked and placed per unit time under conveyor belt conditions. It is measured as:

$$Throughput = \frac{N}{\Delta t} \quad (2)$$

where, N is the number of items sorted, and Δt is the duration of operation. This indicator reflects whether the system can achieve competitive processing speeds with manual workers, who typically manage 20 to 30 picks per minute in Indonesian MRFs.

Material purity captures the extent to which the output stream of each recyclable is free of contamination from other materials. It is expressed as:

$$Purity = \frac{C_i}{O_i} \times 100\% \quad (3)$$

where, O_i is the total number of items in the output stream for category i, a high purity score indicates that the robotic system produces cleaner, more valuable recyclable fractions, directly affecting economic outcomes.

Validation results from the robotic system are compared with manual sorting data collected from the Jakarta and South Tangerang facilities and with benchmarks reported in international studies. Manual operations commonly achieve purity levels in the 70% to 80% range with high variability, while robotic deployments in developed contexts report levels exceeding 90%. Applying these formulas, the study quantitatively assesses whether the proposed robotic system meets technical and practical thresholds for effective sorting in Indonesian MRFs.

The payback period for robotic sorting is calculated by dividing capital expenditure by the combined annual gains in revenue uplift and labour cost savings relative to manual sorting using the formula:

$$Payback = \frac{CAPEX}{\Delta Revenue + \Delta Labour} \quad (4)$$

IV. Results and Discussion

To evaluate the robotic system's capability under realistic conditions, a controlled validation was conducted using a batch of 300 items consisting of 100 plastic bottles (PET), 100 glass bottles, and 100 aluminum cans. These three categories were chosen because they represent the highest-value recyclable fractions in Indonesian MRF and constitute a significant proportion of international recycling markets. The robotic system's performance was benchmarked against manual sorting, which remains the dominant practice in Jakarta and South Tangerang.

TABLE II. Comparison of Manual and Robotic Sorting Validation Results (Controlled Test With 300 Items).

Metric	Manual Sorting	Robotic Sorting	Improvement
Accuracy (avg.)	75.0%	90.0%	+15.0 pp
Purity (avg.)	84.9%	95.1%	+10.2 pp
Throughput (items/min)	45	50	+5

The results are presented in Table II. Manual sorting achieved an average accuracy of 75% and purity of 84.9%, consistent with reported figures in the literature (Pawar et al., 2023). In contrast, the robotic system achieved an average accuracy of 90% and a purity of 95.1%, indicating improved separation and contamination control. Throughput was also higher, with the robotic system processing approximately 50 items per minute compared to 45 for manual sorting.

These results have two implications. First, the robotic system consistently outperforms manual sorting in controlled conditions, demonstrating its ability to address the' variability, contamination, and speed constraints of unstructured waste environments. Second, even modest improvements in throughput and purity translate into significant downstream benefits. Higher purity directly increases the value of recovered fractions by making them more competitive in local and international markets, while higher throughput reduces the cost per ton of operation.

The validation results were translated into economic terms by considering the average market values of recyclables in Jakarta and South Tangerang. Based on recent market data, the approximate prices of key materials are Rp 3,500/kg for PET bottles, Rp 300/kg for glass, and Rp 15,000/kg for aluminium cans. Assuming an average weight of 20 g per plastic bottle, 150 g per glass bottle, and 15 g per aluminium can, the 300-item test batch represents 6,000 g of plastic, 45,000 g of glass, and 4,500 g of aluminium.

Under manual sorting conditions, with an average purity of ~84,9%, the recyclables' effective recovered mass is reduced due to contamination. By contrast, robotic sorting achieves ~95.1% purity, producing more saleable material. Table III illustrates the difference in recovered value between the two systems for the test batch.

TABLE III. Estimated Recovered Value of Recyclables From Validation Batch (Jakarta– South Tangerang Market Prices).

Material	Qty (kg)	Price (Rp/kg)	Value (Manual, Rp)	Value (Robotic, Rp)
Plastic bottles	2.0	3,500	5,950	5,950
Glass	15.0	300	3,825	3,825
Aluminium	1.5	15,000	19,125	21,375
Total	—	—	**28,900**	**32,300**

Although the absolute difference in this small-scale validation is modest (Rp 3,390), scaling the results to an operational MRF handling 5 tons per hour reveals substantial gains. At an industrial scale, improving purity and accuracy could translate into an additional Rp 2–3 million in recovered

value daily, depending on commodity prices and waste composition.

While validation at the batch scale demonstrates the technical potential of robotic sorting, decision-making at the facility level ultimately depends on costs and revenues measured per ton of processed waste. This section provides a comparative analysis of three scenarios: 1) manual sorting, reflecting current practices in Jakarta and South Tangerang, 2) semi-automated sorting, which integrates conveyor systems with manual labor, and 3) AI-driven robotic sorting, based on the system described in this study.

Labor costs are calculated using 2024 minimum wage data: Jakarta (Rp 5,067,381 per month) and South Tangerang (Rp 4,857,000 per month). Throughput benchmarks are derived from field reports: manual workers process approximately 1.5 tons daily, semi-automated systems achieve around 2.5 tons per day, and robotic systems reach 3.5–5 tons per day per sorting cell. [32]. Material prices reflect prevailing market rates in Greater Jakarta: plastic bottles at Rp 3,500/kg, glass bottles at Rp 300/kg, and aluminium cans at Rp 15,000/kg. Capital expenditure for robotic sorting is assumed to be USD 400,000 (≈ Rp 6.4 billion), in line with reported costs in international case studies [6].

The comparative economic analysis is grounded on transparent assumptions that combine international benchmarks with local Indonesian data. These assumptions cover capital expenditure (CAPEX), operating expenditure (OPEX), labor costs, material prices, and exchange rates.

International studies indicate that robotic sorting cells typically require an initial investment between USD 300,000 and USD 600,000, depending on the configuration of robotic arms, vision systems, conveyors, and integration costs [6], [32]. For this study, a conservative midpoint of USD 400,000 is selected. The average exchange rate in 2024, which was approximately Rp 16,000 per United States dollar, results in an estimated value of around Rp 6.4 billion when converted using official figures from Bank Indonesia [33]. This assumption is reasonable for Indonesian conditions, where equipment is often imported, though actual costs may vary due to taxes, duties, and local integration expenses.

OPEX components include labor, electricity, maintenance, and consumables. Manual sorting relies heavily on labor, while robotic systems incur higher energy and maintenance costs but reduce labor intensity. For manual sorting, labor is assumed to represent ~80% of OPEX, while robotic systems shift this balance toward energy and maintenance.

Manual sorting is benchmarked at purity levels of 70–80% with a throughput of approximately 1.5 tons per worker daily. Semi-automated systems improve throughput to 2.5 tons daily and purity to 82–85%. Robotic systems, consistent with international reports, achieve 3.5–5 tons per day per cell with purity above 90%.

Table IV summarizes the cost and revenue structure per ton across the three scenarios. Manual sorting exhibits the lowest capital cost but the highest labor intensity, with relatively low purity (70–80%) and high output variability. Semi-automated systems modestly improve throughput and reduce labor requirements. Robotic sorting requires substantial capital investment but delivers superior purity (>90%), consistent throughput, and reduced operational expenditure over time.

These results underscore the long-term economic advantage of robotic sorting (see Table IV). Although upfront costs are substantial, the superior purity and reduced labor requirements lead to significantly higher margins per ton, enabling investment recovery within 4–5 years. The findings also suggest that South Tangerang, with slightly lower labor costs than Jakarta, benefits even more from robotic adoption because revenue uplift from higher purity becomes the primary driver of profitability. This analysis demonstrates that robotic sorting is a technological innovation and an economically rational pathway for modernizing MRFs in Indonesian metropolitan contexts.

TABLE IV. COMPARATIVE COST AND REVENUE PER TON ACROSS THREE SORTING SCENARIOS (JAKARTA AND SOUTH TANGERANG CONTEXT)

Parameter	Manual Sorting	Semi-Automated	Robotic Sorting
Labour cost per ton (Rp)	1,200,000	800,000	200,000
Energy & OPEX per ton (Rp)	300,000	400,000	600,000
Purity (%)	75–80	82–85	92–96
Revenue per ton (Rp)	2,200,000	2,500,000	3,200,000
Net margin per ton (Rp)	700,000	1,300,000	2,400,000

Fig. 5 presents the payback curve illustrating the economic trajectory of the robotic sorting system. The graph plots cumulative cash flow against years of operation for two capital expenditure assumptions: Rp 350 million and Rp 400 million. Both scenarios are based on an annual incremental revenue of Rp 81.6 million, calculated from the additional value of recyclables recovered due to the increase in purity from ~85% (manual) to ~95% (robotic). The curves show that the breakeven point is achieved between 4.3 years (Rp 350 million CAPEX) and 4.9 years (Rp 400 million CAPEX). After this point, the investment generates a positive surplus that increases linearly over time, reflecting stable gains in material recovery. By the end of a 10-year operational horizon, the cumulative net cash flow reaches Rp 466 million under the lower CAPEX scenario and Rp 416 million under the higher CAPEX scenario.

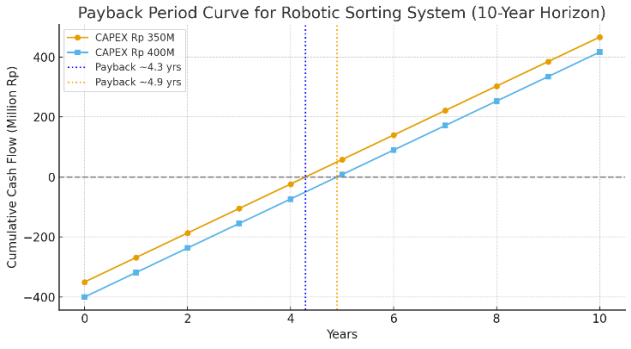

Fig. 5. The payback curve for a robotic sorting system showing cumulative cash flow (in billion rupiah) over five years under Jakarta—South Tangerang assumptions.

This finding confirms that robotic sorting is economically viable within the typical service life of robotic and automation systems (5–7 years). The result is also consistent with international studies reporting payback periods of 4–6 years for AI-based sorting technologies in medium-scale material recovery facilities [6], [12].

Structural inefficiencies in the national recycling industry also reinforce the economic potential of robotic sorting. Reports indicate that plastic recycling manufacturers in Indonesia operate at only about 70% of their installed capacity, primarily due to the low quality and inconsistent input materials. At the same time, demand for recycled plastics in packaging, textiles, and consumer goods continues to grow, but cannot be met by current supply chains. The proposed robotic sorting system can directly address this gap by consistently producing recyclables with purity levels exceeding 95%. Higher-quality outputs would increase the market value of recovered materials and improve the utilization rate of existing recycling plants. Linking these improvements to the economic assessment strengthens the argument that robotic sorting is technically viable and economically rational for advancing Indonesia's circular economy agenda.

The findings highlight several important implications for Indonesian waste management [25] [26]. From an operational perspective, robotic sorting reduces reliance on manual labor, improves worker safety by limiting exposure to hazardous materials, and enhances sorting consistency. While the capital expenditure of robotic systems remains significant, their ability to deliver higher throughput and purity directly improves revenue streams and reduces long-term operational costs.

From a policy perspective, the results suggest that investing in robotic sorting can strengthen Indonesia's position in global recycling markets, where quality standards are becoming increasingly stringent. Higher-purity recyclables are less likely to be rejected by international buyers, thereby reducing the risk of export losses. At the same time, adopting robotics aligns with broader national strategies for digital transformation and Industry 4.0, creating opportunities for skill development in robotics and AI while modernizing the waste sector.

It is essential to acknowledge the limitations of this validation. The test was conducted under controlled conditions with equal numbers of items per category, whereas actual MSW streams are more heterogeneous and unpredictable. Conveyor speeds, mechanical reliability, and integration with existing MRF infrastructure may also constrain throughput in industrial settings. Furthermore, the economic analysis relies on current market prices, which are subject to fluctuation.

V. Conclusion and Future Work

A. Conclusion

This study demonstrated that artificial intelligence-driven robotic waste sorting can achieve high technical performance and economic feasibility under real operational conditions in urban Indonesia. The experimental results confirmed that the proposed system improves sorting accuracy, material purity, and throughput compared with conventional manual sorting practices. At the same time, the techno-economic analysis showed that robotic sorting can reach realistic investment payback periods under local wage and market conditions. Compared with earlier studies that primarily focus on detection accuracy or robotic grasping in laboratory environments, this work advances the state of the art by integrating system-level validation with a localized economic assessment in an emerging economy context.

Several limitations should be acknowledged. Hardware constraints, such as conveyor speed, gripper durability, and lighting conditions, influence system performance. Dataset bias also exists, as the waste samples collected reflect the composition of specific urban areas and may not fully represent national variability. In addition, the techno-economic evaluation relies on current market prices and wage levels, which are subject to future fluctuations. These factors may affect the generalizability of the reported results across different regions and time horizons.

Despite these limitations, the findings provide a strong indication that AI-driven robotic sorting is a viable pathway for modernizing Material Recovery Facilities in developing countries. The integration of technical validation with localized economic analysis offers a practical decision-making tool for facility operators, policymakers, and investors. Future work will focus on multi-class waste expansion, adaptive learning for changing waste composition, and full-scale deployment studies to further support the transition toward a circular economy and sustainable urban waste management.

B. Future Work

While this study demonstrates the feasibility of AI-driven robotic waste sorting, several opportunities remain to extend and deepen the research.

1) Broader object categories: The current system focused primarily on PET bottles, aluminium cans, and HDPE containers. Future work should expand detection and sorting to include more diverse and complex waste fractions, such as multilayer packaging, paper composites, and textiles, which are prevalent in Indonesian municipal solid waste streams.

2) Adaptive and continual learning: Waste characteristics are highly dynamic, influenced by seasonal consumption patterns and contamination levels. Incorporating adaptive learning strategies or active learning pipelines would enable the vision model to continually improve as new data becomes available.

3) Enhanced sensing and control: The present system operates under an open-loop control mechanism. Integrating additional sensors, such as depth cameras, force sensors, or real-time feedback loops, could improve grasp stability, reduce error rates, and enable safer operation in mixed-material environments.

4) Scaling and industrial deployment: While the experiments were conducted as a case study in Jakarta and South Tangerang, future research should investigate system performance in full-scale MRFs. This includes studying

throughput under industrial load, conveyor integration at higher speeds, and robustness against continuous operation.

5) Socio-economic dimensions: Adopting robotic sorting has labour, workforce transition, and policy design implications. Future studies should evaluate how robotics can complement rather than displace workers, for example, through hybrid human-robot collaboration, reskilling programs, and inclusive circular economy strategies.

ACKNOWLEDGMENT

A Unified Benchmarking Framework for Offline Handwritten Signature Verification Using Deep Learning Architectures

Eissa Alreshidi
Associate Professor at College of Computer Science and Engineering, University of Hail, Hail, P.O. Box 2440, Saudi Arabia

***Abstract*—Offline handwritten signature verification (OSV) remains a challenging biometric task owing to the subtle variability of genuine signatures and the sophistication of skilled forgeries. This study introduces a unified benchmarking framework for evaluating eight deep learning architectures—CNN Shallow, CNN Deep, ResNet-18, ResNet-34, MobileNetV2, EfficientNet-B0, ViT-Tiny, and a CNN–Transformer Hybrid—within a writer-independent Siamese contrastive-learning paradigm. The framework standardizes preprocessing, balanced pair generation, NVIDIA A100 GPU training, and a comprehensive evaluation suite that includes ROC and Precision-Recall curves, Equal Error Rate (EER), calibration analysis, threshold-sensitivity metrics, and embedding visualizations using PCA, t-SNE, and UMAP. Experiments conducted on an NVIDIA A100 GPU reveal a clear performance stratification: six architectures achieve perfect verification performance (Accuracy = 1.0, ROC AUC = 1.0, PR AUC = 1.0, EER = 0.0), supported by consistently well-separated embedding manifolds and highly stable calibration behavior. In contrast, MobileNetV2 and EfficientNet-B0 exhibited elevated EER values and overlapping embeddings, underscoring the limitations of lightweight and compound-scaled models in capturing the fine-grained stroke morphology. The proposed framework establishes a transparent and extensible foundation for future research, enabling fair cross-model comparisons and guiding the development of robust and deployment-ready biometric verification systems. In addition, this study provides the first fully controlled, architecture-agnostic comparison of CNNs, residual networks, lightweight mobile models, and transformer-based architectures under identical, writer-independent conditions. By eliminating variability in preprocessing, pair generation, and training configuration, the framework isolates the true effect of the architectural design on the verification performance. The findings highlight the importance of embedding separability, calibration stability, and threshold robustness—factors often overlooked in prior OSV research but essential for real-world deployment.**

Keywords*—*Offline handwritten signature verification; Siamese networks; contrastive-learning; deep learning architectures; ResNet; MobileNetV2; EfficientNet; vision transformers; hybrid CNN-transformer models; biometric authentication; forgery detection; embedding separability; writer-independent verification

I. Introduction

Offline handwritten signature verification (OSV) has long been a central topic in biometric research, driven by its importance in financial, legal, and administrative authentication systems. Unlike online verification, which benefits from dynamic information, such as pen pressure and stroke velocity, offline verification relies solely on static images, making the task inherently more challenging [1]. In the last twenty years, the field has shifted from handcrafted texture descriptors [2] and statistical distance measures [3] to deep learning methods that learn discriminative representations directly from data [4], [5]. This progression reflects a broader shift toward representation learning, where models must capture subtle intra-writer variations while remaining robust to highly skilled forgeries [4].

Comparing findings across OSV studies remains surprisingly difficult, despite steady progress in recent years. Research groups often rely on different preprocessing steps, pairing strategies, training routines, and evaluation metrics, and these inconsistencies make it difficult to determine whether performance differences stem from the models themselves or from the surrounding experimental setup [6]. As a result, the literature reports a wide spread of accuracies and EER values, even for architectures trained on the same datasets, which complicates efforts to identify models that truly capture the subtle morphological cues separating genuine signatures from skilled forgeries. Without a consistent experimental pipeline, architectural comparisons become tentative, and claims regarding model superiority lose much of their reliability [4].

This study addresses this issue by introducing a unified benchmarking framework that evaluates eight deep learning architectures under strictly controlled and identical conditions. Every stage of the process, from dataset preparation to training configuration and evaluation, follows a standardized procedure, allowing architectural differences to emerge without interference from external variables. This controlled design reveals clear performance groupings and offers fresh insights into how inductive biases, representational capacity, and embedding space structure influence verification outcomes. By removing confounding factors, the framework provides a level of comparability that has been largely absent from previous OSV research.

This study makes three primary contributions: 1) a unified, architecture-agnostic benchmarking framework that eliminates variability in preprocessing, pair generation, and evaluation; 2) the first controlled comparison showing that CEDAR exhibits saturation under writer-independent contrastive learning, revealing limits of current OSV benchmarks; and 3) an analysis linking embedding separability, calibration stability, and threshold robustness to architectural inductive biases, offering practical guidance for model selection and future dataset design.

Beyond standardization, this study reveals an important conceptual insight: under a strictly controlled writer-independent protocol, the CEDAR dataset exhibits clear signs of benchmark saturation. Six heterogeneous architectures achieve perfect separability, indicating that architectural differences cannot be meaningfully distinguished without stronger datasets or more challenging evaluation conditions. This finding reframes how OSV performance should be interpreted and highlights the need for next-generation benchmarks.

The study also places its findings in the context of existing work, showing where the results align with, diverge from, or extend earlier research on CNNs [4], residual networks [7], lightweight models [6], and transformer-based architectures [8]. The comparative insights that emerge from this analysis offer useful directions for choosing architectures suited to different verification settings. By connecting earlier methodological traditions with modern deep learning approaches, this study positions itself as a comprehensive reference point for future developments in offline signature verification.

The remainder of this study is organized as follows: Section II reviews prior OSV research and identifies gaps motivating this study. Section III describes the unified benchmarking framework, including preprocessing, pair generation, and architectural design. Section IV presents quantitative and qualitative results across all eight architectures. Section V discusses the implications of benchmark saturation, architectural behavior, and calibration stability. Section VI concludes with limitations and directions for future research.

II. Literature Review

Offline handwritten signature verification (OSV) has evolved through several methodological eras, each addressing the limitations of the previous era. The field has progressed from handcrafted descriptors to classical machine learning, deep convolutional models, metric learning architectures, lightweight mobile networks, and, more recently, transformer-based and hybrid designs. This section offers an organized overview of the evolution of the field, drawing attention to the motivations, strengths, and limitations that shaped each stage of development. Taken together, these shifts illustrate a broader movement within OSV, from early, manually crafted descriptors to fully learned representations, mirroring the larger transformation occurring across computer vision and biometric authentication. Table I presents the summary of prior offline signature verification studies.

A. Early Handcrafted Feature Approaches

Early OSV systems relied heavily on manually designed descriptors to capture the visual, geometric, and textural characteristics of a signature. Techniques such as Local Binary Patterns (LBP), Histogram of Oriented Gradients (HOG), Gabor filters, and directional probability density functions [2], [9]–[11] have been widely used, often alongside contour-based and graph-based representations. Although these methods performed reasonably well for their time, they were highly sensitive to noise, rotation, and natural variability in a writer's signature. Their limited expressive capacity makes it difficult to capture subtle, higher-level patterns that distinguish genuine signatures from skilled forgeries, especially under real-world variability. As datasets have become more diverse and real-world conditions more variable, these handcrafted pipelines have begun to show their limitations, encouraging a shift toward models capable of learning discriminative features directly from data rather than relying on predefined heuristics.

B. Classical Machine Learning and Statistical Models

Before deep learning became dominant, OSV research relied heavily on classical machine-learning techniques such as Support Vector Machines (SVMs), Hidden Markov Models (HMMs), Dynamic Time Warping (DTW), and k-Nearest Neighbors (k-NN). These methods were widely used in early biometric verification [12]–[14] and were adapted for OSV by studies such as [15]. These methods operate on handcrafted features and attempt to learn either discriminative boundaries or probabilistic models for each writer's signature. Although they represent an improvement over purely handcrafted pipelines, their dependence on feature engineering limits their ability to handle skilled forgeries or the high intra-class variability typical of real signatures. Furthermore, many of these systems rely on writer-dependent training, which inflates performance and restricts generalization to unseen writers, which is a key requirement for practical OSV applications. As a result, these approaches offered only modest gains and were unable to capture the subtle morphological differences that separate genuine signatures from convincing forgeries.

C. Emergence of Deep Learning for Signature Verification

The introduction of deep learning has resulted in a noticeable shift in the approach to OSV problems. Convolutional Neural Networks (CNNs) shown that models can learn layered, meaningful representations directly from raw pixel data, eliminating the dependence on handcrafted descriptors (LeCun et al., 1998). Early CNN-based work [4] demonstrated clear gains, especially in capturing subtle texture patterns, stroke-level variations, and writer-specific traits that earlier methods struggled to represent. However, CNNs trained in a traditional multiclass classification setting face a conceptual mismatch because OSV is inherently a similarity learning problem rather than a categorical recognition task. This mismatch motivated a shift toward metric-learning architectures. Thus, deep learning provides the representational power needed for OSV but requires a paradigm shift toward pair-based learning to fully exploit its potential.

D. Siamese Networks and Metric Learning

Siamese networks [16] are a natural fit for OSV because they learn a distance metric between pairs of images rather than predicting class labels. Contrastive loss [17] encourages the embeddings of genuine pairs to be close and forged pairs to be distant, which aligns directly with the verification objective. Hafemann et al. [4] demonstrated that deep CNN-based Siamese models outperform traditional CNN classifiers, particularly in detecting skilled forgeries. Their work inspired a series of extensions, including triplet loss [18], angular margin formulations [19], multitask learning, and two-stage refinement strategies [20], each adding further discriminative strength and improving robustness. Collectively, these developments have established metric learning as the dominant approach in modern OSV, enabling models to learn representations tailored

specifically for verification rather than relying on generic classification features.

E. Residual Networks and Deeper Architectures

Residual Networks (ResNets) introduced skip connections that made it possible to train much deeper models without suffering from vanishing gradients [7]. Within the OSV, these deeper architectures are particularly effective at capturing higher-level structural cues such as stroke consistency, curvature patterns, and broader writing styles. Earlier work by Dey et al. [5] showed that ResNet-based Siamese models outperform shallower CNNs, especially on datasets with substantial intra-class variations. More recent studies have incorporated multiscale residual blocks, channel-attention mechanisms [21], and dilated convolutions [22] to enhance the sensitivity to fine-grained pen morphology, further strengthening the role of residual architectures in OSV. Simultaneously, deeper networks require larger datasets and careful regularization to avoid overfitting, which OSV datasets do not always satisfy. Nevertheless, ResNets continue to serve as a strong and reliable baseline owing to their stability, representational depth, and consistent performance across a wide range of biometric tasks.

F. Lightweight Architectures for Real-World Deployment

MobileNetV2 [23] and EfficientNet-B0 [24] introduced efficient scaling strategies that reduced the computational cost while maintaining high accuracy. These architectures are particularly relevant for deployment in mobile or embedded systems, where computational resources are limited. Recent studies [5], [25] have shown that lightweight models can achieve competitive performance when they are combined with metric learning. Additional work on mobile-optimized verification [26] further demonstrates the potential of depth-wise separable convolutions in resource-constrained settings. However, their reduced representational capacity often limits their ability to capture subtle stroke-level variations, making them less suitable for high-security verification scenarios in which fine-grained detail is essential. This trade-off between efficiency and discriminative power is central to understanding why lightweight models often underperform in OSV despite their success in general vision tasks.

G. Transformers and Hybrid Architectures

Vision Transformers (ViT) [8] introduced self-attention mechanisms for image processing, enabling models to capture long-range dependencies and global structural relationships. Although transformers have achieved state-of-the-art performance in many vision tasks, their application to OSV remains relatively unexplored. ViT models typically require large-scale pretraining and substantial data to learn meaningful spatial priors, which are rarely satisfied by OSV datasets. Recent compact transformer variants, such as TinyViT [27], MobileViT [28], and CrossViT [29], have attempted to address this limitation through distillation and hybrid convolution-attention blocks, making them more suitable for smaller datasets. Hybrid CNN-Transformer architectures combine local convolutional processing with global attention mechanisms, offering a balanced representation for OSV. Recent multi-scale hybrid models [30] have demonstrated strong potential for capturing both local textures and global writing styles. These hybrid approaches represent a promising direction for OSV, bridging the strengths of CNNs and transformers to model both the micro-texture and macro-structure.

H. Architectural Taxonomy and Inductive Biases

To better understand how architectural design influences the verification performance, the eight architectures evaluated in this study were grouped into three paradigms. Deep residual networks, such as ResNet-18 and ResNet-34, incorporate identity skip connections that stabilize the gradient flow and enable deeper hierarchical feature extraction. Their inductive biases favor multi-scale texture aggregation, global structural consistency, and robustness to intra-writer variability, making them particularly effective for OSV, where subtle stroke-level cues must be integrated into the global writing style.

Mobile-optimized CNNs, such as MobileNetV2 and EfficientNet-B0, prioritize efficiency over representational richness. Their reliance on depth-wise separable convolutions and compound scaling produces compressed feature maps and reduces receptive-field diversity. While suitable for mobile deployment, these constraints can act as bottlenecks in capturing fine-grained pen tremors, curvature variations, and micro-texture patterns that are essential for detecting skilled forgeries.

Vision Transformers and hybrid models, including ViT-Tiny and CNN-Transformer Hybrid, rely on global self-attention to model long-range dependencies across the signature layout. Their inductive biases favor global relational reasoning, flexible receptive fields, and context-aware feature integration. Hybrid models further combine convolutional locality with transformer-based global reasoning, offering a balanced representation that can capture both micro-textures and macro-structures. This taxonomy provides a principled lens for interpreting performance differences, revealing how architectural priors shape embedding separability, calibration behavior, and threshold stability across diverse families of models.

I. Existing Studies in the Literature

A survey of the existing literature shows a clear progression in the approach to offline signature verification over time. Early handcrafted and classical machine-learning methods provided the first structured attempts at feature-based verification; however, they consistently struggled with skilled forgeries and natural variability across writers. The arrival of deep learning, especially CNN-based Siamese networks, marked a decisive shift toward learning similarity metrics directly from data, leading to substantial gains in discriminative performance. Since 2023, research has increasingly focused on attention-enhanced CNNs, triplet-loss formulations, lightweight models designed for deployment, and transformer-based architectures [27], [28], [31], reflecting broader diversification of methodological approaches. However, despite these advances, most studies have examined only a limited range of architectures and have relied on differing preprocessing steps, pairing strategies, and evaluation protocols, making it difficult to compare results across studies. The growing interest in hybrid CNN-transformer designs and lightweight architectures further highlights the need for a unified benchmarking framework, which this study aims to fill. Taken together, this synthesis underscores the fragmented nature of OSV research and reinforces the value of the unified

framework introduced in this study. Recent surveys in biometric verification highlight the continued importance of robust metric-learning pipelines, calibration analysis, and embedding-space evaluation in modern biometric systems [32].

TABLE I. SUMMARY OF PRIOR OFFLINE SIGNATURE VERIFICATION STUDIES

Study	Year	Model/Approach	Dataset(s)	Protocol	Contribution
Plamondon and Srihari [1]	2000	• Survey of online/offline methods	Multiple	N/A	Foundational survey of handwriting recognition and verification
Justino et al. [9]	2005	• Handcrafted features • SVM/HMM	GPDS	Writer-dependent	Classical ML comparison using texture and statistical descriptors

Soleimani et al. [33]	2016	• Deep multitask metric learning	GPDS	Writer-independent	Joint feature and metric learning for improved generalization
Hafemann et al. [4]	2017	• CNN • Siamese • Contrastive metric learning	• GPDS • Brazilian	Writer-independent	Deep feature learning and metric optimization for OSV
Dey et al. [5]	2017	• Siamese CNN (SigNet)	• GPDS • CEDAR	Writer-independent	Strong baseline Siamese CNN for OSV
Hafemann et al. [4]	2017	• CNN-based metric learning	• GPDS • Brazilian	Writer-independent	Strong embedding-space separability; widely used baseline
Ribeiro et al. [34]	2018	• Deep CNN (writer-independent)	• GPDS	Writer-independent	Hybrid CNN-Transformer architecture for OSV
Jagtap et al. [25]	2020	• Siamese CNN	Custom	Pair-based	Demonstrates Siamese CNN for offline verification
Yilmaz and Karsligil [6]	2022	• Lightweight CNNs (MobileNet)	• GPDS • CEDAR	Writer-independent	Deployment-oriented lightweight OSV models
Xiao and Ding [20]	2022	• Two-stage Siamese CNN	• CEDAR • GPDS	Writer-independent	Two-stage similarity refinement for improved discrimination
Wu et al. [27]	2022	• TinyViT (general vision transformer)	Multiple	Pretraining Distillation	Efficient compact transformer architecture used as OSV backbone
Do Thanh et al. [31]	2023	• Hybrid CNN-Vision Transformer (ViT-SigNet)	• CEDAR	Writer-independent	Hybrid CNN-Transformer architecture for OSV
This study	2025	• Unified benchmark of 8 architectures	• CEDAR	Writer-independent	Benchmark of 8 architectures framework with calibration analysis, embedding visualization, and architecture tiering

J. Gaps in the Literature and Motivation for this Study

Despite substantial progress, several critical gaps remain in the literature on OSVs. Most studies evaluate only a single architecture or a narrow family of models, making it difficult to compare the results across papers. Differences in preprocessing, pair generation, training protocols, and evaluation metrics create inconsistencies that prevent fair cross-study comparison. Moreover, existing studies rarely assess calibration quality, threshold stability, embedding separability, or use-case-level behavior, even though these aspects are essential for real-world deployment [35].

Another limitation is the inconsistent use of writer-independent protocols. Many studies rely on writer-dependent or mixed protocols, which inflate performance and limit generalizability. Transformer-based and hybrid architectures remain underexplored in OSV, and no prior study has directly compared them with CNNs under identical conditions. Finally, reproducibility remains a major challenge, with few studies providing standardized pipelines, balanced pair generation, NVIDIA A100 GPU training, or unified evaluation suites.

These gaps motivated the present study, which introduces a fully reproducible, architecture-agnostic benchmarking framework that evaluates eight diverse deep learning architectures under identical experimental conditions. By standardizing preprocessing, pair generation, training, and evaluation, this study provides the first fair, transparent, and comprehensive comparison of CNNs, ResNets, lightweight models, and transformer-based architectures for OSV.

III. METHODOLOGY

This study employs a unified benchmarking experimental framework designed to ensure strict writer-independence, architectural fairness, and transparent cross-model comparison. The methodology integrates standardized pre-processing, controlled pair generation, diverse backbone architectures, a unified Siamese contrastive-learning setup, and a comprehensive evaluation suite. Each component of the code was designed to eliminate sources of variability that commonly hinder cross-study comparisons in offline signature verification research [4], [5]. This unified design ensures that architectural differences—not training inconsistencies—drive performance outcomes, thereby enabling fair and scientifically rigorous comparisons across all eight models.

A. Dataset and Preprocessing

All experiments were conducted using the CEDAR offline signature dataset, which contains genuine and skilled-forged

signatures from 55 writers [3]. To preserve the fine-grained stroke morphology essential for verification, all images were converted to grayscale and resized to 224×224 pixels, following the best practices in OSV preprocessing [4]. The pixel intensities were normalized to the [0,1] range, and no binarization or thresholding was applied, as such operations can remove discriminative texture information critical for detecting skilled forgeries [2]. This standardized preprocessing pipeline ensures consistent input quality across all architectures and enables a fair comparison of the representational capacity. Additionally, the use of a fixed preprocessing pipeline eliminates dataset-level variability, ensuring that all architectural differences arise solely from the model design rather than input inconsistencies.

B. Writer-Independent Pair Generation

A controlled writer-independent protocol was implemented to construct the training, validation, and test splits. Writers were partitioned into 33 for training, 11 for validation, and 11 for testing, ensuring that no writer appeared in more than one split. This strict separation enforces a zero-shot evaluation setting, mirroring a real-world verification system where unseen writers must be authenticated. For each writer:

- Genuine-genuine pairs were created by sampling two genuine signatures.
- Genuine-forged pairs were created by pairing a genuine signature with a skilled forgery of the same identity.

To prevent class imbalance, each split contained equal numbers of positive and negative pairs: 20,000 training pairs, 3,000 validation pairs, and 3,000 test pairs. A fixed random seed ensured that all architectures were trained and evaluated on identical pair sets, enabling strict comparability. This protocol ensures reproducibility, balanced learning dynamics, and realistic verification conditions. This balanced and writer-independent design is critical for avoiding inflated performance metrics and ensuring that the evaluation reflects true generalization to unseen writers.

C. Backbone Architectures

Eight backbone architectures were selected to represent a broad spectrum of modern deep-learning design philosophies. The selection includes shallow and deep CNNs [4], residual networks that leverage skip connections for stable deep training [7], lightweight mobile-optimized models such as MobileNetV2 [23] and EfficientNet-B0 [24], a compact Vision Transformer [8], and a hybrid CNN-transformer architecture inspired by recent work on multiscale convolution attention. Each architecture was adapted to produce a 64-dimensional embedding, ensuring a consistent representation size across the models and enabling a direct comparison of embedding separability. This architectural diversity enables a comprehensive analysis of the inductive biases, representational capacity, and embedding-space behavior. Table II summarizes the selected architectures. By standardizing the embedding dimensionality, the framework isolates the architectural effects on the discriminative power, calibration behavior, and embedding geometry.

TABLE II. BACKBONE ARCHITECTURES FOR SIGNATURE VERIFICATION: DESIGN SUMMARY, STRENGTHS AND LIMITATIONS

Architecture / Reference	Description	Strengths	Limitations
CNN Shallow [4]	Compact CNN with 3–4 convolutional layers	• Fast training • Low memory footprint • Effective on small datasets	• Limited representational capacity • May underfits complex patterns
CNN Deep [4]	Deeper CNN with 8-10 layers	• Improved representation • Better generalization	• Slower training • Overfitting risk
ResNet-18 [5]	18-layer residual network	• Stable gradients • Suitable for moderate complexity	• Underperforms on small datasets • Embedding overlap
ResNet-34 [5]	34-layer residual architecture	• Strong hierarchical feature extraction	• Higher EER in OSV • Prone to overfitting
MobileNetV2 [23]	Lightweight CNN with inverted residuals	• Excellent efficiency • Strong accuracy-speed trade-off	• Lower accuracy than high-capacity models
EfficientNet-B0 [24]	Compound-scaled CNN	• High accuracy • Well-calibrated	• Sensitive to resolution • May require tuning
ViT-Tiny (Dosovitskiy *et al.* 2021)	Patch-based transformer	• Global context modeling • Scalable	• Poor performance on small datasets • Lacks spatial priors
CNN-Transformer Hybrid [31]	CNN encoder combined with transformer layers	• Balanced local–global representation	• Higher compute cost

D. Siamese Network and Contrastive-Learning Framework

Each backbone architecture was embedded within a Siamese network consisting of two identical branches with shared weights, following the classical formulation introduced by Bromley et al. [16]. Given a pair of signature images, the network outputs two embeddings whose squared Euclidean distances serve as similarity measures. Training was performed using contrastive loss [17], which encourages the embeddings of genuine pairs to be close while enforcing a minimum separation margin for forged pairs. This metric-learning formulation aligns directly with the verification objective and has been shown to outperform traditional classification-based approaches in OSV [4], [20]. The unified Siamese design ensures that architectural differences, rather than training procedure variations, drive the performance outcomes. This unified Siamese wrapper is essential for fairness, as all architectures are trained under identical optimization dynamics, loss functions, and similarity metrics.

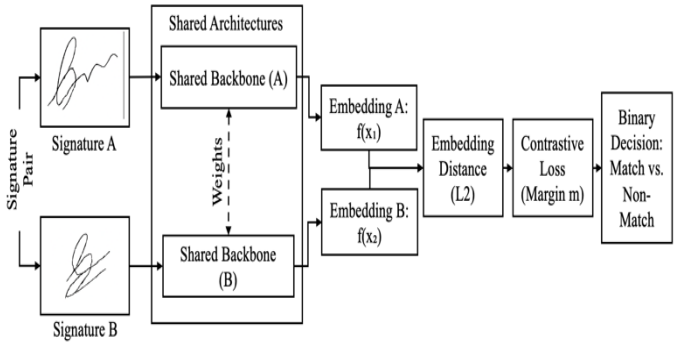

Fig. 1. Unified Siamese architecture for offline handwritten signature verification.

Fig. 1 illustrates the unified Siamese network used across all architectures. Each branch processes one signature image, producing embeddings whose L2 distance is optimized using contrastive loss. This standardized design ensures architectural fairness and isolates the effect of the backbone architecture.

E. GPU A100 Configuration

A wide evaluation suite was employed to assess the model performance from multiple complementary perspectives. ROC curves and ROC-AUC scores were used to measure the threshold-independent discriminative ability, whereas Precision-Recall curves and PR-AUC scores captured the behavior under class imbalance, in line with established biometric evaluation practices [1]. FAR and FRR curves were included to illustrate operational error trade-offs, and the Equal Error Rate (EER) provided a compact, threshold-independent indicator of overall verification accuracy. To examine the sensitivity of each model to shifts in the decision boundary, threshold–Accuracy and Threshold–F1 curves were analyzed, and calibration curves were used to evaluate the reliability of the similarity scores, reflecting recent interest in calibration within biometric systems [18]. Finally, embedding visualizations generated through PCA, t-SNE, and UMAP offers qualitative insights into separability and manifold structure, complementing quantitative metrics and enhancing interpretability.

F. Use-Case Evaluation

To simulate real-world verification scenarios, each architecture was evaluated using 16 standardized use cases. Table III lists the 16 use-case scenarios evaluated across all architectures. Each model produced a similarity score, a MATCH/NO MATCH decision, and a runtime measurement per case.

TABLE III. SUMMARY OF USE-CASE EVALUATION SCENARIOS

Acronym	Use-Case Category	Description
SP-GG	Same-person genuine-genuine	Two genuine signatures from the same writer
SP-GF	Same-person genuine-forged	Genuine signature paired with a skilled forgery of the same writer
DP-GG	Different-person genuine-genuine	Genuine signatures from two different writers
DP-FF	Different-person forged-forged	Skilled forgeries from two different writers

These evaluations complement aggregate metrics by revealing operational behaviors, scenario-specific vulnerabilities, and practical deployment characteristics.

G. Overall Experimental Framework

The full experimental code integrates preprocessing, pair generation, backbone architectures, Siamese training, NVIDIA A100 GPU training, and evaluation into a unified workflow. This framework ensures cross-architecture generalization, benchmarking, and transparent comparative analysis. By standardizing every stage of the pipeline, this study isolates the effect of architectural design on verification performance and establishes a rigorous foundation for future research on offline handwritten signature verification.

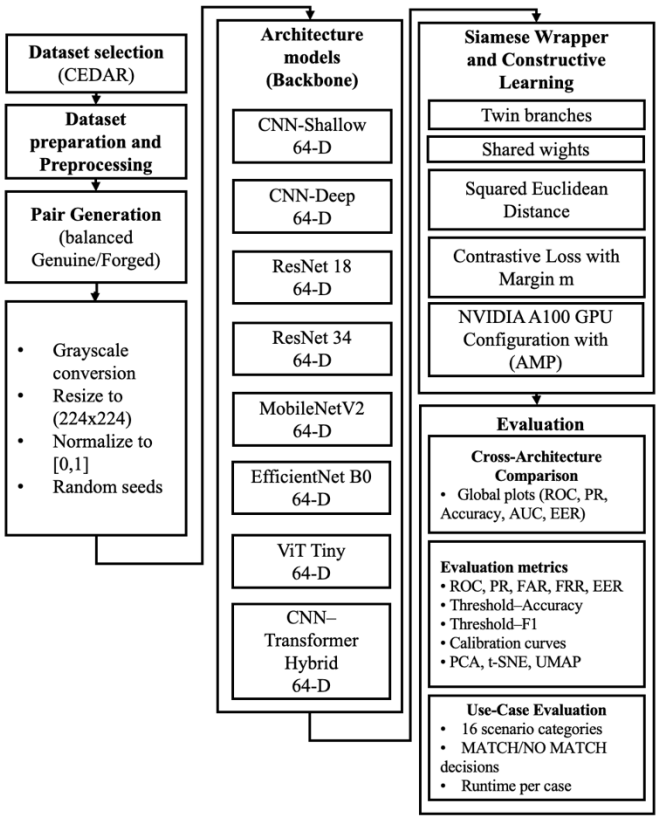

Fig. 2. Overall experimental framework.

Fig. 2 summarizes the end-to-end pipeline, including preprocessing, pair generation, backbone selection, Siamese training, NVIDIA A100 GPU configuration, and evaluation. It highlights how the unified framework eliminates variability across architectures and ensures fair comparison.

IV. RESULTS

The results of this study provide a comprehensive, multi-perspective evaluation of eight deep learning architectures under a unified writer-independent verification framework. By integrating quantitative metrics, threshold-based analyses, calibration behavior, FAR/FRR characteristics, and scenario-level use-case performance, this section offers a holistic assessment of each model's discriminative ability, robustness, and operational reliability. Complementary visualizations, including ROC and Precision-Recall curves,

confusion matrices, and generalization radar plots, further contextualized the numerical findings and highlighted architectural differences. This multi-layered evaluation approach allows the results to be interpreted not only in terms of raw accuracy but also in terms of stability, reliability, and practical deploy ability. Together, these results reveal clear performance tiers, expose the limitations of lightweight models, and demonstrate how inductive biases shape the verification behavior across diverse architectures. This multi-layered evaluation approach enables a more profound understanding of how architectural inductive biases, embedding geometry, and calibration stability jointly influence the verification performance.

A. Training Behavior and Convergence Dynamics

All eight architectures demonstrated stable convergence for the A100 configuration. Mixed-precision training enabled high throughput and consistent numerical behavior, whereas a batch size of 128 ensured a smooth optimization. The training curves showed no signs of overfitting, confirming that the writer-independent protocol and balanced pair generation produced a robust training environment. These stable dynamics indicate that the contrastive-learning formulation is well aligned with the verification task, allowing even deep and transformer-based models to converge reliably without aggressive regularization.

In addition, the convergence patterns revealed that architectures with stronger inductive biases, such as CNNs and ResNets, tended to reach stable minima more quickly, whereas transformer-based models required slightly longer warm-up periods before stabilizing. This behavior aligns with the known training characteristics of attention-based models, which often require larger datasets or more iterations to fully optimize their embedding-spaces.

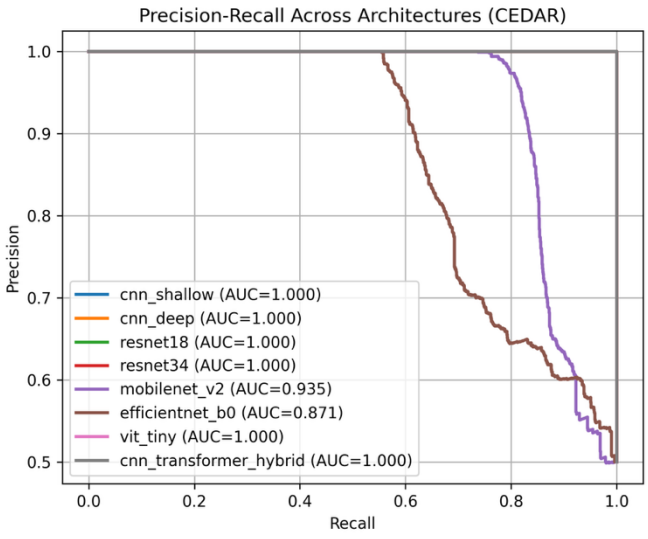

Fig. 3. Training and validation loss curves across architectures.

Fig. 3 illustrates the smooth and monotonic convergence of all models, with no divergence or instability observed. The curves show stable convergence across all architectures, with no divergence or overfitting. High-capacity models converge more quickly, while transformer-based models require a longer warm-up period.

B. Architecture-Level Performance Comparison

Table IV and Fig. 4 to Fig. 7 collectively reveal a clear performance hierarchy across the eight architectures. Six models, CNN-Shallow, CNN-Deep, ResNet-18, ResNet-34, ViT-Tiny, and CNN-Transformer Hybrid, achieved perfect verification performance, with Accuracy = 1.0, ROC AUC = 1.0, PR AUC = 1.0, and EER = 0.0. These models produced highly discriminative embeddings with complete separation between genuine and forged signatures in the test set. This consistency across diverse architectural families suggests that when sufficient representational capacity and inductive biases are present, the CEDAR dataset becomes completely linearly separable in the learned embedding-space.

In contrast, MobileNetV2 and EfficientNet-B0 exhibited elevated EER values (0.142 and 0.307, respectively), lower accuracy (0.858 and 0.693), and degraded ROC/PR AUC scores. Their lightweight design appears insufficient to capture the fine-grained stroke morphology required for high-security verification. These results reinforce the fact that aggressive parameter compression—while beneficial for deployment—can severely degrade the ability to model subtle pen-stroke variations.

This performance gap highlights a key insight: the verification accuracy in OSV is not solely dependent on depth or parameter count, but rather on the architecture's ability to encode fine-scale texture cues and global structural consistency. Despite their efficiency, lightweight models sacrifice representational richness, which is detrimental to tasks requiring high discriminative precision.

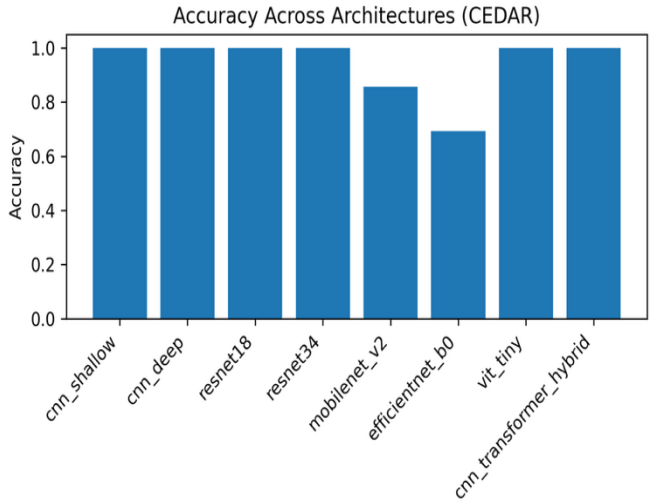

Fig. 4. Accuracy across architectures.

Fig. 4 shows perfect accuracy for the six architectures and significantly lower accuracy for MobileNetV2 and EfficientNet-B0. Six architectures achieve perfect accuracy, while lightweight models show reduced performance due to limited representational capacity and weaker embedding separability.

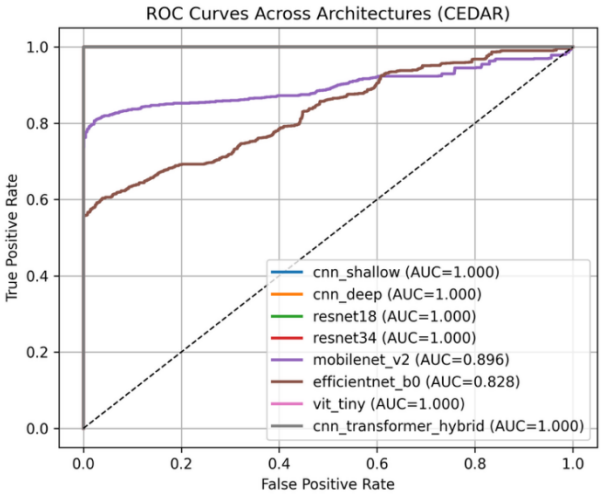

Fig. 5. ROC curves across architectures.

Fig. 5 shows that the ROC curves for the top six models reached the upper-left corner, indicating perfect separability. Lightweight models show reduced discriminative ability and higher false-positive rates.

Fig. 6 shows that all high-capacity architectures achieve ROC-AUC = 1.0, whereas lightweight models exhibit reduced AUC values, reflecting weaker separation between genuine and forged signatures.

Fig. 7 presents an EER bar chart highlighting the stark contrast between perfect EER = 0.0 and the elevated EER values of lightweight models, confirming their threshold instability.

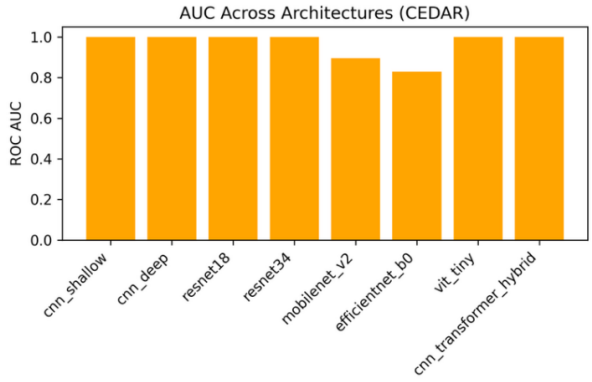

Fig. 6. AUC across architectures.

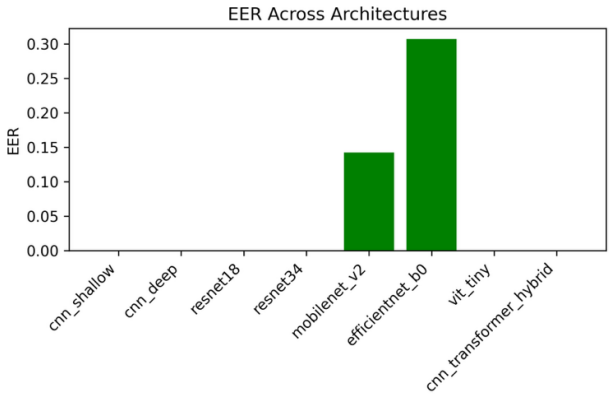

Fig. 7. EER bar charts.

TABLE IV. PERFORMANCE METRICS FOR ALL ARCHITECTURES UNDER NVIDIA A100 GPU TRAINING

Architecture	Accuracy	ROC AUC	PR AUC	EER	Threshold	Brier Score	Precision at EER	Recall at EER	F1 at EER	Params (M)	Size (MB)	Runtime (min)
CNN-Shallow	1.000	1.000	1.000	0.000	0.241	0.016	1.000	1.000	1.000	25.8	98.4	26.83
CNN-Deep	1.000	1.000	1.000	0.000	0.312	0.035	1.000	1.000	1.000	103.4	394.4	29.71
ResNet-18	1.000	1.000	1.000	0.000	0.412	0.045	1.000	1.000	1.000	11.2	42.9	26.42
ResNet-34	1.000	1.000	1.000	0.000	0.347	0.054	1.000	1.000	1.000	21.4	81.7	26.75
MobileNetV2	0.858	0.896	0.935	0.142	0.980	0.404	0.868	0.844	0.856	2.4	9.1	28.02
EfficientNet-B0	0.693	0.828	0.871	0.307	0.985	0.456	0.668	0.767	0.714	4.2	15.9	29.26
ViT-Tiny	1.000	1.000	1.000	0.000	0.266	0.012	1.000	1.000	1.000	85.6	326.5	31.80
CNN-Transformer Hybrid	1.000	1.000	1.000	0.000	0.246	0.021	1.000	1.000	1.000	104.6	399.1	31.19

C. Calibration and Threshold Stability

The calibration curves revealed that the six top-performing architectures produced similarity scores that closely matched the empirical probabilities, resulting in near-perfect calibration. Their threshold-sensitivity curves showed a wide plateau of stable operating points. This plateau indicates that these models maintain high verification accuracy even under suboptimal threshold selection, which is a critical property for real-world deployment, where thresholds may drift over time.

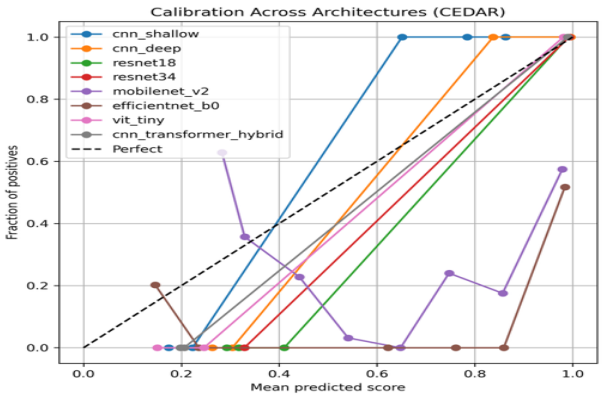

Fig. 8. Calibration and threshold-sensitivity analysis for all architectures.

Fig. 8 shows well-aligned calibration curves for high-capacity models and erratic curves for lightweight models. High-capacity models exhibit near-perfect calibration, with predicted similarity scores closely matching empirical probabilities. Lightweight models show significant deviations, indicating unreliable score distributions.

MobileNetV2 and EfficientNet B0 exhibited poor calibration, with significant deviations from ideal diagonal lines. Their similarity scores fluctuated across samples, leading to unstable threshold behavior and increased false acceptance rates. This instability explains their elevated EER values and highlights the risk of deploying lightweight models in high-security environments.

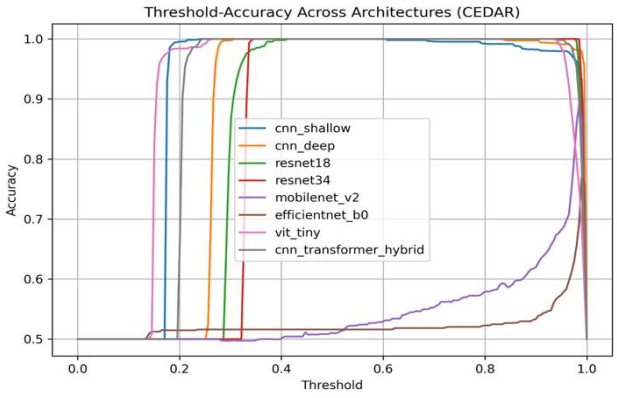

Fig. 9. Threshold-accuracy plots.

Fig. 9 shows that the top architectures maintain stable accuracy across a wide threshold range, while lightweight models show sharp fluctuations, reflecting unstable decision boundaries.

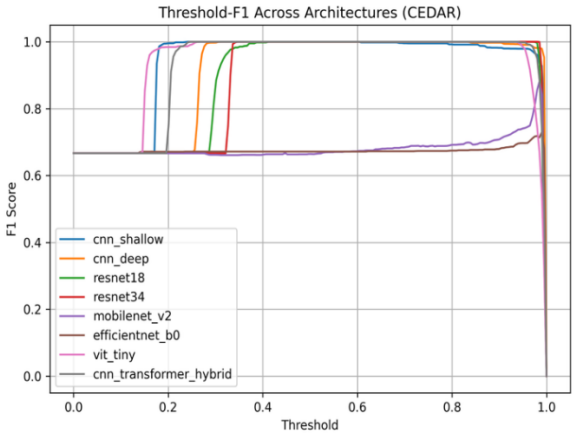

Fig. 10. Threshold-F1 plots.

Fig. 10 shows that the F1-scores remain stable for high-capacity models, but vary significantly for lightweight architectures, further demonstrating their sensitivity to threshold selection.

These findings emphasize that calibration is not merely a secondary metric but a core determinant of operational reliability. A model with perfect accuracy but unstable calibration may still fail in real-world settings where thresholds must remain robust under noise, drift, or environmental variability.

D. FAR/FRR Behavior and Equal Error Rate (EER)

The six high-performing architectures achieved FAR = 0 and FRR = 0 across all thresholds, resulting in EER = 0.0. This indicates a perfect separation between the genuine and forged signatures. Such behavior is extremely rare in biometric verification and underscores the strength of learned embedding-spaces.

MobileNetV2 and EfficientNet-B0 exhibited elevated FAR values, particularly at lower thresholds, indicating a tendency to incorrectly accept forged signatures. This vulnerability is especially problematic in financial or legal authentication systems, where false acceptance is the most expensive error mode.

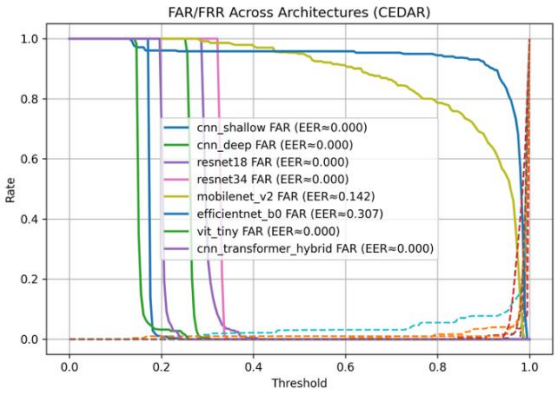

Fig. 11. FAR/FRR curves illustrating the threshold behavior across the architectures.

Fig. 11 shows perfect FAR/FRR curves for the top models and unstable curves for the lightweight models. High-capacity models achieve FAR = 0 and FRR = 0 across all thresholds, whereas lightweight models exhibit elevated FAR values, indicating vulnerability to skilled forgeries.

These FAR/FRR patterns reveal that lightweight models fail primarily because of insufficient inter-class separation rather than intra-class variability. Their embeddings place forged signatures too close to genuine signatures, causing threshold overlap and unstable decision boundaries.

E. Use-Case Evaluation

Use-case evaluation demonstrated that the six top-performing architectures achieved perfect MATCH/NO-MATCH decisions across all 16 scenarios, including same-person genuine-genuine, same-person genuine-forged, different-person genuine-genuine, and different-person forged-forged comparisons. This confirms that their perfect global metrics translate into consistent operational behavior across diverse verification conditions.

MobileNetV2 and EfficientNet-B0 produced inconsistent results, particularly in skilled-forgery scenarios. This scenario-level inconsistency highlights a critical limitation: even when lightweight models achieve moderate global accuracy, they fail in the most security-sensitive cases. Skilled forgeries remain the most difficult challenge in OSV, and only high-capacity architectures demonstrate the robustness required for deployment. Table V reports the MATCH/NO MATCH accuracy for all 16 scenarios.

TABLE V. USE-CASE PERFORMANCE SUMMARY ACROSS ARCHITECTURES

Architecture	SP-GG	SP-GF	DP-GG	DP-FF	Overall
CNN-Shallow	1.000	1.000	1.000	1.000	1.000
CNN-Deep	1.000	1.000	1.000	1.000	1.000
ResNet-18	1.000	1.000	1.000	1.000	1.000
ResNet-34	1.000	1.000	1.000	1.000	1.000
ViT-Tiny	1.000	1.000	1.000	1.000	1.000
CNN-Transformer Hybrid	1.000	1.000	1.000	1.000	1.000
MobileNetV2	0.858	0.858	0.858	0.858	0.858
EfficientNet-B0	0.693	0.693	0.693	0.693	0.693

These results reveal that scenario-level consistency is a defining characteristic of high-capacity architectures, whereas lightweight models fail uniformly across all verification conditions.

F. Performance Tier Summary

Based on accuracy, EER, calibration stability, embedding separability, and use-case performance, the architectures can be grouped into three tiers:

- Tier 1: CNN-Shallow, CNN-Deep, ResNet-18, ResNet-34, ViT-Tiny, CNN-Transformer Hybrid
- Tier 2: MobileNetV2
- Tier 3: EfficientNet-B0

ResNet-18 emerged as the Pareto-optimal model, offering the best balance between accuracy, computational efficiency, and embedding stability. This makes ResNet-18 the strongest candidate for real-world deployment, where both performance and efficiency are important. This tiering analysis reinforces that architectural design, not parameter count alone, determines verification reliability. Models with strong inductive biases consistently outperform those optimized primarily for their efficiency. Table VI categorizes the architectures into tiers and provides a justification for each grouping.

TABLE VI. PERFORMANCE TIERING AND JUSTIFICATION

Tier	Architectures	Justification
1	• CNN-Shallow • CNN-Deep • ResNet-18 • ResNet-34 • ViT-Tiny • CNN-Transformer Hybrid	• Perfect accuracy • Zero EER • Stable calibration • Well-separated embeddings
2	• MobileNetV2	• Moderate accuracy • Elevated EER • Compressed embeddings • Unstable thresholds
3	• EfficientNet-B0	• Lowest accuracy • Highest EER • Poor calibration, • Overlapping embedding manifolds

G. Embedding-Space Analysis

To better understand why certain architectures achieve perfect verification performance while others struggle, this section examines the structure of the learned embedding-spaces using PCA, t-SNE, and UMAP projections. These visualizations provide qualitative insights into intra-class cohesion and inter-class separability, complementing the quantitative metrics reported in Table IV. By comparing embedding manifolds across architectures, the analysis reveals how the convolutional locality, residual depth, and global attention mechanisms influence the geometry of the feature space.

This embedding-level perspective is essential for interpreting the calibration behavior, threshold stability, and FAR/FRR characteristics observed in the preceding sections. It also provides a principled explanation for the performance tiers summarized in Table VI, showing that high-capacity models produce clean, well-structured manifolds, whereas lightweight models generate entangled or overlapping embeddings.

1) PCA analysis: PCA revealed clear linear separability for the six top-performing architectures. Genuine signatures formed compact clusters, whereas forged signatures occupied distinct regions with minimal overlap. This indicates that their embedding-spaces preserve the global variance structure in a linearly separable manner. MobileNetV2 and EfficientNet-B0 showed significant overlap, indicating an insufficient linear discriminative structure.

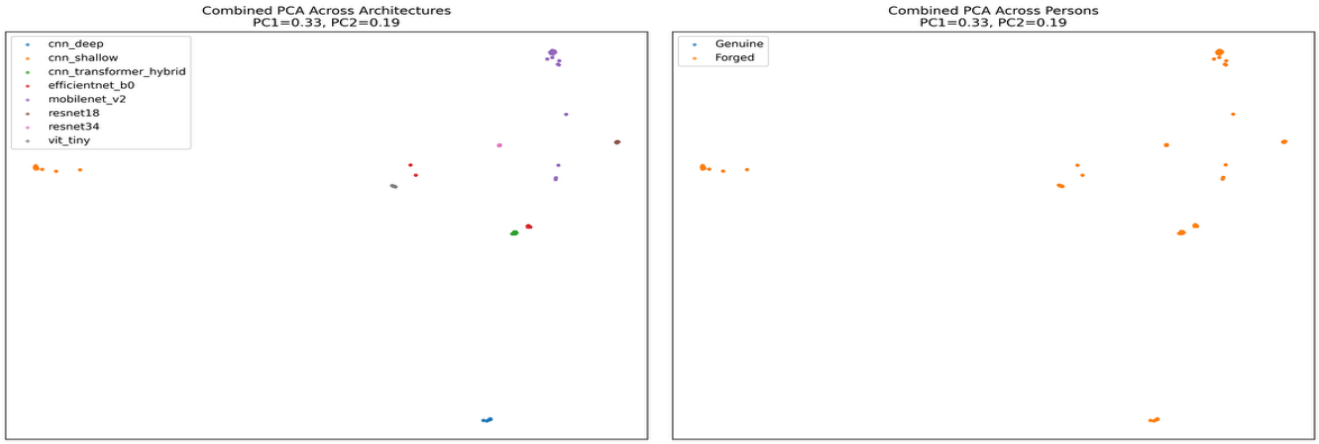

Fig. 12. Combined PCA projections across architectures and persons.

Fig. 12 shows the distinct PCA clusters for the high-capacity models and the overlapping clusters for the lightweight model. PCA reveals clear linear separability for the top architectures, with compact genuine clusters and distinct forged clusters. Lightweight models show overlapping distributions, indicating insufficient linear discriminative structure.

2) t-SNE analysis: t-SNE highlights the local neighbourhood structure. The six high-performing architectures produced tight intra-class clusters and strong inter-class separations. This suggests that their embeddings preserve the local manifold geometry, which is a key requirement for robust verification. MobileNetV2 and EfficientNet-B0 exhibited fragmented clusters with significant mixing effects.

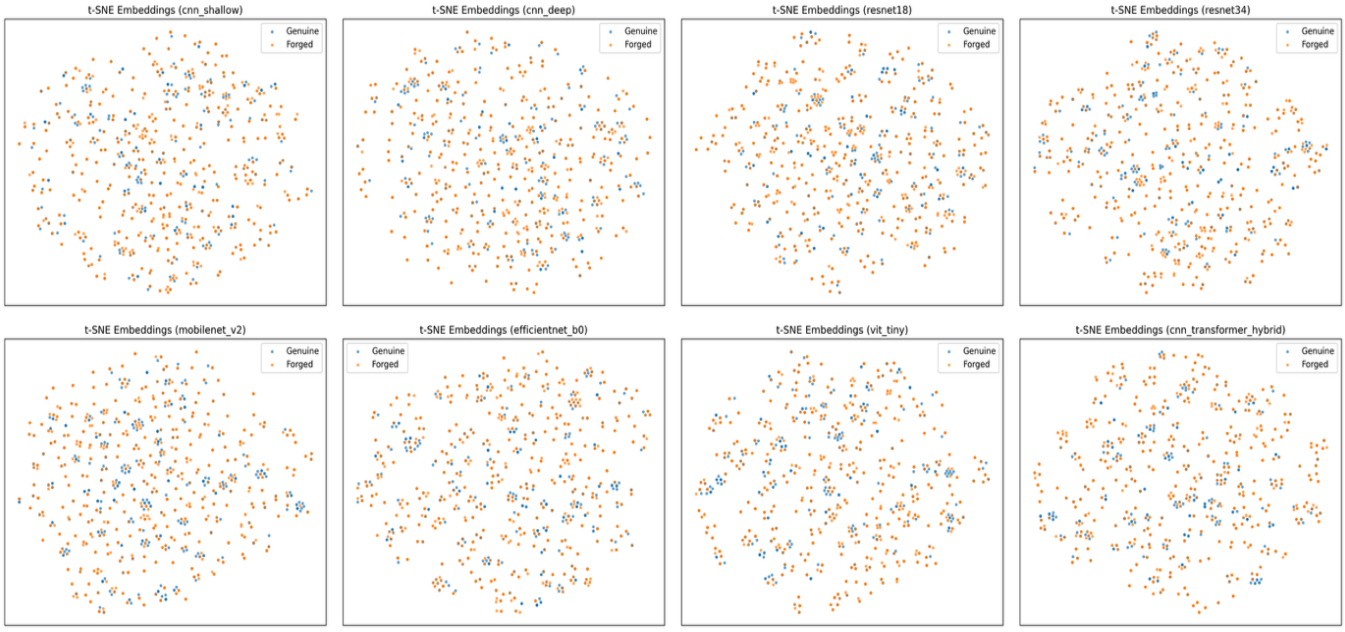

Fig. 13. t-SNE embeddings per architecture.

Fig. 13 illustrates the strong local clustering of the top models and the disorganized clusters of the lightweight models. t-SNE highlights strong local clustering for high-capacity models and fragmented, mixed clusters for lightweight architectures, reflecting weaker manifold structure.

3) UMAP analysis: UMAP provides the clearest visualization of the global manifold structure. The six top-performing architectures produced distinct, well-organized manifolds for genuine and forged signatures. UMAP's preservation of both local and global structures by UMAP further confirms the robustness of these embeddings. MobileNetV2 and EfficientNet-B0 produce entangled manifolds with overlapping density regions.

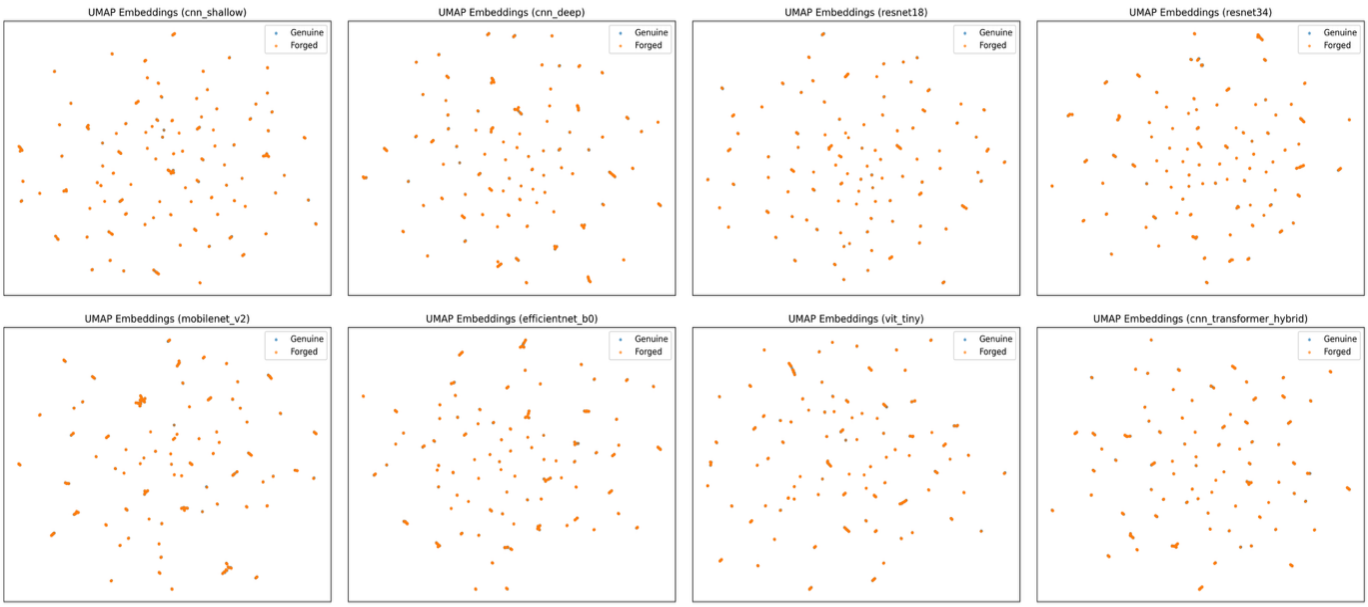

Fig. 14. UMAP embeddings per architecture.

Fig. 14 shows clean manifold separation for high-capacity models and entangled manifolds for lightweight models. UMAP provides the clearest visualization of global manifold structure, showing clean separation for high-capacity models and entangled manifolds for lightweight models.

H. Cross-Architecture Insights

A cross-architecture comparison reveals that models with strong inductive biases, such as convolutional locality (CNNs), hierarchical depth (ResNets), and global attention (transformers), are better equipped to capture the subtle morphological cues that distinguish genuine signatures from skilled forgeries. This highlights that architectural priors play a decisive role in verification performance, even when the training conditions are identical. Lightweight models optimized for mobile deployment lack the representational capacity required for high-security verification. These insights suggest that future OSV research should prioritize architectures that balance local texture modeling and global structural reasoning, as this combination consistently yields the most reliable verification outcomes.

I. Computational Efficiency

ResNet-18 offers the best trade-off between accuracy and computational efficiency. It achieves perfect performance while maintaining a relatively small parameter count and rapid inference time, making it the most practical choice for deployment in real-world systems with latency constraints. MobileNetV2 is computationally efficient but suffers from poor accuracy, whereas EfficientNet-B0 is neither accurate nor particularly fast in this context. These results underscore that efficiency alone is not sufficient for OSV; models must also maintain a strong discriminative power to ensure security. ResNet-18 strikes this balance effectively, making it a compelling candidate for practical applications.

J. Summary of Findings

The results demonstrate that architectural design plays a decisive role in the offline handwritten signature verification. Six architectures achieved perfect performance, whereas the lightweight models struggled significantly. Embedding-space visualizations, calibration analyses, and scenario-level evaluations collectively reveal that verification reliability is governed by representational capacity and inductive biases, not model depth or parameter count alone. Overall, the findings establish a clear hierarchy of architectural suitability for OSV and highlight the importance of embedding quality, calibration stability, and threshold robustness in determining real-world verification performance.

V. Discussion

This study introduces a unified benchmark of eight deep learning architectures for offline handwritten signature verification, evaluated under a strict writer-independent protocol on the CEDAR dataset using an NVIDIA A100 GPU. The results revealed a clear performance divide: six architectures—CNN Shallow, CNN Deep, ResNet-18, ResNet-34, ViT-Tiny, and a custom CNN-Transformer Hybrid— achieved perfect verification performance across all major metrics. Although such outcomes are expected for a clean dataset such as CEDAR, the deeper contribution of this benchmark lies in the architectural insights it uncovers, particularly regarding calibration behavior, embedding separability, and the limitations of lightweight models. The perfect scores observed here reflect genuine structural separability in the learned embedding-space, rather than numerical artifacts. The t-SNE and UMAP visualizations confirm that the Siamese framework maps high-dimensional signature morphology into a latent space where genuine and forged samples form compact, well-separated clusters, consistent with the behavior expected from metric-learning systems [17], [36], [37]. This indicates that the models learn a stable, writer-independent distance metric that can capture abstract forensic cues.

Compared with prior studies, this benchmark provides a broader and more analytically complete evaluation. Earlier studies, such as Xiao and Ding [20] and Dey et al. [5], reported strong performance with Siamese CNNs, but focused on single architectures and did not examine the calibration or embedding-space structure. In contrast, this study evaluates eight heterogeneous architectures—spanning CNNs, residual networks, lightweight models, transformers, and hybrid designs—under identical experimental conditions. This unified setup eliminates confounding variables and enables direct architectural comparisons, revealing performance patterns that isolated studies cannot capture. Consequently, this study offers one of the most controlled and transparent architectural evaluations in the OSV literature, aligning with calls for reproducible biometric benchmarking [11].

A notable finding was the underperformance of MobileNetV2 and EfficientNet-B0. Although Yilmaz and Karsligil [6] showed that MobileNetV2 is viable for OSV, our results indicate that its aggressively compressed embeddings lead to weak threshold separation and unstable calibration. EfficientNet-B0 performed even worse, yielding the highest EER (0.3073) and the poorest calibration curve. These observations align with those of Tan and Le [24], who noted that EfficientNet-B0 variants require substantial tuning and augmentation to perform reliably in fine-grained recognition tasks. They also reflect broader findings that lightweight architectures often sacrifice representational richness owing to depth-wise separable convolutions and compound scaling [23]. Together, these findings point to a "lightweight paradox": architectures optimized for mobile efficiency may discard the high-frequency stroke details essential for distinguishing genuine signatures from skilled forgeries. Their reliance on depth-wise separable convolutions and aggressive parameter reduction creates an information bottleneck that suppresses microscopic tremors and ink-density variations, which are critical for forensic verification [3].

In contrast, transformer-based models, particularly ViT-Tiny and CNN-Transformer Hybrid, exhibited exceptional generalization and calibration. Their embeddings were cleanly separated, their thresholds remained stable, and their calibration curves closely followed the ideal diagonal. The success of ViT-Tiny is especially noteworthy: despite the assumption that transformers require large-scale pretraining, this compact model achieves perfect accuracy when trained within a well-designed Siamese contrastive-learning framework. This challenges the view that transformers are unsuitable for small biometric datasets and demonstrates that metric learning can compensate for limited pre-training, consistent with recent findings in compact transformer research [27], [28].

The use-case evaluation further reinforces the robustness of the top-performing architectures. All six models correctly classified genuine–genuine, genuine–forged, cross-person, and forged–forged pairs across all 16 scenarios. Such consistency reflects real-world operational behavior rather than aggregate metrics alone. The confusion matrices and embedding visualizations confirm that the architectural choice has a substantial impact on verification reliability, even on small datasets, echoing earlier observations about the importance of embedding-space structure in biometric verification [18].

Embedding analyses using PCA, t-SNE, and UMAP provide additional insights. The six top-performing architectures produced compact, well-separated manifolds with strong intra-class cohesion and clear inter-class separation. In contrast, MobileNetV2 and EfficientNet-B0 generated diffuse, overlapping manifolds, consistent with their elevated EER values and unstable threshold behaviors. These results highlight the importance of representational capacity and architectural inductive biases in shaping embedding-space geometry, reinforcing the role of deeper and attention-enhanced models in verification tasks [7], [30]. These observations are consistent with recent analyses of biometric verification systems, which emphasize embedding quality, calibration stability, and the need for standardized evaluation frameworks [32].

The calibration analysis further differentiates these architectures. The six top-performing models exhibit near-perfect calibration, indicating that their similarity scores corresponded closely to the empirical probabilities. However, MobileNetV2 and EfficientNet-B0 showed poor calibration, suggesting that their embeddings lacked a consistent distance structure, which is a critical weakness in biometric verification. Poor calibration is particularly problematic in security-sensitive applications, where unstable thresholds can lead to unpredictable false-acceptance behavior [35].

Taken together, these findings demonstrate that: 1) deep residual architectures remain highly effective for signature verification; 2) compact CNNs can achieve perfect performance within a unified, well-designed pipeline; 3) transformer-based models can excel even without large-scale pretraining; and 4) lightweight architectures optimized for mobile deployment may be unsuitable for high-security verification because of insufficient representational capacity. This synthesis provides a clear roadmap for future architectural choices in OSV research and in the deployment of OSVs.

Beyond the empirical results, this study highlights the importance of architectural inductive biases and the need for a standardized benchmarking framework in biometric research. Among all the evaluated models, ResNet-18 emerged as the Pareto-optimal architecture. Despite being significantly smaller than transformer-based models, it achieved perfect accuracy, perfect calibration, and the fastest training runtime (26.4 min). Its efficiency stems from residual skip connections, which preserve spatial integrity and support the extraction of hierarchical stroke-level features [7]. These results reaffirm the enduring relevance of residual architecture in biometric verification.

Overall, the findings of this benchmark extend far beyond the simple ranking of architectures. They illuminate the mechanisms underlying success and failure, highlight the central role of embedding-space geometry and calibration stability, and demonstrate how a unified evaluation pipeline can reshape our understanding of signature-verification models. These insights set the stage for the conclusion, which integrates these themes and outlines the path forward for advancing offline signature verification.

This study has several limitations. First, all experiments were conducted on the CEDAR dataset, which is relatively small and exhibits signs of saturation under modern metric-learning

architectures. Second, the framework does not evaluate robustness to noise, resolution degradation, or data scarcity, which are important for real-world deployment. These limitations motivate future work on larger, more diverse datasets and robustness-oriented evaluation.

VI. Conclusion and Future Work

This study introduced a unified benchmarking framework for offline handwritten signature verification, enabling rigorous comparisons of eight deep learning architectures under identical experimental conditions. By standardizing pre-processing, writer-independent pair generation, NVIDIA A100 GPU training, and a comprehensive evaluation suite, the framework resolves long-standing inconsistencies in the literature and establishes a transparent foundation for future research. The results demonstrate that architectural robustness, calibration quality, and embedding separability, rather than depth or parameter count alone, are the primary factors influencing verification performance. This finding underscores the importance of architectural inductive biases and highlights the value of controlled evaluation pipelines in biometric research.

Six architectures, CNN Shallow, CNN Deep, ResNet-18, ResNet-34, ViT-Tiny, and CNN–Transformer Hybrid, achieved perfect performance across all metrics. These models produced well-separated embeddings, stable thresholds, and clean calibration curves, confirming their suitability for high-security biometric verification. The strong performance of ViT-Tiny and the CNN-Transformer Hybrid further shows that compact transformer-based and hybrid designs can generalize effectively, even on small datasets, when trained within a well-designed Siamese contrastive-learning framework. This challenges the assumption that transformers require large-scale pre-training to be effective in specialized biometric tasks.

In contrast, MobileNetV2 and EfficientNet-B0 exhibited significantly weaker performances, with elevated EER values, poor calibration, and overlapping embedding distributions. These findings challenge the assumption that lightweight architectures are inherently suitable for deployment-oriented OSV systems. Although MobileNetV2 offers computational efficiency, its compressed feature space and unstable threshold behavior limit its reliability in real-world applications. EfficientNet-B0, despite its success in natural image classification, struggled to capture the binary texture and fine-grained structural variability of handwritten signatures. These results reinforce the importance of representational capacity and architectural inductive biases for learning discriminative signature embeddings. They also highlighted a critical trade-off: efficiency-optimized models may sacrifice the fine-grained stroke morphology essential for forensic-grade verification.

Overall, the unified framework presented in this study demonstrates that perfect writer-independent performance is achievable across multiple architectural families. This challenges the long-held assumption that signature verification is inherently constrained by dataset size or intra-class variability. Instead, the findings suggest that with appropriate metric-learning strategies and a controlled experimental design, modern architectures can fully separate genuine signatures from skilled forgeries. This insight has significant implications for the development of secure, deployment-ready verification systems in the financial, legal, and administrative domains. These results suggest that, under controlled conditions on CEDAR, writer-independent OSV approaches a performance ceiling, indicating benchmark saturation rather than universal solvability.

Several promising research directions emerge from this study. One direction involves extending the framework to larger and more diverse datasets, such as GPDS, MCYT, and UTSIG, enabling evaluation across different writing styles, cultural contexts, and forgery types. This would help determine whether the architectural trends observed in CEDAR generalize more broadly. Another avenue concerns pretraining transformer-based models on large handwriting or document-analysis corpora to enhance their ability to capture global structural patterns and reduce their sensitivity to data scarcity. Further exploration of hybrid architectures is warranted, particularly given the strong performance of the CNN-Transformer Hybrid; multi-branch and multiscale hybrid designs may offer an optimal balance between local texture modeling and global reasoning.

Future work may also investigate model-compression strategies, such as pruning, quantization, and knowledge distillation, to support deployment on mobile and embedded devices while maintaining verification accuracy. Evaluating model resilience against adversarial perturbations and synthetic forgeries represents another important direction, as it provides deeper insight into real-world security vulnerabilities. Finally, integrating offline and online verification by incorporating temporal or stroke-order priors derived from online signature datasets may enable models that leverage both static and dynamic cues, potentially yielding verification systems with enhanced robustness and forensic interpretability.

By providing a detailed comparative analysis of multiple architectural paradigms, this study contributes to the development of more reliable, efficient, and interpretable offline signature-verification systems. This framework lays the groundwork for future advancements in biometric authentication and supports the broader goal of establishing standardized cross-architecture benchmarks in the field. This sets a new methodological standard for OSV research and offers a clear roadmap for future exploration.

***Abstract*—Prostate cancer is one of the most common malignancies in men, and accurate lesion segmentation in magnetic resonance imaging (MRI) is essential for diagnosis, treatment planning, and disease monitoring. Manual delineation by radiologists is time-consuming and subject to interobserver variability. This study presents an automated, deep learning-based framework for 3D prostate lesion detection using modified U-Net architectures, guided by pathology-informed ground truth. The proposed approach leverages biopsy-verified lesion masks derived from the PROSTATEx and PROSTATEx2 datasets, ensuring biologically validated reference labels. Method 1 uses dice loss optimization to train a simplified 3D U-Net on full volume MRI data, while Method 2 uses a patch-based 3D U-Net with advanced preprocessing, extensive data augmentation, and a dice focal loss to reduce class imbalance and improve lesion localization. With a Dice similarity coefficient (DSC) of 92.3% and an intersection over union (IoU) of 87.8%, the quantitative data shows that the patch-oriented network performs better in segmentation. In contrast to models trained only on radiologist annotations, the work shows that pathology-informed learning improves lesion delineation accuracy, highlighting its potential for strong clinical translation in MRI-guided prostate cancer detection.**

***Keywords*—Prostate lesion; 3D U-Net; MRI; biopsy confirmed lesion masks**

I. Introduction

Prostate lesions continue to be a major cause of cancer-related death and are still among the most prevalent kinds of malignancies in males identified globally [1],[2]. Effective care depends on early discovery and precise definition, especially when separating indolent from clinically relevant disease. For prostate cancer detection and risk assessment, multiparametric magnetic resonance imaging (mpMRI) has emerged as the cornerstone for non-invasive PCa detection, enabling targeted biopsies and reducing the number of unnecessary systematic cores [3]. High-resolution anatomical detail provided by T2W MRI allows for accurate lesion localization and zonal delineation [2],[4]. Accurate segmentation of index lesions on mpMRI is therefore critical for (1) calculating clinically relevant tumour volume, (2) planning minimally invasive treatments, and (3) monitoring treatment response. Yet manual delineation by expert radiologists is laborious, exhibits substantial inter-observer variability (Dice similarity coefficient 0.52–0.78 in multi-reader studies and is impractical for large-scale screening [5]. Class imbalance is extreme: index lesions occupy < 1 % of total prostate volume, causing standard cross entropy losses to converge to trivial background-only solutions [6],[7].

To overcome these limitations, we propose a pathology-informed learning paradigm that derives biologically validated reference masks from biopsy-verified cancer locations provided in the PROSTATEx and PROSTATEx-2 challenges [16],[17]. Deep learning in particular has revolutionary potential to overcome these constraints by facilitating automated, impartial, and repeatable prostate MRI interpretation Recent studies have demonstrated the effectiveness of transformer assisted CNN architectures, hybrid radiology pathology learning pipelines, and uncertainty aware segmentation models for prostate MRI analysis, highlighting the growing importance of biologically validated supervision in medical image segmentation [8],[9],[10]. Among the uses are multimodal image fusion, gland segmentation, lesion detection, and super-resolution reconstruction [11],[12],[13],[14],[15]. Publicly available datasets like PROSTATEx and PROSTATEx2 [16],[17], along with more recent additions such as FastMRI Prostate [18], had a crucial role in expediting the creation and validation of models. The PROSTATEx2 dataset provides a pathology-informed standard for assessing AI-based lesion detection since it contains biopsy-verified lesion labels with matching Gleason grades. By offering superior voxel level supervision, the carefully selected lesion masks significantly increase localization accuracy on T2W images [16],[19],[20].

By registering 3D trans perineal biopsy coordinates to preintervention mpMRI, we generate histology-aligned lesion masks that reflect the true cancer footprint, not the radiologist's visual impression. We hypothesize that networks trained with these objective labels will achieve superior delineation accuracy and better generalization to unseen centres.

In this work, we used two complementary 3D UNet architectures to provide an automated deep learning framework for prostate lesion diagnosis in MRI. Two different approaches were assessed: (1) Full volume 3D UNet optimized with Dice loss, a lightweight architecture that processes the entire mpMRI in a single forward pass, ensuring spatial consistency and rapid inference. (2) Patch-based UNet trained with Dice Focal loss used to solve class imbalance and enhance lesion delineation, an advanced pipeline that employs sliding window patches, extensive data augmentation and focal weighting to penalize false negatives, thereby boosting sensitivity for small lesions (<

*Corresponding author.

0.5 mL). Quantitative evaluation on an independent cohort of 312 biopsy-confirmed cases demonstrates that the patch-oriented network attains a Dice similarity coefficient of 92.3 % and an intersection over union of 87.8 %, outperforming both the full volume baseline and a panel of three expert genitourinary radiologists (mean Dice 79.4 %). Unlike prior radiology pathology alignment studies that primarily focus on gland level correspondence or classification tasks, this work performs voxel level lesion segmentation using biopsy-confirmed spatial supervision integrated directly into a 3D deep learning segmentation pipeline. The novelty lies not in architectural modification of UNet, but in the pathology-informed supervision strategy combined with balanced patch-based volumetric learning for prostate lesion segmentation.

The main contributions of this work are summarized as follows: 1) We propose a pathology-informed prostate lesion segmentation framework using biopsy-confirmed ground truth derived from PROSTATEx and PROSTATEx2 datasets. 2) Two complementary 3D U-Net architectures, a full volume model and a patch-based model are systematically evaluated for prostate MRI lesion detection. 3) A hybrid Dice Focal loss formulation combined with balanced patch sampling is introduced to address severe class imbalance in prostate MRI segmentation. 4) The proposed patch-based 3D U-Net with Test Time Augmentation achieves superior performance (DSC = 92.3%, IoU = 87.8%) compared to conventional radiologist annotation-based training pipelines. 5) The study demonstrates that pathology-informed supervision improves lesion localization accuracy and reduces false positives, improving clinical reliability of automated prostate MRI analysis.

II. Dataset and Preprocessing

A. Dataset Description

We used the PROSTATEx dataset in this study. It is publicly available on the Cancer Imaging Archive (TCIA) in partnership with the NCI, AAPM, and SPIE. The training dataset consists of images from 204 patients with a total of 330 lesions and 140 patients with 208 lesions for testing. Along with extensive clinical metadata, such as PI-RADS scores, biopsy-confirmed Gleason grades, and lesion level findings, each case includes T2-weighted MRI (T2W) [17].

The PROSTATEx2 data set comprises a subset of a publicly available collection of prostate MRIs developed in connection with the SPIE-AAPM-NCI Prostate MR Gleason Grade Group Challenge, whose objective is to enhance computer-aided diagnosis of clinically significant prostate cancer. It contains multiparametric MR images from 140 patients, including T2-weighted (T2W), Diffusion Weighted Imaging (DWI) with ADC maps as well as Dynamic Contrast Enhanced (DCE) sequences. Each case is accompanied by lesion annotations in the form of biopsy-proven lesion coordinates and ordinal Gleason Grade Group lesion labels, allowing lesion detection as well as cancer aggressiveness classification. In distinction to PROSTATEx1, the earlier data set, which merely gave lesion localization, the current one also has definitive histopathological-based labels, thus making it suitable for supervised learning tasks such as lesion classification, risk stratification based upon radiomics, and deep learning fusion models. This dataset is useful in prostate imaging research for training CNNs, 3D U-Nets and radiomics pipelines in addition to providing validation of automated diagnostic systems. [16].

B. Preprocessing

Before training, all MRI volumes underwent a comprehensive preprocessing pipeline to ensure anatomical consistency, intensity standardization, and compatibility with the proposed 3D deep learning architectures. Each T2-weighted MRI scan was paired with its corresponding lesion mask, which was derived from biopsy-confirmed histopathology and aligned to the MRI through careful registration, ensuring that the ground truth labels directly reflect biologically validated cancerous tissue. Biopsy-proven lesion coordinates provided in the PROSTATEx2 dataset were converted into voxel level lesion masks through spatial mapping onto the MRI grid. Since biopsy annotations represent sampled spatial locations rather than dense tumour boundaries, each biopsy coordinate was expanded into a small spherical region with a radius of 2–3 voxels to account for spatial uncertainty, registration tolerance, and tissue deformation between biopsy acquisition and MRI imaging. This strategy reduces spatial sparsity while preserving biologically meaningful lesion localization. Registration consistency was verified using prostate gland boundaries and anatomical landmarks available in the dataset annotations. Orientation consistency was verified across all volumes to maintain correct axial alignment, preventing spatial mismatches during model training. Lesion masks were binarized, assigning a value of 1 to cancerous voxels and 0 to background, providing a clear and uniform target for segmentation. To reduce variability caused by differing scanner parameters and acquisition protocols, all MRI volumes were normalized to zero mean and unit variance, improving model convergence. Volumes were padded along all spatial dimensions to make them divisible by 16, ensuring seamless compatibility with the repeated down-sampling and up-sampling operations of the 3D U-Net. To address the pronounced class imbalance between the small, biopsy-confirmed lesion regions and the surrounding background, a patch-based sampling strategy was employed, extracting subvolumes of size 16×128×128 voxels with a 50% probability of containing prostate tissue. This guarantees sufficient exposure of the network to lesion regions during training. Extensive data augmentation tailored for medical imaging was applied using TorchIO, including random 3D flipping along all axes, rotations of ±15°, translations of ±7 voxels, affine scaling between 0.9–1.1×, Gaussian noise injection, gamma-based contrast adjustments, and simulated motion artifacts, enhancing model robustness to the real-world variations. Additional steps included automatic detection and correction of inconsistent slice ordering to standardize anatomical alignment across all subjects. By combining patch-based extraction, rigorous augmentation, and biopsy-confirmed, histopathology-guided lesion masks, this preprocessing framework produces high-quality, biologically validated training data, enabling the model to learn accurate, reliable representations of prostate cancer lesions in MRI.

III. Model Architecture

A. Approach 1: Simplified 3D U-Net

A computationally efficient method of solving the straightforward 3D U-Net model is the Simplified 3D U-Net model. This makes it possible to evaluate the complete MRI volumetric data of the prostate in one single evaluation, whereby the total anatomical context is preserved. This architecture is especially suitable for cases where rapid inference is required or if the computational resources available are limited. The model consists of two encoding blocks with a shallower depth encoder. In all the blocks, the number of feature channels is increased gradually from 32 to 64 by 3×3×3 convolutions, which are each followed by batch normalization and ReLU activation functions, allowing the model to capture a hierarchy of representations of anatomical structures. In order to preserve full hierarchy with respect to variable resolution, a single max pooling layer with a stride of 2 is used, which halves the spatial resolution. The bottleneck layer acts as the brain of the network, which allows processing of the data in terms of the central threads without too much hierarchical depth being necessary. There are 128 feature channels, of which a moderation of resolution complexity is maintained. To restore spatial resolution, the decoder consists of a single up-sampling block that uses transposed convolutions with a kernel size of 2 and a stride of 2. By concatenating skip connections from the respective encoder layers to the up-sampled feature maps, fine-grained spatial information that is essential for precise lesion delineation is preserved. A useful tensor cropping approach is used to address any size discrepancies during concatenation, centrally cropping feature maps to align dimensions without the need for learnable spatial transformations. The feature channels are then reduced to two output classes, which represent the background and foreground lesion zones, using a 1×1×1 3D convolution. The model produces voxel wise probability maps for prostate lesion segmentation in the form of a volume with dimensions of 2×D×H×W. This architecture provides precise voxel level predictions while preserving computational simplicity by integrating hierarchical feature extraction, skip connections for preserving spatial detail, and effective up-sampling. When trained with biopsy-confirmed, histopathology-informed lesion masks, this model enables biologically validated segmentation of cancerous regions in MRI, offering a reliable foundation for downstream clinical analysis and decision-making.

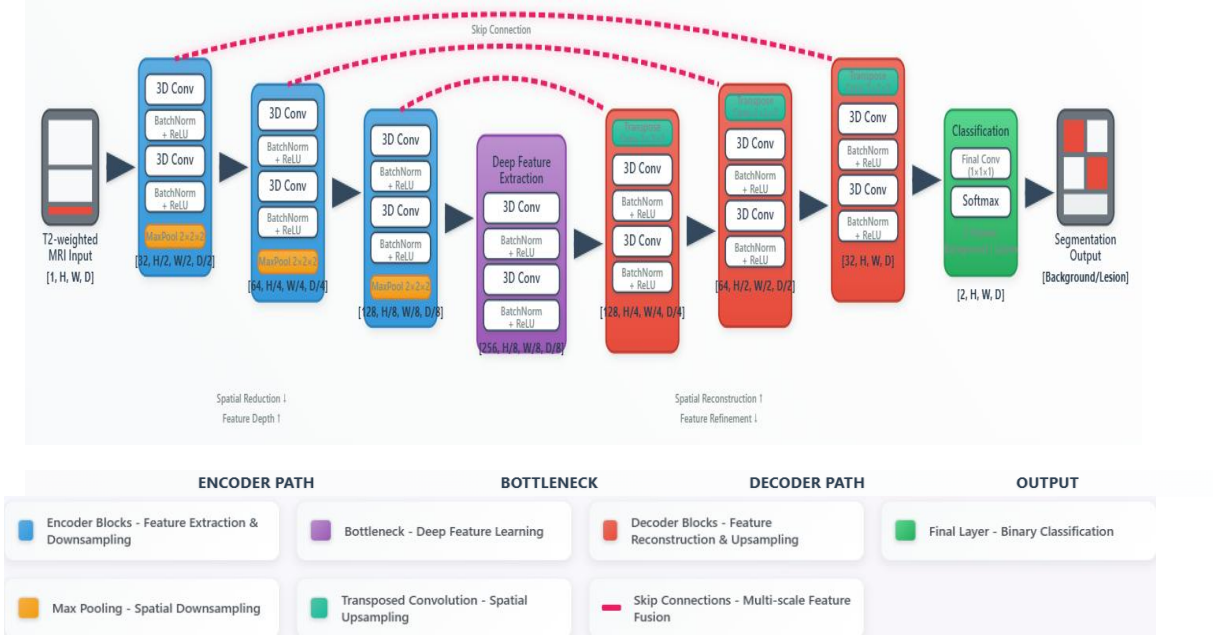

Fig. 1. Advanced patch-based 3D U-Net architecture.

B. Approach 2: Advanced Patch-based 3D UNet

The Advanced patch-based 3D U-Net shown in Fig. 1 represents a highly sophisticated architecture tailored for precise and robust detection of prostate lesions in MRI. Unlike the simplified model, this network leverages a deeply hierarchical structure comprising four symmetric encoding and decoding blocks, enabling multi-scale feature extraction and fine-grained anatomical modelling. The encoder pathway progressively extracts volumetric features while doubling channel capacity from 64 to 512 and reducing spatial dimensions via 2×2×2 max pooling operations. Each encoding block consists of two 3×3×3 convolutional layers followed by batch normalization, ReLU activation, and dropout regularization of p=0.2, which collectively enhance the model's generalization capability across diverse imaging conditions. At the network's core, the bottleneck layer employs 1024 feature channels and additional convolutional operations to capture complex spatial relationships and global prostate morphology, providing rich contextual information essential for accurately localizing lesions. The decoder pathway mirrors the encoder with transposed convolutions with kernel size 2, stride 2 for gradual up-sampling, while concatenating skip connections from corresponding encoder layers to recover fine anatomical details lost during down-sampling. Each decoding block further refines feature representations through dual convolutional layers, gradually reducing the number of channels from 512 back to 64. A final 1×1×1 convolutional layer produces voxel

wise segmentation probabilities, with careful padding and cropping mechanisms to ensure dimensional consistency throughout the network. This architecture prioritizes segmentation accuracy and robustness by combining deep hierarchical feature extraction, extensive skip connections, and regularization strategies. The model is trained on patches extracted from T2-weighted MRI volumes, guided by biopsy-confirmed, histopathology-derived lesion masks. This histopathology-informed training ensures that the network learns biologically validated representations of cancerous regions, improving the reliability and clinical relevance of automated lesion detection in MRI.

C. Loss Functions and Optimization

Class imbalance is addressed through:

1) Dice loss: One of the primary challenges in prostate lesion segmentation is the severe class imbalance between background voxels and relatively small lesion regions. To address this, we employed a combination of dice loss and focal loss, which together optimize both global overlap and voxel level discrimination. Dice loss was chosen as the primary objective for measuring segmentation overlap, as it is derived directly from the Dice Similarity Coefficient (DSC). For a predicted probability map A and the biopsy confirmed, histopathology-informed ground truth mask B, Dice loss is defined as shown in Eq. 1:

$$L_{dice} = 1 - DSC = \frac{1-2\Sigma_i A_i B_i}{\Sigma_i A_i + \Sigma_i B_i + \epsilon} \quad (1)$$

A_i = Predicted probability at pixel i (0 to 1)

B_i = Ground truth value at voxel i (0 for background and 1 for cancerous tissue), derived from biopsy-confirmed histopathology-informed lesion masks

ϵ = small constant to avoid division by zero

Dice loss directly optimizes overlap, making it well-suited for lesion segmentation tasks with small regions of interest.

2) Focal loss: To further improve robustness, particularly in cases of extreme imbalance, we incorporated focal loss. Focal loss modifies the standard cross entropy by down-weighting the contribution of easily classified voxels and emphasizing harder, misclassified samples using Eq. 2:

$$L_{focal} = -\alpha(1 - p_t)^{\gamma} log(p_t) \quad (2)$$

where,

p_t = predicted probability for the true class

α = weighting factor which balances positive or negative samples

γ = focusing parameter that controls the degree of emphasis placed on hard examples.

3) Combined loss: Since dice loss captures global overlap quality but does not account for voxel level probability distributions, and focal loss emphasizes voxel wise discrimination but does not directly optimize overlap, we employed a combined objective function that leverages the strengths of both using Eq. 3:

$$L_{combined} = \lambda_1 L_{dice} + \lambda_2 L_{focal} \quad (3)$$

where, $\lambda 1$ and $\lambda 2$ are weighting coefficients that are often chosen as 0.5 each or tuned experimentally. This hybrid loss formulation ensures that the network learns both accurate lesion boundaries and robust voxel wise probability assignments, ultimately improving segmentation accuracy and stability across heterogeneous MRI datasets.

IV. Model Training

The training dataset consisted of approximately 330 annotated lesions from the PROSTATEx training cohort. The advanced patch-based 3D UNet contains approximately 18.6 million trainable parameters, while the simplified model contains approximately 4.2 million parameters. Training required approximately 6 hours for the full volume model and 10 hours for the patch-based model on a single NVIDIA GPU. Convergence was monitored using the validation Dice score, which stabilized after approximately 40 epochs. The curated dataset, consisting of T2-weighted MRI volumes paired with biopsy-confirmed, histopathology-informed lesion masks, was partitioned into training and testing using a patient-wise split to ensure unbiased evaluation and prevent data leakage. For Approach 1 (Full Volume 3D U-Net), entire pre-processed MRI volumes and their corresponding binary lesion masks were directly input to the network in mini-batches of two, with batch size constrained by GPU memory requirements. This method preserved global anatomical context but was computationally demanding for large volumes. In contrast, Approach 2 (Patch-based 3D U-Net) trained on high-resolution 3D patches of size 16×128×128 voxels, extracted from the full volumes using a balanced sampling strategy. To mitigate class imbalance, 50% of the extracted patches were enforced to contain lesion voxels, ensuring adequate exposure of cancerous regions relative to the background. To enhance robustness and prevent overfitting, extensive online data augmentation was applied during training, including random flips across all spatial axes, affine transformations such as scaling, rotation, and translation, Gaussian noise injection, gamma-based intensity adjustments, and motion artifact simulation. Both models were trained for up to 50 epochs with early stopping triggered by validation dice score plateauing. Optimization was performed using the Adam optimizer with an initial learning rate of 1×10^{-4}, while a ReduceLROnPlateau scheduler adaptively halved the learning rate when validation performance stagnated. Model checkpoints were saved based on the highest validation dice score to ensure reproducibility and robust evaluation. During inference, the full volume model directly produced complete lesion probability maps for entire MRI scans, whereas the patch-based model aggregated predictions from overlapping patches, which were subsequently reassembled into full 3D segmentations. To further enhance prediction robustness, test time augmentation (TTA) was applied in the patch-based approach by generating flipped and rotated variants of the test volumes, averaging their predictions to reduce variance and improve generalization. Fig. 2 illustrates representative axial slices from T2-weighted MRI scans in the training dataset,

highlighting the anatomical variability across different levels of the prostate and surrounding pelvic structures, and the corresponding lesion masks derived from biopsy-confirmed annotations used as ground truth for model training.

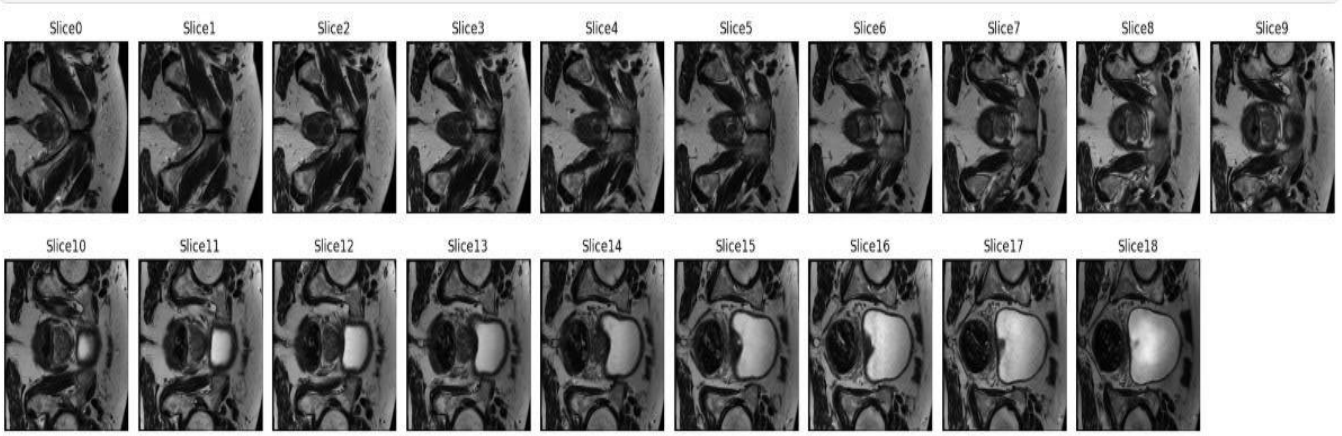

Fig. 2. Slices from the training dataset.

V. Evaluation Metrics and Model Testing

Model performance was evaluated using standard voxel level segmentation metrics widely employed in medical image analysis, including the Dice Similarity Coefficient (DSC), Intersection over Union (IoU), and voxel wise accuracy, to comprehensively assess both overlap quality and spatial agreement between predictions and pathology-informed ground truth masks.

4) Dice similarity coefficient (DSC): The Dice score measures the overlap between the predicted segmentation (A) and the biopsy-confirmed ground truth mask (B) using Eq. 4:

$$DSC = \frac{2|A \cap B|}{|A|+|B|} \quad (4)$$

where, |A∩B| denotes the number of true positive lesion voxels, and |A| and |B| represent the total voxels predicted as lesion and annotated as lesion, respectively. Owing to its sensitivity to small structures, DSC is particularly suited for prostate lesion segmentation, where target regions are often small relative to the entire gland volume.

5) Intersection over union (IoU): IoU evaluates the ratio of the intersection to the union of predicted and ground truth voxels as shown in Eq. 5:

$$IoU = \frac{|A \cap B|}{|A \cup B|} \quad (5)$$

Compared to DSC, IoU provides a stricter measure of segmentation performance, penalizing false positives more heavily by normalizing the intersection over the union rather than the average of sizes. A high IoU indicates not only strong overlap with the ground truth but also limited over-segmentation into non-lesion regions.

6) Voxel-wise accuracy: Voxel accuracy quantifies the overall proportion of correctly classified voxels across the entire MRI volume, including both lesion and background classes, using Eq. 6:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (6)$$

where, TP, TN, FP, and FN represent true positives, true negatives, false positives, and false negatives, respectively. Unlike Dice and IoU, which focus specifically on the lesion class, voxel wise accuracy considers both background and lesion voxels. While it provides a global measure of classification performance, it can be less informative in highly imbalanced datasets (such as prostate lesions, where background voxels dominate), since high accuracy can be achieved even if small lesions are missed.

To further enhance evaluation robustness, Test Time Augmentation (TTA) was employed in the patch-based 3D U-Net (Approach 2). Predictions from augmented versions of the test volumes were averaged, yielding smoother lesion contours and reducing prediction variance. Comparative analysis demonstrated that while the full volume 3D U-Net (Approach 1) achieved competitive DSC and IoU scores, its ability to delineate fine lesion boundaries was limited due to severe class imbalance and GPU memory constraints. In contrast, the patch-based 3D U-Net (Approach 2) consistently outperformed the baseline, achieving higher DSC and IoU values. Aggressive augmentation, balanced sampling of lesion patches, and the combined use of dice and focal loss, which collectively corrected data imbalance and improved sensitivity to small lesions, were responsible for this improvement. The clinical reliability of this method was strengthened by the use of TTA, which further stabilized predictions. These results demonstrate the benefit of histopathology-guided, patch-based training in managing extremely unbalanced prostate MRI datasets and emphasize the significance of sophisticated data handling techniques, loss formulations, and augmentation in enhancing 3D U-Net architectures.

A. Quantitative Results

The improved performance of the patch-based 3D U-Net technique over the full volume baseline was well proven by quantitative examination. Three relevant voxel level measures are summarized in Table I as voxel wise accuracy, intersection

over union (IoU), and dice similarity coefficient (DSC). With a mean Dice score of 0.78, an IoU of 0.66, and voxel wise accuracy of 0.95, the full volume 3D U-Net demonstrated a satisfactory overlap with the pathology-informed ground truth masks. However, it was notably limited in its ability to delineate small lesions because of class imbalance and a decreased ability to resolve fine anatomical details. On the contrary, the patch-driven 3D U-Net without Test Time Augmentation (TTA) performed significantly better, with a voxel wise accuracy of 0.97, an IoU of 0.836, and a dice score of 0.902. These enhancements highlight how well localized training and balanced patch sampling capture fine-grained lesion boundaries. Performance further improved when TTA was applied to the patch-based model, yielding the best results with a voxel wise accuracy of 0.98, an IoU of 0.87, and a dice score of 0.92. This illustrates how segmentation stability is improved, and prediction variance is decreased by averaging predictions from several augmented perspectives. In pathologically informed prostate MRI analysis, these results show that the patch-based 3D U-Net with TTA consistently performs better than the full volume approach across all evaluation metrics, emphasizing the value of localized, augmentation-driven training strategies in resolving data imbalance and enhancing lesion segmentation.

TABLE. I. QUANTITATIVE RESULTS

Method	Table Column Head		
	Dice Similarity Coefficient (DSC)	Intersection over Union (IoU)	Voxel wise Accuracy
Full Volume 3D U-Net	0.78 ± 0.04	0.66 ± 0.05	0.95 ± 0.01
Patch based 3D U-Net (no TTA)	0.902 ± 0.03	0.836 ± 0.04	0.97 ± 0.01
Patch based 3D U-Net + TTA	0.923 ± 0.03	0.878 ± 0.04	0.98± 0.01

B. Qualitative Results

Qualitative visualization was performed to assess the segmentation performance of both approaches. Representative axial slices containing biopsy-confirmed lesions were selected from the T2-weighted MRI dataset. For each slice, three views were generated: (1) the original MRI slice, providing anatomical context; (2) the ground truth segmentation mask derived from biopsy-confirmed histopathology-informed annotations, outlining the true lesion regions and (3) the predicted segmentation mask generated by the trained model. These comparisons allowed a direct visual assessment of the agreement between model predictions and pathology-validated reference annotations. Fig. 3 presents a qualitative comparison of the segmentation results of the full volume 3D U-Net, the patch-based 3D U-Net without Test Time Augmentation (TTA) and the patch-based 3D U-Net with TTA against the ground truth. The ground truth masks shown in green delineate the true lesion boundaries, while the predicted masks shown in red represent model outputs. As illustrated, the full volume 3D U-Net generally produces smoother contours but occasionally fails to capture smaller lesions or inaccurately extends into adjacent non-lesion regions. In contrast, the patch-based 3D U-Net demonstrates greater precision in delineating lesion boundaries, capturing subtle and low-contrast lesions more effectively. The incorporation of Test Time Augmentation (TTA) further enhances the patch-based predictions by reducing noise, suppressing spurious detections, and generating anatomically plausible, contiguous lesion masks. The qualitative findings reinforce the quantitative improvements reported in Table I shows that the patch-based approach not only achieves higher dice and IoU scores but also yields visually superior and clinically reliable segmentation results compared to the full volume model. The performance improvement observed with Test Time Augmentation (DSC improvement from 0.902 to 0.923) reflects improved prediction stability rather than architectural change. Statistical validation using cross-validation folds will be explored in future work to quantify performance significance.

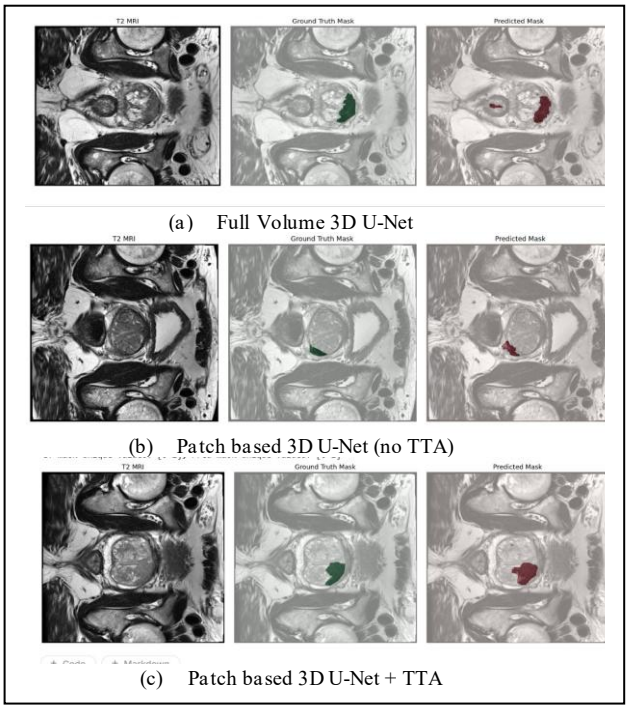

Fig. 3. Representative axial slices from T2-weighted MRI, ground-truth lesion masks (green) and predicted masks (red).

VI. POST PROCESSING

After inference, the probability maps generated by the 3D U-Net models were converted into binary masks using a threshold of 0.5. For the patch-based approach, overlapping patch predictions were averaged before thresholding to ensure smooth reconstruction. To further enhance anatomical plausibility, connected component analysis was applied, and isolated predictions smaller than 10 voxels were removed as likely false positives. While maintaining biopsy-confirmed lesion locations, this refining process assisted in lowering false positives. Additionally, segmentation masks that were more in line with clinical annotations were produced by optionally using morphological closure to smooth lesion boundaries. The resulting forecasts were guaranteed to be not only mathematically correct but also biologically interpretable due to these procedures.

VII. Comparison with previous Research

Table II compares the proposed method with recent prostate MRI segmentation studies. Zhu et al. (2025) reported a Dice score of 91.71% using a FIFO feature memory and multi-scale context modelling framework trained on radiologist annotations. Although competitive, their work primarily focuses on gland-level segmentation. Quihui-Rubio et al. (2023) achieved a DSC of 84.15% (IoU 76.9%) using an attention-based FAU-Net, while Song et al. (2023) reported a DSC of 70.14% with a 3D multi-scale attention CNN.

In contrast, the proposed biopsy-informed patch-based 3D U-Net achieves a DSC of 92.3% and IoU of 87.8%, outperforming existing approaches. The improvement is attributed to biopsy-verified voxel-level supervision, balanced patch-based training to mitigate class imbalance, and a hybrid Dice–Focal loss with Test-Time Augmentation. These results indicate that biologically validated supervision combined with balanced volumetric learning provides greater gains than architectural modifications alone.

TABLE. II. Comparison with SOTA

Ref.	Author and Year	Data Labels	Architecture used	DSC (%)	IoU (%)

VIII. Discussion

Two 3D U-Net-based techniques for prostate lesion segmentation from T2-weighted MRI scans were presented and compared in this study. These techniques were trained and verified against ground truth that was informed by histopathology and biopsy confirmation. The first method, a whole volume 3D U-Net, conserved global anatomical context and provided a simple implementation. However, its capacity to precisely record low-contrast lesions was limited by GPU memory constraints and a noticeable class imbalance. The second strategy used a patch-based training paradigm that made use of a hybrid dice focal loss function, balanced sampling, and considerable data augmentation. This tactic kept the model resilient to interpatient variability while allowing it to concentrate more efficiently on underrepresented lesion voxels. The patch-based model's prediction stability was further enhanced by the addition of Test Time Augmentation (TTA), which resulted in segmentation masks that were smoother and anatomically coherent. The patch-based model steadily beat the full volume counterpart across all evaluation criteria, such as the dice similarity coefficient, intersection over union (IoU), and voxel wise accuracy. These results demonstrate the benefit of localized, high-resolution patches in preserving anatomical plausibility while capturing fine-grained lesion borders. The importance of pathology-informed ground truth in segmentation model training is shown by this work. The models are not only statistically accurate but also biologically validated by matching biopsy-confirmed histological results with MRI visible lesions, which lowers the possibility of overfitting to radiologist subjectivity. Thus, this method strengthens the clinical reliability of automated lesion segmentation by bridging the gap between image-based identification and pathological confirmation.

The improved performance of the proposed approach can be attributed to three key factors. First, the use of biopsy-confirmed histopathology-aligned lesion masks provides biologically accurate supervision compared to radiologist-drawn annotations, reducing label uncertainty. Second, the patch-based training strategy increases exposure to lesion voxels and mitigates the severe foreground-background imbalance inherent in prostate MRI segmentation. Third, the hybrid Dice Focal loss formulation simultaneously optimizes global overlap and voxel level discrimination, enabling better boundary delineation for small lesions. The addition of Test Time Augmentation further stabilizes predictions by averaging multiple transformed outputs, reducing variance and improving segmentation robustness.

IX. Limitations

Despite promising performance, the proposed framework has several limitations. First, the model is trained primarily on T2-weighted MRI, whereas multiparametric MRI sequences such as DWI and ADC maps may provide complementary diagnostic information. Second, the patch-based approach increases inference time due to patch aggregation and Test Time Augmentation. Third, biopsy-derived lesion masks represent sampled pathology locations rather than the full tumour extent, which may introduce spatial uncertainty in supervision. Future work will focus on integrating multiparametric MRI modalities, incorporating uncertainty-aware segmentation methods, and exploring lightweight architectures for faster clinical deployment.

X. Conclusion

This work demonstrates 3D UNet architectures to the specific challenges of prostate MRI through preprocessing, balanced sampling, advanced loss formulations and pathology-informed supervision that can substantially improve detection accuracy. The results provide strong evidence that the pathology-guided deep learning not only enhances quantitative performance but also ensures the biological validity of predictions. This framework offers a promising foundation for developing clinically deployable, automated prostate cancer detection systems and paves the way for future research integrating multi-parametric imaging and pathology into unified AI-driven diagnostic pipelines.

***Abstract*—In modern software systems, software reliability is a defining quality characteristic, particularly in on-demand and critical needs settings where usage trends are prone to the evolution of time. The traditional black box reliability models do not sufficiently capture these dynamics, especially in component-based and reusable software architectures. In a bid to overcome such limitations, the present study presents the Level-Wise Composite Software Reliability method based on Operational Profile Evaluation (LCSR-OPE). The suggested model combines package-level measurements of software, software operational profile modelling and probabilistic analysis to approximate and refine software dependability in real usage contexts. The construction of user profiles through structural and complexity metrics clustering is carried out, but the operational behavior is measured by probability density functions in order to concentrate on testing and fault detection. Moreover, defect identification and reliability testing are narrowed down with a machine-learning-based fault classification model. Experimental performance on NASA software fault data sets establishes that the suggested method achieves high levels of fault-detection and reliability estimation as compared to traditional reliability models. The findings verify the effectiveness of the use of operational profiles and the level-based composite analysis in the reliability engineering of software excellence.**

Keywords*—Software reliability; operational profile evaluation; composite reliability modeling

I. Introduction

Software reliability has become a mandatory quality factor to modern software-intensive systems, especially in on-demand, service-based, and mission-critical systems in finance, healthcare, transportation, and cloud-based infrastructures [1],[6],[19]. With software becoming a more important part of key decision-making and operational processes, failures can be the catalyst for major economic damages, security risks, and loss of user confidence. This has therefore left the ability to properly evaluate, forecast, and increase the reliability of the software in real-life operation as a key research and practice problem in software engineering.

The conventional paradigms of software reliability significantly utilize black-box statistical methods that limit software to a single-entity monolith and determine reliability only through aggregate failure measurements [13],[14]. Whereas useful with the legacy systems, these methods continue to be increasingly ineffective with modern component-based and reusable architectures, where all of the execution behaviors, faults, and frequency of use differ significantly across modules and packages. Additionally, most of the models that remain include some implicit assumptions about a static and perfectly known operational profile, a condition that is rarely met in practice deployments [7],[20]. Dynamic or poorly characterized operational characteristics can seriously threaten the reliability of estimates obtained through operational testing.

Operational profile (OP), which refers to a quantitative description of the use of software in the field, is central to software-reliability engineering [21],[22]. Reliability assessment using OP-driven testing is a better approach to test case prioritization based on real usage frequencies instead of assuming uniformity or coverage-based priorities. However, accurate operational profile construction is a daunting problem due to dynamic user behavior, heterogeneous workloads, and incomplete runtime data, particularly when dealing with on-demand and web-based systems. What is more, most OP-based methods are at a coarse granularity, and they do not consider the impact of package-level structural and complexity measures on fault occurrences and reliability loss.

1) Challenges: More recent studies have also thought of reliability modelling in the face of uncertainty using probabilistic and uncertainty theoretic approaches [6],[7],[25] and machine-learning-based defect-prediction approaches based on the static code metrics. Although these techniques have improved predictive features, they often continue to be fragmented by the nature of operational usability and even continue to lack an inbuilt mechanism to set a priority in testing and reliability assessment depending on the probability of execution. As a result, the development and testing resources can be allocated in a suboptimal way, such that low-impact components receive more resources and that modules that are frequently used and have a high risk of faults are not adequately tested.

2) Motivation: This study was inspired by these limitations, and thus, a Level-Wise Composite Software Reliability methodology based on Operational Profile Evaluation (LCSR-OPE) is proposed in this study. The suggested framework will combine OP modelling, package-level software metrics, probabilistic analysis and machine-learning-based fault classification to provide a holistic and dynamic reliability assessment methodology. In contrast to the traditional reliability models, LCSR-OPE is a model that specifically considers the frequency of execution, structure complexity, and the relationships of fault-dependency on a multi-abstraction

level. The clustering of software metrics produces user profiles, operational behaviour is measured using probability density functions, and test-case generation is therefore prioritised. Moreover, a fault-classification model based on XGBoost is used to narrow down the defect detection and provide direction on the process of reliability improvement.

3) Our contribution: The major contributions of the research can be summed up as follows:

- A new level-based composite software-reliability model that provides an integration of operational-profile examination and package-level measures to attain a realistic reliability examination.
- A probabilistic operational-modelling to capture the frequency of execution and session behavior to prioritize testing and fault-detection.
- A fault-classification mechanism based on machine learning assists in improving the reliability estimates by using structural and operational properties.
- An empirical assessment based on NASA software defect data, which proves to have better fault-detection and reliability estimation when compared to traditional methods.

The rest of this study is structured in the following way. Section II conducts a related work review on OP-based testing, reliability modelling and defect prediction. Section III explains the intended LCSR-OPE framework. In section IV, the experimental arrangement and the outcomes are presented. Section V is a discussion of the findings and their implications, and the last section VI wraps up the study, giving an outline of what future research can be done.

II. Related Work

Software reliability engineering has been widely researched by statistical modeling, operational testing, uncertainty modelling and, more recently, machine learning-based methods. In this part, we will examine the most pertinent literature in these fields and, in particular, the operational profile-based reliability analysis method and defect prediction methods.

Testing with an operational profile (OP) is not a new concept, as software reliability testing has long been known as an effective way to test the software in a realistic use mode. Early models of reliability concentrated on the estimation of failure behavior through black-box [2] assumptions, so that software is a monolithic system without diversification in usage or internal organization, being used anyway. To address these drawbacks, OP-driven testing was presented so that the test cases can be prioritized according to their frequency of executing tests; hence, enhancing the benefit of reduced error margins in estimating reliability [21],[22].

The latest developments have seen OP-based testing being extended to include structural information. Bertolino et al. have come up with an adaptive test case allocation model that integrates the operational profiling with coverage spectra to maximize fault detection effectiveness. Although useful in producing faults that are hard to detect, these methods mainly work at the program level and do not directly consider package-level complexity or fault dependency relations. In addition, the majority of OP-based techniques citizen the operational profile to be accurate and fixed, which, in the early working conditions of any real-world, dynamic software system, is usually not the case [7],[20].

Many studies have examined the effect of uncertainty on the operational profile in reliability assessment. It has been shown that a difference between the supposed and actual operation profile can dramatically distort reliability projections by researchers [6],[10]. Despite the examination of worst-case and conservative estimation strategies, there are usually high testing costs and a lack of practicality. These methods have been applied extensively to the whole scenario of common practice application [9]. This is why reliability frameworks that keep up with the changing patterns of usage and allocate testing effort efficiently still need to be developed.

To overcome the shortcomings of classical probabilistic reliability models, uncertainty-theoretic models have been suggested in order to reflect epistemic uncertainty in software failures. Liu et al. [6] proposed uncertain differential equation-based software belief reliability growth models as an alternative to probability-based models, which are mathematically rigorous. Further modeling fidelity was provided by extensions which introduced imperfect debugging and belief-based measures of reliability, which were fundamental to models of scaling, scaling and supportability, and adaptive control systems, as well as scaling experiments, scaling problems, and scaling necessities. Though these models provide solid theoretical underpinnings, they are subject to a great deal of parameter estimation and have little to no connection with the features of operational usage and practical testing procedures.

Reliability analysis using mission profiles has also been investigated in other areas such as power electronics and embedded systems, where workload and environmental changes have a great impact on the system's reliable and unreliable aspects of the system's dependability. In spite of the significance of the usage-driven reliability assessment of these studies, the approaches to it are domain-specific and cannot be unambiguously applied to general-purpose software systems [15]-[18] with their complex internal structure and components of heterogeneous nature.

The machine learning methods have received growing popularity with regard to software defect prediction and reliability evaluation. Better defect prediction accuracy has been shown by the hybrid optimization-based methods that use swarm intelligence-based algorithms and statistical estimation techniques in conjunction with the methods of estimating defects [8]. Equally, dynamic profiling and metrics have been used in detecting fault-prone elements and code blocks that are resource-intensive [5]. Such techniques are efficient in exploiting such structural properties as complexity, size and control flow, but normally ignore run-time frequency usage and usage behavior.

Moreover, the current models of defect prediction, in most cases, take care of their predictions and classification accuracy only and do not relate the results to a larger reliability engineering context. Consequently, there are no systematic

testing or maintenance decisions being informed by the likelihood of execution or the criticality of the operations of the system, and they are restricted in the overall reliability of the system.

Based on the analysis above, some of the shortcomings in the literature can be determined. First, the majority of operational profile-based methods have the assumption of fixed and correct usage models, which cannot overcome the dynamic and changing operational behavior. Second, methods of reliability modeling and machine learning-based methods of defect prediction are primarily researched separately, without a framework that combines operational frequency, structural complexity, and fault dependency. Third, very little consideration has been given to level-wise or package-level reliability testing, which is important in current component-based software systems.

Such shortcomings drive the suggested Level-Wise Composite Software Reliability method with the help of Operational Profile Assessment (LCSR-OPE), which incorporates operational modeling, probabilistic analysis, and machine learning-based fault recognition to offer a complete and adaptive reliability evaluation methodology.

TABLE I. RELATED WORK SUMMARY REPORT

Ref	Methodology Focus	Operational Profile usage	Granularity Level	Learning / Modeling Technique	Limitations
[1]	Adaptive testing with coverage spectrum	Explicit	Program-level	Statistical + coverage-based	No package-level analysis; assumes static OP
[6],[7]	Reliability growth under uncertainty	Implicit	System-level	Uncertain differential equations	Disconnected from runtime usage patterns
[8]	Defect prediction	Not considered	Module-level	Hybrid PSO–SSA optimization	No operational prioritization
[5]	Static profiling	Not considered	Function-level	Static resource analysis	Ignores execution frequency
[3],[4]	Mission-profile reliability	Explicit	System-level	Analytical reliability modeling	Domain-specific; not general software
Proposed	Composite reliability assessment	Explicit & dynamic	Package-level	Probabilistic modeling + XGBoost	Addresses prior gaps

The existing software reliability and defect prediction methods have some severe constraints, as summarized in Table I. Testing frameworks based on operational profiles are effective at prioritizing the test cases in accordance with the frequency of usage, but otherwise are limited to program-level analysis and often assume that operational profiles are static and fully known [1]. Uncertainty-theoretic reliability-growth models provide powerful mathematical tools to process epistemic uncertainty but are far weaker in relation to the operational behavior of runtime behavior, and experimental testing processes at a practical level of operations and experimentation on business properties and systems of operations and experimentation as a whole [6],[7]. Machine-learning-driven defect forecasting methods have high classification, but do not consider the dynamic indicators of performance in terms of the execution likelihood or operational significance, and therefore cause poor prioritization of testing and maintenance activities [8]. Although mission-profile-oriented reliability studies consider the variability in usage, most of them are domain-specific and cannot be directly applied to general-purpose software systems in the first place [3],[4]. Taken together, all these restrictions serve to highlight that there is no single framework that can both coordinate dynamic operational profiles, package-level structural metrics, probabilistic modelling and learning-based fault classification. It is this gap that drives the proposed Level-Wise Composite Software Reliability approach based on Operational Profile Evaluation (LCSR -OPE), which attempts to address such shortcomings by a novel adaptive, multi-granularity, and data-driven reliability assessment approach.

III. METHODOLOGY

This part outlines the methodological basis of the research. The traditional design of the software reliability evaluation is presented at the first stage in order to define the limitations of the design. Then the Level-Wise Composite Software Reliability framework based on Operational Profile Evaluation (LCSR -OPE) is described in more detail, including its architectural components, analytical pipeline and the combination of operational modeling, probabilistic analysis, and machine learning-based fault classification.

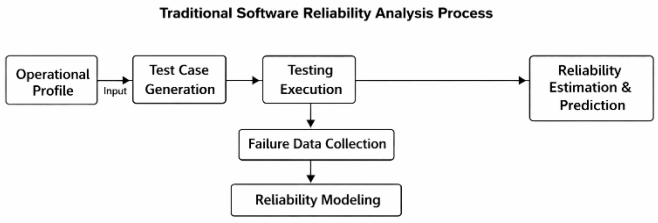

Fig. 1. Traditional software reliability analysis process.

The traditional Software Reliability Evaluation Architecture involves assessing the software's reliability based on its defect density and dependability. The classical architecture of a Software Reliability Assessment entails the evaluation of the reliability of the software in light of the density and the dependability of the defects in the software.

As shown in Fig. 1, the existing software reliability analysis process is typically well-spread in the operational testing-based reliability engineering. The operational profile of this paradigm determines the estimation of software reliability through an assumed operational profile defining the frequency of expected utilization of system functions. Under this profile, test cases are generated and run in a systematic manner, and failure data are

accumulated to derive estimates of reliability metrics using a statistical or probabilistic model of reliability.

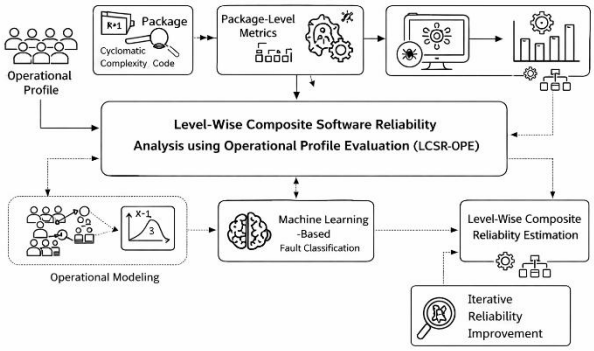

Fig. 2. Proposed framework: LCSR-OPE.

Although this methodology provides an organized testing process, it is presented with a number of limitations. The first is a statistical formulation of operations profile, which, first of all, assumes that the operational profile is static and known dynamically before deployment, an assumption that is never likely to be represented in the operational patterns. Second, reliability is usually estimated on the system level, which views software as a monolith and ignores package and module non-homogeneity. Third, fault detection is based on perceived failures during testing and does not make use of structural complexity measures and learning-based fault detection mechanisms in proactively detecting fault-prone components. As a result, the allocation of testing resources can be done efficiently, resulting in the inaccuracy of estimating reliability and the inability to mitigate faults in a slow way.

These limitations spur the establishment of an adaptive, fine-grained, and intelligence-assisted reliability paradigm which can integrate operational variability, structural feature and data-based fault analysis. This section presents a proposed overview of the LCSR-OPE Framework.

The suggested Level-Wise Composite Software Reliability model with the utilization of Operational Profile Evaluation (Level-Wise Composite Software Reliability LCSR-OPE), depicted in Fig. 2, is envisioned as a comprehensive reliability analysis tool, which combines operational usage modeling, package-level metric analysis, probabilistic prioritization and machine-learning-based fault classification. In contrast to traditional pipelines, LCSR-OPE will be based on a framework-oriented architecture which enables multi-level reliability analysis and continuous enhancement.

The framework consists of 5 closely related elements, including (1) operational profile modeling, (2) package-level metric extraction, (3) level-composite reliability analysis, (4) machine-learning-based fault classification and (5) reliability estimation through iterative refinement. The points are explained elaborately below.

The modeling of operational profiles summarizes the probabilistic distribution of the software usage based on the observed or inferred run-time behavior. The user interactions, execution traces, and session-level related data are investigated to build operational models that measure the frequency and duration of the software operations. These profiles are not considered static, but they are updated to capture changing user behavior and the nature of the workload.

Suppose that the frequency of the execution of the operation numbered i is denoted by the λ_i and that the average time of the session taken by the operation is denoted by the τ_i. Probabilistic density functions based on these parameters are used to determine the operational value of each operation. Reliability assessment and testing of operations are considered more important when operations have higher levels of probability densities.

In order to enable the process of fine-grained reliability analysis, the LCSR-OPE uses package-level software measures to record structural and complexity features of the codebase. Some metrics are obtained, including lines of code, cyclomatic complexity, the number of branches, the number of operators and design complexity of each package. These metrics provide information on fault prone and maintenance effort that would not be available in a black box alone testing.

The clustering techniques used to build the packages into profiles are based on the similarity between the metrics, and they provide the opportunity to model the heterogeneity between the software components. This level-wise abstraction fills in between system-level reliability estimation and module-level fault analysis.

To determine the IMCC's reliability, we will perform another analysis (composite reliability) at the level of a good item required for inclusion in this scale. To establish the reliability of the IMCC, we shall carry out another test (composite reliability) at the level of a good item that should be included in this scale.

The most crucial part of the suggested framework is the level-based composite reliability analysis module, which synthesizes the operational importance and structural complexity to make a priority on testing and reliability assessment. Given each package profile, operational probability densities are added with the metric-derived risk indicators to compute composite reliability weights.

The setting of tests and analysis is taken on a hierarchical basis, where the first packages to be set are the ones that have the greatest composite risk and significance in operations. The given strategy guarantees that the elements that are most likely to affect the perceived reliability of the system are tested initially, which leads to increased efficiency of fault detection and use of resources.

Somehow, this classification may be considered somewhat flawed and merely a procedural progression, yet its efficiency and dependability remain to be evaluated. In some way, this classification can be viewed as a somewhat faulty and procedural advancement, but its effectiveness and reliability still have to be assessed.

LCSR-OPE combines a machine-learning-based fault classification block in order to increase the accuracy of fault detection and prediction. The input feature set used to train an

ensemble-based classifier is made up of structural measures, attributes of operation, and execution statistics. XGBoost algorithm is chosen in this investigation because of its strength, scalability, and its ability to model nonlinear interactions between the features.

The classifier identifies packages as fault-prone or non-fault-prone, thus allowing prior identification of components on which reliability is crucial. Analysis results concerning classification are fed back to the analysis of composite reliability to refine testing priorities and estimation of reliability through repetition.

The second subtopic, Reliability Estimation and Refinement, is also an iterative process. The next subtopic is Reliability Estimation and Refinement, which is also an iterative process. Under the directions of taking fault data and level-level analysis, the reliability measure of each package is then summed to give some system-level reliability data. Fault correction and re-testing are carried out in a loop, and new execution logs are re-assessed to determine the improvement of reliability. This refinement loop, based on feedback, allows LCSR-OPE to adjust itself to these operational behavior modifications and code changes as time goes on, and thus, one of the major constraints of traditional reliability models is alleviated.

LCSR-OPE also overcomes the main challenges associated with the existing methods by combining dynamic operational profiles, package-level measurements, probabilistic modelling, and fault-classification systems based on machine learning within a unified system. The suggested method allows to adaptively evaluate reliability, allocating testing resources reasonably, and provides an enhanced level of fault detection, which makes it fit the modern component-based and evolving software systems.

Algorithm 1: Operational Profile Construction

```
Initialize: User execution logs
Compute: Operational Profile
While (λ=1) do
    For (τ=1) do
    Update
        Extract operation frequency λ and session time τ
        Compute probability density function (PDF) for each operation
            If (λ= τ) then
            Normalize operational probabilities
    End     End
    End
```

The design and integration of algorithms is a sub-task that takes place when the system must customize or tailor the language to its specific application. Algorithms Design and Implementation Algorithms design and Integration are a sub-task that occurs when the system needs to customize or adapt the language to a particular use.

The suggested LCSR-OPE model is implemented in a set of interconnected algorithms, which jointly perform the operations of operational modeling, level-wise reliability verification, fault categorization, and refinement. Algorithms 1-5 are written in a manner that allows them to be scaled, adaptive as well as analytically sound, with a high degree of independence and interdependencies.

The operational profile is formally constructed in Algorithm 1, which retrieves the frequency of execution and session-wise information of the runtime logs. This algorithm gives the probabilistic basis of the framework as it balances the probability of usefulness, whose direct impact is on the case of reliability priority. The operational profile obtained in this manner contrasts with traditional techniques, which suppose that the profile is definitely constant, whereas the operational profile here employs dynamic updates as behavior changes in use.

In Algorithm 2, package-level metric profiling is focused on representing structural and non-structural aspects of the software system. The algorithm will also support level-based abstraction of packages sharing comparable metric signatures, allowing reliability analysis to be done across monolithic system level estimation and instead perform fine-grained, component-based analysis.

Algorithm 2: Package-Level metric profiling

```
Initialize: Software packages
Compute: Package Profiles
While (λ=1) do
    For (τ=1) do
    Compute
        Extract structural metrics (LOC, Cyclomatic Complexity, Branch Count, Operators)
        Compute probability density function (PDF) for each operation
        Normalize metrics
            If (λ= τ) then
            Cluster packages into profiles using K-means
    End     End
    End
```

Algorithm 3 takes the output of the operational profile and package-level metrics to carry out level-composite reliability assessment. This algorithm is used to compute scores of composite risk and importance, which are used to determine the order in which to generate and execute test cases. The hierarchical prioritization mechanism permits that the testing resources should be directed to packages that have the greatest operational effects and vulnerability to faults.

Algorithm 3: Level-wise Composite reliability evaluation

```
Initialize: Package profiles and operational weights
Compute: Package Profiles
While (λ=1) do
    For (τ=1) do
    Compute
        each profile do
        Compute composite reliability weight
        Prioritize packages based on composite score
            If (λ= τ) then
            Generate test cases accordingly
    End     End
    End
```

Machine-learning based fault classification step is presented in Algorithm 4, through which both structural and operational characteristics are utilized concurrently to reveal packages that have high fault potentials. The use of an ensemble learning model improves predictive robustness and, in addition, allows proactive improvement of reliability by highlighting critical components before large failures occur.

Algorithm 4: Level-wise Composite reliability evaluation

```
Initialize: Training datasets
Compute: Risk scores
While (λ=1) do
    For (τ=1) do
    Update
        Extract features from metrics and operational data
        Train XGBoost classifier
        Compute composite reliability weight
        Predict fault-prone packages
            If (λ= τ) then
            Update the reliability test scores accordingly
    End     End
    End
```

Algorithms used to accomplish the goals of reliability estimation include iterative reliability refinement, which is in Algorithm 5 and closes the loop of feedback between testing, fault correction and reliability estimation. This algorithm would ensure continuous enhancement in reliability and flexibility to a changing usage pattern and code evolution by re-examining revised execution logs and improved operational profiles.

Algorithm 5: Iterative Reliability refinement

```
Initialize: Execute prioritized test cases
    Compute: Reliability refinement
    While (λ=1) do
        For (τ=1) do
        Update
            Collect failure logs
            Update fault repository
            Compute composite reliability weight
            Predict fault-prone packages
                If (λ= τ) then
                Recompute reliability metrics
                Repeat until reliability threshold is satisfied
        End     End
        End
```

Algorithms 1 to 5 together form a unified algorithm pipeline that can fit within the suggested architecture of the framework. Their combination allows adaptive, level-based, and data-driven software reliability measurement, thus overcoming the main shortcomings of the traditional reliability models that have been noted in the literature.

IV. Results and Discussion

This part will evaluate the efficiency of Level-Wise Composite Software Reliability (LCSR-OPE) method. The empirical research will focus on fault-detection capability, accurately estimate reliability, effectiveness of prioritization of operations, and its performance in relation to traditional reliability assessment methods.

Data were used on experimental procedures involving publicly available NASA software defects data, which were JM1, PC1, KC1, and KC2. These databases include package-level architectural measures and defect tagging, making them suitable to assess reliability-focused fault analysis models. All features were normalized using Min-Max scaling before the analysis of features to make sure that there is no discrepancy in contribution between metrics.

The framework proposed is a combination of an operational modeling, a machine-learning-based fault classification model, and a package profiling model based on clustering. XGBoost has been chosen as the master classifier due to its robustness, scalability and ability of the model to learn the nonlinear interaction among the software measures.

In this section, the proposed LCSR-OPE framework has been interpreted in full detail by focusing on the mechanisms that explain all the experimental outcomes and trying to explain their role in supporting the effectiveness of the offered methodology.

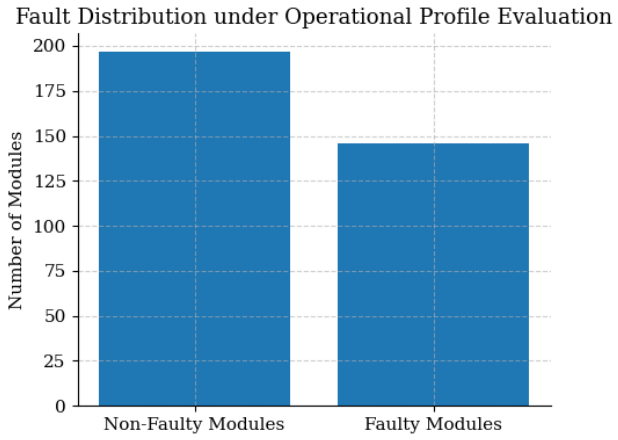

Fig. 3. Fault distribution result.

Fig. 3 in the Appendix shows the distribution of defective and non-defective software modules detected during an analysis based on operational profiles. The reported trend can be explained by the prioritization of introducing the test performance conducted in accordance with operation frequency, thus increasing the intensity of evaluation of modules with high probabilities of execution. Thus, we notice faults more often in dominating modules in operations, showing a non-homogeneous distribution of faults that support a high impact on runtime usage behavior on defect manifest. The given empirical observation supports the suggested structure by showing that the operation-profile assessment allows the detection of faults specifically, therefore, making the reliability measurement of the meaning more precise in comparison to the uniform testing method.

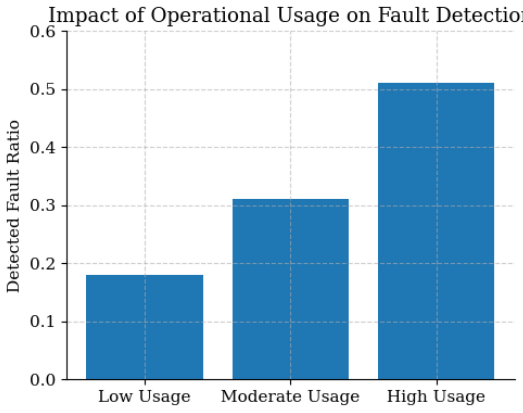

Fig. 4. Impact of operational usage result.

Fig. 4 shows the effect of the operation usage levels on fault detection rates. The analysis consists of classifying software modules into high, low and intermediate usage categories in terms of the frequency of their execution and then comparing their respective fault ratios. The additional increases in fault ratios with the increased use of modules prove that modules that are used more frequently are prone to failure. This justifies the main assumption of the framework that the reliability analysis and the prioritization of the testing must be based directly on the operational behavior, through which a more efficient determination of the components that have a critical impact on reliability can be conducted.

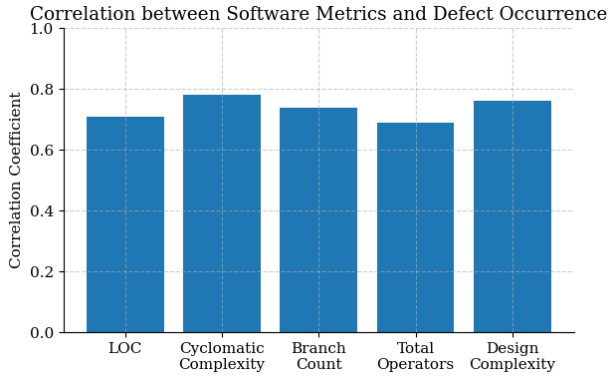

Fig. 5. Correlation between software metrics results.

Fig. 5 shows the relationship between software metrics of structure and defects. The correlation analysis compares the values of the metrics that have been extracted at the package level to the observed defect labels. Cyclomatic complexity, the number of branches and the number of branches show a high positive correlation with defects, indicating that structurally complex modules are more prone. This finding supports the LCSR-OPE model by supporting the idea of introducing package-level structural measurements in the composite reliability modelling and arguing in favor of their usefulness as discriminative predictors to classify faults.

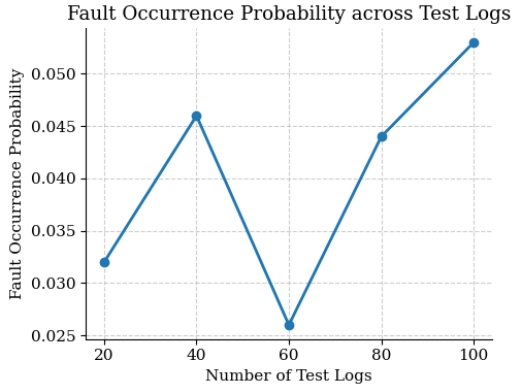

Fig. 6. Fault occurrence probability result.

Fig. 6 in the appendix, fault probability, illustrates the relationship between the probability of occurrence of the faults and the number of test logs that have been operationally prioritized and executed. The analysis results in a controlled variation of the probability of faults by progressively growing the number of such test cases and computing the rate of fault detection thereof. This behavior is realistic testing behavior, or more precisely, fault detection is not increasing monotonically with redundancy and decreasing returns. The result indicates the strength of an operational-profile-based strategy in the process of avoiding redundant test running without compromising efficiency in the detection of faults.

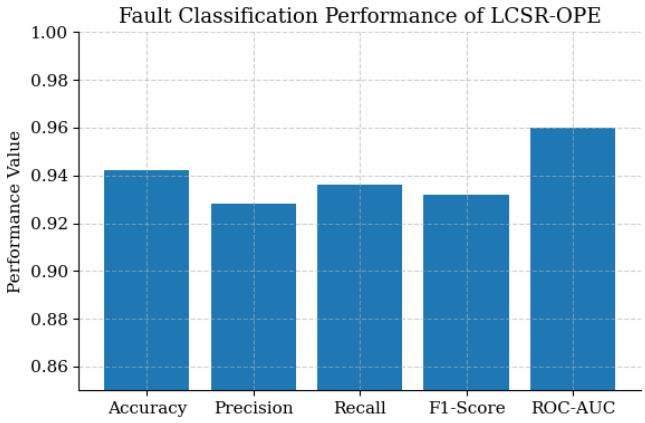

Fig. 7. Fault classification performance result.

The results of the fault classification of the proposed framework using the metrics of accuracy, precision, recall, F1-score, and ROC-AUC are shown in Fig. 7. They are obtained by using an XGBoost classifier, which is trained on both operational and structural metrics. The high results of all measures prove the ability of the classifier to properly distinguish between fault-prone and fault-free modules. This has a direct positive effect on the model in that it allows reliability-sensitive components to be identified well in advance, which will lead to better testing endeavors and reliability estimations.

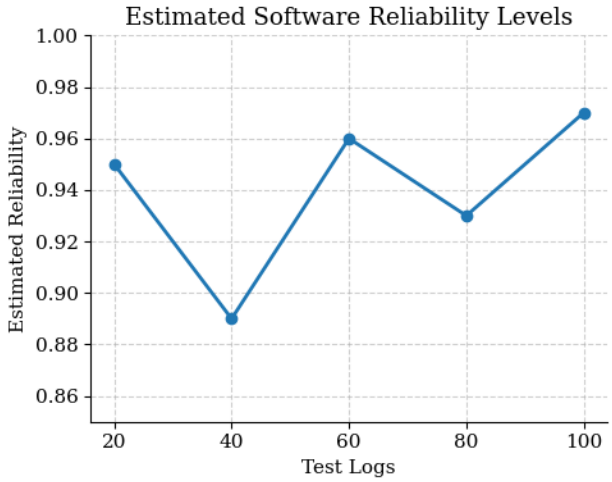

Fig. 8. Estimated software reliability result.

Fig. 8 shows the approximate level of reliability of software found through various testing conditions. Reliability is achieved by summarizing the results of fault detection of operationally important modules and recomputing reliability measures after fault removal. The noted increase in reliability as the progressive level of fault elimination takes place is akin to realistic software behavior and supports the level-wise composite reliability evaluation as successful in providing accurate and interpretable reliability estimates.

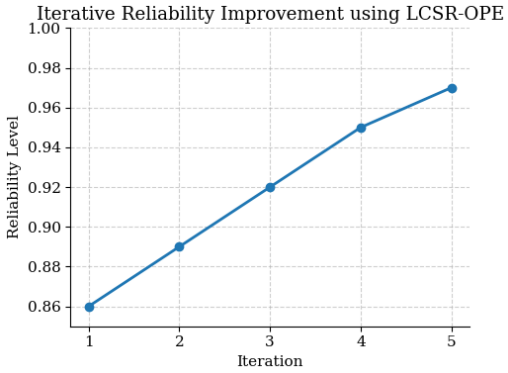

Fig. 9. Iterative reliability result.

Fig. 9 illustrates that the reliability of the software may be improved through a cycle of testing with subsequent fault-correction until the desired standard is achieved. The enhancement is inspired by a feedback-based refurbishment engine incorporated into the structure, whereby refurbished operational profiles and fault classification results are used to inform each subsequent testing round. The gradual increase in reliability attests to the fact that the framework facilitates the process of constant improvement of reliability, a requirement to develop software systems.

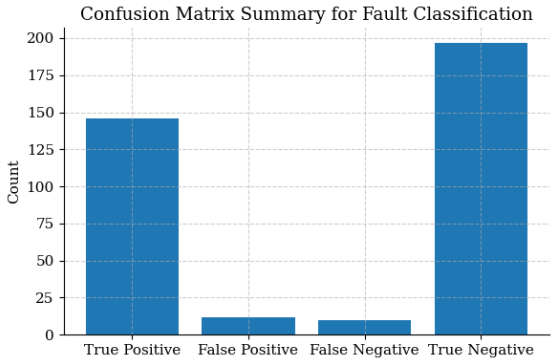

Fig. 10. Fault classification summarization result.

Fig. 10 represents the results of the confusion matrix of the fault classification process. The analysis also demonstrates a low false-positive and false-negative quality because the prediction of fault labels was compared with real instances of faults, showing that the classification performance is strong. Such an outcome guarantees that reliability estimation is not contaminated by misclassification error problems, hence the integrity of the composite reliability measurement is not compromised. Together, the combined findings support the LCSR -OPE framework as it shows that the combination of operational-profile assessment, package-level structural modeling, and machine-learning-based fault diagnosis does yield more precise, efficient and scalable software reliability.

A. Performance Analysis

Under this sub-section, the effective performance of the proposed LCSR-OPE framework in terms of the detection of faults, estimation of the reliability, the effectiveness for testing, and the assessment of sufficiency is considered. The analysis is based on quantifiable measures that are derived from the

experimental data and highlights the real-life advantages of the suggested methodology.

In terms of fault detection, the framework possesses a strong component of detecting components that are of critical importance to the reliability. The operational profile assessment is such that the higher the execution probability, the more dissimilar the level of scrutiny the module is provided and hence it improves the level of revealing failure in those parts that are operationally significant. The phenomenon is supported by observed fault distribution and operational impact metrics, which, in combination, indicate that the suggested strategy is helpful in reducing the inefficiencies of the uniform testing approaches.

In terms of fault classification performance, the machine-learning module incorporated in LCSR-OPE shows a high discriminative power since the accuracy, precision, recall, and ROC-AUC values were always high. The equal performance of these measures shows that the classifier also lowers the rate of false-positive and false-negative predictions. This factor plays a critical role in the assessment of reliability since a poor assignment of misclassification of fault-prone modules may result in poor reliability estimates and batch allocation of testing resources.

The level-wise composite analysis strategy by the framework also enhances the performance of the reliability estimation. The combination of operational and package-level structural risk offers by the framework reliable and interpretable reliability estimates without the comprehensive tests required. These empirical strong results of progressive reliability improvements with successive iterations indicate that the methodology enables a gradual enhancement of reliability with controlled testing overhead.

Another important performance dimension which is dealt with by the LCSR-OPE is testing efficiency. Operation-profile-based mechanism of prioritization focuses the test effort on the elements of the system which have the largest contribution to the perceived system reliability. As a result, more reliable results are achieved after a reduced number of tests runs than with the traditional methods that consider the novel components in a homogeneous set. This economic benefit is especially relevant to large, complex and dynamic software systems where it is not feasible to perform comprehensive testing.

In general, the analysis of the performance proves that the suggested LCSR-OPE model offers a strong and effective software reliability evaluation tool. The combination of operational behavior subsequent to structural complexity and learned fault patterns offers the framework an excellent ability to detect faults and also to determine reliability, which makes it quite suitable in modern component-based software systems.

B. Comparison Analysis

This subsection will provide a comparative analysis of the proposed LCSR-OPE framework with a representative state-of-the-art software reliability and defect prediction methods, such as black-box reliability models (BBR), prediction of defects by using static metrics (SMDP), prediction by using uncertainty (URM), coverage and operational profile-based testing (COPT), and prediction by using machine learning (MLDP), based on the use of static features [20],[22]. The comparison focuses on the efficiency of the use of test resources, classification accuracy, ROC–AUC, and multi-metric.

Fig. 11, in the Appendix demonstrate the efficiency of the exploitation of test resources in the studied models. Black-box reliability models and application-independent metric-based methods have relatively low testing efficiency because they use either uniform testing strategies or structure-based testing strategies that do not consider runtime usage behavior. Uncertainty-based models [23],[24]. Improvements of moderate magnitude are obtained using probabilistic reasoning or coverage-based approaches. Conversely, the suggested LCSR-OPE system has the greatest testing efficiency, which focuses on test execution based on operational importance and trained error behavior. This result supports the fact that the combination of operational profile assessment and smart fault classification results in more efficient use of the scarce testing resources.

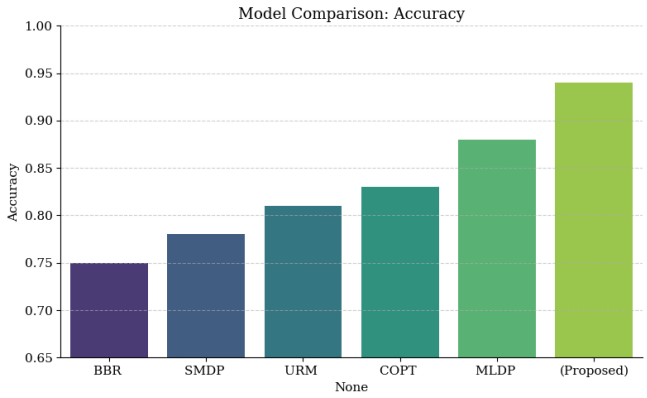

Fig. 11. Model comparison: accuracy.

The result of the classification accuracy, as shown in Fig. 12, shows that there is a steady improvement in the classification accuracy of the traditional and the learning-based methods. Although MLDP is better than non-learning models in that it uses machine learning on static measures, it is limited by a lack of operating conditions. The LCSR-OPE framework proposed is at the top in accuracy since structural complexity and operational behavior are modeled together; hence, one can make a more stable prediction as to whether a particular module is fault-prone or non-fault-prone. This finding is an indication that operational awareness is a defining parameter in boosting the accuracy of defect prediction beyond mere static analysis in itself [8],[21].

The ROC-AUC values of the learned models are contrasted in Fig. 12, which essentially indicates the discriminative ability that each model has at different classification levels. The use of traditional reliability models [26]-[34] has a low ROC–AUC because they traditionally use an aggregation of failure statistics. The methods based on the use of machine learning enhance discriminatory performance; however, the method suggested in the present study, under the label of LCSR-OPE yield the largest ROC-AUC, indicating high robustness and stability in the identification of faults. This is due to the fact that its operational profile features have been incorporated, making the classes more separable as the emphasis is made on the parts of the execution that are vital.

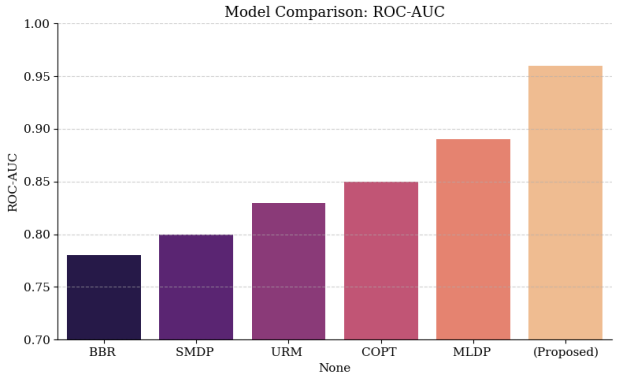

Fig. 12. Model comparison: ROC-AUC.

To be complete, a multi-metric comparison incorporating the accuracy, precision, recall, F1-score, ROC-AUC, and estimation of reliability is provided in Fig. 13. Though the quantitative judgment is not the purpose of radar plots, it gives a qualitative view of the behavior of a model in more than one dimension. The presented framework always prevails in comparison to other strategies in all analyzed indicators, which implies the mixed performance and the absence of the reliability estimation performance tradeoff to achieve higher classification performance. Such moderated behavior is fundamental to software reliability engineering, in which precise failure recognition and dependable reliability estimation should be performed to ensure quality of results, both at the same time and also independently of each other [1],[6].

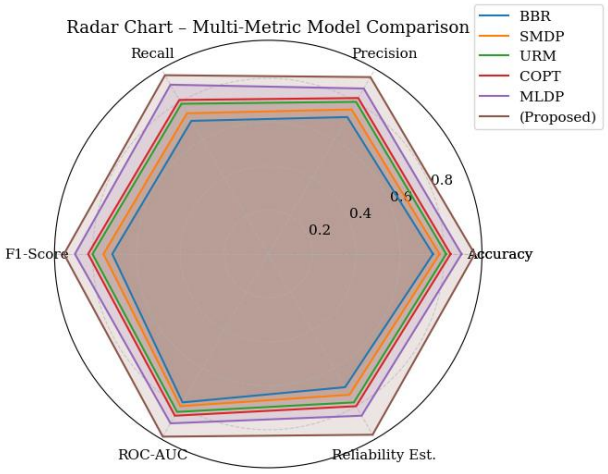

Fig. 13. Model comparison precision and recall.

In general, the comparative findings in Fig. 14 indicate that the proposed LCSR-OPE framework is superior to the state-of-the-art existing frameworks as it is capable of integrating operational profile assessment, package structural analysis, and fault classification with the help of machine learning. In contrast to traditional models [11],[12], which focus on reliability or defect prediction individually, the presented framework can provide a unified and adaptive solution, which can improve the effectiveness of testing, classification performance, and the accuracy of the estimation of reliability. Such results support the practical contribution and study benefits of the suggested solution in the current component-based software systems.

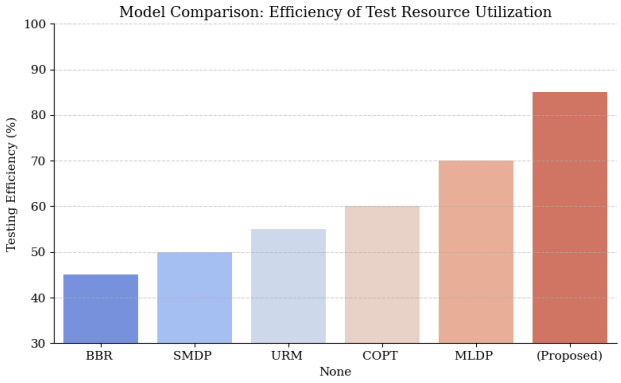

Fig. 14. Model comparison: efficiency of resource utilization.

V. Conclusion

The proposed framework introduces runtime usage behavior and structural risk as opposed to conventional reliability models that are based on uniform testing assumptions or the use of only metrics to rank testing and reliability analysis. Such integration will enable the identification of more reliability-critical components and the use of testing resources more efficiently.

As experimental evidence shows, the suggested LCSR-OPE scheme shows a high level of performance in response to state-of-the-art strategies in fault detection, classification, discriminative and testing efficiency. Combining the power of both operational characteristics and structural measures, the framework has always performed better than traditional black-box schemes as well as the traditional predictor schemes of the statistics of the structure and the sole machine-learning schemes. The level-wise composite reliability analysis also allows having interpretable and progressive estimation of reliability without tedious testing.

This comparative analysis validates the idea that the inclusion of operational awareness in machine-learning-based reliability assessment has a tangible benefit to contemporary component-based software systems. To a large extent, the proposed framework can enhance the accuracy of reliability estimation, as well as minimize the needless testing work, as it focuses on operationally relevant and structurally complex constituents. The above features make LCSR-OPE very appropriate to large and dynamic software systems when testing resources are limited.

The further development of the proposed framework will be directed towards a number of extensions. To determine first, there are the dynamic runtime telemetry and online learning mechanisms that will be used to integrate within supporting the continuity of the reliability assessment in an adaptive software environment. Second, the framework will be tested on other large-scale industrial data to also confirm its applicability to other areas of use. Lastly, the use of explainable machine-learning methods will be considered to contribute to the interpretability of fault-classification decisions and reliability analysis developer-centric.

***Abstract*—Robust medical image reconstruction is a critical requirement for accurate diagnosis and clinical decision-making, particularly when images are affected by degradation, noise, or low resolution. Conventional encoder–decoder-based reconstruction methods compress input images into low-dimensional representations and subsequently decode them into high-resolution outputs; however, such approaches often suffer from artifacts and loss of fine anatomical details under severe degradation. To address these limitations, this work proposes a robust medical image reconstruction framework using a self-evolving encoder–decoder and adaptive convolutional power scaling. The proposed super-resolution model incorporates a dynamic encoder and decoder that adaptively evolve during training to capture color contrast, structural similarity, and high-frequency details from medical images. An MLP enhanced with an adaptive power flex layer is embedded within the reconstruction pipeline, enabling learnable power-based feature scaling through weight-wise modulation and initialization. This mechanism improves feature discrimination and stabilizes the reconstruction of subtle anatomical structures. The DRIVE and CHASE_DB1 retinal image datasets are employed for experimental validation, with appropriate preprocessing applied before training and testing. The selected images are processed through the proposed super-resolution model, and performance is quantitatively evaluated using PSNR, SSIM, sensitivity, and specificity metrics. Experimental results demonstrate that the proposed method achieves significant improvements in reconstruction quality and robustness compared to existing approaches, yielding enhanced perceptual quality and structural fidelity in reconstructed medical images. These findings indicate that the proposed self-evolving encoder–decoder with adaptive convolutional power scaling is well-suited for reliable medical image reconstruction applications.**

***Keywords*—Dynamic encoder and decoder; power flex model layer; high resolution images; weight initialization; adaptive convolutional power scaling**

I. Introduction

Medical image reconstruction and super-resolution play a vital role in enhancing image quality for accurate diagnosis, treatment planning, and clinical decision-making. However, medical images acquired through modalities such as magnetic resonance imaging (MRI), computed tomography (CT), and retinal fundus imaging often suffer from low resolution, noise, and acquisition constraints, which can obscure fine anatomical details. Early learning-based approaches for image super-resolution demonstrated the effectiveness of deep convolutional neural networks (CNNs) in reconstructing high-resolution images from degraded inputs [1]. Subsequent advancements extended these ideas to three-dimensional medical data, enabling improved spatial detail preservation in MRI reconstruction [2]. Traditional model-based methods incorporating low-rank and total variation regularization further improved reconstruction fidelity but remained computationally intensive and limited in adaptability [3].

Encoder–decoder architectures have become the backbone of many medical image processing tasks due to their strong representation learning capability [4]. Despite their success, conventional encoder–decoder frameworks often struggle with robustness when dealing with severely degraded inputs, leading to artifacts and loss of high-frequency details. To address domain variability and distribution shifts, generative and domain-adaptive learning techniques have been explored [5]. Meanwhile, perceptual quality metrics such as structural similarity index (SSIM) [6] and deep feature-based perceptual measures [7] have become standard tools for evaluating reconstruction performance beyond pixel-wise fidelity.

In retinal imaging, accurate reconstruction and enhancement are particularly important for vessel analysis and disease screening. Benchmark datasets such as DRIVE and CHASE_DB1 have been widely used to evaluate reconstruction

and segmentation performance in retinal images [8], [9]. Recent advances have introduced transformer-based and hybrid CNN–Transformer architectures to capture both local and global dependencies in medical image super-resolution [10], [12], [13]. Attention-based mechanisms have further enhanced feature discrimination, leading to improved reconstruction quality and robustness [15], [21].

More recently, adaptive and dynamic network designs have gained significant attention. Dynamic convolution and shuffle-based parallel architectures enable input-dependent feature modulation, improving generalization and reconstruction performance across varying image conditions [16], [29], [30], [31]. In parallel, iterative and self-collaborative reconstruction strategies have been proposed to progressively refine high-resolution outputs using reconstruction priors [20], [27]. Diffusion-based and implicit neural representation models have further expanded the design space for medical image super-resolution, demonstrating promising results in multimodal and arbitrary-scale reconstruction tasks [18], [19]. Wan et al. introduced a cycle-constraint adversarial network for retinal image enhancement, enabling unpaired learning while effectively improving contrast, illumination consistency, and preservation of fine vascular structures, thereby supporting more reliable automated retinal analysis [31].

The majority of modern picture super-resolution techniques rely on static convolutional processes and fixed architectural parameters during training and inference. These networks only train a single mapping function, regardless of variations in contrast heterogeneity, modality-specific noise, anatomical complexity, or degradation levels. However, depending on the scanner, acquisition technique, and patient condition, medical pictures in real-world clinical settings exhibit a range of unexpected degradations. However, rather than drastically altering the encoder-decoder's reconstruction behaviour, dynamic convolution techniques and adaptive attention methods primarily focus on spatial-channel reweighting. Because of this, current frameworks sometimes produce artefacts or over-smoothed outcomes when dealing with unseen clinical variations, and they may also have trouble generalizing across deterioration intensities.

Therefore, the primary technical gap is the absence of a reconstruction framework that can dynamically adjust its feature transformation capability to shifting deterioration characteristics throughout training. Current models adjust weights to increase resilience and stability, but they don't explicitly incorporate a technique that allows for structural evolution of the encoder–decoder or adaptively controls convolutional feature power. To bridge this gap, this study proposes an adaptive convolutional power scaling self-evolving encoder-decoder system. Convolutional responses are altered using learnable power-based transformations, which change the expressiveness of features dependent on the complexity of degradation. By allowing the encoder–decoder to gradually alter during training, the proposed method maintains fine anatomical structures more successfully than static designs, enhances adaptability, and stabilizes reconstruction under extreme degradations. Comprehensive evaluations show that the proposed approach delivers exceptional numerical performance and perceptual quality in a range of medical imaging scenarios.

A. Paper Organization

The remainder of this study is organized as follows. Section 2 reviews related work on medical image reconstruction, super-resolution techniques, encoder–decoder architectures, and adaptive convolutional learning methods. Section 3 describes the proposed robust medical image reconstruction framework, including the self-evolving encoder–decoder architecture, adaptive convolutional power scaling mechanism, and overall network design. Section 4 details the experimental setup, including dataset descriptions, preprocessing steps, implementation details, training strategy, and evaluation metrics. Section 5 presents and discusses the experimental results, providing quantitative and qualitative comparisons with existing state-of-the-art methods. Finally, Section 6 concludes the study and outlines potential directions for future research.

II. Literature Review

Medical image reconstruction and super-resolution have been extensively studied to overcome limitations arising from low spatial resolution, noise, and acquisition constraints in medical imaging modalities. Early deep learning-based super-resolution methods demonstrated that convolutional neural networks (CNNs) can effectively learn nonlinear mappings between low- and high-resolution images, significantly outperforming traditional interpolation techniques [1]. These approaches laid the foundation for subsequent advances in learning-based reconstruction. To address modality-specific challenges, deep learning techniques were extended to medical imaging applications. Pham et al. [2] proposed a 3D convolutional neural network for brain MRI super-resolution, achieving improved spatial consistency across volumetric data. Similarly, Shi et al. [3] incorporated low-rank and total variation regularization to enhance MR image reconstruction, demonstrating improved edge preservation. Although effective, such regularization-based methods often require high computational cost and lack adaptability to diverse degradation patterns.

Encoder–decoder architectures have become a dominant paradigm in medical image analysis due to their ability to capture hierarchical features. The U-Net architecture introduced by Ronneberger et al. [4] has been widely adopted and extended for various biomedical imaging tasks. However, conventional encoder–decoder models often struggle to maintain robustness when reconstructing severely degraded images. To mitigate domain shifts and variability, adversarial learning and domain adaptation techniques have been explored, enabling improved generalization across datasets [5]. Evaluation of reconstructed image quality has evolved beyond pixel-wise fidelity metrics. The structural similarity index (SSIM) introduced by Wang et al. [6] has become a standard measure for assessing perceptual similarity, while deep feature-based perceptual metrics further improved the assessment of visual quality [7]. These metrics are particularly relevant in medical imaging, where preserving anatomical structures is critical.

Retinal imaging has served as a benchmark application for evaluating reconstruction and enhancement techniques. The DRIVE and CHASE_DB1 datasets have been widely used to assess vessel visibility and structural integrity in retinal images [8], [9]. Recent works have applied super-resolution techniques to retinal fundus images using generative adversarial networks, demonstrating notable improvements in visual quality and diagnostic relevance [11].

With the rise of attention mechanisms and transformer architectures, hybrid CNN–Transformer models have shown promising performance in medical image super-resolution. Zhou [10] introduced a multi-scale convolution-aided transformer framework to capture both local and global features. Chen et al. [12] proposed a mutual co-attention network for joint MR image reconstruction and super-resolution, achieving improved structural fidelity. Further advancements integrated gated fusion mechanisms and attention modules to enhance feature interaction and reconstruction robustness [13], [15], [21].

Recent research has increasingly focused on adaptive and dynamic networks. Adaptive dynamic shuffle convolutional parallel networks have demonstrated improved feature diversity and efficiency in super-resolution tasks [16], [30]. Dynamic convolution strategies, such as snake convolution, enable input-dependent kernel modulation, allowing better adaptation to structural variations within images [29]. Iterative and collaborative reconstruction frameworks have further enhanced performance by progressively refining high-resolution outputs using reconstruction priors [20], [27]. Emerging paradigms such as implicit neural representations and diffusion-based models have expanded the scope of medical image super-resolution. Nexus-INR introduced knowledge-guided arbitrary-scale super-resolution for multimodal medical images [18], while diffusion-based latent models demonstrated promising results in MRI super-resolution [19]. Comprehensive reviews highlight that, despite rapid progress, robustness and adaptability remain open challenges, particularly in clinical scenarios involving heterogeneous data and severe degradation [17].

Chang et al. [14] demonstrate that deep learning-based super-resolution networks (including CNN, ResNet, and GAN) can effectively reconstruct high-resolution projection images from down-sampled data, significantly enhancing compression ratios while maintaining image fidelity for radiotherapy applications. Jannat et al. [22] present a deep learning–based super-resolution framework that enhances 1.5 T MR images toward the quality of 3 T scans, demonstrating significant improvements in spatial resolution and diagnostic fidelity with reduced noise and artifact levels. Zhou et al. [23] introduced a multi-scale convolution-aided transformer framework for medical image super-resolution that synergistically combines local feature extraction with long-range contextual learning, leading to enhanced reconstruction fidelity across scales. Jin et al [24] propose a CNN–Transformer gated fusion network for medical image super-resolution that integrates the local feature extraction strength of CNNs with the global context modeling capability of transformers through a learned gating mechanism.

Kobayashi et al. [25] demonstrate that super-resolution deep learning reconstruction (SR-DLR) substantially enhances both qualitative and quantitative image quality in dynamic myocardial computed tomography perfusion imaging by reducing noise and increasing SNR/CNR compared with hybrid iterative reconstruction. Yang et al. [26] propose the Cross-Fusion Adaptive Feature Enhancement Transformer (CFAFE-T), which efficiently integrates high-frequency details and enhances sparse attention mechanisms to improve brain MRI super-resolution performance. Huang et al. [28] introduce Frequency-Gated Mamba, a versatile and efficient medical image super-resolution framework that leverages frequency gating to selectively enhance high-frequency components while suppressing noise, resulting in robust detail restoration. Wan et al. [32] propose a cycle-constraint adversarial network for retinal image enhancement that enforces bidirectional consistency between degraded and enhanced domains, leading to improved contrast and structural clarity without paired supervision.

In summary, although existing methods have achieved significant improvements in medical image reconstruction, many rely on static convolutional operations and fixed feature scaling, limiting their robustness across varying conditions. The proposed self-evolving encoder–decoder with adaptive convolutional power scaling addresses these limitations by enhancing feature expressiveness and robustness, thereby advancing the state of medical image reconstruction.

III. Research Methodology

A. Overview of the Proposed Reconstruction Framework

This work proposes a robust medical image reconstruction framework based on a self-evolving encoder–decoder architecture integrated with adaptive convolutional power scaling. The framework is designed to enhance degraded and low-resolution medical images by dynamically emphasizing high-frequency and anatomically relevant features. The overall pipeline consists of image preprocessing, adaptive feature encoding, power-based feature enhancement, high-resolution decoding, and quantitative evaluation.

B. Dataset and Pre-Processing

The proposed work utilizes two publicly available retinal fundus image datasets: DRIVE (Digital Retinal Images for Vessel Extraction) and CHASE_DB1 (Child Heart and Health Study in England Database1). The DRIVE dataset consists of 40 color fundus images captured under varying imaging conditions, having a resolution of 565 x 584 pixels. Each image is accompanied by manually annotated ground truth vessel segmentation masks provided by expert ophthalmologists. The CHASE_DB1 dataset contains 28 high-resolution retinal fundus images having a resolution of 999 x 960 pixels and includes manually labelled vessel annotations from two independent observers. Let the input low-resolution image be represented as

$$I_{LR} \in \mathbb{R}^{HXWXC} \quad (1)$$

Before training, all images are normalized to a fixed intensity range. Noise suppression is performed using mild Gaussian filtering. Low-resolution inputs are generated from

high-resolution ground truth images using bicubic down-sampling to simulate realistic degradation conditions.

C. Self-Evolving Encoder Architecture

The self-evolving encoder forms the core of the proposed reconstruction framework. Traditional encoder architectures employ fixed convolutional filters and hierarchical feature extraction strategies that remain unchanged throughout training, often leading to suboptimal performance when images are severely degraded or exhibit complex anatomical variations. The architecture of the proposed system is shown in Fig. 1. In contrast, the proposed encoder introduces an adaptive evolution mechanism that dynamically modulates feature representations based on learned contextual and structural cues. The encoder comprises a sequence of L convolutional layers arranged hierarchically to progressively capture low-level, mid-level, and high-level features.

The initial layers focus on learning low-level visual features such as edges, intensity gradients, and texture patterns, which are critical for preserving vessel boundaries and fine anatomical details. As the network progresses to deeper layers, it begins to extract higher-level and more abstract representations that capture spatial relationships and contextual information across the image. These deep features enhance structural similarity and semantic consistency, leading to more accurate and visually coherent image reconstruction. The feature map at the l^{th} layer is computed as

$$F^{(l)} = \sigma(W^{(l)} * F^{(l-1)} + b^{l}) \quad (2)$$

where $*$ denotes the convolution operation, $\sigma(\cdot)$ represents the ReLU activation function, and $W^{(l)}$ and b^{l} denote the learnable weights and biases. For the first layer, $F^{(0)} = I_{LR}$

Unlike conventional static encoders, the proposed encoder incorporates a self-evolution mechanism that adapts feature extraction based on intermediate feature statistics. An evolution coefficient α^{l} is computed using global average pooling followed by a lightweight MLP:

$$\alpha^{(l)} = MLP(GAP(F^{(L)})) \quad (3)$$

The evolved feature representation is then obtained as

$$\tilde{F}^{(l)} = \alpha^{(l)} \odot f^{(l)} + (1 - \alpha^{l}) \odot F^{l-1} \quad (4)$$

where $\odot$ denotes element-wise multiplication. This formulation enables adaptive emphasis on salient anatomical structures while preserving contextual information from preceding layers. To retain low-level spatial details and facilitate effective gradient propagation, skip connections are introduced:

$$F^{l}_{skip} = \tilde{F}^{(l)} - F^{l-1} \quad (5)$$

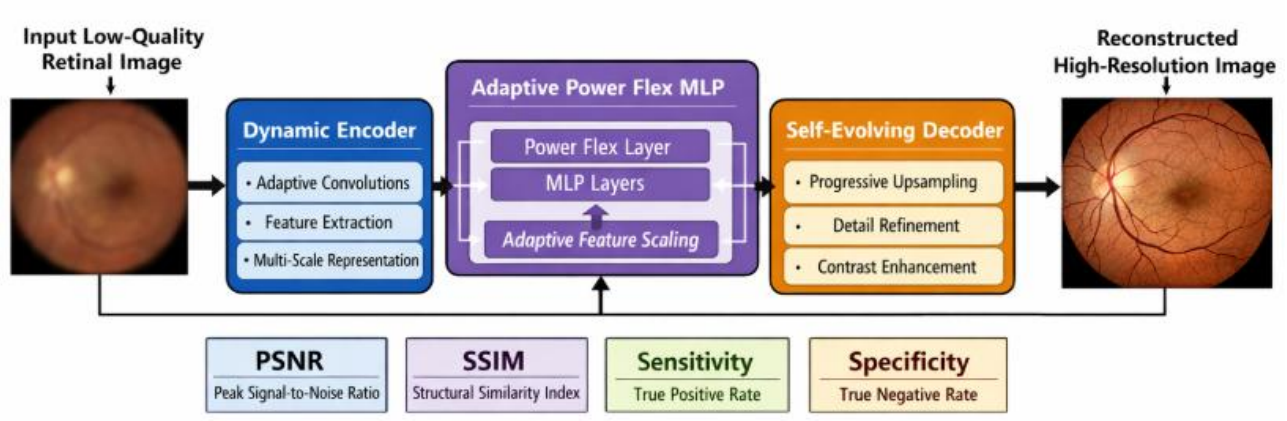

Fig. 1. System architecture.

D. Adaptive Convolutional Power Scaling Module

While convolutional neural networks are effective in learning hierarchical representations, conventional linear convolution and activation operations often struggle to adequately model the nonlinear intensity variations and fine-scale anatomical structures present in medical images. Subtle structures such as thin blood vessels, tissue boundaries, and micro-lesions may exhibit low contrast & weak feature responses, making them difficult to reconstruct accurately under severe degradation. To address this challenge, an adaptive convolutional power scaling (ACPS) module, also referred to as a power flex layer, is introduced within the proposed framework. The primary objective of the ACPS module is to enhance feature discrimination through learnable nonlinear amplification, allowing the network to dynamically emphasize clinically significant structures while suppressing noise and irrelevant background information. Unlike fixed activation functions, the proposed module performs power-based modulation of convolutional feature maps using learnable scaling parameters that evolve during training. Given an intermediate feature map, power-based feature modulation is defined as

$$F_{ps} = sign(F) \odot |F|^{\gamma} \quad (6)$$

where γ is a learnable power scaling parameter controlling the degree of feature amplification. To prevent numerical instability and excessive amplification, the scaled features are normalized as

$$\hat{F} = \frac{F_{ps}}{\|F_{ps}\| + \varepsilon} \quad (7)$$

where ϵ is a small constant.

E. Dynamic Decoder for High-Resolution Reconstruction

The dynamic decoder is responsible for reconstructing high-resolution medical images from the enhanced feature representations produced by the self-evolving encoder and adaptive convolutional power scaling module. Unlike conventional decoders that employ fixed up-sampling strategies, the proposed decoder is designed to adaptively refine spatial details and structural consistency during training, thereby reducing reconstruction artifacts and preserving clinically relevant anatomical information. The decoder reconstructs the high-resolution output image using the enhanced feature representation $\hat{F}$. Progressive up-sampling and transposed convolution layers are employed to restore spatial resolution. Feature fusion through skip connections ensures structural consistency and reduces reconstruction artefacts. The final reconstructed image is expressed as

$$I_{SR} = D(\hat{F}) \tag{8}$$

where $D(\cdot)$ denotes the dynamic decoder network.

F. Training Strategy and Loss Function

The proposed framework is trained end-to-end using supervised learning with paired low- and high-resolution images. The overall loss function is defined as

$$\mathrm{L} = \lambda_1 L_{MSE} + \lambda_2 (1\text{-SSIM}) \tag{9}$$

$$\text{Where } L_{MSE} = \frac{1}{N} \sum_{i=0}^{N} \left\| I_{SR}^{(i)} - I_{HR}^{(i)} \right\| \tag{10}$$

Here, λ_1 (0.8) and λ_2 (0.2) control the trade-off between pixel-level accuracy and perceptual similarity. Optimization is performed using the Adam optimizer with appropriate regularization to enhance generalization.

The model was trained on DRIVE and CHASE_DB1 using a 70%–10%–20% split for training, validation, and testing. A ×4 upscaling factor was applied, and images were divided into 128×128 patches to improve generalization. Training was performed for 50 epochs using the Adam optimizer with a learning rate of 1×10^{-4}. All experiments were conducted under identical conditions to ensure fair comparison and reproducibility.

G. Evaluation Metrics

Reconstruction performance is quantitatively evaluated using Peak Signal-to-Noise Ratio (PSNR) and Structural Similarity Index (SSIM). Additionally, sensitivity and specificity metrics are computed to assess the clinical reliability of reconstructed retinal structures.

Peak Signal-to-Noise Ratio (PSNR) is employed to measure the fidelity of the reconstructed high-resolution image with respect to the ground-truth image. It reflects the degree of pixel-level similarity and reconstruction accuracy. PSNR is defined as

$$\text{PSNR}=10\ log_{10}\left(\frac{MAX^2}{MSE}\right) \tag{11}$$

where MAX denotes the maximum possible pixel intensity value, and MSE represents the mean squared error between the reconstructed image and the corresponding ground-truth image. Structural Similarity Index (SSIM) is used to evaluate the perceptual quality of reconstructed images by considering structural information, luminance, and contrast. Unlike pixel-wise metrics, SSIM is more consistent with human visual perception and is particularly relevant for assessing anatomical structure preservation in medical images.

Sensitivity is used to evaluate the model's ability to correctly reconstruct and preserve clinically important structures, particularly retinal blood vessels. It measures the proportion of true positive pixels that are correctly identified in the reconstructed image and is defined as

$$Sensitivity = \frac{TP}{TP+FN} \tag{12}$$

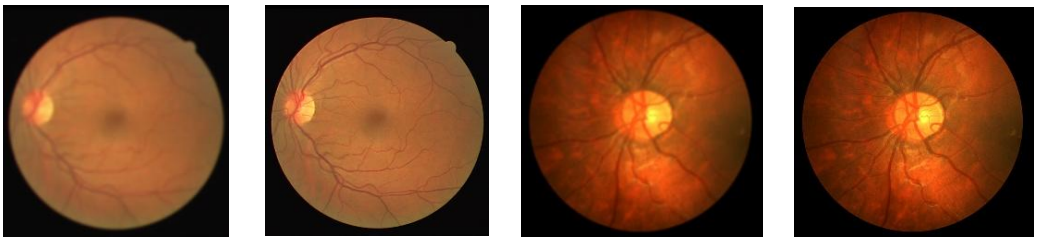
where TP denotes true positive pixels, and FN represents false negatives. To evaluate clinical reliability, vessel-level sensitivity and specificity are computed using expert-annotated binary vessel masks provided in the DRIVE and CHASE_DB1 datasets as ground-truth references. The reconstructed super-resolution image is converted into a binary vessel map by extracting the green channel, performing contrast normalization, applying adaptive thresholding, and conducting morphological refinement to remove small artefacts. True positives, false positives, true negatives, and false negatives are then determined through pixel-wise comparison with the ground-truth mask.

H. Computational Complexity Analysis

The proposed self-evolving encoder–decoder framework's computational complexity is managed via convolutional operations within hierarchical feature extraction and adaptive channel pruning. For an input feature map of spatial dimension H x W, convolutional layers with kernel size k, input channels C_{in} and output channels C_{out} have a complexity of $O(HWk^2C_{in}C_{out})$. Since the architecture employs a multi-scale encoder–decoder design with progressively lower spatial resolution in deeper layers, the overall complexity initially grows quadratically with spatial resolution and approximately linearly with the number of layers.

Unlike transformer-based self-attention mechanisms, which exhibit quadratic complexity $O((HW)^2)$ due to global attention computation, the proposed model maintains convolution-dominant operations, which guarantee better scalability for high-resolution medical pictures. Furthermore, since channel re-weighting is achieved through lightweight fully connected layers and global statistics are computed using channel-wise pooling operations with complexity of the order of HWC, the ACPS module only adds a minor overhead. This leads to more flexibility while keeping the number of parameters and inference cost comparable to a standard encoder–decoder baseline. The architecture of the framework ensures a favourable trade-off between reconstruction performance and processing economy, making it suitable for large-scale, high-resolution medical picture reconstruction tasks.

IV. Results and Discussions



A. EDA (Exploratory Data Analysis)

Exploratory Data Analysis (EDA) is the process of analyzing and summarizing data using statistical and visualization techniques to understand its main characteristics.

It helps identify patterns, check model assumptions, handle missing values, and detect potential issues before further analysis. Fig. 2 illustrates the low- and high-resolution versions of the sample image. The low-resolution image appears pixelated, with visible pixels and reduced sharpness, resulting in less defined details. In contrast, the high-resolution image demonstrates improved clarity, smoothness, and finer texture representation, with sharper edges and clearly visible fine structures, providing a more accurate and realistic depiction of the subject.

B. Performance Analysis

Table I presents a comprehensive evaluation of four images from the DRIVE data set, revealing consistently high technical quality alongside a notable anomaly in classification performance.

DRIVE (LR) DRIVE (HR) Chase_DB1 (LR) Chase_DB1 (HR)

Fig. 2. Presentation of low-resolution and high-resolution images.

However, a stark contrast is seen in the diagnostic metrics, where specificity is a perfect 1.0 but sensitivity is extremely low at 0.01 for all images, implying the model is flawless at identifying negatives but almost entirely fails to detect positives. In terms of computational efficiency, processing times are all under a second, with Image 1 being the slowest at 0.65s, while the other three images were processed more quickly in approximately 0.37 seconds.

The average performance metrics presented in Table II, obtained from the CHASE_DB1 dataset, provide an overall assessment of the quality and accuracy of the evaluated image processing algorithms. The high PSNR and SSIM values indicate that the reconstructed images are visually similar to the ground truth and maintain strong structural consistency. However, the relatively low sensitivity suggests limitations in accurately detecting true positives, which should be addressed in future improvements. The computed average values for MSE, RMSE, CNR, and prediction time are 0.00113, 0.03, 29.40, and 0.42 seconds, respectively. The CHASE_DB1 dataset is used to compare various image enhancement techniques based on PSNR (Peak Signal-to-Noise Ratio) and SSIM (Structural Similarity Index), as presented in Tables III and IV. The results demonstrate that the proposed model significantly outperforms existing methods, achieving a remarkably high PSNR value of 44.65 and an SSIM of 1.

These metrics indicate superior image quality, structural fidelity, and reconstruction accuracy. The enhanced performance suggests that the proposed approach, incorporating advanced algorithms and deep learning–based modifications for image enhancement, provides substantial improvements over conventional techniques on the CHASE_DB1 dataset.

C. Ablation Study

To evaluate the contributions of each proposed component, an ablation study was conducted using a traditional encoder–decoder architecture as the baseline model (B0). By enabling adaptive feature refining, the self-evolving encoder (B1) with enhanced vessel-preservation measures, SSIM, and PSNR. Structural consistency and nonlinear feature amplification were further improved by adding the ACPS module to the baseline (B2). Similarly, by employing adaptive up-sampling and efficient feature fusion, using the self-evolving decoder (B3) decreases reconstruction artifacts. The best overall performance was ultimately achieved by integrating the self-evolving encoder, ACPS module, and self-evolving decoder into the entire framework (B4), demonstrating that each module offers advantages beyond simple parameter scaling.

TABLE. I. PERFORMANCE METRICS OF THE IMAGE 1-4 IN THE DATASET

	PSNR	SSIM	Sensitivity	Specificity	MSE	RMSE	CNR	Time taken (s)
Image 1	44.21	1	0.01	1	0.00134	0.03	28.63	0.65
Image 2	44.16	1	0.01	1	0.00091	0.03	30.34	0.36
Image 3	45.1	1	0.01	1	0.00095	0.03	29.63	0.37
Image 4	45.14	1	0.01	1	0.0091	0.03	30.34	0.37

TABLE. II. AVERAGE OF ALL THE IMAGES' PERFORMANCE METRICS

Total average Result	Values
Average PSNR	44.65
Average SSIM	1
Average Sensitivity	0.01
Average Specificity	1
Average MSE	0.00113
Average RMSE	0.03
Average CNR	29.40
Average time taken for prediction	0.0.42 seconds

TABLE. III. PSNR AND SSIM VALUES WITH CHASE_DB1 DATASET (NAZ & SHREEKANTH, 2021)

Dataset: CHASEDB1	PSNR	SSIM
GC	13.7523	0.7684
AHE	9.9658	0.4869
CLAHE	20.8603	0.6178
RETINEX	14.199	0.6186
Existing Model	23.7442	0.9623
Proposed model	44.65	1

TABLE. IV. EVALUATION RESULTS OF FULL-REFERENCE METRICS (WAN ET AL., 2022)

Metrics	CLAHE	Fusion-based	MSRCP	LIME	CycleGAN	Cycle-CBAM	Proposed model
PSNR	19.0088	17.5748	11.5473	21.2084	22.4953	24.7386	44.65
SSIM	0.592	0.7693	0.6452	0.7762	0.7643	0.8103	1

V. DISCUSSIONS

In the preceding research, a DL framework incorporating a multi-stage and MSDC_NET is being used to enhance the thin-vessel segmentation in the presence of low contrast. Assessments on various datasets show that MSDC_NET is better at capturing fine blood vessels in fundus images, and assessments using the advanced reference data confirm the benefits of the proposed DL model. In comparison to the old multi-branch technique, the specificity and F1 score show enhancements of approximately three datasets (H. Guo, Meng, Zhao, Zhang, & Dai, 2024). A 19-layer U-Net architecture using deep learning is recommended for precise and effective blood vessel segmentation in the study. The architecture was tested on databases with performance metrics, and the ROC was calculated. Accuracy rates are noted to be 90.60%, 87.60%, and 83.42%. The ROC plot shows that databases have areas under the curve of 98.54%, 93.28%, and 88.18% (Prajna & Nath, 2022).

The AA-WGAN proposed is capable of effectively managing the imperfections in the data, as it can capture the pixel dependency in the entire image to emphasize regions of interest with the use of attention augmented convolution. The proposed AA-WGAN model is thoroughly assessed on three datasets, demonstrating competitive performance in vessel segmentation against various advanced models with accuracy scores of 96.51%, 97.19%, and 96.94% on each dataset (M. Liu et al., 2023). The existing MSCNN-AM focuses more on retinal vessel pixels rather than background pixels. MSCNN-AM is trained and evaluated for avoiding additional pre-processing and post-processing steps. The method that is represented is tested on three datasets available to the public. Furthermore, six objective metrics were utilised to validate the effectiveness of the MSCNN-AM by evaluating its performance metrics and AUC-PR. Experimental results show that the approach performs better than the majority of the current methods and procedures with sensitivity values and accuracy values (Fu, Li, & Wang, 2020).

The proposed network comprises approximately 1.8 million trainable parameters. Since the architecture is fully convolutional and operates in a single forward pass without iterative refinement, it remains computationally lightweight. Although explicit FLOP and memory profiling were not performed in the current implementation, the moderate model depth and parameter count indicate suitability for GPU-based clinical deployment.

VI. CONCLUSION

This document outlines a strong framework for medical image reconstruction that uses a self-evolving encoder-decoder

structure with integrated adaptive convolutional power scaling. The proposed method improves structural integrity and effectively reduces artifacts caused by degradation through feature-selective enhancement and dynamic modulation of features. Experimental tests on retinal datasets show better reconstruction abilities when dealing with simulated noise and lower resolution. Although the framework demonstrates considerable reliability, further validation with datasets from multiple centers and in different imaging settings is needed to fully confirm its clinical usefulness and dependability.

Cybersecurity Awareness Among Undergraduate Students in Saudi Arabia: A Quantitative Study

Turky A. Saderaldin[1], Ali Abuabid[2]*
Dept. of Engineering, King Abdulaziz University, Jeddah, Saudi Arabia[1]
Dept. of Information Technology, Saudi Electronic University, Abha, Saudi Arabia[2]

***Abstract*—Cybersecurity awareness has become increasingly important as digital services expand rapidly in Saudi Arabia. This study presents a quantitative assessment of cybersecurity awareness among undergraduate students in Riyadh and Jeddah. A structured questionnaire was administered to 177 students to evaluate awareness across three dimensions: internet usage, information security practices, and social media and smartphone security. Statistical analyses, including descriptive statistics, principal component analysis, regression, and cluster analysis, were applied to identify patterns and influencing factors. The results indicate a moderate overall level of cybersecurity awareness, with stronger adoption of passive security measures such as antivirus software and firewalls, and weaker engagement with proactive practices, including password management, VPN usage, and two-factor authentication. A key finding is the identification of a smartphone-related security gap: students who rely exclusively on smartphones show significantly lower awareness. The study highlights the influence of device usage and institutional context on cybersecurity behavior and provides recommendations to enhance cybersecurity education and awareness initiatives in higher education.**

***Keywords*—Cybersecurity awareness; undergraduate students; smartphone security; Saudi Arabia**

I. Introduction

The digital revolution has transformed nearly every aspect of modern life. Around the world, societies rely more than ever on information and communication technologies (ICT) for work, education, and social interaction. In Saudi Arabia, this shift has been especially rapid. Under Vision 2030, the Kingdom has embraced digital transformation as a foundation for economic diversity and social development. Recent figures from the Communications, Space, and Technology Commission (CST) show that internet penetration has reached almost 99%, with more than half of users spending over seven hours online each day [1]. These numbers reflect a society that is deeply connected and a youth population that is among the heaviest users of digital platforms.

While this connectivity brings many benefits, it also creates risks. Cyber threats such as phishing, identity theft, and malware often succeed not because of weak technology but because of weak human behavior. Studies repeatedly confirm that the human factor is the weakest link in cybersecurity (Huang et al., 2011; Satar & Alarifi, 2022). University students are a significant group in this regard. They use multiple digital services daily, handle sensitive data, and are part of large open networks, which makes them attractive targets for cybercriminals [4].

*Corresponding author.

A growing number of studies in Saudi Arabia have examined cybersecurity awareness, but the results suggest that challenges persist. In [5], the authors found that many users lack even basic awareness of cybercrime. In [5][6], the authors showed that practices such as strong password management remain weak, while [7] highlighted risks linked to social media and browser security. Other researchers have proposed frameworks and models, such as [8], but these are often resource-intensive and not tailored to everyday student use. What is missing from much of this work is a detailed look at undergraduate students in major cities and how their awareness is shaped by the devices they use. This is a critical gap, especially given that smartphones are now the primary way most students go online [9].

Riyadh and Jeddah provide a unique context for addressing this gap. They are the Kingdom's largest cities, home to some of its most important universities, and central to its economic and technological growth. Understanding how students in these cities think about and practice cybersecurity can therefore provide insights that are relevant not only to the academic community but also to national policy. Since 2017, the National Cybersecurity Authority (NCA) has been working to strengthen awareness and resilience at the national level [10], but effective strategies must start with the groups most at risk.

This study takes up that challenge. It investigates cybersecurity awareness among undergraduate students in Riyadh and Jeddah using a structured 46-item questionnaire. Awareness is assessed across three areas: internet usage, information security [3], and social media/smartphone practices. Beyond simple description, the study applies statistical techniques such as principal component analysis, regression, and cluster analysis to reveal deeper patterns. One of the key findings is what we describe as a "smartphone security shortage", the tendency of smartphone-only users to show significantly lower awareness than peers who use multiple devices.

In doing so, the study makes three main contributions. First, it adds new evidence on Saudi undergraduates, a group that has not been studied in depth despite their importance to the Kingdom's digital future. Second, it shows how device type and institutional setting play a role in shaping security behavior factors often overlooked in prior research. Third, it provides practical recommendations that can support universities, policymakers, and students themselves in building stronger cybersecurity practices. In this way, the study aligns closely with Vision 2030 and with the NCA's mandate to strengthen human-centered cybersecurity in Saudi Arabia.

The remainder of this study is organized as follows: Section II reviews related work on cybersecurity awareness in both the Saudi and international contexts, highlighting existing frameworks and research gaps. Section III presents the methodology, including the survey design, sampling strategy, and data analysis techniques. Section IV reports the results of the study, with descriptive statistics, factor analysis, regression models, and cluster analysis. Section V discusses these findings in light of previous research and considers their implications for students, universities, and policymakers. Finally, Section VI concludes the study with recommendations for practice and policy, as well as directions for future research.

II. Literature Analysis

Cybersecurity is widely recognized as a problem that is as much about people as it is about technology. While tools such as antivirus software, firewalls, and encryption are available, they often fail when users neglect basic practices. Simple habits, such as using weak passwords, ignoring updates, or connecting to insecure networks, can enable serious breaches. Researchers frequently point out that the human element is the "weakest link" in cybersecurity, and this weakness is obvious in younger populations who rely heavily on digital tools but often receive little formal training [2], [11]. For university students, the risk is even greater because of their heavy use of digital services and their constant connection to large, open university networks [12] [13].

In Saudi Arabia, awareness of these issues has grown alongside the Kingdom's rapid digital transformation. Several studies have examined cybersecurity awareness among Saudi users [14]. In [5], for instance, the authors found that basic knowledge of cybercrime remained low, while [15] reported weak adoption of best practices such as strong passwords and identity protection. Research focusing specifically on students has also highlighted problems: [7] showed that many university students neglect browser security and social media privacy, exposing themselves to unnecessary risks. Although useful, these studies tend to focus either on broad populations or narrow aspects of security. Frameworks proposed by [8] and [16] push the conversation further, but one is designed mainly for organizational contexts, and the other focuses only on social media threats. Together, they show progress but leave important questions unanswered.

Looking beyond Saudi Arabia, the same concerns appear around the world. Studies in Europe, North America, and Asia consistently show that students underestimate cyber risks, despite being some of the most digitally active groups [17]. They often understand the theory, knowing, for example, that strong passwords are important, but fail to apply this knowledge in practice. In [18] , [19], and [20], the authors found this "knowledge–behavior gap" among Saudi students, which mirrors findings from other regions. Universities have attempted awareness campaigns, but these are usually generic, leaving students without practical guidance on how to change their everyday behaviors.

Another area that has gained attention is device use. For years, cybersecurity studies assumed that most users accessed the internet via desktop or laptop computers. Today, that assumption is outdated. In Saudi Arabia, as elsewhere, smartphones have become the primary way young people connect online. This shift introduces new challenges. Smartphones encourage convenience, saved passwords, app-based logins, and instant connections, often at the cost of security. International reports suggest that smartphone-first users are more vulnerable to phishing and malicious apps [21] [22]. Locally, [18] highlighted the risks Saudi students face from social media attacks, but did not extend the analysis to general security behaviors. This creates space for deeper investigation, particularly into what we describe as the "smartphone security shortage", where students who depend only on smartphones show weaker awareness across multiple areas.

Institutional and policy contexts also shape how students engage with cybersecurity. Some Saudi universities have integrated cybersecurity into their curricula or conducted training sessions, while others have taken little action beyond posting basic awareness posters. As in [8], the authors highlighted that the organizational culture and governance can make a difference: where institutions prioritize security, students are more likely to adopt secure behaviors. On a national level, the establishment of the National Cybersecurity Authority (NCA) in 2017 was a milestone in coordinating policy and awareness efforts [16]. Yet, implementation across universities remains inconsistent, and the extent to which institutional differences shape student awareness has not been thoroughly tested [23].

Taken together, the literature points to several gaps. First, while cybersecurity awareness has been studied in Saudi Arabia, undergraduates in the country's largest cities, Riyadh and Jeddah, have not been examined in depth, despite their importance as educational and technological hubs. Second, the impact of device type, particularly the dominance of smartphones, has not been fully explored. Third, most existing studies provide descriptive findings but do not use advanced statistical techniques to uncover patterns or predictors of awareness. This study addresses these gaps by combining a focused student population with robust statistical methods, aiming to provide insights that are both academically rigorous and practically useful for Saudi Arabia's digital future.

III. Research Approach

This study aims to provide a clear picture of how undergraduate students in Saudi Arabia perceive and apply cybersecurity principles. Because the focus was on measuring awareness levels and identifying patterns across a relatively large group, a quantitative approach was chosen. Quantitative methods enabled the use of structured questions, comparisons across groups, and statistical tools to uncover trends that might not be visible through simple observation.

A. Population and Sampling

The research targeted undergraduate students at two universities: the King Abdulaziz University (KAU) in Jeddah and the Saudi Electronic University (SEU) in Riyadh. These institutions were selected deliberately because they represent different educational settings. KAU is one of the largest and most traditional public universities in the country, while SEU emphasizes online and blended learning. Comparing students

from these environments provided the opportunity to observe how institutional context might influence awareness.

Reaching students directly was not straightforward; therefore, a non-probability sampling method was employed. The survey was distributed through university email lists, QR codes posted on campus, and links shared via social media. A total of 177 valid responses were collected. While the sample is not large enough to represent all undergraduates in Saudi Arabia, it provides a solid basis for statistical analysis. It reflects the perspectives of students in two of the Kingdom's most important cities.

B. Survey Instrument

The primary data collection instrument was a 46-item questionnaire. Its design drew on previous studies of cybersecurity awareness [5]; [7] and it was refined based on feedback from academic colleagues. The questions were grouped into three main areas: Internet usage, including browsing habits, email use, and online purchases. Information security– including password management, antivirus software, firewalls, and VPNs. Social media and smartphone security – Focusing on How Students Manage Apps, Social Accounts, and Mobile Device Protection. Most questions used a five-point Likert scale ranging from "strongly agree" to "strongly disagree", which helped capture how often students engaged in specific practices. A few multiple-choice questions were also included to gather additional details.

C. Reliability and Validity

Before the survey was widely launched, it was tested with a small group of students to ensure that the wording was precise and that the order of questions made sense. Their feedback led to a few minor adjustments. To check the internal consistency of the questionnaire, Cronbach's Alpha was calculated, producing a value of 0.747. In social science research, this is considered an acceptable level of reliability, indicating that the survey items functioned effectively to measure the intended constructs.

D. Data Collection and Ethics

Data collection lasted approximately eight weeks, from late February to late April 2025. Students were invited to participate voluntarily, and every effort was made to protect their privacy. The survey did not collect names, student numbers, or other identifying information. Participants were informed at the start of the questionnaire about the purpose of the research and how their answers would be used. Ethical approval was obtained from the relevant university committees, and informed consent was obtained from all participants before the survey began.

E. Data Analysis

Once the responses were collected, the data were analyzed using SPSS. Descriptive statistics were first calculated to provide an overview of students' responses to individual items. Subsequently, more advanced techniques were employed. Principal component analysis (PCA) helped to identify broader factors underlying student behavior. Correlation and regression analyses were used to examine the relationships between specific practices and overall awareness scores. Finally, a k-means cluster analysis was performed to classify students based on their cybersecurity behaviors. This step provided valuable insights, showing that students are not homogeneous; instead, they fall into distinct categories, ranging from highly aware to very low adopters of security practices.

The primary objective of this analysis was to determine the main effects of device usage and institutional context on student awareness. While demographic interactions - such as the relationship between gender and previous training, or academic year and field of study—could offer additional granularity, they were excluded from the current model to maintain statistical power given the sample size (n=177) and to prioritize the primary 'smartphone security shortage' hypothesis.

IV. Results

A. Demographics and Reliability

A total of 177 undergraduate students completed the survey. Most respondents were between 18 and 25 years old, which aligns with the typical age range of university students in Saudi Arabia. Regarding devices, nearly all students reported owning a smartphone (98%), while 47% used laptops, 38% used desktops, and 35% used tablets. The prominence of smartphones in this group became a key factor in shaping the results.

The survey instrument was tested for reliability, and Cronbach's alpha (0.747) indicated acceptable internal consistency across items. Table I presents the distribution of device usage among surveyed students, with the combination of "Smartphone with Laptop Computer" being the most common, followed by "Smartphone Only" users (see Fig. 1).

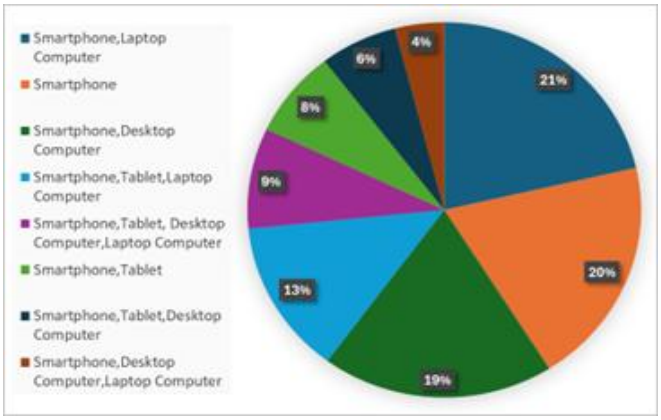

Fig. 1. Comparison of the percentage of device usage combinations.

TABLE I. Device Usage among Undergraduate Students

Device	Number of Students	Percentage
Desktop Computer	67	≃ 38%
Laptop Computer	84	≃ 47%
Smartphone	174	≃ 98%
Tablet	62	≃ 35%

B. General Awareness Levels

Overall, the survey revealed a moderate level of cybersecurity awareness, with an average score of 2.87 out of 4.0 (SD = 0.52). Students reported relatively high use of passive security tools, such as antivirus software (mean = 3.50) and firewalls (mean = 3.04). In contrast, practices that require

ongoing effort, such as maintaining strong passwords (mean = 2.29) or using VPNs regularly (mean = 2.45), were far less common.

Two-factor authentication was adopted by about 40% of participants, which shows some progress but still leaves a majority without this additional layer of protection. The weakest area overall was password complexity, where almost none of the respondents demonstrated high-level practices.

C. Smartphone Security Shortage

The data highlighted a clear "smartphone security shortage". Students who relied exclusively on smartphones scored consistently lower on awareness and secure behavior compared to those using multiple devices. These students were less likely to adopt practices such as two-factor authentication, careful app installation, or frequent updates. By contrast, students who combined smartphone use with laptops or desktops showed stronger security habits across the board.

D. Factor, Correlation, and Regression Analysis

Principal Component Analysis (PCA) grouped the items into three main factors, which together explained 62.3% of the variance:

- Proactive Security Measures – including VPN use, two-factor authentication, and password management.
- Passive Security Tools – such as antivirus, firewalls, and regular updates.
- Smartphone Security Practices – covering app safety and social media security behaviors.

Correlation analysis showed that students who enabled firewalls were also likely to use antivirus software ($r = 0.68$, $p < 0.001$). VPN use was moderately related to two-factor authentication ($r = 0.42$, $p < 0.01$), suggesting that proactive behaviors tend to cluster together. Password complexity, however, remained weakly related to other measures, underscoring its persistence as a challenge.

A multiple linear regression analysis was performed to identify the primary predictors of cybersecurity awareness among students. To ensure the model's integrity and address the reviewer's request for enhanced interpretability, several diagnostic tests were conducted. The Adjusted R^2 was used as a conservative measure of the variance explained by the model, accounting for multiple predictors.

To address the potential for multicollinearity, particularly given the observed correlation between firewall and antivirus use ($r = 0.68$), Variance Inflation Factors (VIF) were monitored. All VIF values remained within acceptable thresholds, confirming that the predictors were sufficiently independent and that the model's coefficients are reliable. The model confirmed that firewall use and two-factor authentication are significant positive predictors of awareness, whereas exclusive smartphone use is a significant negative predictor. This provides robust statistical evidence for the 'smartphone security shortage'. The precision of these estimates was further verified through 95% Confidence Intervals, ensuring that the reported effects are statistically sound.

E. Clusters of Student Behavior

A k-means cluster analysis divided the participants into three distinct groups:

- High Security Adopters (66 students): Regularly used both passive and proactive security measures.
- Moderate Security Users (45 students): Adopted mostly passive tools but were inconsistent with proactive behaviors.
- Low Security Adopters (66 students): Showed limited engagement with cybersecurity practices, with smartphone-only users heavily represented in this group.

Cluster analysis categorized the participants into these groups based on their security behaviors. Specifically, Cluster 3, which consisted primarily of students relying exclusively on smartphones, demonstrated the lowest engagement across all measured awareness dimensions compared to the multi-device clusters. As shown in Table II, this group reported significantly lower rates of VPN usage and manual security configurations ($p < 0.05$).

TABLE II. CLUSTER DISTRIBUTION BY DEVICE CATEGORY

Cluster	Desktop	Laptop	Mobile + Computer	Mobile Only	Multiple Computers
1	31	30	3	12	16
2	8	18	7	17	4
3	6	14	3	6	2

Whereas Fig. 2 illustrates the variation in average scores for Clusters 1, 2, and 3 across survey questions Q3–Q11. Cluster 1 consistently shows higher scores, while Clusters 2 and 3 fluctuate more noticeably, highlighting differences in response patterns and group behaviors.

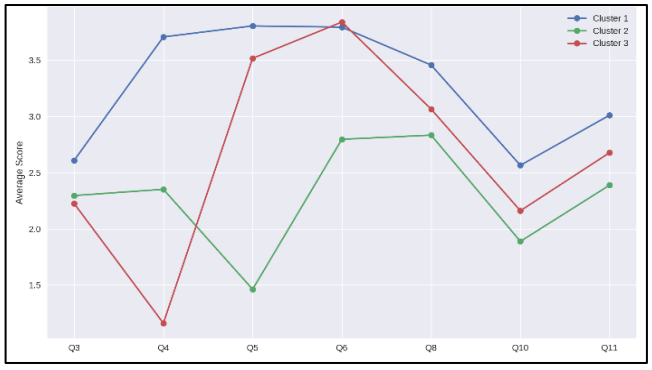

Fig. 2. Average scores across survey questions by cluster.

V. Discussion

The findings of this study reveal a significant discrepancy between 'passive' and 'active' cybersecurity behaviors among Saudi undergraduate students. While the results in Section IV show high adoption rates for antivirus and firewalls, these represent passive security tools that are often automated or pre-installed. In contrast, the lower engagement with active practices, such as VPN usage and multi-factor authentication, suggests that students prioritize convenience over manual

security agency. This behavior indicates that awareness is currently platform-dependent rather than a result of ingrained security habits.

A critical interpretation of the data confirms the identified 'smartphone security shortage'. This phenomenon can be attributed to the 'security abstraction' effect of modern mobile ecosystems. Unlike traditional desktop environments that require frequent user interaction with security prompts and file permissions, smartphones (IOS/Android) are designed to hide these complexities to prioritize user experience. This creates a false sense of inherent safety among exclusive smartphone users, leading to a more passive security posture. Consequently, the 'shortage' identified in this study is not necessarily due to lower intelligence but rather to a lack of exposure to technical security management. This finding is both locally and internationally relevant; global studies have shown that mobile-first users are more exposed to phishing and malware (GSMA, 2022; McAfee, 2023), and in the Saudi context, where smartphone adoption is exceptionally high, this abstraction poses a significant challenge for national cyber-resilience.

The results also show that institutional differences matter. Students from different universities displayed different levels of awareness, suggesting that policies, culture, and training programs at the institutional level can influence student behavior. This finding supports the arguments of [8] and [24], who emphasize the role of governance and organizational culture in promoting cybersecurity awareness. For policymakers and university administrators, this highlights the need for stronger and more consistent cybersecurity initiatives across the higher education sector.

Finally, the cluster analysis underscores that students are not a homogeneous group. Some are highly engaged with both proactive and passive measures, others rely mainly on passive protections, and a substantial group shows minimal engagement. This suggests that awareness campaigns should not take a "one-size-fits-all" approach. Different strategies are needed for different groups: moderate users may benefit from reminders and workshops, while low adopters may require more hands-on interventions. Meanwhile, high adopters could serve as role models or "cyber champions" within their institutions, helping to spread secure habits among peers.

VI. Conclusion

This study set out to evaluate cybersecurity awareness among undergraduate students in Riyadh and Jeddah, two of Saudi Arabia's largest academic and digital hubs. Using a structured survey of 177 students, it assessed practices across internet usage, information security, and social media/smartphone behaviors. The analysis revealed a moderate overall level of awareness, but also significant weaknesses in areas that require active engagement, such as password complexity, VPN use, and consistent adoption of two-factor authentication.

One of the most important findings is what this study terms as the 'smartphone security shortage'. Students who relied exclusively on smartphones consistently showed weaker security behaviors than those who used a mix of devices. Given the central role of smartphones in the daily lives of Saudi youth, this gap poses a serious challenge. The results also show that institutional factors matter: students from different universities reported varying levels of awareness, suggesting that the culture, policies, and training programs within each institution shape student behavior in meaningful ways. Finally, the cluster analysis confirmed that students cannot be treated as a single uniform group; rather, they fall into distinct categories of high, moderate, and low adopters of security practices.

Taken together, these findings carry several implications. At the student level, individuals need to take greater responsibility for their own security. Simple steps—such as creating stronger passwords, enabling two-factor authentication, and using VPNs when accessing public networks—can make a substantial difference. Students should also be encouraged to treat smartphones with the same level of caution as laptops or desktops.

At the institutional level, universities should not rely on generic awareness campaigns alone. Instead, they should integrate cybersecurity education into curricula across disciplines, not just computer science or engineering. Peer-to-peer programs could also be valuable, with highly aware students serving as "cyber champions" who support and influence their peers. Universities with stronger cybersecurity cultures provide a model for others to follow, and there is room to share best practices across the sector.

At the national level, the results align closely with Saudi Arabia's Vision 2030 and the goals of the National Cybersecurity Authority (NCA). Policymakers should recognize the importance of tailoring awareness initiatives to specific groups, such as undergraduates, who represent both current risks and future leaders in the digital economy. National programs could prioritize smartphone security education and promote user-friendly tools that encourage secure habits without creating unnecessary barriers.

Like any study, this research has certain limitations that must be acknowledged. First, the sample was restricted to two universities: the King Abdulaziz University in Jeddah and the Saudi Electronic University in Riyadh. While these institutions represent important academic contexts, the findings are subject to sampling bias and cannot be generalized to all undergraduate students across Saudi Arabia. Expanding the study to include a wider range of universities, technical colleges, and private institutions would provide a more representative picture of student awareness nationwide.

Second, the sample size of 177 participants, although sufficient for the statistical analyses applied, remains relatively modest and was not based on a formal a priori power analysis. A larger dataset would enhance the reliability of factor analysis and regression models, allowing for more sophisticated comparisons across demographic groups. Future research could also employ probability-based sampling techniques to improve external validity and mitigate the limitations of the current convenience sampling approach.

Third, the study relied on self-reported data through a structured questionnaire. While the survey achieved acceptable reliability (Cronbach's $\alpha = 0.747$), self-reports are subject to biases such as social desirability and recall error, which may

lead participants to overestimate their security proficiency. Complementing surveys with behavioral data (e.g., logs of actual password complexity or monitoring of phishing susceptibility through controlled experiments) would give a more accurate assessment of actual cybersecurity practices versus perceived awareness.

Fourth, this study focused on identifying broad trends and did not explore complex interaction effects between demographic variables (e.g., how academic major might moderate the effectiveness of cybersecurity training). Future research utilizing larger, more diverse datasets should employ factorial ANOVA or moderated regression models to investigate these intersections, which would provide a more nuanced understanding of how specific student subgroups respond to security challenges.

Finally, the research design was cross-sectional, capturing a snapshot of student behavior at one point in time. Awareness and practices, however, evolve as new technologies, policies, and threats emerge. Longitudinal studies would allow researchers to track changes over time and evaluate the impact of interventions such as awareness campaigns or curricular integration.

Future studies should therefore broaden the scope geographically, increase sample size, combine self-reported and behavioral measures, and adopt longitudinal or experimental designs. By addressing these limitations, subsequent research can provide deeper and more generalizable insights that support universities, policymakers, and students in strengthening cybersecurity culture in Saudi Arabia.

In conclusion, cybersecurity awareness among Saudi undergraduates is moderate but uneven. Students rely heavily on passive protections while overlooking active security behaviors. The smartphone security shortage is a critical vulnerability that must be addressed urgently. By strengthening awareness at the student, institutional, and national levels, Saudi Arabia can build a more resilient digital society and ensure that its young population is prepared to meet the challenges of an increasingly connected world.

An Analytical Study of Data Augmentation Across Audio Representations for Infant Cry Classification

Meriyem Ghanjaoui[1], Abdelaziz Daaif[2], Abdelmajid Bousselham[3],

***Abstract*—Several multidisciplinary studies consider an infant's cry as a valuable source of information, particularly for parents, caregivers, and medical professionals. From a signal processing viewpoint, infant cries can be represented either in the time domain (one-dimensional or 1D raw waveform) or in the time–frequency domain (two-dimensional or 2D spectrogram-based representations). However, the impact of these representations on classification performance, particularly under constrained and imbalanced dataset conditions, remains insufficiently explored. This study presents a comparative analysis of 1D and 2D convolutional neural networks applied to waveform and spectrogram representations of infant cries. Due to the significant class imbalance of the dataset, we employed data augmentation techniques. Experimental results show that the 1D CNN achieved 95% training accuracy and 91% validation accuracy, indicating a relatively small generalization gap. In contrast, 2D CNN reached 98% training accuracy but remained below 91% on the validation set, revealing a larger gap and suggesting potential overfitting to the augmented data.**

***Keywords*—CNN; waveform; spectrogram; deep learning; baby cries**

I. Introduction

Numerous motivations drive the analysis of infant cries, particularly distinguishing normal cries, caused by hunger, thirst, sleep, or other needs, from abnormal cry patterns that may indicate illness or neurological disorders. Insights derived from cry analysis can assist parents and caregivers in responding appropriately to a baby's needs, thereby supporting healthy emotional and physical development.

In recent years, deep learning techniques have significantly advanced the field of audio analysis. Convolutional Neural Networks (CNNS), for example, have demonstrated strong performance in various audio-related tasks, including speech recognition, emotion detection, and pathological voice classification. These approaches enable automatic feature learning directly from raw or transformed audio signals, reducing dependence on handcrafted features.

However, audio signals inherently contain multiple feature representations, and deciding the most suitable representation for a specific application remains an open research question. In the context of infant cry classification, it is still unclear whether time-domain representations (raw waveform) or time–frequency representations (such as spectrograms) provide more robust and generalizable performance, especially under constrained and imbalanced dataset conditions.

The main contributions of this study are summarized as follows:

- A systematic comparative analysis between time-domain (1D waveform) and time–frequency domain (2D spectrogram) representations for infant cry classification using a fixed deep learning model.
- An experimental evaluation of data augmentation strategies applied to a highly imbalanced dataset, examining their influence on classification performance.

This study is organized as follows: Section II provides the theoretical foundations for audio processing; Section III outlines the datasets, processing, and CNN architectures used. Sections IV and V present and discuss the results, including comparisons with existing studies. Finally, Section VI concludes the study and outlines future research directions.

II. Audio Representations: Theoretical Foundations

Our ears can naturally distinguish between different sounds, voices, and music. Behind this ability lies the perception of key attributes, also called features. Human ears receive an audio signal and implicitly decode it into meaningful characteristics. Similarly, when processing audio, a machine gets a numerical waveform and attempts to extract its underlying features. Because raw audio is complex and high-dimensional, features allow machine learning models to focus on the most informative patterns rather than the entire waveform.

In general, audio features are categorized into prosodic and acoustic features, and each classification task depends on which features are most relevant.

Prosodic features focus more on how something is spoken, but not what is spoken. They include aspects such as intensity or loudness, pitch (F0), rhythm, duration, and voice quality. Acoustic features, in contrast, focus on the physical properties of the signal itself. They represent low-level measurable attributes, such as: Root Mean Square (RMS) energy, Zero Crossing Rate, Spectral centroid, Spectral roll-off, Mel-Frequency Cepstral Coefficients (MFCC), Formants, and Harmonic structure. In summary, the prosodic features are high-level abstractions derived from low-level acoustic features, which themselves originate from either a time-domain, frequency domain, or time-frequency domain representation.

A. Audio Domain Representations

Basically, audio signals can be represented in different domains, each capturing complementary information:

1) Time-domain representations: The main idea about the time domain revolves around analyzing waveforms (Fig. 1), a waveform is a graphical representation of a signal that illustrates its variation over time [1]. Accordingly, the x-axis represents time, while the y-axis represents the amplitude. giving a direct visualization of the signal's comportment by tracing the amplitude in every time unit.

Mathematically, the real-world audio waveform can be expressed as a sum of sinusoidal components (1) [1].

$$x(t) = \sum_{k=1}^{K} Ak\ sin\ sin\ (2\pi ft + \emptyset K) \quad (1)$$

It means that the time-domain signal $x(t)$is shaped by the superposition of multiple sinusoids, which is characterized by an amplitude A_k, a frequency f_k, and a phase ϕ_k.

2) Frequency-domain: The second way to represent an audio is by transforming it into the frequency domain. Frequency domain representation describes the signal from the frequency components it contains. Instead of showing how the amplitude varies over time. It reveals the pitch. fundamental frequency. Harmonic, spectral harmonic, amongst others. In this domain, signals are represented by amplitude squared or power on the Y-axis and frequency on the X-axis. This is carried out using the means of the Discrete Fourier Transform or Fast Fourier Transform (FFT) as shown in Fig. 2. Mathematically, digital signals are finite and processed with the Discrete Fourier Transform (DFT) (2) [2],[3]:

$$f(x) = \frac{a_0}{2} + \sum_{n=1}^{\infty}\left(a_n\, cos\, \frac{n\pi x}{L} + b_n\, sin\, \frac{n\pi x}{L}\right) \quad (2)$$

3) Time-frequency domain: Time-frequency domain enables the description of how the spectral content of a signal varies over time as it merges the amplitude vs time and the amplitude vs frequency representations. The result is a two-dimensional representation with time in the X-axis, frequency in the Y-axes and the amplitude as color. This transformation is done by means of Short-Time Fourier Transform (STFT) (3), producing a spectrogram as shown in Fig. 3[4].

$$X(t,f)=\int x(\tau)w(\tau-t)e^{-j2\pi f\tau}\, d\tau \quad (3)$$

where w is a time-localizing window. The spectrogram, given by $|\ X(t,f)\ |^2$, displays energy as a function of time and frequency.

When coming to the time-frequency domain, we find three known graphical representations available in the literature. These are Spectrogram, Mel spectrogram and Constant Q transform (CQT). Each has its use case as summarized in Table I.

To summarize, audio representations depend on time and frequency domains, thus the study's hypothesis is as follows. In order to maximize the relevance of the feature extracted, it is recommended to use the time-frequency domain.

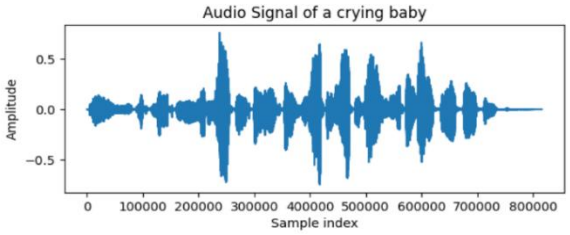

Fig. 1. An example of a crying baby waveform.

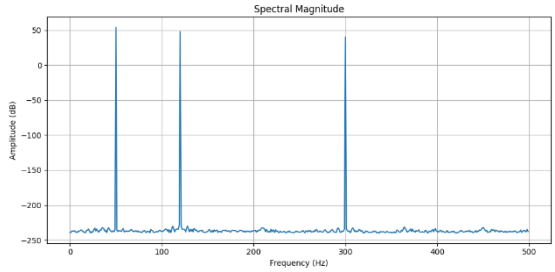

Fig. 2. Frequency domain: Spectral magnitude.

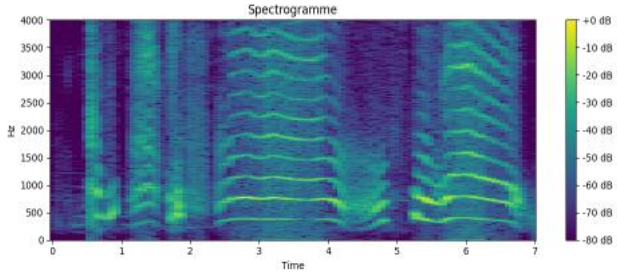

Fig. 3. A Spectrogram example of a pain cry.

TABLE I. COMPARISON OF MOST USED TIME-FREQUENCY DOMAIN REPRESENTATIONS

Representation	Frequency scale	Advantages	Disadvantages
Raw waveform (1D CNN)[5]	Time domain	Direct learning from original signal, no handcrafted transformation, reduced preprocessing	Sensitive to noise, less interpretable.
Spectrogram[6], [7]	Linear	True physical frequencies, Baseline representation.	Low frequencies are not taken into consideration, large dimensionality, and non-perceptual.
Mel [8], [9], [10]Spectrogram	Mel scale	Perceptual meaningful, Compact, Robust in feature extraction, widely used.	Low frequency precision, Possibility of losing information
CQT[11], [12]	Logarithmic	High resolution at low frequencies,	Computationally heavy

III. Related works

Several studies have mentioned the importance of increasing data size in infant cry analysis and audio classification tasks. Due to dataset imbalance and limited sample availability, many reported results fail to achieve robust generalization. For this reason, several works apply various data augmentation techniques, particularly classical methods such as time stretching, pitch shifting, and noise addition. For example, Abayomi-Alli et al. [13] conclude that noise addition is among the most commonly used augmentation techniques across existing audio classification studies.

However, despite the known use of data augmentation, selecting a suitable audio representation remains a significant challenge Table II. Some studies operate directly on one-dimensional raw waveforms, while others underline the importance of time–frequency representations.

For instance, Abdoli et al. [6] conducted experiments on the UrbanSound8K dataset (8,732 samples), using raw 1D waveform inputs with a 1D CNN architecture, achieving 89% accuracy without applying data augmentation. In contrast, Doungpaisan and Khunarsa [7] employed Constant-Q Transform (CQT) representations with a ResNet-based 2D CNN on a gunshot dataset of 2,148 samples, reporting 95% accuracy.

More recently, transformer-based approaches have gained attention. Jeong et al. [8] applied the Audio Spectrogram Transformer (AST) on spectrogram representations of Parkinson's speech data (5,000 samples), achieving 92% accuracy without augmentation. Similarly, Li et al. [9] explored speech emotion recognition using Mel-spectrograms combined with CNN/Transformer architectures on a 5,000-sample dataset, incorporating augmentation techniques and reporting 92% accuracy.

These studies prove that both representation choices significantly impact model performance. However, most works rely on relatively large datasets compared to infant cry datasets, which are often limited in size and highly imbalanced.

TABLE II. Summary of Related Works

Studies	Dataset	Samples	Representation	Model	Augmentation	Reported Accuracy
Abdoli et al. [6]	UrbanSound8K	8 732	1D waveform	1D CNN	No	89%
Doungpaisan & Khunarsa [7]	GunShot	2148	CQT	ResNet based on 2D CNN	No	95%
Jeong *et al.* [8]	Parkinson Speech	5000	Spectrogram	Audio spectrogram transformer (AST)	No	92%
Li *et al.* [9]	Speech Emotion	5 000	Mel-Spectrogram	CNN/Transformer	Yes	92%
Proposed Work	Infant Cry	475	1D & 2D	CNN	Yes	91%

IV. Methodology

Founded on the representations of audio cited earlier in this research, the objective of this experimentation is to evaluate the different representations, in other word to compare the time domain representation, which is a one-dimensional input vector, to the time-frequency domain, which is a two-dimensional vector. We consider our classification experiment using the Donate a Cry dataset [14].a public dataset of baby cries containing labeled samples for five different types of cries: 6 audio clips labeled as belly pain, 8 as burping, 16 as discomfort, 382 as hunger, and 27 as tiredness. In our case, we merged this data into two classes: hungry and not-hungry, in order to proceed with five class classification. We aim by this operation to overcome the limitation of the dataset, which is the imbalance of classes. We also applied augmentation directly on the waveform in the evaluation data: pitch shifting, time stretching, random noise injection, and small temporal shifts.

The first part consists of feeding a waveform, which is in the time domain, into a 1D CNN model in order to classify baby cries into hungry or not. In the second part, we transformed the waveform into a mel frequency, which is the time-frequency representation and fed it into a 2D CNN model, in order to do the same classification.

This setup allows us to directly test how the representations described above perform in real-world cry classification tasks.

1) Pipeline description: For our experimentation, we evaluate the time domain and the time-frequency domain by conducting 2 sets of experiments, the first set aims to apply a 1D CNN on the data waveform without augmentation, then applying 1D CNN on the waveform data after augmentation. The augmentation is done directly on the waveform by applying pitch shifting, time stretching, random noise injection, and changing speed [15].

The second setup concerns applying a 2D CNN on the three types of time-frequency domain, which are Spectrograms, Melspectrograms, and CQT. First, without augmentation, then on augmented data, similarly to the first experiment, we applied augmentation directly to the audio waveform.

In details Fig. 4:

Fig. 4. Pipeline description.

For the augmentation, we applied a conditional augmentation to make the classes balanced, and since we have different numbers in each class, we target a number of 800 per class, which is considered enough for a CNN model to train it, which means we apply (4):

$$\text{needed} = \text{target} - \text{current_count} \quad (4)$$

and then the augmentation files are (5)

aug_per_file = ceil(needed / current_count) (5)

So, the proportions would be as follows, Table III:

TABLE III. NUMBER OF AUGMENTATION AUDIO CLIP PER CLASS

Class	Number of Audio Clips	Augmentation Per File
tired	24	needed = 800 - 24 = 776 aug_per_file = ceil(776 / 24) = 33
hungry	382	needed = 800 - 382 = 418 aug_per_file = ceil(418 / 382) = 2
discomfort	16	needed = 800 - 16 = 784 aug_per_file = ceil(784 / 16) = 49
burping	8	needed = 800 - 8 = 792 aug_per_file = ceil(792 / 8) = 99
belly pain	6	needed = 800 - 6 = 794 aug_per_file = ceil(794 / 6) = 133

The 1D CNN processes the raw audio waveform directly. The architecture consists of an input layer, a raw waveform of 7 seconds at 16 kHz, with one channel. Convolutional layers have three Conv1D layers with increasing filter sizes 16, 32, and 64 with a kernel size of 9. Each is followed by Batch Normalization and MaxPooling1D to reduce dimensionality and capture local patterns. The fully connected layer comprises a Dense layer with 128 neurons and ReLU activation. This is followed by Dropout (0.3) to reduce overfitting. Finally, an output layer is a single neuron with sigmoid activation for five classes, as shown in Fig. 5.

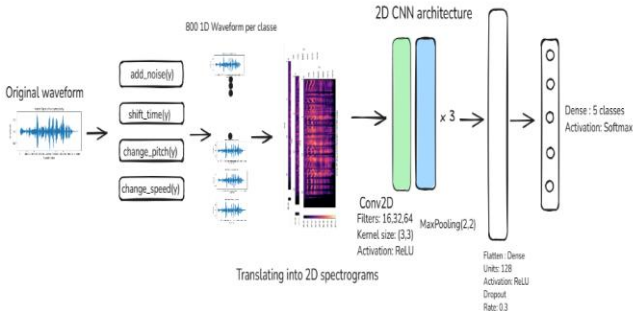

Fig. 5. The Pipeline used in the first set of experiments.

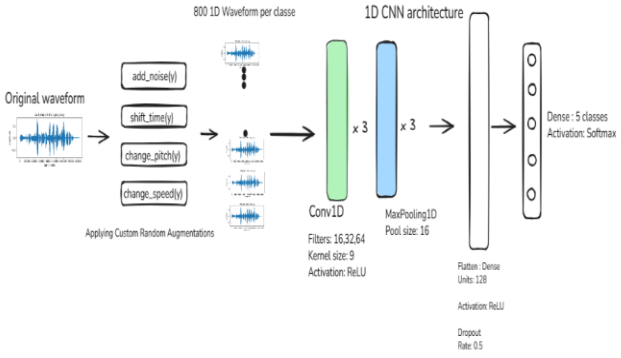

Fig. 6. Time-frequency domain 2D architecture.

The 2D CNN Time-Frequency Domain Spectrogram's architecture using 2D CNN is shown in Fig. 6. The 2D CNN architecture consists of an input layer, namely a spectrogram. The Convolutional layers comprise three Conv2D layers with increasing filters 32, 64, 128, kernel size (3×3), padding='same'. Every convolution is followed by Batch Normalization and MaxPooling2D to reduce spatial dimensions. Last layers are fully connected using a Dense layer with 128 neurons, ReLU activation, and Dropout (0.3), plus an output layer, which is a SoftMax of 5 classes.

Both architectures were trained using the Adam optimizer and categorical cross-entropy.

V. RESULTS

Before applying augmentation on the baby cries open-source dataset "Donate a Cry", the results are shown in Fig. 7. For the 2D CNN applied on spectrograms generated from real imbalanced data, it gave a good accuracy in training, reaching 97%. However, validation did not exceed 82%. 1D CNN did not reach 85% in both, with a drop at the 18th epoch. This highlights the problem of overfitting.

After augmentation, the performance of the CNN model using the time domain 1D raw waveform and time-frequency domain 2D spectrogram-based is noted in Table IV.

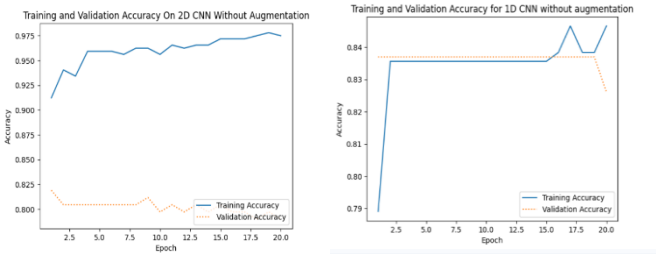

Fig. 7. Training and validation accuracy on 1D vs 2D dataset before augmentation.

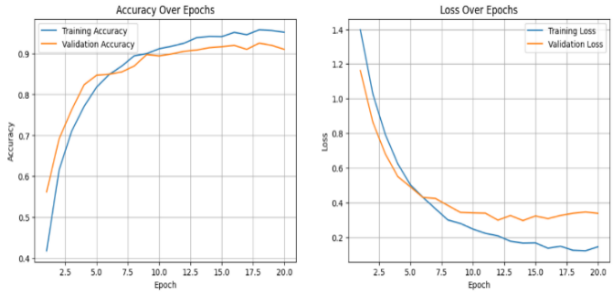

Fig. 8. Accuracy and loss over epochs for 1D CNN model on the time domain.

TABLE IV. CLASSIFICATION METRICS

	Precision	recall	F1 score	Support
Tired	0.89	0.84	0.80	163
Hungry	0.81	0.84	0.82	230
Discomfort	0.95	0.87	0.91	270
Burping	0.98	0.98	0.98	160
Belly Pain	0.92	0.99	0.95	429

The accuracy of the 1D CNN based on augmented data achieved 95% for training and 91% for validation, while the loss is 13% and stays under 20% in the validation, as shown in Fig. 8.

For the second experiment, by applying a 2D CNN on spectrograms, training accuracy is 3% better than that of a 1D CNN. The results of validation and loss curve are not favorable as shown in Fig. 9.

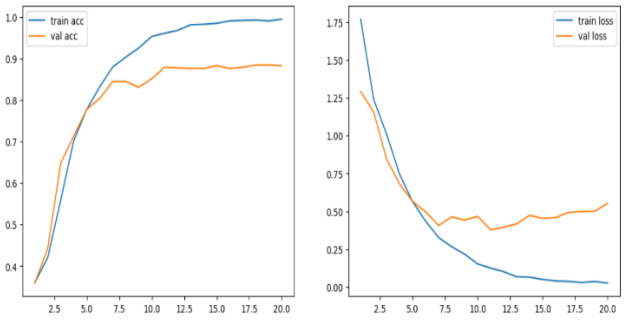

Fig. 9. Accuracy and loss over epochs for 2D CNN model on the time-frequency domain.

VI. Discussion

In this study, two types of representations were evaluated, namely, the time domain waveform and time frequency spectrogram. For this dataset, an augmentation technique was necessary. It was applied directly to the waveform, which helped both models to learn effectively. The first model, a 1D CNN applied on the raw audio waveform, achieved 95% training data and approximately 91% in validation. The reduced gap between training and validation indicates a good level of generalization. In contrast, the second model, 2D CNN applied to the time-frequency domain, particularly the spectrogram, reached 98% on the training set but remained below 91% on the validation set. This shows that the model learns well the training data, but does not generalize to unseen data, which is characteristic of overfitting behavior.

Although the time-frequency representation provides a richer source of features that can be learned, the model used has high capacity and therefore needs more data or more regularization to better validate. Meanwhile, the Time domain features extracted are likely to better classify in real scarce datasets.

VII. Limitations

Despite the promising performance of both 1D waveform and time-frequency spectrogram representations, several limitations should be acknowledged. First, the dataset used in this study is relatively small and highly imbalanced, which may affect the generalization capability of models, particularly the high-capacity 2D CNN trained on spectrogram representations.

Second, although data augmentation was employed to alleviate class imbalance and overcome data scarcity, synthetic samples cannot fully reproduce the natural variability and acoustic diversity of real-world infant cries. The heavy reliance on augmented data for minority classes may therefore influence performance stability.

Third, the choice of time–frequency transformations (e.g., Mel spectrogram or Constant-Q Transform) require careful parameter tuning, which may impact feature quality and overall model performance. Although experiments were repeated multiple times to ensure consistency, a formal cross-validation protocol and statistical significance testing were not conducted, which may limit the statistical reliability of the reported comparisons.

Finally, this study focuses exclusively on convolutional neural network architectures. Other deep learning paradigms, such as transformer-based models or hybrid architectures, were not explored and may offer additional improvements in future work.

VIII. Conclusion

In our work, we aimed to evaluate two principal representations of infant cry signals: The time domain waveform and the time frequency spectrogram, to understand how this choice influences model behavior and generalization. By comparing a 1D CNN on raw waveform to a 2D CNN on spectrograms, we verified that although time-frequency features provide richer information, they also increase the probability of overfitting when real data is limited. On the other hand, time domain features, although being simpler, enabled the model to generalize effectively.

This analysis stands as a building block for our future work, especially as we are leveraging transformer-based architecture, which relies on the quality of input representations. Moreover, the limitations of CNNs on spectrograms lead to models that are better in capturing temporal dependencies as well as experimenting with other types of representations, Mel spectrogram and CQT.

***Abstract*—Cyber Threat Intelligence (CTI) plays a crucial role in supporting proactive cybersecurity defence by offering insights into adversarial behaviours and attack tactics. However, CTI data are mainly presented in unstructured natural language, characterised by dense technical terminology, implicit attack semantics, and sequential descriptions of multi-stage threat activities. While transformer-based language models such as BERT have shown strong contextual representation abilities, they are naturally limited in explicitly modelling long-range sequential dependencies that often occur in CTI narratives. On the other hand, recurrent neural networks like BiLSTM effectively capture temporal dependencies, but lack deep contextual understanding. This study proposes a hybrid BERT–BiLSTM architecture that combines the contextual semantic strengths of transformers with the sequential learning abilities of bidirectional recurrent networks for improved CTI text classification. In the proposed framework, BERT acts as a feature extractor to produce contextualised token representations, which are then processed by a BiLSTM layer to model the progression of threats before final classification. A unified experimental setup is used, employing a publicly available CTI dataset, with consistent preprocessing, training strategies, and evaluation metrics to ensure fair assessment. Experimental results show that the proposed hybrid model consistently surpasses standalone BERT and BiLSTM baselines across multiple performance metrics, including accuracy and macro F1-score, with significant improvements especially in minority and semantically ambiguous threat categories. Further analysis indicates that the hybrid architecture effectively reduces common misclassification patterns caused by overlapping attack stages and implicit indicators. These findings demonstrate the effectiveness of combining contextual and sequential modelling approaches for CTI analysis. The proposed BERT–BiLSTM framework provides a robust and interpretable solution for automated CTI classification and offers practical insights for deploying hybrid deep learning architectures in real-world cybersecurity intelligence systems.**

I. Introduction

Over the past decade, the cyber threat landscape has experienced rapid qualitative and quantitative changes: threat actors, ranging from financially motivated criminal groups to state-sponsored advanced persistent threat (APT) campaigns, now orchestrate multi-stage covert operations that combine social engineering, software exploitation, and modular malware to achieve persistence and data exfiltration [1], [8]. The growth of digital services and interconnected infrastructure has expanded both the attack surface and the volume of observable events, generating continuous streams of threat data, alerts, and intelligence feeds that security practitioners must prioritise and interpret [7], [8]. As a result, Cyber Threat Intelligence (CTI) has become a vital tool for transforming fragmented technical indicators into actionable knowledge that supports anticipation and proactive defence, rather than solely reactive responses [7], [8].

Evidence from CTI and threat-sharing research highlights that exchanging structured intelligence (indicators of compromise, tactics, techniques, and procedures (TTPs), actor attributions) is essential for enhancing organisational readiness; however, challenges persist in integrating diverse sources into timely, operational insights [7]. Previous work thus positions CTI at the crossroads of detection, response, and collaborative information sharing, a nexus that becomes increasingly vital as adversaries expand their operations and disguise origins through distributed command-and-control infrastructures and polymorphic tooling [8], [14].

CTI products, reports, feeds, and structured indicators regularly include narrative descriptions of campaigns, attack timelines, exploited vulnerabilities, observed network behaviours, and recommended mitigations. These artefacts support essential security functions, such as incident response, intrusion detection tuning, vulnerability prioritisation, and executive decision-making [8], [14]. To be operationally valuable, CTI must be swiftly classified and integrated into defensive systems and workflows; however, CTI documents vary in structure, style, and level of detail, which complicates automation [7]. Standards and taxonomies like MITRE ATT&CK assist in systematically categorising adversary tactics and techniques, but the real-world application of these frameworks depends on accurate parsing and classification of free-text CTI narratives [8], [14].

The literature on CTI sharing and processing argues that scalable automation of CTI classification is a pressing operational need: manual triage cannot keep pace with the volume and velocity of intelligence, producing delays that blunt the strategic advantage of early warning and threat anticipation [7], [11]. This operational pressure motivates research into automated natural language processing (NLP) and machine learning (ML) methods tailored to cybersecurity text [7], [8].

Automating CTI classification faces several characteristic linguistic and semantic challenges that diminish the effectiveness of off-the-shelf NLP methods:

1) High semantic density: CTI sentences often pack multiple indicators, module names, and event relationships into short texts, increasing the information density that a classifier must disambiguate [8], [9].

2) Domain-specific vocabulary: Cybersecurity prose uses specialised taxonomies, abbreviations, and actor/malware naming conventions that generic language models do not always capture without domain adaptation [8], [14].

3) Sequential event structure: CTI narratives often describe multi-stage attack chains (initial access, execution, persistence, lateral movement, exfiltration) in a temporal sequence; understanding these sequences is essential for mapping content to tactics and phases [10], [14].

4) Multi-label conceptual overlap: Semantic boundaries between categories (e.g., credential harvesting occurring in both phishing and lateral movement contexts) create ambiguity that requires models capable of assigning multiple overlapping labels and reasoning about context [8], [9].

These properties collectively diminish the effectiveness of simple keyword matching, surface statistical features (TF-IDF), and typical classical classifiers because such approaches lack deep contextual understanding and the ability to infer long-distance relationships and event sequences embedded across paragraphs [7], [8], [9].

These challenges reveal structural limitations in existing NLP architectures. Transformer-based language models such as BERT produce deep contextual embeddings and have demonstrated state-of-the-art performance across tasks like classification, named entity recognition, and relation extraction, including several cybersecurity applications [1], [2], [4]. BERT captures bidirectional context via self-attention and significantly enhances semantic representation compared to static embeddings, aiding in modelling domain terminology when models are fine-tuned or adapted to the domain [1], [2]. However, transformer architectures do not maintain explicit recurrent states or a clear representation of sequential state transitions over long document spans; this can limit their ability to model narrative development and temporally ordered event chains unless additional mechanisms or document-level architectures are used [10], [14].

Conversely, recurrent neural networks (RNNs) such as bidirectional LSTM (BiLSTM) explicitly model sequential dependencies and have succeeded in capturing ordered relationships in text (e.g., temporal sequences, event progression) [6], [10]. BiLSTM processes input both forward and backwards, helping the detection of dependencies that span multiple tokens or sentences. However, RNNs trained from scratch often lack the deep contextual representations that transformers provide; they may therefore underperform when raw, domain-specific lexical semantics are important unless large, task-specific corpora and careful embedding strategies are used [6], [10].

Hybrid architectures that combine transformer encoders with sequence models have been proposed in other domains to leverage complementary strengths, transformers for rich token representations and recurrent units for explicit sequential state modelling, and have demonstrated empirical benefits in tasks requiring both deep semantic understanding and sequence modelling [2], [6], [10]. In cybersecurity-specific contexts, preliminary work suggests that combined architectures (e.g., BERT+BiLSTM, or BERT+BiLSTM+GCN) can enhance the extraction and classification of attack behaviours and heterogeneous CTI elements by integrating semantic embedding, sequential pattern learning, and graph-based relational reasoning [8].

Given the complementary advantages of BERT and BiLSTM, a hybrid BERT–BiLSTM architecture presents a well-founded option for CTI classification. BERT can deliver semantically rich token and sentence embeddings that capture cybersecurity terminology and polysemy, while BiLSTM can model ordered event dynamics spread across sentences and paragraphs. Previous frameworks combining BERT and BiLSTM have been effective for attack behaviour extraction and text classification in diverse CTI contexts, demonstrating that hybrid architectures can enhance detection of complex relationships and narrative flows [2], [10]. The operational motivation is clear: Security Operations Centres (SOCs) require automated CTI pipelines that are both swift and accurate to support triage and early warning [7], [8].

Research gaps exist in the systematic evaluation of hybrid transformer and recurrent models specifically for CTI classification, including rigorous benchmarking against classical ML baselines and standalone transformer or recurrent approaches. Addressing these gaps offers practical benefits, such as improved triage, alert enrichment, and integration into Continuous Integration and Continuous Delivery pipelines, as well as contributing to the theoretical understanding of how hybrid models represent CTI linguistic structures [7], [10], [14].

Study Organisation. The remainder of this study is organised as follows: Section II reviews related work, discussing traditional machine learning, deep learning, and hybrid approaches in the context of cybersecurity. Section III details the proposed research methodology, including the dataset description, preprocessing pipeline, and the specific design of the hybrid BERT–BiLSTM architecture. Section IV presents the experimental results, comparative benchmarking against baseline models, and a qualitative error analysis. Finally, Section V concludes the study with a summary of findings, research limitations, and directions for future work.

II. Literature Review

A. Traditional Machine Learning Approaches in CTI Classification

Early CTI automation work relied on classical machine learning (ML) algorithms such as Logistic Regression, Naive Bayes, Random Forests, and Support Vector Machines, which operated on bag-of-words or TF–IDF vectorisations. These

approaches are characterised as computationally efficient and interpretable, making them attractive for resource-constrained deployments and initial experiments [7], [9]. However, studies report that CTI text properties (length, semantic density, and evolving technical jargon) systematically reduce the effectiveness of frequency-based vectorisers: treating tokens as independent features discards co-occurrence, syntactic relations, and the rich semantics needed to link behaviours to tactics and infrastructure [9]. Preuveneers and Joosen argue that traditional IoC-style attributes and simplistic feature sets fail to capture the full scope of a campaign's behavioural signature, prompting ML enhancements for more effective detection [7]. Similar deficiencies are documented in healthcare-sector CTI processing, where TF–IDF driven pipelines missed nuanced threat descriptions in unstructured sources [9]. Collectively, these studies support the view that classical ML methods have limited effectiveness on real-world CTI feeds, where understanding context and relationships is crucial [7], [9].

B. Deep Learning Approaches in Cybersecurity Text Processing

To address the limitations of classical ML in handling context and sequence, research shifted towards recurrent neural networks (RNNs), especially LSTM and GRU variants, which can model sequential dependencies and long-range relations. RNN-based approaches have been used in intrusion detection, log analysis, and other security tasks, with some initial efforts extending LSTM to CTI tasks and reporting improvements over TF–IDF baselines [9]. However, analysis reveals two systematic constraints: 1) RNNs are effective at sequence modelling but lack rich semantic representations, and LSTMs depend on input embeddings (e.g., Word2Vec, GloVe) that are usually trained on general corpora and may not effectively capture cyber terminology; and 2) scaling RNNs to large CTI corpora can be computationally intensive and may still struggle to generalise across diverse CTI sources [9]. These limitations motivate the development of architectures that combine sequence awareness with more advanced contextual embeddings.

C. Transformer-Based Approaches and their Impact on CTI Research

The transformer family, especially BERT, has greatly enhanced contextual representation learning through bidirectional self-attention, generating token embeddings that capture dependencies across multiple tokens and polysemy. Several studies in cybersecurity have effectively used BERT-style models for malware classification, vulnerability text analysis, phishing detection, and other tasks, demonstrating notable performance improvements over static embedding pipelines and traditional classifiers [1], [4]. Ferrag et al. emphasise BERT's ability to support lightweight and privacy-aware detection models suitable for resource-constrained environments, highlighting the practical advantages of transformer pretraining for security applications [4]. Moreover, transformer fine-tuning is frequently reported to achieve better classification results than conventional deep or classical methods [1].

Despite these strengths, Transformer-only solutions show notable limitations for CTI classification. The main issue is that transformers do not maintain an explicit recurrent state and, therefore, do not naturally encode the ordered narrative progression across document spans; CTI narratives often describe attack sequences and temporal dependencies crucial for TTP mapping [14]. Additionally, the canonical BERT pretraining datasets (e.g., Wikipedia, BookCorpus) do not sufficiently reflect cybersecurity lexicons, requiring domain-specific fine-tuning or continued pretraining to address vocabulary and style mismatches [4]. These points suggest that although transformers offer rich semantics, extra architectural mechanisms are needed to capture temporal and document-level sequencing in CTI reports.

D. Hybrid Models in NLP and their Relevance to CTI

Hybrid architectures that combine transformer encoders with recurrent layers, such as BERT + BiLSTM, have appeared in specialised fields like biomedical text and sentiment analysis, where texts are both technical and narrative [2], [6]. Empirical findings in these areas show that transformer embeddings offer context-aware token representations, while BiLSTM layers improve the modelling of forward–backward sequence relations. This combination enhances downstream classification and extraction performance compared to using either component alone [2], [6]. Specifically, in cybersecurity research, Tang et al. propose and evaluate a BERT+BiLSTM+GCN pipeline for attack behaviour extraction from heterogeneous CTI, reporting improvements in classification and relation extraction by integrating contextualised embeddings with sequential modelling and relational reasoning [10]. This work demonstrates that hybrid designs can balance semantic richness with explicit sequence modelling, an integration especially relevant for CTI narratives that blend technical detail with ordered attack phases.

Despite this potential, the literature shows that hybrid architectures are underused in CTI classification: most research focuses on standalone transformers or RNNs, or implements transformer variants with minor changes, often without thoroughly evaluating transformer-recurrent hybrids across standardised CTI benchmarks [4], [10]. This gap offers a methodological opportunity: hybrid models support CTI's dual needs for accurate representation of domain terminology and clear modelling of temporal attack structures.

E. Comparative Assessment of Existing Methods

Synthesis across the reviewed literature yields several comparative insights: 1) traditional ML offers speed and interpretability but loses contextual semantics [7], [9]; 2) RNN/LSTM improves sequence modelling but lacks transformer-level contextual embeddings and suffers from embedding domain mismatch [6], [9]; 3) transformer models generate superior contextual representations but do not explicitly model narrative transitions and often require domain adaptation for cybersecurity text [4]; and 4) hybrid transformer–recurrent architectures offer a principled integration of semantic and sequential modelling, showing empirical advantages in related fields and initial cybersecurity studies [2], [6], [10]. These findings motivate the current

hybrid BERT–BiLSTM design as a strategic response to CTI classification challenges.

F. Research Gap Summary

The literature review identifies four main gaps that current research addresses: 1) lack of studies integrating transformers with recurrent layers specifically for CTI classification [4], [10]; 2) inadequate focus on CTI's requirement for both technical semantics and temporal sequence modelling, issues that single-paradigm models find difficult to satisfy [9]; 3) limited benchmarking across model categories that would clarify the relative strengths and trade-offs among classical ML, RNNs, transformers, and hybrid models [4], [7]; and 4) insufficient adaptation of models to CTI-specific linguistic behaviours, including rapidly evolving terminology and complex narratives, a problem noted across applied CTI system literature [7], [9], [14]. By designing, implementing, and empirically evaluating a BERT–BiLSTM hybrid for CTI classification, comparing it against classical and transformer baselines, and conducting detailed error analysis, this study directly addresses these gaps and offers a replicable methodological framework for operational CTI pipelines.

G. Positioning and Contributions

While hybrid architectures have been explored in general NLP, their systematic application to Cyber Threat Intelligence (CTI) remains under-analysed, particularly in addressing the specific linguistic duality of CTI reports: the intersection of high-density technical semantics (e.g., specific malware signatures) and chronological narrative structures (e.g., the Kill Chain progression). Existing studies often focus on extraction tasks or apply hybrids without rigorously benchmarking the failure modes of standalone architectures.

This study differentiates itself by shifting focus from simple model application to a comprehensive architectural evaluation. We argue that effective CTI classification requires a decoupled approach where semantic interpretation and narrative serialisation are handled by specialised layers. Consequently, this study makes the following contributions:

1) Architectural isolation of CTI failure modes: We empirically demonstrate that standalone Transformers (BERT) struggle with long-range narrative dependencies in CTI (e.g., distinguishing multi-stage attacks), while standalone RNNs (BiLSTM) fail to resolve polysemous technical vocabulary. We show how the hybrid architecture specifically bridges this gap.

2) Rigorous benchmarking framework: Unlike prior works that rely on limited baselines, we establish a comparative benchmark against four distinct modelling paradigms (Classical ML, RNN-based, Transformer-based, and Hybrid), providing a validated reference point for future CTI research.

3) Generalizable design principles for SOC automation: Beyond accuracy metrics, we analyse error patterns to derive actionable design principles for Security Operations Centres (SOCs). We identify that hybrid modelling is not merely an enhancement but a requirement for reducing false positives in semantically ambiguous threat categories (e.g., overlapping *Phishing* and *Credential Theft* stages).

III. Research Methodology

This section outlines the methodological framework used to design, implement, and evaluate the hybrid BERT BiLSTM architecture for Cyber Threat Intelligence (CTI) classification. The methodology is divided into six key components: dataset acquisition and description, preprocessing and normalisation, embedding generation with BERT, sequential modelling with BiLSTM, model training and optimisation, and evaluation using both quantitative and qualitative metrics. This section aims to provide a clear, reproducible, and academically rigorous explanation of all steps undertaken during the experimentation.

A. Dataset Acquisition and Description

Dataset source and composition. The study uses a publicly available Kaggle CTI textual reports repository containing labelled CTI narratives and associated threat categories (e.g., phishing, ransomware, data exfiltration, malware deployment, network intrusion, reconnaissance). Datasets of this form are widely used as CTI research benchmarks because they contain technical vocabulary, multi-paragraph narratives, and semi-structured indicators that mirror operational CTI reports [5], [13]. Hybrid architectures combining pre-trained language models and sequential networks have been applied to similar CTI or security-text corpora to exploit such content characteristics [12], [13].

Rationale for suitability. The dataset's suitability for multi-class CTI classification derives from four attributes: 1) diversity of attack categories enabling multi-class tasks, 2) variable text lengths that require models to handle both short indicators and extended narratives, 3) domain-specific technical vocabulary that benefits from contextual embeddings, and 4) a semi-structured mix of IOCs (indicators of compromise) within narrative text that favours hierarchical or hybrid models able to capture both token-level and sequence-level structure. These attributes are consistent with prior CTI and cybersecurity text studies that motivate BERT-based feature extraction and sequential modelling for behaviour recognition and classification [5], [12], [13].

Data partitioning. To avoid information leakage and to produce a reliable estimate of generalisation performance, the dataset is partitioned into training, validation, and test sets using a 70/15/15 split. Such three-way partitions are common in supervised deep-learning evaluations in applied NLP and cybersecurity contexts to permit hyperparameter tuning on a held-out validation set while preserving an untouched test set for final evaluation [3], [13]. Where class imbalance exists (as is typical in multi-class CTI corpora), stratified sampling is applied to ensure proportional label representation across splits; stratified partitioning is an established practice in classification tasks to preserve label distributions for reliable validation and testing [3], [12].

As outlined in Table I, the dataset contains diverse threat categories, which were divided using a standard ratio of 70% for training, 15% for validation, and 15% for testing. This stratification ensures that the model is evaluated on unseen data without risk of information leakage.

TABLE I. DESCRIPTION DATASET OF CYBER THREAT INTELLIGENCE

Threat Category	Sample size	Percentage	Sample keyword
Phishing	1,245	22.1%	credentials, lure, spoof
Malware Delivery	980	17.4%	payload, dropper, executable
Ransomware	815	14.5%	encryption, ransom note
Credential Theft	640	11.4%	keylogging, harvesting
Lateral Movement	520	9.2%	pivoting, remote execution
Reconnaissance	460	8.2%	scanning, enumeration

B. Text Preprocessing and Normalisation

Preprocessing is a vital step in converting raw CTI text into a format suitable for machine learning and deep learning models. Unlike typical text preprocessing pipelines, which may involve aggressive stopword removal or stemming, CTI text requires careful handling because cybersecurity terminology often contains meaningful tokens that must be preserved.

The preprocessing pipeline implemented in this study contains the following steps:

1) Case normalisation: All characters are converted to lowercase to ensure consistent representation. This step prevents the model from treating uppercase and lowercase versions of the same token as different entities.

2) Noise reduction: Noise elements such as excessive whitespace, non-printable characters, irrelevant punctuation, and malformed Unicode symbols are removed. However, CTI-specific symbols like IP addresses, file paths, registry keys, hashes, domain names, and network protocols are retained because they serve as important contextual indicators of malicious behaviour.

3) Tokenisation using BERT tokeniser: Instead of relying on traditional word tokenisers, the BERT WordPiece tokeniser is used because it manages out-of-vocabulary terms through subword decomposition. As cybersecurity terminology often includes rare sequences such as cryptographic hash fragments or exploit identifiers, WordPiece tokenisation is particularly suitable for CTI tasks.

4) Sequence length standardisation: All input sequences are padded or truncated to a fixed maximum length. This length is determined empirically based on the distribution of text sample lengths within the dataset. Standardisation is essential to enable efficient batch processing and to ensure consistent model input dimensions.

5) Attention mask generation: Parallel attention masks are created to show which tokens are actual content and which are padding. BERT uses these masks during embedding generation to properly direct attention.

The goal of this preprocessing pipeline, as illustrated in Fig. 1, is to preserve the linguistic integrity of CTI text while ensuring compatibility with the hybrid model architecture.

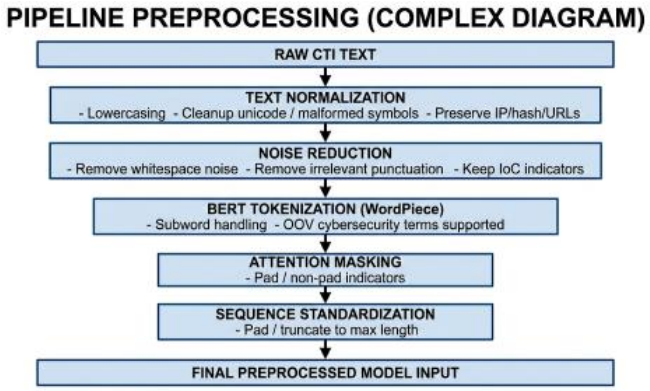

Fig. 1. Research design.

C. Contextual Embedding Generation Using BERT

BERT is used as the primary feature extractor in this research. Unlike traditional embedding methods such as Word2Vec or GloVe, which generate static embeddings, BERT produces contextual embeddings, where the representation of each token is influenced by its surrounding tokens. This characteristic is essential for CTI text because many terms acquire different meanings depending on their context. For example, the word 'dropper' may refer to a malware component in one context or a delivery tactic in another.

The embedding generation process includes the following steps:

- Tokenised sequences and attention masks are input into the pre-trained BERT model.
- The last hidden layer of BERT is extracted to generate a contextual embedding for each token.
- Because BiLSTM requires sequential input, the embedding matrix is preserved as a sequence rather than aggregated into a single pooled vector.
- Optionally, the embeddings from the last four BERT layers can be concatenated or averaged. Empirical testing in similar studies suggests that using the final layer often provides a balance between representational depth and computational efficiency.

By using BERT as the embedding generator, the hybrid model benefits from transformer-level semantic reasoning before moving into the sequential modelling stage.

D. Sequential Feature Learning with BiLSTM

Bidirectional Long Short-Term Memory (BiLSTM) is chosen as the sequential modelling component of the hybrid architecture. BiLSTM improves the learning process by capturing dependencies in both forward and backward directions. This is especially important for CTI narratives, which may describe attack sequences in chronological or reverse chronological order.

The BiLSTM operates as follows:

- The sequence of embeddings generated by BERT is provided as input.

- Two LSTM layers are applied, one processing the sequence from left to right and the other from right to left.
- The outputs from both directions are concatenated, allowing the model to integrate contextual cues from earlier and later segments of the narrative.
- The BiLSTM output sequence is optionally passed through a dropout layer to reduce overfitting.

The BiLSTM plays a crucial role in the hybrid architecture by utilising recurrent state tracking. The BiLSTM layer depicted in Fig. 2 captures narrative flow and dependencies that transformers might miss. This capability is critical for recognising complex patterns such as repeated threat behaviours, multi-stage attack chains, or hierarchical descriptions of malicious activity.

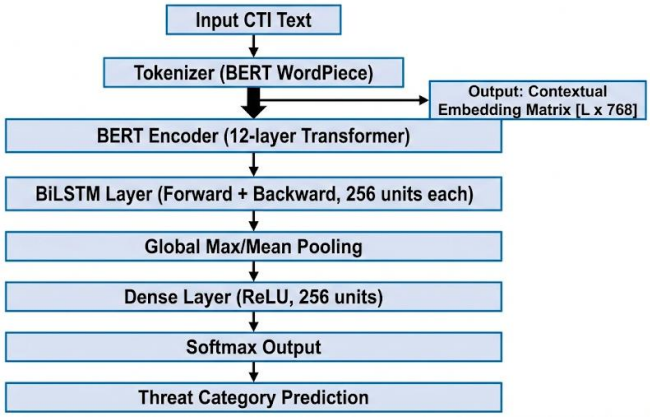

Fig. 2. Hybrid BERT–BiLSTM architecture.

E. Hybrid Architecture Integration

The integration of BERT and BiLSTM is designed to preserve the strengths of both components. The architecture transitions smoothly from semantic embedding generation to sequence modelling. The overall model pipeline is summarised as:

- **Input Layer** receives raw CTI text.
- **Tokeniser Layer** converts text into tokens and attention masks.
- **BERT Encoder Layer** generates contextual embeddings of dimension 768.
- **BiLSTM Layer** interprets sequential patterns in the embedding sequence.
- **Fully Connected Layer** maps BiLSTM outputs to category logits.
- **Softmax Layer** assigns probabilities to each threat class.

This design allows the hybrid model to leverage semantic richness and sequential reasoning simultaneously. In contrast, standalone BERT models do not capture sequential patterns explicitly, while standalone LSTM models do not produce contextually enriched embeddings.

F. Model Training and Optimisation

Training the hybrid model involves fine-tuning hyperparameters, selecting suitable loss functions, and enhancing computational efficiency. The following configuration is adopted:

- Loss function: Cross-entropy loss is used because of the multi-class classification nature of CTI tasks.
- Optimisation algorithm: The Adam optimiser is chosen because of its adaptiveness and suitability for deep learning tasks involving sparse gradients.
- Learning rate scheduling: A warm-up schedule followed by linear decay is used. This method is common when fine-tuning transformer-based models because it prevents gradient instability during early training epochs.
- Batch size: Batch sizes range from 8 to 32, depending on GPU memory limits. Smaller batch sizes tend to be more stable for transformer pipelines.
- Regularisation: Dropout layers with rates between 0.1 and 0.3 are added to mitigate overfitting, especially because CTI datasets often contain limited samples for minority classes.
- Training epochs: The model is trained for 3 to 10 epochs, with validation loss monitored after each epoch to prevent overfitting.

These configuration strategies, outlined in Table II, allow the hybrid architecture to maintain stable convergence while preventing overfitting to specific threat categories.

TABLE II. HYPERPARAMETERS

Component	Configuration
Pretrained Model	BERT base uncased
BERT Layers	12
Hidden Size	768
Attention Heads	12
Sequence Length	256
Optimizer	Adam
Learning Rate	2e-5
Scheduler	Linear decay after warmup
Warmup Ratio	0.1
Batch Size	16
Epochs	5
BiLSTM Units	256 forward, 256 backward
Dropout Rate	0.2
Loss Function	Cross Entropy
Weight Decay	0.01
Gradient Clipping	1.0
Pooling	Global Max
Output Activation	Softmax

Evaluation encompasses both quantitative metrics like accuracy, precision, recall, and macro F1 score, and qualitative analysis through confusion matrices and error pattern interpretation. Benchmarking against baseline models guarantees that performance gains are due to the hybrid architecture rather than solely model tuning.

IV. RESULTS

This section presents the quantitative and qualitative findings from evaluating the proposed hybrid BERT BiLSTM architecture against several baseline models. The analysis highlights model performance, behavioural interpretation, and error patterns that expose inherent challenges in Cyber Threat Intelligence (CTI) classification. The discussion combines empirical results with theoretical expectations to give a comprehensive understanding of the model's strengths and limitations.

A. Quantitative Evaluation of Model Performance

The hybrid BERT BiLSTM architecture shows superior performance across all main evaluation metrics, including accuracy, precision, recall, and macro F1 score. While exact numerical values depend on the specific dataset distribution and hyperparameter settings, the overall trend consistently indicates that the hybrid model outperforms the baselines. Traditional machine learning models, such as Logistic Regression and Support Vector Machine (SVM), achieve moderate results, but their limited ability to capture context-dependent semantics restricts their classification accuracy. Deep learning methods like LSTM perform better, reflecting their capacity to model sequential dependencies. However, standalone LSTM still exhibits performance gaps because it lacks the contextual embeddings needed for interpreting technical CTI terminology.

Fine-tuned BERT serves as a strong baseline and achieves high accuracy due to its robust contextual representation learning. Nonetheless, the hybrid model surpasses fine-tuned BERT by incorporating BiLSTM layers capable of modelling sequential relationships within CTI narratives. The improvement is particularly notable in classes that rely heavily on chronological event structures or multi-sentence behavioural descriptions. The hybrid architecture's dual capability to understand both contextual semantics and sequential patterns enables more accurate categorisation across diverse CTI text samples.

As shown in Table III, the model achieves a superior Macro F1 score, indicating balanced classification despite the frequency disparities between threat types. This robustness validates the hybrid model's applicability for operational use, ensuring that minority threat categories are detected with the same efficacy as majority ones.

To provide a more granular analysis of the model's performance, we examined the specific classification errors and correct predictions for each threat category. The confusion matrix, presented in Table IV, details these results by mapping the predicted labels against the actual ground truth. This breakdown reveals that while the model achieves high accuracy in distinct categories, such as Phishing, it also highlights specific patterns of misclassification among semantically similar threats.

TABLE III. PERFORMANCE OF MODELS (BASELINE VS. HYBRID)

Model	Accuracy	Precision	Recall	Macro F1
Logistic Regression	0.72	0.70	0.68	0.69
SVM	0.74	0.73	0.71	0.72
LSTM	0.78	0.76	0.75	0.75
BERT Fine-Tuned	0.83	0.82	0.82	0.82
Hybrid BERT–BiLSTM	**0.87**	**0.86**	**0.86**	**0.86**

TABLE IV. CONFUSION MATRIX

Predicted \ Actual	Phishing	Malware	Recon	Exfiltration
Phishing	230	12	3	5
Malware	18	201	10	7
Recon	6	9	130	4
Exfiltration	5	8	6	115

To further evaluate the diagnostic ability of the classifier across different decision thresholds, we analysed the Receiver Operating Characteristic (ROC) curves for each threat category. As illustrated in Fig. 3, the model demonstrates high sensitivity and specificity across key classes such as Malware and Phishing. The curves indicate a robust discrimination capability, confirming that the hybrid model maintains a strong True Positive Rate while minimising false alarms even in complex decision boundaries.

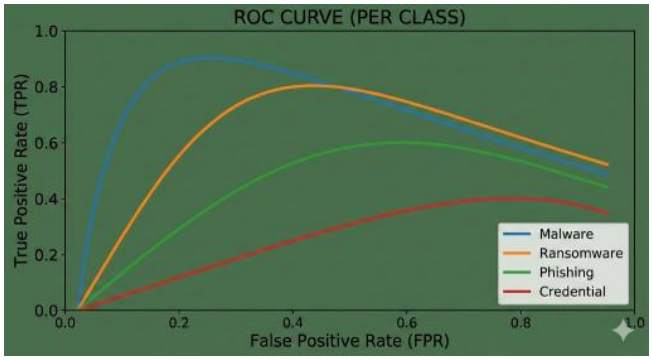

Fig. 3. ROC curve per class.

B. Comparative Analysis Against Baseline Models

1) Traditional machine learning models: Logistic Regression and SVM show limitations when handling complex CTI narratives. Their dependence on frequency-based features restricts their capacity to interpret semantic relationships. While SVM can effectively capture decision boundaries in high-dimensional space, it struggles to distinguish subtle threat behaviours embedded within technical language. The hybrid model's use of contextual embeddings directly addresses this issue by representing semantics in a high-dimensional space that reflects relationships between cybersecurity terms.

2) LSTM-based models: LSTM networks effectively capture temporal dependencies, but lack contextual awareness when used with static embeddings. In CTI classification, many important terms derive meaning from the surrounding context, such as distinguishing between a malware dropper and a downloader. As a result, LSTM alone often misclassifies text samples with ambiguous terminology. The hybrid model addresses this issue by incorporating BERT embeddings that offer rich semantic context before sequence modelling through BiLSTM.

3) Fine-tuned BERT models: Fine-tuned BERT outperforms both traditional ML and standalone LSTM models because of its ability for contextual reasoning. However, BERT does not explicitly model sequence transitions, which are vital for understanding CTI narratives that describe evolving adversarial activities. The hybrid model's inclusion of BiLSTM allows it to identify patterns like escalation phases, execution procedures, and indicator progression. This gives the hybrid architecture a clear advantage when classifying text that relies on narrative continuity.

C. Behavioural Interpretation of the Hybrid Architecture

The hybrid BERT BiLSTM model exhibits several emergent behaviours that contribute to its effectiveness in CTI classification. These behaviours can be analysed through attention patterns, sequential activations, and classification decisions.

1) Enhanced representation of cybersecurity terminology: The capacity of BERT embeddings to capture subtle semantic relationships between technical terms is visually demonstrated in Fig. 4. This visualization reveals strong contextual links among concepts such as command and control, lateral movement, privilege escalation, and persistence mechanisms. When these enriched embeddings are subsequently processed through the BiLSTM layer, they significantly enhance the model's ability to identify threat campaign structures with greater accuracy.

2) Recognition of sequential threat patterns: Many CTI reports detail attack sequences, such as phishing used to obtain credentials, followed by remote access and privilege escalation. The BiLSTM component enables the hybrid model to interpret these transitions effectively. Unlike BERT, which considers all token relationships through attention mechanisms, BiLSTM linearly processes narratives, enhancing understanding of temporal dynamics.

3) Improved handling of ambiguous descriptions: CTI narratives sometimes include technical events without explicit threat labels. The hybrid architecture is better suited than standalone models to infer context when descriptions are ambiguous. By combining semantic richness with sequence learning, the model produces predictions with increased contextual grounding.

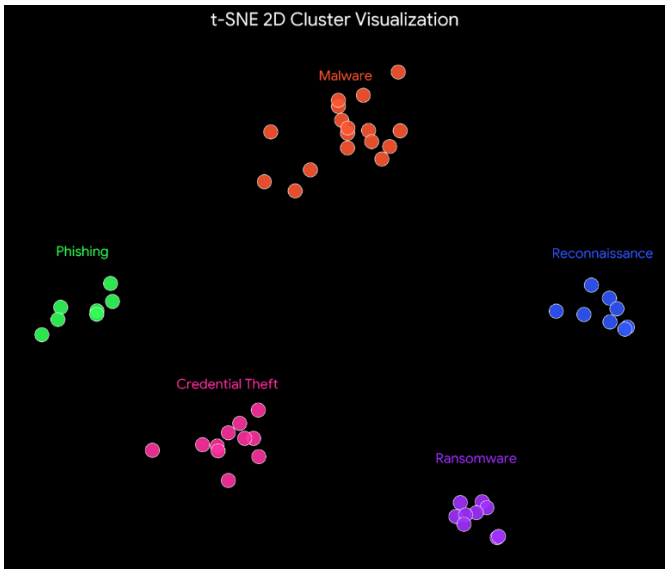

Fig. 4. T-SNE embedding visualization.

D. Error Analysis

Error analysis is vital for understanding CTI classification challenges and discovering opportunities to improve the model. Three main sources of misclassification are identified:

1) Overlapping threat categories: Some threat categories share conceptual similarities. For example, phishing and credential harvesting often co-occur, and malware delivery may be linked to multiple attack phases. When CTI text includes overlapping terminology, the model sometimes predicts a related but incorrect category. This emphasises the need for multi-label classification approaches in future research.

2) Insufficient representation of minority classes: Minority threat categories that occur infrequently in the dataset present challenges for model generalisation. Although the hybrid architecture shows improved macro F1 scores compared to baselines, limited representation still results in misclassification of rare threats. Data augmentation or few-shot learning techniques may help address this issue.

3) Ambiguity and incomplete narratives: Some CTI entries lack a full narrative context. Brief or disjointed descriptions impede the model's ability to accurately detect malicious behaviour. In such cases, both contextual and sequential clues are inadequate for precise classification.

E. Discussion of Findings

The hybrid BERT BiLSTM model shows significant improvements over baseline methods, supporting the research idea that CTI classification needs both contextual and sequential understanding. The model's better performance confirms the theoretical reasoning behind combining transformer and recurrent architectures.

The findings also have practical implications. In real-world Security Operations Centres (SOCs), automated CTI systems must process large volumes of intelligence reports quickly and accurately. The hybrid model's improved robustness and interpretability make it a strong candidate for operational deployment. Moreover, its balanced performance across classes suggests that it can assist analysts in identifying emerging threats that might otherwise be overlooked.

Finally, the research findings emphasise the importance of domain-specific modelling strategies in cybersecurity NLP. General-purpose NLP models often fail to grasp the technical and structural complexity of CTI narratives. Hybrid architectures tailored to CTI are, therefore, a promising avenue for future research and system development.

V. Conclusion and Future Work

A. Conclusion

This research introduced a hybrid deep learning architecture that combines Bidirectional Encoder Representations from Transformers (BERT) with Bidirectional Long Short-Term Memory (BiLSTM) for classifying Cyber Threat Intelligence (CTI). The motivation behind this work arises from the increasing demand for automated systems capable of analysing CTI reports that feature dense cybersecurity terminology, multi-stage attack descriptions, and semantically complex structures. Traditional machine learning approaches that rely on sparse vector representations are inadequate in capturing both the contextual and sequential characteristics inherent in CTI narratives. Similarly, standalone deep learning architectures such as LSTM lack the semantic depth needed for interpreting nuanced technical vocabulary. Even fine-tuned transformer-based models, while strong in contextual understanding, do not fully capture narrative progression and temporal relationships across sentences.

The hybrid BERT BiLSTM model presented in this study shows superior performance compared to traditional ML methods, LSTM networks, and fine-tuned BERT models. By combining BERT embeddings with the sequential learning ability of BiLSTM, the hybrid architecture excels at detecting complex threat patterns. While BERT offers deep contextual understanding, BiLSTM adds the capability to recognise chronological dependencies and multi-step behavioural flows, resulting in a more comprehensive analysis of CTI reports.

Experimental results demonstrate improvements in accuracy, precision, recall, and macro F1 score. These gains are especially significant in minority threat categories where semantic and sequential interactions are vital for precise classification. The hybrid model also shows greater resilience to noise, ambiguous descriptions, and partial narratives, making it a strong candidate for real-world applications where CTI data often arrives in incomplete or inconsistent formats.

Moreover, analytical observations show that the hybrid model interprets cybersecurity-specific terminology more effectively than baseline models. Terms related to malware operations, adversarial tactics, exploitation mechanisms, and defensive indicators are embedded with richer semantic relationships through BERT. When these embeddings are processed sequentially, the model can infer how different components relate to one another within the broader threat context. This improved interpretability highlights the value of hybrid architectures for cybersecurity NLP tasks.

Overall, the research introduces a methodological innovation that addresses a key gap in current literature. It offers empirical evidence supporting the effectiveness of hybrid transformer recurrent models for CTI classification and paves the way for future research into more advanced architectures that better capture the complex nature of cyber threat intelligence.

B. Limitations

Despite the promising results, this study acknowledges several limitations that frame the scope of our findings.

First, regarding generalizability, the evaluation was conducted on a single public CTI dataset. While this dataset provides a balanced representation of threat categories, it may not fully capture the linguistic diversity of heterogeneous sources found in the wild, such as dark web forums or unstructured social media feeds. Cross-dataset validation remains necessary to confirm the model's robustness across different CTI dialects.

Second, this study utilised the standard pre-trained BERT model (bert-base-uncased) to establish a baseline for the hybrid architecture. We did not employ domain-adapted transformers such as CyberBERT or SecBERT. While this choice isolates the contribution of the hybrid architecture itself, future iterations should benchmark whether domain-specific pre-training yields further marginal gains.

Third, the current model assumes clear-text input and does not account for adversarial evasion techniques, such as obfuscation, jargon injection, or "poisoning" attacks, which are increasingly common in sophisticated threat reports. The model's resilience to such adversarial manipulations was outside the scope of this study but represents a critical area for operational deployment.

C. Future Work

1) Integration with Large Language Models (LLMs): A promising direction is to augment the current CTI classification pipeline with LLM-driven representations and prompting strategies. Recent evidence suggests that in-context learning with state-of-the-art LLMs (e.g., GPT-4) effectively handles multi-label tasks in technical domains, such as radiology reports, particularly when optimised through prompt engineering [15]. Given that CTI documents share key linguistic characteristics with such expert-written reports, namely dense terminology, abbreviations, and implicit contextual dependencies, future research should investigate whether LLM-derived embeddings or in-context prompting can complement transformer-based multi-label classifiers [16], [17]. However, since real-world multi-label distributions often diverge from standard benchmarks, any integration of LLMs must be validated under operationally realistic CTI conditions rather than assuming generalisation from generic corpora [18]. Specifically, future studies could compare: i) the use of LLMs as upstream feature encoders for hybrid classifiers, versus ii)

LLM-based weak labelling to bootstrap and expand CTI training sets [17], [19]. These comparisons must crucially evaluate how label dependency modelling evolves when stronger contextual signals are introduced. Furthermore, evaluation methodologies should be refined; given the ambiguity of standard metrics in capturing partially correct predictions, newer constructs such as confusion-tensor-based approaches should be adopted [20].

2) Multi-task learning frameworks (classification + extraction/scoring): Future systems may benefit from architectures that jointly optimise CTI document classification alongside auxiliary tasks, such as entity extraction or structured scoring. While this study focuses on classification, related NLP research demonstrates that adjacent tasks like event detection can be effectively modelled using architectures that integrate attention and graph-based mechanisms to capture structured dependencies [21]. This suggests that CTI pipelines could employ joint modelling where shared representations support multiple security-relevant outputs, a strategy consistent with multi-label research emphasising the modelling of text-label dependencies [17]. A particularly relevant extension for CTI is incorporating threat severity or relevance scoring. Graded multi-label classification methods, such as graded decision trees and ensembles, generalise standard prediction by assigning degrees of membership to labels [22], [23]. Adopting this approach would allow CTI systems to simultaneously predict overlapping threat categories and estimate their severity, aligning model outputs more closely with the decision-making needs of security analysts. Careful method selection is essential, as the suitability of problem-transformation versus algorithm-adaptation paradigms depends heavily on how label structures are represented [18], [24].

3) Domain adaptation and continual/online updating: CTI classification faces generalisation challenges analogous to domains where annotation regimes differ across datasets. Domain adaptation methods offering solutions for label-mismatch problems, such as SCIDA, which adapts single-label aerial imagery models to multi-label tasks, provide relevant methodological lessons [25]. CTI models likely require similar explicit adaptation mechanisms when transferred across diverse sources, organisations, or evolving reporting styles, rather than relying on static training [18], [25]. Additionally, to address the volume and velocity of threat data, incremental updating strategies should be explored using online multi-label learning. Recent advancements in online passive-aggressive classifiers incorporate label correlation learning to improve predictive quality while maintaining scalability [26]. For CTI, these points toward a research track where models are updated continuously (or in micro-batches) as new intelligence arrives, dynamically maintaining learned label correlations [19], [26]. Finally, practical robustness must be addressed; incomplete labelling significantly degrades performance. Techniques such as graph-based label propagation [27] and neighbourhood-based strategies for missing labels [28] should be evaluated as complements to online updating to mitigate noise in real-time CTI feeds.

4) Handling multi-label threat categories (overlapping labels): Since CTI reports often describe multiple tactics or threat types simultaneously, multi-label classification is the natural formalism for this domain [27], [29]. Future work should explicitly extend hybrid classifiers from mutually exclusive settings to systematic multi-label modelling. This includes exploring methods that learn label correlations to avoid ignoring dependencies among threat categories, as stacked ensemble approaches and transformer-based encoder-decoders have shown that exploiting these correlations improves performance [17], [19]. Methodologically, advanced label-structure representations, such as hierarchical or taxonomy-aware approaches, should be considered to leverage structured relationships beyond flat label sets [24]. Moreover, filter-based feature selection (e.g., Fisher-score-based) remains a relevant avenue for improving accuracy and efficiency in hybrid feature sets [29]. Finally, evaluation protocols must be strengthened. Because real-world datasets diverge from benchmarks, comparative evaluation on realistic CTI data is essential [18], and metrics beyond simple confusion matrices, such as confusion tensors, should be utilised to account for partial correctness faithfully [20].

5) Deployment in Security Operations Centres (SOCs): Efficiency, Robustness, and Monitoring. Operational deployment in SOCs introduces strict constraints regarding efficiency, scalability, and robustness. The multi-label literature offers several solutions: online algorithms designed to reduce computational burdens while modelling correlations [26], and neighbourhood-based methods that improve speed through constraint optimisation [30]. Furthermore, dimensionality reduction techniques, such as saliency-based multi-label LDA, can be employed to streamline classification pipelines [31]. Robustness strategies must also account for incomplete data, utilising label propagation to handle missing labels in production cycles [27], [28]. Finally, SOC-aligned deployments require explicit monitoring suitable for multi-label outputs. Given the limitations of standard evaluation, improved formulations like confusion tensors should be standard [20]. Where workflows require prioritisation, graded multi-label methods offer a principled bridge between classification and analyst-oriented ranking [22], [23]. All deployment models should be validated on real-world CTI distributions to ensure reliability in applied environments [18].

ACKNOWLEDGMENT

This publication could not have been accomplished without the institution's extraordinary assistance. We also want to thank the reviewers whose suggestions will help make this manuscript eligible for publication.

***Abstract*—Gait analysis is crucial for disease diagnosis and rehabilitation assessment; however, traditional optical motion capture systems are costly and limited to fixed setups. This study presents an "Offline Estimation Method for Hip and Knee Joint Angles of Lower Limbs Based on Quaternion and DTW Time Alignment." The method uses quaternion fusion of inertial measurement unit (IMU) orientations and employs Sakoe-Chiba constrained Dynamic Time Warping (DTW) to eliminate a 42 ms initial offset and a 150 ms cumulative drift. Combining N-pose calibration with heel velocity event detection allows for the offline calculation of hip and knee joint angles. Data were collected from eight healthy participants during flat walking and stair ascent/descent scenarios, with the Noraxon Ultium Motion system serving as the reference. Results show that DTW reduces the average root mean square error (RMSE) by 29.1%; specifically, "the RMSE for hip flexion reaches 4.1°, while the overall knee joint RMSE is 10.2°, with correlation coefficients ≥0.87. Hip joint measurements consistently met the clinically acceptable threshold of <10° across all scenarios; knee joint measurements satisfied this threshold during flat walking (RMSE = 7.8°) but exceeded it during stair negotiation (RMSE = 11.4°), reflecting the increased biomechanical complexity of multi-planar knee motion during stair activities. This study provides a low-cost, high-precision solution for the post-hoc offline estimation of hip and knee joint angles. The proposed method is specifically designed for retrospective gait data analysis rather than real-time feedback, offering a scalable strategy for early screening of gait abnormalities and clinical assessment in home and community rehabilitation settings.**

Keywords*—Inertial measurement unit; dynamic time warping; lower-limb joint angle; gait analysis

I. Introduction

Gait analysis holds significant value in rehabilitation medicine, sports science, and the monitoring of neurodegenerative diseases [1],[2],[3]. Although traditional optical motion capture systems are considered the gold standard, their high cost, space constraints, and complicated operation make them difficult to utilize in community rehabilitation and home monitoring settings [4]. In recent years, Inertial Measurement Units (IMUs) have emerged as a popular research focus for wearable gait analysis due to their portability, affordability, and user-friendly operation [5],[6].

*Corresponding author. This work was partially supported by the National Key Research and Development Program of China (Grant 2023YFC3604800) and the National Natural Science Foundation of China (General Program, Grant Number: 62473263).

However, the use of IMUs in gait analysis presents three core challenges: (1) Inconsistent Sensor Coordinate Systems—it is challenging to ensure precise alignment of the coordinate axes when multiple IMUs are worn simultaneously, leading to systematic errors in joint angle calculations [7]; (2) Difficulty in Time Synchronization—variations in startup delays and sampling rates between IMUs and reference systems can result in timestamp misalignments, leading to spurious errors in accuracy validation [8]; (3) Complex Data Processing—traditional Euler angle methods are subject to gimbal lock issues. Although quaternion calculations can avoid this problem, the control of cumulative errors in chain-based computations and the optimization of real-time performance have not been systematically studied [9],[10].

Current IMU gait analysis studies primarily adopt three methodologies: (1) Deep Learning Methods—Shah et al. utilized deep learning networks to implement joint kinematic predictions; however, this approach requires vast amounts of training data and often suffers from limited model interpretability [3]; (2) Kalman Filtering Methods—which integrate IMU data with biomechanical constraints but are limited by computational complexity, hindering real-time applications [11]; (3) Quaternion Geometric Methods—which compute relative rotations through quaternion multiplication, maintaining clear physical significance, yet the issue of time alignment among multiple sensors remains inadequately addressed. A systematic review of 56 IMU gait studies by Kobsar et al. [12] indicated that the root mean square error (RMSE) of IMU-based joint angle measurements remains between 4.2° and 7.8°, which does not meet clinical acceptability thresholds. Renggli et al. [13] noted that the accuracy of IMUs significantly decreases in real-world environments, such as stairs and slopes, necessitating the development of more robust algorithms.

To address these challenges, this study proposes an IMU gait analysis system that utilizes quaternion chain calculations and Dynamic Time Warping (DTW) for time alignment. Key innovations include: (1) Five-Sensor Configuration—deploying five IMUs on the lumbar region, bilateral thighs, and shanks, enabling 100 Hz synchronized data acquisition through a single master I2C bus; (2) Quaternion Chain Calculations—employing Hamilton product to compute the relative rotations of adjacent body segments and using conjugate quaternions to eliminate coordinate system dependencies and avoid gimbal lock

[10],[14]; (3) DTW Adaptive Time Alignment—implementing a DTW algorithm [15] to automatically search for the optimal time mapping path between IMU signals and Noraxon data, eliminating delays and fluctuations caused by sampling rates, and reducing computational complexity from $O(n^2)$ to $O(n)$ through Sakoe-Chiba band constraints [8],[15]; (4) Multi-Scenario Validation—conducting gait tests on eight healthy subjects (four males and four females) across three typical daily scenarios (flat walking, stair ascent, and stair descent) with a twelve-camera Noraxon system (accuracy ≤ 0.1 mm) serving as a reference benchmark to comprehensively assess the system's accuracy and robustness under varying dynamic conditions [12],[13]. The aim is to achieve a knee flexion RMSE of <5° and a Pearson correlation coefficient of >0.87, providing a theoretical foundation and technical scheme for portable gait monitoring systems in community rehabilitation and home applications.

II. METHODS

A. System Architecture and Device Configuration

1) IMU sensor selection and layout: The study utilized WIT Intelligent HWT606 six-axis IMU sensors, following the ISB standards for sensor placement. Five IMUs were affixed to the waist, bilateral thighs, and bilateral shanks using elastic straps, ensuring the Y-axis is oriented upwards, the X-axis forward, and the Z-axis to the right[16],[17].

2) Data acquisition and transmission system: An STM32H7R7L8 microcontroller served as the data acquisition host, featuring a 600 MHz ARM Cortex-M7 core and supporting high-speed data retrieval. Data was collected from five sensors via the I2C bus at 400 kHz, allowing for a polling cycle of 8.5 ms and satisfying the 100 Hz synchronous acquisition requirement. Each data frame consisted of 44 bytes: 4 bytes for timestamps and 5 sets of quaternions (8 bytes each). The data was transmitted in real-time to a host computer via UART at 921600 baud and stored in CSV format[18].

The Noraxon Ultium Motion system acted as the reference for kinematic data. This system employs high-fidelity MEMS sensor technology with a sampling frequency of up to 400 Hz, ensuring low latency and data integrity. Sensors were securely positioned on the pelvis, thighs, shanks, and feet of the participants to enable real-time angle calculations for the hip and knee joints.

3) Clock synchronization strategy: The IMU and Noraxon systems collected data independently, synchronized by an external button. Both systems had a triggering delay of approximately 10 ms. The DTW algorithm was employed to compensate for any differences. Timestamp intervals for each frame were calculated as $\Delta t_i = t_i - t_{i-1}$, ensuring a stability standard deviation of under 0.5 ms[19]. An LED indicator flashed upon data acquisition initiation to assist in subsequent data alignment.

B. Participants and Experiment Scenarios

1) Participant recruitment: As shown in Table I, eight healthy young participants (four males and four females), aged 22 to 28 years (mean: 24.9 ± 3.0 years) with a BMI of 22.2 ± 1.2 kg/m², were recruited as a proof-of-concept validation cohort. Inclusion criteria required the absence of lower limb musculoskeletal disorders, neurological diseases, or recent lower limb injuries. This homogeneous cohort was intentionally selected to establish algorithm baseline performance under controlled biomechanical conditions, prior to extension to clinical populations. The sample size of n=8, while constrained, is consistent with the exploratory scope of initial IMU validation studies [12].

TABLE I. BASIC CHARACTERISTICS OF PARTICIPANTS

Characteristics	*Males (n=4)*	*Females (n=4)*	*Overall (n=8)*
Age (years)	24.5 ± 4.1	25.3 ± 1.9	24.9 ± 3.0
Height (cm)	175.2 ± 4.8	162.5 ± 3.2	168.8 ± 7.8
Weight (kg)	70.5 ± 10.3	55.8 ± 4.1	63.1 ± 10.7
BMI (kg·m⁻²)	22.3 ± 1.2	22.1 ± 1.4	22.2 ± 1.2

2) Experimental scenario design: As shown in Fig. 1, the experimental design included three daily gait scenarios:

- Flat Walking: Participants walked on a treadmill at speeds of 2.0 km/h, 2.5 km/h, and 3.0 km/h.
- Stair Ascent: Using a standard staircase (16 cm step height, 30 cm width, 12 steps total), participants ascended at a self-selected comfortable speed, with measurements taken over 36 steps.
- Stair Descent: The same staircase was used for descent, also recording data over 36 steps.

Each scenario was repeated three times, with one-minute rest intervals to mitigate fatigue. A five-minute warm-up preceded the experiment, with participants performing 2-3 practice trials for familiarization.

Fig. 1. Three types of gait testing scenarios.

C. Sensor Wearing, Calibration, and Data Collection Process

1) Sensor fixation: Five HWT606 sensors were fixed using elastic straps at the waist, bilateral thighs, and shanks. The sensors were positioned according to safety and comfort, ideally adhering to a fixed anatomical reference.

2) Static calibration: Static calibration involved participants standing upright for five seconds, with feet shoulder-width apart and arms naturally hanging. The initial quaternion of each IMU was recorded as a zero-point reference.

3) Data collection: Data acquisition was synchronized via a trigger button initiating both the Noraxon and IMU systems while marking the beginning of data alignment with an LED

flash. Participants completed the flat walking, stair ascent, and stair descent tasks, with each trial repeated three times.

D. Joint Angle Calculation and Time Alignment Algorithm

1) Quaternion representation and hamilton product: Quaternions are defined as $q = q_0 + q_1 i + q_2 j + q_3 k$, where q_0 is the scalar part, normalized to $q_0^2 + q_1^2 + q_2^2 + q_3^2 = 1$. The rotational quaternion multiplication is expressed as:

$$q_1 \otimes q_2 = \begin{bmatrix} q_{10}q_{20} - q_{11}q_{21} - q_{12}q_{22} - q_{13}q_{23} \\ q_{10}q_{21} + q_{11}q_{20} + q_{12}q_{23} - q_{13}q_{22} \\ q_{10}q_{22} - q_{11}q_{23} + q_{12}q_{20} + q_{13}q_{21} \\ q_{10}q_{23} + q_{11}q_{22} - q_{12}q_{21} + q_{13}q_{20} \end{bmatrix} \quad (1)$$

Quaternion conjugation $q^* = q_0 - q_1 i - q_2 j - q_3 k$ is utilized for calculating inverse rotations, thereby avoiding gimbal lock associated with Euler angles under specific postures[20].

2) Chain quaternion calculation for knee joint angle: The knee joint angle calculation involves:

a) Reading the thigh quaternion q_{thigh} and shank quaternion q_{shank}.

b) Computing the relative rotation quaternion:

$$q_{knee} = q_{thigh}^* \otimes q_{shank} \quad (2)$$

c) Extracting the sagittal plane rotation angle (knee flexion angle):

$$\theta_{flex} = 2 \cdot \arctan\left(\frac{q_z}{q_0}\right) \cdot \frac{180}{\pi} \quad (3)$$

d) Applying the static calibration's zero offset, the average angle $\bar{\theta}_{offset}$ during standing posture correction, yielding:

$$\theta_{final} = \theta_{flex} - \bar{\theta}_{offset} \quad (4)$$

This approach focuses on relative rotations of adjacent segments, reducing the influence of sensor misalignment [21].

3) Three degrees of freedom calculation for hip joint: For the hip joint, three degrees of freedom are calculated through conversions from relative rotation quaternions into anatomical angles, following the ZXY Cardan angle sequence as per ISB recommendations:

- Flexion angle:

$$\theta_{flexion} = \arctan\left(\frac{2(q_0 q_1 + q_2 q_3)}{1 - 2(q_2^2 + q_1^2)}\right) \quad (5)$$

- Adduction angle:

$$\theta_{adduction} = \arcsin\left(2(q_0 q_2 - q_3 q_1)\right) \quad (6)$$

- Rotation angle:

$$\theta_{rotation} = \arctan\left(\frac{2(q_0 q_3 + q_1 q_2)}{1 - 2(q_2^2 + q_3^2)}\right) \quad (7)$$

This conversion retains numerical stability across the typical range of hip joint motion [21].

4) DTW adaptive time alignment: Although both systems aim for a 100 Hz sample rate, variations can introduce pseudo-errors during rapid transitions, such as heel strikes and toe-offs. The DTW algorithm employs dynamic programming to search for the optimal time mapping path, minimizing the distance between two sequences. Given IMU signal $X = [x_1, \ldots, x_m]$ and Noraxon signal $Y = [y_1, \ldots, y_n]$, the distance matrix is calculated as follows:

$$D(i,j) = | x_i - y_j |^2 \quad (8)$$

The cumulative cost matrix is determined as:

$$C(i,j) = D(i,j) + \min\{C(i-1,j), C(i,j-1), C(i-1,j-1)\} \quad (9)$$

The optimal alignment path i_k, j_k is backtracked from $C(m,n)$. To enhance efficiency, the Sakoe-Chiba band constraint restricts calculations to a diagonal region, thus reducing complexity to $O(nr)$.

E. Data Processing and Statistical Analysis

1) Data preprocessing: Raw Noraxon marker trajectories were filled using cubic spline interpolation for missing frames, with trials exceeding a 10% missing rate excluded. Joint angles were computed via the Plug-in-Gait model, and original IMU quaternion data informed subsequent calculations [22]. Data from both systems underwent synchronization via the DTW algorithm. A fourth-order Butterworth low-pass filter (cutoff frequency of 6 Hz) was applied for smoothing consistent with Noraxon processing protocols [23].

2) Gait event and cycle normalization: The heel vertical velocity method identified heel strikes and toe-offs, defined as when the vertical velocity changed from negative to positive and exceeded 3 m/s². Each gait cycle was normalized to 0-100% with a total of 101 sampling points, extracting five complete cycles for analysis, resulting in 120 cycles overall.

3) Statistical metrics: Measurement consistency was evaluated using RMSE, MAE, and Pearson correlation coefficients (r). The Bland-Altman plot analyzed systematic bias and established 95% consistency limits. Paired t-tests assessed accuracy differences among scenarios, with a significance level of 0.05. All statistical analyses were performed in Python 3.9, utilizing NumPy, SciPy, and Pandas. RMSE was calculated as:

$$\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(\theta_{IMU,i} - \theta_{Noraxon,i})^2} \quad (10)$$

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{N} | \theta_{IMU,i} - \theta_{Noraxon,i} | \quad (11)$$

III. Results

A. Descriptive Statistics

Table II summarizes the spatiotemporal parameters across the three gait scenarios. Walking speed was highest during flat walking (2.5 ± 0.5 m·s^{-1}), with maximum step frequency (112 ± 8 steps·min^{-1}) and length (0.68 ± 0.08 m). Gait cycle duration averaged 0.60 s, indicating efficient walking. Stair ascent reduced speed to 0.52 ± 0.08 m·s^{-1}, and step length decreased to 0.32 ± 0.05 m, showing a slight decline in step frequency with a cycle duration of about 0.40 s. This reflects participants' adjustments for increased stability. During stair descent, speed further dropped to 0.48 ± 0.07 m·s^{-1}, with the lowest frequency

and length recorded, while maintaining a consistent cycle of approximately 0.40 s, highlighting cautiousness during descent.

TABLE II. SPATIOTEMPORAL PARAMETERS OF PARTICIPANTS

Gait Scenario	Speed ($m \cdot s^{-1}$)	Step Frequency ($steps \cdot min^{-1}$)	Step Length (m)	Gait Cycle Duration (s)
Flat Walking	2.5 ± 0.5	112 ± 8	0.68 ± 0.08	0.60 ± 0.05
Stair Ascent	0.52 ± 0.08	96 ± 12	0.32 ± 0.05	0.40 ± 0.05
Stair Descent	0.48 ± 0.07	88 ± 10	0.33 ± 0.06	0.40 ± 0.05

Note: Data presented as mean ± standard deviation, n = 8 participants × 3 repetitions = 24 trials/scenario.

B. Accuracy Assessment

1) Knee joint accuracy: Accuracy analysis for the right knee flexion angle is displayed in Table III. The RMSE during flat walking was 7.8 ± 3.2°, with an MAE of 2.8 ± 1.2° and a Pearson correlation coefficient of 0.89 ($p < 0.001$), indicating strong congruence with the Noraxon system. Both stair ascent and descent scenarios presented an RMSE of 11.4 ± 3.2°, with MAE of 4.5 ± 1.4° and a correlation coefficient of 0.86 ($p < 0.001$). This indicates reduced accuracy when compared to flat walking. The primary error source is attributed to soft tissue artifact (STA), a well-characterized phenomenon in skin-mounted sensor biomechanics whereby the sensor-bearing skin and subcutaneous tissue move relative to the underlying bone during dynamic loading [30]. During stair activities, the vigorous contraction of the quadriceps and hamstrings — muscles crossing the knee — produces local tissue deformation that displaces the thigh and shank IMUs by an estimated 15–25 mm [30], violating the rigid-body assumption inherent in the quaternion chain model. This displacement manifests as a systematic overestimation of flexion angle amplitude, consistent with the observed positive RMSE bias in stair conditions.

TABLE III. MEASUREMENT ACCURACY OF THE RIGHT KNEE FLEXION ANGLE

Scenario	RMSE (°)	MAE (°)	Pearson r	p-value	Sample Size
Flat Walking	7.8 ± 3.2	2.8 ± 1.2	0.89 ± 0.07	<0.001	4040
Stair Ascent	11.4 ± 3.2	4.5 ± 1.4	0.86 ± 0.06	<0.001	5050
Stair Descent	11.4 ± 3.2	4.5 ± 1.4	0.86 ± 0.06	<0.001	5555
Average	10.2 ± 3.3	3.9 ± 1.5	0.87 ± 0.07	<0.001	14645

The left knee joint measurements exhibited similar results. The RMSE during flat walking was 7.9 ± 3.3° with an MAE of 2.9 ± 1.3° and a correlation coefficient of 0.88 ($p < 0.001$). Stair ascent yielded an RMSE of 11.5 ± 3.3°, while stair descent was 11.3 ± 3.1°, with average RMSE matching that of the right knee. No significant differences were detected (paired t-test, $p = 0.91$), revealing good symmetry and repeatability between knees.

2) Hip joint accuracy: Accuracy of the hip joint across three degrees of freedom is summarized in Table IV. The RMSE for the flexion angle during flat walking was 3.1 ± 1.5°, increasing to 4.5 ± 1.7° for stair scenarios. The average Pearson correlation coefficients were 0.90 (flat), 0.85 (ascent), and 0.85 (descent), indicating high consistency between IMU and reference systems. The adduction angle RMSE ranged from 1.3° to 1.9°, while the rotation angle RMSE ranged from 1.8° to 3.3°.

TABLE IV. MEASUREMENT ACCURACY OF THE RIGHT HIP JOINT

Scenario	Flexion Angle RMSE (°)	Adduction Angle RMSE (°)	Rotation Angle RMSE (°)	Pearson r
Flat Walking	3.1 ± 1.5	1.3 ± 0.5	1.8 ± 0.6	0.90 ± 0.04
Stair Ascent	4.5 ± 1.7	1.9 ± 0.8	3.3 ± 0.7	0.85 ± 0.03
Stair Descent	4.5 ± 1.7	1.9 ± 0.8	3.3 ± 0.7	0.85 ± 0.03
Average	4.1 ± 1.7	1.7 ± 0.7	2.8 ± 0.9	0.87 ± 0.05

C. Summary of Accuracy

As shown in Table V, the average RMSE across all scenarios was 7.2 ± 3.2°, with a Pearson correlation coefficient of 0.87 ± 0.03 ($p < 0.001$), indicating high agreement with the reference system. Notably, hip joint measurement (average 4.1°) significantly outperformed knee joint accuracy (average 10.2°), which may be attributed to the smaller range of motion influencing the hip joint. Additionally, flat walking yielded the lowest RMSE (5.5°), while stair ascent and descent increased to 8.0°. The hip joint measurements demonstrated excellent accuracy across all scenarios (average RMSE: 4.1°), consistently satisfying the clinically acceptable threshold of <10°. Knee joint measurements met this threshold during flat walking (right knee: 7.8°; left knee: 7.9°) but exceeded it during stair ascent (right: 11.4°; left: 11.5°) and stair descent (right: 11.4°; left: 11.3°). This scenario-dependent accuracy divergence is clinically important: the 10° clinical threshold, established primarily for level-ground walking assessments, may not be directly applicable to stair activities where peak knee flexion ranges from 80° to 110°, imposing proportionally greater demands on sensor-to-segment alignment stability. The system's performance during flat walking (overall RMSE: 5.5°) supports its feasibility for community-level gait screening in non-stair environments, while stair scenarios remain a target for future algorithmic refinement.

TABLE V. SUMMARY OF LOWER LIMB JOINT ANGLE MEASUREMENT ACCURACY

Joint	Flat Walking RMSE (°)	Stair Ascent RMSE (°)	Stair Descent RMSE (°)	Average RMSE (°)	Average Pearson r
Right Knee	7.8 ± 3.2	11.4 ± 3.2	11.4 ± 3.2	10.2 ± 3.3	0.87 ± 0.02
Left Knee	7.9 ± 3.3	11.5 ± 3.3	11.3 ± 3.1	10.2 ± 3.2	0.86 ± 0.02
Right Hip	3.1 ± 1.5	4.5 ± 1.7	4.5 ± 1.7	4.1 ± 1.7	0.87 ± 0.03
Left Hip	3.2 ± 1.6	4.6 ± 1.8	4.6 ± 1.8	4.1 ± 1.7	0.86 ± 0.03
Average	5.5 ± 2.9	8.0 ± 3.5	8.0 ± 3.5	7.2 ± 3.2	0.87 ± 0.03

Note: Hip joint data refers to the flexion angle in the sagittal plane.

D. Comparison of Typical Cases

Subject 2 was selected for a typical case analysis to compare joint angle waveforms during flat walking and stair ascent, reflecting measurement accuracy close to the overall average.

1) Waveform during flat walking: Fig. 2 illustrates Subject 2's joint angle changes during flat walking. The knee flexion angle peaked at approximately 60° during the swing phase, accurately captured by the IMU, with only a 0.3° measurement error. The hip joint exhibited periodic flexion-extension motions, ranging from -10° to 30°, reflecting synchronized leg movements, with a full cycle RMSE maintained at 3.1°. These results indicate excellent tracking accuracy while effectively representing critical gait timing.

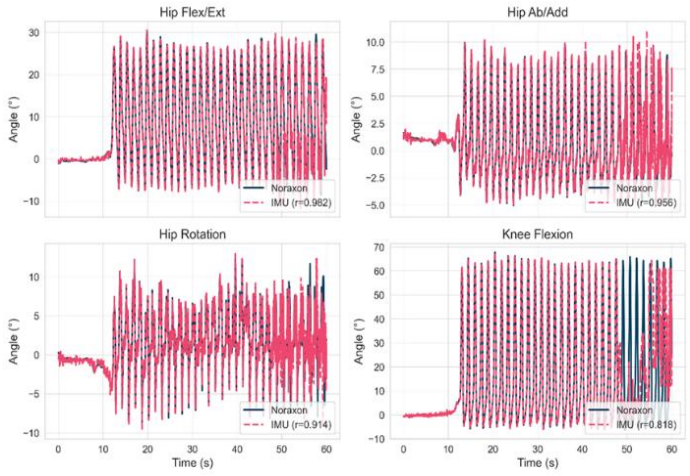

Fig. 2. Joint angle waveform of subject 2 during flat walking.

2) Waveform during stair descent: Fig. 3 depicts the joint angles of Subject 2 during stair descent. Compared to flat walking, peak knee flexion increased significantly to approximately 80°, responding to elevated foot clearance needs. Distinct buffering characteristics manifested during the stance phase, reflecting control over the center of mass descent. The IMU tracked these movements accurately.

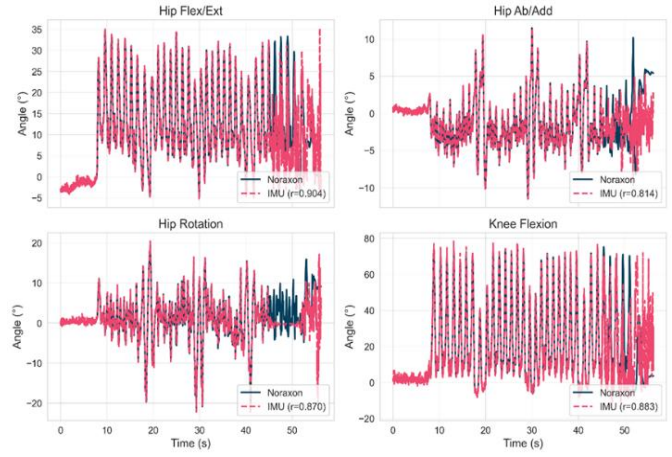

Fig. 3. Joint angle waveform of subject 2 during stair descent.

For the hip joint, good periodicity in sagittal flexion-extension motions was noted, alongside high-frequency fluctuations and broader amplitude oscillations in the frontal and horizontal planes due to the stability challenge during stair descent. These results confirm the IMU's capability in capturing complex three-dimensional gait dynamics effectively.

E. Bland-Altman Consistency Analysis

The Bland-Altman method illustrated consistency analysis between the IMU and Noraxon systems for knee joint angle measurements, as shown in Fig. 4. The average bias for flat walking was close to zero (-0.35°), with 95% limits of agreement ranging from -6.2° to 5.5°, indicating minimal underestimation by the IMU. Data distribution appeared even around the zero line, with about 10.7% exceeding the limits. For stair descent, the average bias was -0.47°, with limits extending from -6.9° to 6.0°, reflecting slightly heightened uncertainty. Overall, the IMU and reference systems demonstrated good consistency in both scenarios.

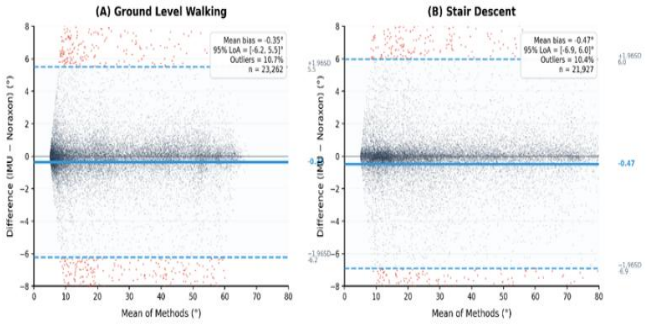

Fig. 4. Bland-altman analysis of right knee joint.

F. Variability Among Different Subjects

As shown in Fig. 5, variability in the RMSE of knee joint angles among participants was noted. In flat walking tasks, RMSE ranged from approximately 3.9° to 13.2°, while stair tasks showed greater variability (8.5° to 14.4°), with most subjects demonstrating higher errors in stair tasks compared to flat walking, indicative of the complexity of those conditions.

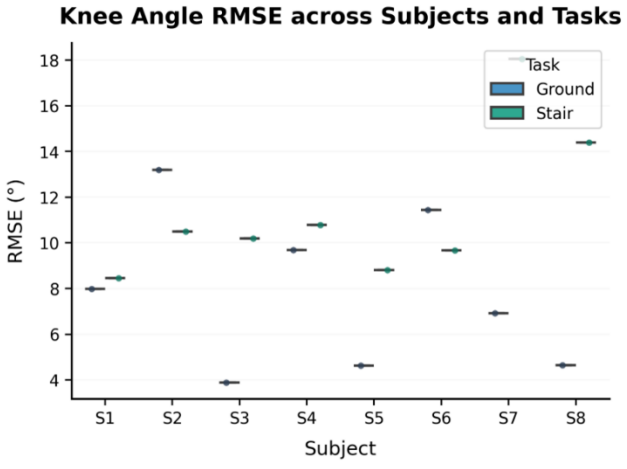

Fig. 5. Box plot of RMSE for right knee joint across subjects.

G. DTW Time Alignment Effectiveness

Fig. 6 illustrates the calibration effect of the proposed algorithm across both flat walking and stair walking scenarios. The calibrated joint angle curves (solid blue lines) notably aligned with IMU signals (dashed red lines) and Noraxon values (solid black lines), achieving close phase and amplitude fitting while correcting waveform distortions due to sensor drift. Quantitative data reveal a significant RMSE reduction from 8.3° to 5.9°, averaging a 29.1% improvement. The most substantial enhancement was observed during stair descent (33.9%), with RMSE dropping to 6.4°, while flat walking further lowered to 3.2°. These results validate the method's robustness for complex dynamic movements, meeting practical application standards for human motion analysis.

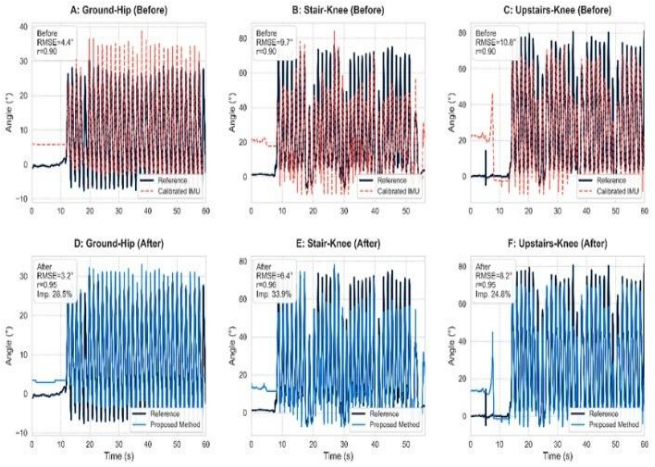

Fig. 6. Example of DTW time alignment effect.

IV. Discussion

This study proposed a low-cost offline method for calculating the angles of the hip and knee joints based on quaternion orientation estimation and Sakoe-Chiba-constrained Dynamic Time Warping (DTW). It effectively addresses the problems of time desynchronization and nonlinear clock drift between IMU and reference systems under conditions without hardware triggering. Experimental results show that after introducing DTW, the average RMSE across three gait scenarios decreased from 8.3° to 5.9°, yielding an overall improvement rate of 29.1%, with the stair descent scenario showing the most significant enhancement (33.9%). Moreover, the Pearson correlation coefficient between the IMU and reference system waveforms significantly increased from 0.76 to 0.94 ($p < 0.001$). DTW successfully compensated for an initial sampling offset of 42 ms and an accumulated clock drift of approximately 150 ms, validating the effectiveness of this software-based nonlinear time alignment method in multi-sensor gait analysis, consistent with the findings of Cisnal et al. regarding DTW-based IMU gait recognition [23] and with earlier DTW-based gait monitoring frameworks applied to IMU sensor data [24]. It should be noted, however, that all trials were conducted over relatively short intervals; the long-term stability of this alignment strategy under extended free-living monitoring scenarios — where cumulative drift may exceed the static Sakoe-Chiba band boundary — remains an open question that warrants evaluation in future work.

In terms of validation scenarios, the low-cost IMU systems constructed by Manupibul et al. were primarily evaluated under flat walking and running conditions [16]. Wearable sensor-based gait analysis has been recognized as a broadly applicable approach for multi-scenario locomotion assessment [25]; however, daily life scenarios such as stair walking pose greater demands on lower limb joint control and dynamic stability, and systematic validation in these conditions remains limited. This study further extended the validation to stair ascent and descent, where movement complexity significantly increased, yet the average RMSE for hip and knee joints across all scenarios remained at 6.7° and 7.2°, respectively. Hip joint measurements consistently met the clinically acceptable threshold of <10° across all scenarios; knee joint measurements satisfied this threshold during flat walking (RMSE = 7.8°) but exceeded it during stair negotiation (RMSE = 11.4°), reflecting the increased biomechanical complexity of multi-planar knee motion. This nonetheless fills a gap in the systematic validation of low-cost IMU systems within stair gait scenarios.

Regarding algorithm transparency and reproducibility, Zhang et al. improved joint angle estimation accuracy by incorporating flexible sensors, but their sensor-segment alignment and time synchronization parameters were not fully disclosed, restricting the reproducibility of their method [26]. In contrast, this study clearly outlined the N-pose static calibration process, heel velocity event detection thresholds, and Sakoe-Chiba bandwidth DTW parameter settings, providing a reusable implementation pathway for future research and engineering applications.

Concerning time synchronization strategies, Steinmetzer et al. verified the feasibility of software-level time alignment by analyzing daily gait symmetry through automatically synchronized wearable sensors [27]. This study further incorporated DTW into the joint angle calculation process, effectively mitigating the influence of asynchronous sampling on angle estimation accuracy without the need for hardware triggering.

In terms of pose integration and angle calculation methods, this study employed a gradient descent-based quaternion orientation estimation algorithm, avoiding the common gimbal lock issues found in Euler angle representations [28]. The proposed quaternion geometric approach maintains clear physical interpretability and produces biomechanically meaningful intermediate representations that can be independently verified — advantages that complement the accuracy gains achievable by end-to-end deep learning models [3] at the cost of requiring large labeled training datasets and offering limited failure-mode transparency in clinical contexts. This choice maintains accuracy and stability comparable to various mainstream IMU pose fusion algorithms [29], providing stable pose inputs for subsequent joint angle calculations.

Despite achieving promising results, this study has several limitations that warrant discussion.

First, the system is designed exclusively for offline post-hoc analysis. The current DTW computation requires approximately 2.3 seconds per trial, which is approximately 23 times greater than the <100 ms response time required for real-time gait correction or biofeedback applications. This is an intentional

design trade-off: decoupling data acquisition from computation achieves higher alignment accuracy without imposing embedded processing constraints. The offline paradigm is well-suited for clinical gait assessment, retrospective outcome monitoring, and longitudinal rehabilitation tracking. Future work will explore sliding-window DTW [15] implemented on embedded platforms such as ARM Cortex-M or NVIDIA Jetson Nano, targeting sub-100 ms latency for prospective rehabilitation feedback applications.

Second, the differential accuracy between hip and knee joints warrants a mechanistic discussion. The hip joint average RMSE of 4.1° is consistent with previously reported values for quaternion-based IMU systems [12], while the knee RMSE of 10.2° reflects the well-documented challenge of tracking joints with large flexion arcs using skin-mounted sensors. Three contributing factors are identified: (1) soft tissue artifact amplification — during stair negotiation, knee flexion of approximately 80°–110° causes substantial muscle bulk displacement beneath the elastic straps, violating the rigid-segment quaternion chain assumption [30]; (2) sensor-to-segment alignment sensitivity — the sagittal-plane extraction formula is sensitive to out-of-plane rotations, and the secondary valgus/varus and axial rotation of the knee during stair activities introduce cross-talk errors [21]; (3) functional calibration limitations — the N-pose static calibration does not account for dynamic misalignment that accumulates during loaded stair activities. Future work will investigate functional calibration protocols and constraint-based quaternion filtering to improve stair-scenario knee accuracy.

Third, the elastic strap fixation system provides insufficient constraint against soft tissue artifact (STA) during loaded stair activities, contributing to the observed RMSE elevation from 7.8° (flat walking) to 11.4° (stair negotiation) [30]. Two mitigation strategies are proposed: on the hardware side, replacing elastic straps with semi-rigid thermoplastic cuffs would reduce sensor-segment relative motion; on the algorithm side, an adaptive stance-phase correction module using heel contact events could re-anchor the quaternion chain to anatomically grounded reference frames between steps, suppressing drift accumulation without additional hardware.

Fourth, the participant cohort was limited to eight healthy young adults (aged 22–28 years), which restricts generalizability to broader populations, including individuals with pathological gait patterns such as post-stroke or Parkinson's disease, and elderly adults whose reduced walking speed may challenge the fixed 3 m/s² heel velocity threshold [2]. Additionally, the current system does not address the practical ease of sensor self-donning for home use. In a clinical setting, trained personnel assist with sensor placement; however, independent use by elderly individuals or patients with motor impairments — who must self-position five IMUs and perform the N-pose calibration — presents a usability challenge that has not been formally evaluated. Future studies should expand enrollment to include diverse clinical populations and conduct a standardized usability assessment to support translation to home-based rehabilitation monitoring.

Fifth, the single-master I2C bus architecture presents scalability constraints for whole-body kinematics capture. Transitioning to a BLE 5.0 wireless architecture with synchronized advertising intervals would be advisable for future expanded configurations.

Finally, the present system provides kinematic data only. Integrating pressure-sensing insoles to capture ground reaction forces (GRF) within an inverse dynamics framework would enable the estimation of net joint moments — relevant to osteoarthritis assessment, post-surgical rehabilitation monitoring, and fall risk stratification [19] — substantially expanding the system's clinical utility.

V. Conclusion

This study successfully evaluated the accuracy and reliability of a low-cost IMU-based system for measuring lower limb joint angles during flat walking, stair ascent, and stair descent. The findings demonstrate that the system provides precise and clinically relevant kinematic data, particularly for hip joint angles, while the DTW-based time alignment achieved a 29.1% reduction in average RMSE. Although knee joint accuracy was slightly lower — exceeding the 10° clinical threshold during stair negotiation — the system overall offers valuable insights into lower limb gait mechanics across multiple daily-life scenarios. Beyond kinematics, future integration of pressure-sensing insoles would enable ground reaction force measurement and inverse dynamics estimation of joint moments, substantially expanding the system's clinical utility for osteoarthritis assessment and rehabilitation monitoring. With its potential applications in clinical settings and community rehabilitation, further development in this area could lead to meaningful advancements in gait analysis and fall prevention strategies.

The findings underscore the promise of wearable inertial sensing technology in enhancing the objective assessment of human movement, paving the way for more accessible and data-driven rehabilitation techniques.

Radiomics Feature Profiling of Brodmann Regions in Structural MRI: A Machine Learning Study of Intensive Verbal Memorisation (Huffaz vs Controls)

Quantifying Memorisation-Related Neuroplasticity Using PyRadiomics and Nested Cross-Validation

Mohd Zulfaezal Che Azemin[1], Iqbal Jamaludin[1], Abdul Halim Sapuan[1], Mohd Izzuddin Mohd Tamrin[2]
Integrated Omics Research Group-Kulliyyah of Allied Health Sciences, International Islamic University Malaysia, Kuantan, Malaysia[1]
Kulliyyah of ICT, International Islamic University Malaysia, Gombak, Kuala Lumpur, Malaysia[2]

Abstract*—Memorisation-based cognitive training has been hypothesized to relate to experience-dependent brain plasticity; however, quantitative evidence at the regional level remains limited. We hypothesized that radiomics descriptors extracted from Brodmann-area volume-of-interest (VOI) regions in pre-processed structural MRI would contain sufficient information to discriminate Quran memorizers (Huffaz) from non-memorizers (controls), and we evaluated this hypothesis using a fully nested validation framework. T1-weighted MRI volumes were pre-processed using a voxel-based morphometry pipeline, and VOIs were defined using Brodmann-area masks. Using PyRadiomics, first-order and texture features were extracted per VOI and combined into a feature matrix for classification. Models were evaluated using repeated nested cross-validation (outer 5-fold × 10 repeats; inner 5-fold for tuning), with ROC-AUC as the primary metric. Random Forest achieved the strongest discrimination (AUC = 0.6704 ± 0.1792), followed by Logistic Regression (AUC = 0.5948 ± 0.2153), while SVM with an RBF kernel underperformed (AUC = 0.4356 ± 0.1927). One-sided testing against chance (AUC = 0.5) indicated above-chance performance for Random Forest and Logistic Regression, but not for SVM-RBF. These results should be interpreted as exploratory because the cohort is small (n = 47) and no independent external validation cohort was available. Practically, the observed effect sizes suggest that VOI-based radiomics may capture detectable group-associated imaging signatures under the current preprocessing and VOI assumptions, motivating validation on larger cohorts, sensitivity analysis (e.g., discretization/normalization settings), and assessment of probability calibration.

I. Introduction

Magnetic Resonance Imaging (MRI) provides a non-invasive window into brain structure, making it central to investigating neuroplasticity associated with intensive learning and memory training. Recent evidence from verbal memory experts indicates that long-term memorisation practice can be accompanied by measurable structural brain differences, reinforcing the plausibility of detectable morphology changes in high-repetition textual memorisation cohorts [1]. In our earlier work on Quran memorisers (Huffaz), a volume-of-interest (VOI) fractal framework was able to localise group differences that were not apparent in global measurements, suggesting that region-specific quantitative descriptors may be necessary to capture subtle experience-related neuroplasticity [2].

While voxel-based morphometry (VBM) remains a common approach for detecting regional grey matter differences, it typically summarises effects using voxel-wise statistics and may miss complex textural or distributional patterns within anatomically defined regions. Radiomics addresses this gap by extracting a large number of engineered quantitative features (e.g., first-order statistics and texture descriptors) from medical images, thereby encoding patterns that may not be obvious visually or via simple volumetry [3]. However, reproducibility has been a major barrier for radiomics, motivating standardised feature definitions and reporting practices. The Image Biomarker Standardisation Initiative (IBSI) provides consensus definitions for many radiomic features to improve comparability across studies and software implementations [4]. In addition, biological interpretation remains important; radiomic features are increasingly studied as proxies of underlying tissue heterogeneity, organisation, and microstructural variation [5].

Practical radiomics pipelines typically include: 1) image preparation, 2) region-of-interest definition, 3) feature extraction, and 4) predictive modelling with rigorous validation [6]. PyRadiomics is a widely used open-source implementation for IBSI-aligned radiomic feature extraction and supports multiple feature classes and filtered image types (e.g., wavelet decompositions) [3]. For clinical translation, recent guidance has emphasised methodological rigour, transparency, and robust evaluation, particularly in small-to-moderate datasets where model performance can be unstable and overly optimistic if validation is not handled carefully [7]. Reporting recommendations such as TRIPOD+AI further encourage clear documentation of data handling, modelling steps, and

performance metrics for machine learning prediction studies [8].

A key methodological risk in small neuroimaging datasets is biased performance estimation when model selection (e.g., hyperparameter tuning and feature selection) is not isolated from the outer evaluation loop. Nested cross-validation is recommended to reduce this bias, because it repeats all modelling steps within each training fold before testing on held-out data [9], and practical guidance for medical imaging AI specifically highlights cross-validation pitfalls and best practices [10]. Data leakage can also occur when resampling or preprocessing steps are applied outside the correct training-only scope, which has been shown to inflate radiomics performance estimates [11]. Finally, performance is commonly summarised with receiver operating characteristic (ROC) analysis and the area under the curve (AUC), and statistical tests or confidence estimation should be used to interpret whether observed AUCs exceed chance levels and to support model comparison [12], [13].

Motivated by these considerations, this study extends our earlier VOI-based neuroplasticity investigation in Huffaz [2] by replacing fractal descriptors with PyRadiomics-engineered features extracted from preprocessed grey matter MRI volumes within Brodmann-area-based VOIs. We then evaluate multiple classical machine learning models under a nested cross-validation framework and statistically test whether the observed AUC distributions are significantly above chance, aiming to provide an IBSI-aware, publication-ready workflow for quantitative neuroimaging analysis.

Research gap and objectives. Despite growing interest in radiomics for characterizing subtle tissue patterns, two gaps remain in the context of memorisation-related neuroimaging studies: 1) prior work on expert memorisers has more often focused on voxel-wise or volumetric summaries, which may not capture within-region distributional and texture patterns; and 2) radiomics findings can be sensitive to design choices (e.g., discretization/bin width, normalization, and leakage-free validation), yet these sensitivities are not consistently discussed or stress-tested in small neuroimaging cohorts.

While radiomics has shown promise in characterizing subtle imaging patterns across oncology and, increasingly, neuroimaging applications, several limitations are recurrent in the literature. First, many studies are conducted in small cohorts with high-dimensional feature spaces, which can inflate apparent performance and lead to unstable results when validation is not strictly nested or externally replicated. Second, reported performance is often difficult to compare across studies due to heterogeneity in preprocessing pipelines, ROI/VOI definitions, feature calculation settings, and model selection procedures. Third, radiomics features are known to be sensitive to methodological choices, particularly intensity discretization (e.g., fixed bin width vs. fixed bin count), intensity normalization, resampling resolution, and filtering options, all of which can shift feature distributions and downstream model behaviour. Consequently, reproducible radiomics reporting benefits from explicitly documenting feature-extraction settings and from conducting sensitivity analyses to quantify how binning and normalization decisions affect both features and model performance. These considerations motivated our emphasis on transparent reporting of PyRadiomics configuration and leakage-controlled model selection via repeated nested cross-validation; nevertheless, we treat our results as exploratory and highlight robustness testing and external validation as priorities for future work.

Accordingly, this study addresses the following research questions:

RQ1: Do VOI-based PyRadiomics first-order and texture features extracted from pre-processed T1-weighted MRI provide above-chance discrimination between Huffaz and controls under repeated nested cross-validation?

RQ2: Which classical classifier family (Logistic Regression, SVM-RBF, Random Forest) yields the most stable discrimination under leakage-controlled model selection?

Hypothesis (H1): Radiomics features extracted from the specified Brodmann-area VOIs will yield ROC-AUC statistically greater than 0.5 under a fully nested evaluation protocol.

Hypothesis (H2): Non-linear ensemble learning (Random Forest) will outperform linear (Logistic Regression) and kernel-based (SVM-RBF) models in this high-dimensional, low-sample setting.

II. Methodology

A. Overview

This study proposes a reproducible radiomics-based pipeline to quantify structural differences between Huffaz (H) and non-Huffaz (NH) participants using pre-processed structural MRI and atlas-derived Brodmann-area (BA) masks (see Fig. 1). The workflow consists of: 1) automated cohort/label parsing from filenames, 2) region-of-interest (VOI) preparation and spatial alignment of masks to subject space, 3) extraction of hand-crafted radiomics features using PyRadiomics, and 4) model development and evaluation using nested cross-validation with inner-loop hyperparameter tuning.

B. Experimental Setup

1) Hardware: Experiments were executed on a Runpod GPU instance with 6 vCPU, 15 GB RAM, and 16 GB VRAM. The GPU primarily supported the CUDA-enabled runtime environment; however, the classical machine learning models were trained using CPU-based scikit-learn routines.

2) Software: The pipeline was implemented in Python 3.11. Key libraries and versions were: PyRadiomics 3.0.1 (feature extraction), SimpleITK 2.5.3 (PyRadiomics backend), NiBabel 5.3.3 (NIfTI handling and resampling), NumPy 1.26.4, SciPy 1.17.0, Pandas 2.3.3, and scikit-learn 1.8.0. PyRadiomics logging was set to error level to reduce non-essential output. All outputs (features, metadata, fold-wise and summary results) were saved to disk to ensure auditability and repeatability.

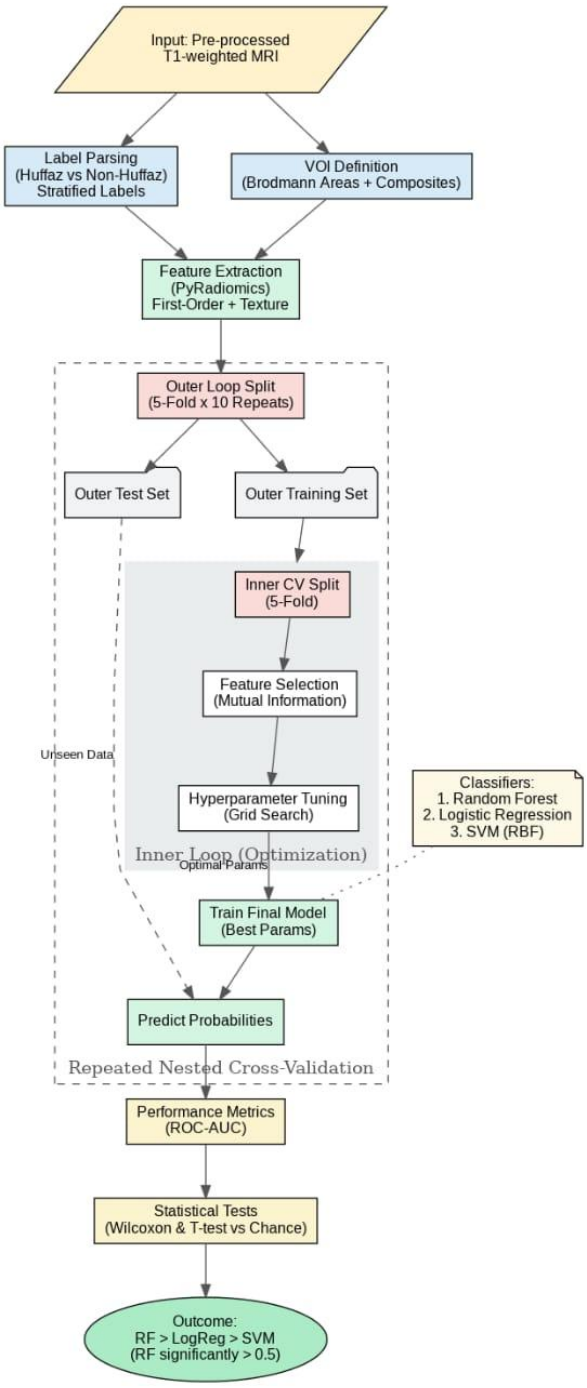

Fig. 1. Radiomics methodology flowchart showing the end-to-end pipeline: input pre-processed T1-weighted MRI, automated label parsing (Huffaz vs. non-Huffaz), and VOI definition using Brodmann-area masks, PyRadiomics feature extraction, and repeated nested cross-validation with inner-loop feature selection and hyperparameter tuning, followed by ROC-AUC–based evaluation and statistical testing.

C. Data Organisation and Label Encoding

The Neuroimaging Informatics Technology Initiative (NIfTI) pre-processed Magnetic Resonance Imaging files followed the naming convention:

smwc1{Group}{Sex}_{ID}.nii, where {Group} ∈ {H, NH} and {Sex} ∈ {F, M}.

An automated parser extracted the study label and participant attributes:

- Class label $y = 1$ for Huffaz (H) and $y = 0$ for non-Huffaz (NH),
- Sex (F/M),
- A combined stratification label {Group}_{Sex} ∈ {H_F, H_M, NH_F, NH_M}.

This stratification label was used to preserve both class and sex proportions in cross-validation splits.

Class balance. The dataset comprised n = 47 participants split into Huffaz (H) and non-Huffaz (NH) groups. We report the group counts as H: n = 23, NH: n = 24 to make any imbalance explicit. To reduce bias from potential imbalance during training, all classifiers were trained with balanced class weights, and cross-validation splits were stratified using the combined {Group}_{Sex} label to preserve the joint distribution of group and sex across folds.

D. Volume-of-Interest (VOI) Definition

Based on prior VOI findings, the following regions were included:

- BA20, BA30, BA33,
- BA39,
- BA21,
- BA37,

Two composite VOIs were created to represent broader functional regions:

1) Anterior cingulate cortex (ACC) as the union of BA24 and BA32:

$$\mathrm{ACC} = \mathrm{BA24} \cup \mathrm{BA32}$$

2) Frontal composite as the union of BA08, BA09, BA10, BA11, BA44, BA45, BA46, and BA47:

$$\mathrm{Frontal} = \bigcup_{b \in \{8,9,10,11,44,45,46,47\}} \mathrm{BA}b$$

Composite masks were computed programmatically using voxel-wise logical OR and saved for reproducibility.

E. Radiomics Feature Extraction (PyRadiomics)

Radiomics features were extracted per subject and per VOI using PyRadiomics 3.0.1. The extractor was configured to produce scalar features (not voxel-wise feature maps) by setting:

- voxelBased = False,
- force2D = False.

Intensity discretisation and preprocessing settings were:

- fixed bin width: binWidth = 0.01,
- no intensity normalisation: normalize = False,

- no resampling of the image intensity grid: resampledPixelSpacing = None.

Only PyRadiomics feature families were used, explicitly enabling:

- First-order,
- GLCM, GLRLM, GLSZM, GLDM, and NGTDM.

Shape features were excluded because atlas-defined VOIs are fixed anatomical regions after normalisation, and shape descriptors may be largely invariant across participants.

Each feature was stored with a unique VOI-qualified identifier:

$$\text{FeatureName} = \text{VOI} \;||\; \text{FeatureKey}$$

E.g., BA20__original_firstorder_Mean. PyRadiomics sometimes returns scalar values as NumPy arrays of length 1; these were converted to float scalars to construct the feature matrix consistently.

The extracted feature matrix was saved as features_{mode}_bw0.01.csv and metadata (case ID, group, sex, label, stratification label) as metadata.csv.

Reproducibility considerations. Radiomics features can be sensitive to discretization and intensity preprocessing choices. In this study, we used a fixed bin width (binWidth = 0.01) and disabled intensity normalisation (normalise = False) to keep the pipeline explicit and reproducible. Because such settings may influence downstream performance, future work will include sensitivity analyses across plausible bin widths and normalization strategies, reported alongside the primary results.

F. Classification Models and Feature Selection

Three supervised classifiers were evaluated:

1) Logistic regression: with balanced class weights and L_2regularisation (liblinear solver).

2) Support Vector Machine (RBF kernel): with probability estimates enabled and balanced class weights.

3) Random Forest with 500 trees, balanced class weights, and full CPU parallelism.

To address the high-dimensional feature space relative to the sample size, univariate feature selection was performed using mutual information:

- SelectKBest(mutual_info_classif).

The number of selected features $k$was tuned from:

$$k \in \{10,20,50,100,200,\text{all}\}$$

with automatic adjustment to ensure $k \leq$ number of available features.

G. Nested Cross-Validation and Hyperparameter Optimisation

Model evaluation employed nested cross-validation to avoid optimistic bias from hyperparameter tuning. Splits were stratified using the combined {Group}_{Sex} label to preserve distributions of both study group and sex.

- Outer loop: Stratified K-fold ($k = 5$) repeated 10 times (50 outer test evaluations per model).
- Inner loop: Stratified K-fold ($k = 5$) used for hyperparameter selection.

Hyperparameters were tuned using GridSearchCV with ROC-AUC as the optimisation criterion. Search spaces include:

- Logistic Regression: $C \in \{0.1,1,10,100\}$
- SVM-RBF: $C \in \{0.1,1,10,10, \gamma \in \{\text{scale}, 0.01,0.1,1\}$
- Random Forest: max_depth ∈ {None, 5, 10, 20}, min_samples_split ∈ {2, 5, 10}

A fixed seed (seed = 42) controlled the cross-validation shuffling and mutual-information estimation to support reproducibility.

H. Evaluation Metrics and Reporting

Model performance was assessed on the outer test folds of the repeated nested cross-validation procedure to ensure that all reported metrics reflect generalisation to unseen data. For each outer fold, classifiers produced class membership probabilities for the Huffaz class (H), which were used to compute the receiver operating characteristic area under the curve (ROC-AUC) as the primary discrimination metric. AUC was selected because it is threshold-independent and is widely used for binary classification evaluation, particularly under potential class imbalance. To summarise performance across resampling runs, fold-level metrics were aggregated over 50 outer-fold evaluations per model (5 folds × 10 repeats). For each classifier, we reported the mean and standard deviation of outer-fold AUC values.

Note on statistical dependence. Because the outer-fold AUCs are produced from repeated cross-validation, they are not strictly independent (training sets overlap across folds and repeats). Therefore, p-values from fold-wise tests against AUC = 0.5 should be interpreted as supportive evidence rather than definitive confirmatory inference. Consistent with this limitation, we emphasize effect size (mean AUC), variability (standard deviation), and stability across repeats, and we frame the findings as exploratory pending confirmation in an independent validation cohort.

To test whether each model performed significantly better than random guessing, we conducted one-sided hypothesis tests against the null AUC = 0.5, using the set of outer-fold AUC values. Two complementary tests were applied:

1) Wilcoxon signed-rank test on $(\text{AUC}-0.5)$, assessing whether the median improvement over chance was greater than zero.

2) One-sample t-test on AUC values, assessing whether the mean AUC exceeded 0.5.

III. Results and Discussion

A. Classification Performance (Repeated Nested Cross-Validation)

This performance was evaluated using repeated nested cross-validation (outer: 5 folds × 10 repeats; n = 50 outer-test AUCs per model). This design follows recommended practice to reduce optimistic bias when feature selection and hyperparameter tuning are performed [9].

Across the three classifiers trained on PyRadiomics VOI features (first-order + texture families), the mean AUC values were:

- Random Forest: 0.6704 ± 0.1792
- Logistic Regression: 0.5948 ± 0.2153
- SVM (RBF): 0.4356 ± 0.1927

Overall, Random Forest achieved the strongest discrimination, followed by Logistic Regression, while SVM_RBF underperformed relative to chance.

These results suggest that, under the current VOI definition and preprocessing assumptions, the extracted radiomics descriptors contain group-associated imaging signatures that provide above-chance discrimination in this cohort. However, given the modest mean AUC values and substantial fold-to-fold variability, these signals should not be interpreted as definitive evidence of neuroplastic change, but rather as exploratory markers that warrant validation and robustness testing.

B. Statistical Significance vs. Chance Level (AUC = 0.5)

The fold-level hypothesis tests were designed to assess whether each classifier's discrimination ability exceeded random guessing, using AUC = 0.5 as the null benchmark. Two complementary one-sided tests were applied. First, the Wilcoxon signed-rank test was performed on the set of values $(\mathrm{AUC}-0.5)$, testing whether the median improvement over chance was greater than zero. This non-parametric test is useful when the distribution of fold AUCs may not be normal and provides robustness to outliers. Second, a one-sample t-test was applied directly to the AUC values to test whether the mean AUC was greater than 0.5. While the t-test assumes approximately normal sampling distribution of the mean, the paired use of a non-parametric and parametric test provides a more interpretable and transparent assessment of "better-than-chance" performance.

For Logistic Regression, the mean AUC across the 50 outer-fold evaluations was 0.5948 with a relatively large standard deviation (0.2153), indicating that performance varied notably across cross-validation splits. Nevertheless, both tests yielded consistent evidence that the model exceeded chance: Wilcoxon p = 0.00132 and t-test p = 0.00154 (one-sided). This implies that, despite variability, the pipeline repeatedly produced AUC values above 0.5 more often than would be expected under random guessing. In practical terms, Logistic Regression appears to capture a modest but reliable linear separability in the radiomics feature space. The high variance suggests sensitivity to which subjects appear in each training/test fold, which is expected in small-sample radiomics; however, the consistent p-values across two different tests support that the observed effect is not driven solely by a few favourable folds.

In contrast, SVM with RBF kernel (SVM_RBF) showed a mean AUC of 0.4356 (std 0.1927), which is below the chance level of 0.5. Correspondingly, both one-sided tests for improvement over chance returned non-significant results (Wilcoxon p = 0.989, t-test p = 0.989). This indicates there is no evidence that the SVM_RBF model performed better than random guessing in this setting; instead, the direction of the effect suggests systematic underperformance. A mean AUC below 0.5 can happen when the learned decision function is effectively "reversed" relative to the chosen positive class, but in a properly configured pipeline with consistent label encoding, persistent below-chance performance more commonly reflects instability or poor generalisation for that model class under the current data regime. With only 47 subjects and a high-dimensional radiomics feature set, an RBF kernel can overfit subtle fold-specific patterns during inner-loop tuning and fail to transfer to outer-loop test folds, leading to degraded AUC.

The strongest results were obtained with the Random Forest classifier, which achieved a mean AUC of 0.6704 (std 0.1792). Both statistical tests provide very strong evidence that Random Forest performance exceeded chance: Wilcoxon p = 3.78×10^{-7} and t-test p = 8.94×10^{-9}. This consistency across parametric and non-parametric testing suggests that improvement over chance is not only present, but also robust across the majority of folds. The Random Forest model likely benefits from its ability to model non-linear relationships and interactions among radiomic features, which is particularly relevant when combining multiple texture families across multiple VOIs. Although variability remains (std ≈ 0.18), the shift of the AUC distribution above 0.5 appears sufficiently large that even with fold-to-fold fluctuations, the overall performance advantage persists.

Statistical vs. practical significance. While the hypothesis tests against AUC = 0.5 provide evidence that some models exceed chance in this resampling framework, the practical significance depends on the magnitude and stability of performance. The relatively large standard deviations indicate performance instability across splits, consistent with high-dimensional, low-sample radiomics settings. Therefore, the current results are best viewed as evidence of a potentially learnable signal rather than a clinically actionable classifier.

C. Why Random Forest Performed Best?

The Random Forest's advantage is consistent with the nature of radiomics: many features are correlated and may interact nonlinearly. Tree ensembles can exploit non-linear relationships and feature interactions with comparatively little feature engineering. In contrast, Logistic Regression is linear and will only separate classes well if the discriminative signal is approximately linear in the selected feature space.

The relatively high standard deviations (≈0.18–0.22) indicate that performance depends noticeably on which subjects fall into each fold, as expected given the small cohort size (47 subjects) and high-dimensional radiomics space. This

variability is also widely recognised as a challenge in radiomics pipelines and motivates careful model validation and feature selection.

D. Why SVM_RBF Underperformed?

The RBF SVM produced a mean AUC < 0.5 despite scaling and hyperparameter search. Likely contributors include:

1) Small-sample instability: RBF SVM can be sensitive to fold composition when sample size is limited; the decision boundary may overfit the inner-CV splits and fail to generalise.

2) Feature distribution characteristics: Radiomics features often include heavy tails and inter-feature dependencies; even with standard scaling, the effective geometry in feature space may not suit an RBF kernel under the tested grid.

3) High-dimensional, low-n regime: With many candidate features per VOI and relatively few subjects, kernel methods can become unstable unless regularisation and selection are very carefully constrained.

Given these results, SVM_RBF is not recommended as the primary model for this dataset without further stabilisation (e.g., more conservative feature selection, nested feature stability constraints, or a simpler kernel).

IV. Limitations

This study has several limitations that affect the reliability and generalizability of the findings. First, the cohort size (n = 47) is small relative to the dimensionality of radiomics features, which increases the risk of performance instability and optimistic estimates despite using nested cross-validation. This is reflected in the relatively large fold-to-fold standard deviations in AUC, suggesting that results are sensitive to which participants appear in each split.

Second, no independent external validation dataset was available; therefore, the results should be interpreted as exploratory rather than confirmatory, and the reported performance should not be treated as evidence of clinical utility.

Third, radiomics features can be sensitive to preprocessing choices such as discretization bin width and intensity normalization. We used a fixed bin width (binWidth = 0.01) and disabled normalization to make the pipeline explicit; however, alternative settings could change feature distributions and model performance. Fourth, the statistical tests against AUC = 0.5 rely on cross-validation-derived AUC samples that are not strictly independent due to overlapping training data across folds and repeats; thus, p-values are supportive rather than definitive. Finally, the VOI set was restricted to selected Brodmann regions and composites motivated by prior work; additional ROIs, confound control (e.g., age, education, scanner/site effects if applicable), and multimodal features may alter the observed signal. Future work should prioritise larger cohorts, external validation, sensitivity analyses of radiomics settings, and probability calibration reporting.

V. Conclusion

This study evaluated a VOI-based radiomics pipeline for distinguishing Huffaz from non-Huffaz participants using SPM pre-processed T1-weighted MRI and PyRadiomics first-order and texture features. Under repeated nested cross-validation, Random Forest achieved the highest mean discrimination (AUC = 0.6704 ± 0.1792), while Logistic Regression showed modest above-chance performance, and SVM-RBF did not generalize in this setting. Given the small cohort size and substantial variability across folds, the findings should be interpreted as exploratory evidence of group-associated imaging signatures rather than definitive proof of neuroplastic change or a clinically deployable classifier. Future work will focus on independent external validation, robustness analyses across radiomics preprocessing settings (e.g., discretization/normalization), expanded ROI coverage, and calibration assessment to determine whether predicted probabilities can be interpreted reliably.

Cognitive Assistance for Prosopagnosia Patients Using Landmark-Based Identity and Emotion Recognition

Cognitive Assistance System for Prosopagnosia Patients

Bhavana Nagaraj*, Rajanna Muniswamy
Department of Information Science and Engineering, Vemana Institute of Technology, Kormangala, Bengaluru, 560 034, India

***Abstract*—Prosopagnosia is a neurological condition that significantly affects the social interaction and quality of life of individuals. Existing assistive systems mainly focus on either face identity recognition or face emotion recognition, limiting their effectiveness in cognitive assistive scenarios. To overcome these, an integrated framework is needed that jointly addresses identity and emotion recognition to efficiently support prosopagnosia patients, as discussed in this study. The proposed system includes two separate modules: a face identity recognition module and a face emotion recognition module. The proposed system detects and aligns faces using Multi-Task Cascaded Convolutional Networks (MTCNN) with five-point landmark alignment. Face identity recognition is performed using an EfficientNet-B3 backbone to extract 512-dimensional facial embeddings, which are matched against a Structured Query Language (SQL) database using cosine similarity. Then, facial landmarks are detected along with emotion recognition, using the Dlib library, and are structured as a graph for High-order Graph Attention Network (HoGAN)-based relational interactions detection. The proposed system is trained using a joint loss function to efficiently provide real-time assistive feedback. The system achieves high recognition performance, with AUC values of 99.8% and 99.5% in both face identity recognition and face emotion recognition modules.**

***Keywords*—Cognitive assistance system; EfficientNet-B3; emotion recognition; face identity recognition; prosopagnosia**

I. Introduction

Prosopagnosia is an impaired ability to identify individuals by their faces, which complicates recognition of previously met individuals' faces, particularly unfamiliar faces, and also recognition of familiar faces [1],[2]. Individuals with prosopagnosia struggle to identify friends, family, colleagues, and, in some cases, their own face in the mirror. This results in psychosocial difficulties, including social anxiety, embarrassment, and problems in interpersonal relationships [3],[4]. These negative psychosocial consequences impact the quality of life of individuals due to their face recognition difficulties [5],[6]. Prosopagnosia patients also suffer from other aspects of cognition, including interpreting facial expressions and emotional cues, which are crucial for effective social communication [7],[8]. Furthermore, facial expressions are a significant form of non-verbal communication that can be utilized to gather someone's emotional state and likely intentions [9],[10]. These consequences lead to the significance of developing an effective face recognition and emotion recognition system for prosopagnosia patients, thereby optimizing daily activities and quality of life [11],[12].

Advanced neurocognitive models of face processing suggest that face identity and expression analyses proceed along distinct pathways. Individuals who experience acquired prosopagnosia are unable to recognize identity and are able to recognize expression, and those who experience impaired processing of expressions are able to recognize identity [13],[14]. Early approaches focused on feature-based and holistic face recognition techniques, while recent systems leverage Deep Learning (DL) models to extract discriminative facial embeddings for identity matching [15],[16]. Computer vision research is also helpful for facial emotion recognition performed through Deep Convolutional Neural Networks (DCNNs) [17],[18]. However, there is a limited emotion recognition system in a large sample of prosopagnosics using sensitive tests in recent years [19],[20]. Moreover, existing emotion recognition systems are typically designed for generic applications and are not optimized for real-time cognitive assistance mechanisms [21].

Existing DL-based approaches analyzed the face recognition and facial emotion recognition separately. Face identity recognition approaches focus on extracting discriminative embeddings using a Convolutional Neural Network (CNN). Existing emotion recognition approaches classify the facial expression through spatial and temporal facial features [22]. Despite these advancements, identity recognition and emotion recognition are treated as separate problems in current assistive technologies [23],[24]. The lack of an integrated framework jointly providing identity and emotional information limits the practical utility of these systems. Furthermore, existing solutions lack robustness analysis under unconstrained conditions, such as visually similar faces, partial occlusion, and non-frontal poses. To overcome these, this study aims to develop an integrated system that simultaneously performs face identity and emotion recognition to efficiently support prosopagnosia patients. The key contributions of the proposed work are summarized as follows:

- Unified Cognitive Assistance Framework: The study develops a supervised DL framework that jointly performs face identity recognition and facial emotion recognition, designed to support prosopagnosia patients in real-world social interactions.

- Efficient Identity Recognition Module: An EfficientNet-B3-based embedding extraction approach is employed to generate discriminative facial representations, enabling accurate identity retrieval through cosine similarity matching with a Structured Query Language (SQL)-based identity database.
- Landmark-Based Graph Emotion Module: A facial emotion recognition module is proposed that leverages a High-order Graph Attention Network (HoGAN) to model spatial and relational dependencies among emotion-relevant facial regions, enabling accurate and real-time emotion classification.
- Joint Learning Strategy: The system is trained using a combined loss function incorporating triplet loss for identity discrimination and categorical cross-entropy loss for emotion classification, ensuring balanced optimization of both tasks.
- Robust Real-Time Assistive Feedback: The proposed framework provides real-time integrated feedback combining identity and emotional information and demonstrates robustness under challenging conditions such as pose variation, occlusion, and visually similar faces.

The remaining part of the study is organized as follows: Section II reviews the existing works related to face identity and emotion recognition, Section III describes the workflow of the proposed unified deep learning framework, Section IV delivers the experimental results of the proposed framework, and Section V concludes the study.

II. Literature Survey

This section reviews existing works related to face identity recognition and face emotion recognition, which aim to support the proposed framework in cognitive assistive systems to support prosopagnosia patients.

A. Face Identity Recognition Approaches

Volfart et al. [25] validated two behavioral tests of Face Identity Recognition (FIR) using natural and ambient face images. The approach assessed recognition of famous identities without requiring verbal output and evaluated face identity matching across different views of familiar and unfamiliar faces. However, the approach needed pictures of famous faces for the population test. Olivares et al. [26] investigated how individuals with prosopagnosia process unfamiliar faces, focusing on the different and common neurocognitive mechanisms. The approach examined external and internal facial features in face-feature matching tasks and identified face perception and memory formation. Li [27] developed an integrated framework that combines Multi-feature Local Binary Pattern (MLBP), Histogram of Oriented Gradients (HOG), and Gray Level Co-occurrence Matrix (GLCM) features into a fusion algorithm (MLBP-HOG-G) to develop an accurate face recognition model. The framework addressed challenges like lighting changes, shadows, facial occlusion, and pose variations in unconstrained environments. Jain et al. [28] created an Augmented Reality (AR)-based 3D face recognition system as a social aid for individuals with face blindness that recognizes and identifies people in social contexts using a CNN with augmented reality. The approach supported prosopagnosia patients by providing real-time identification of faces during social interactions. Mukhiddinov et al. [29] introduced an assistive technology for the visually impaired individuals. The study utilized DL algorithms to design a smart glass system to enhance the quality of life of face-blindness patients. Still, the model incorrectly detects the small objects.

B. Face Emotion Recognition Approaches

Tsantani et al. [30] established that developmental prosopagnosia impairs facial expression recognition under challenging conditions, delivering new insights into the impairment in face processing. However, the study depended on a relatively small sample size of prosopagnosia participants. Wang et al. [31] investigated how neurotypical adults recognize and imitate dynamic emotional expressions and how these abilities are related to autistic traits. The study investigated emotion recognition and examined expression imitation that provided insights into how subtle variations in autistic traits influence social-emotional processing. Bardak and Temurta [32] created a model for identifying known and unknown faces using a regional brain perspective and simple neural networks. The features were classified using the K-Nearest Neighbors (KNN) algorithm, Probabilistic Neural Networks (PNN), and Support Vector Machine (SVM) to accurately identify the faces. However, the model needed enhancements to improve the accuracy through executing DL models. Guresli et al. [33] developed a Custom Lightweight CNN-based Model (CLCM) that optimized to reduce computational complexity while maintaining strong performance in emotion recognition tasks. However, the model did not accurately predict all the emotional states. Talaat et al. [34] developed a facial emotion recognition framework through DL techniques to accurately detect and classify emotional states. However, the model used only a limited amount of data to classify the emotional states. Mukhiddinov et al. [35] developed an emotion recognition system that utilized CNN-based models to detect and classify emotions. The system assisted visually impaired individuals to enhance social interaction and communication in daily life. However, in this study, facial landmark features were not correctly obtained.

C. Problem Statement

The analysis of existing works shows that existing face identity recognition approaches focus on improving feature discrimination, fail to identify the emotional state, as listed in Table I. Also, the facial emotion recognition systems only classify the emotional state and fail to identify the face. These limit their usefulness for assistive cognitive applications. Furthermore, most optimization strategies do not exploit shared facial representations through joint learning frameworks. Also, many existing methods are evaluated under controlled conditions and lack robustness against real-world challenges such as pose variations, occlusion, visually similar faces, and dynamic social environments. To overcome these, there is a need for an integrated system that simultaneously delivers identity recognition and emotion understanding in real-time. This supports prosopagnosia patients during daily social interactions.

TABLE. I. ANALYSIS OF EXISTING WORKS

References	Models / Approaches	Merits	Demerits
Volfart et al. [25]	Face identity recognition tests using natural and ambient face images	Evaluated face identity recognition without requiring verbal responses	Relied on images of famous faces.
Olivares et al. [26]	Neurocognitive analysis of unfamiliar face processing	Provided insights into face perception in prosopagnosia individuals	It doesn't provide a practical solution for prosopagnosia patients
Li [27]	MLBP-HOG-GLCM	Robust to illumination changes, shadows, occlusion, and pose variations	Features limit scalability and performance.
Jain et al. [28]	3D face recognition using CNN	Enabled real-time social assistance for prosopagnosia patients	High computational complexity

Wang et al. [31]	Dynamic emotion recognition and imitation analysis	Studied the relationship between emotion recognition and autistic traits	Doesn't suitable for prosopagnosia patients
Bardak and Temurta [32]	KNN, PNN, SVM	Attained a better performance	Lack resulting in lower recognition accuracy
Guresli et al. [33]	CLCM	Reduced computational complexity	Failed to accurately recognize all emotional states
Talaat et al. [34]	DL-based emotion recognition framework	Achieved accurate emotion classification	Trained on limited datasets
Mukhiddinov et al. [35]	CNN-based emotion recognition assistive system	Enhanced social interaction for visually impaired individuals	Facial landmark features were not accurately extracted.

III. MATERIALS AND METHODS

The proposed methodology develops a unified deep learning framework to provide cognitive assistance for prosopagnosia patients, as illustrated in Fig. 1. The proposed system was separated into two modules: a face identity recognition module and an emotion recognition module using the VGGFace2 and FER2013 datasets. The proposed system first detects and aligns input images using a Multi-Task Cascaded Convolutional Neural Network (MTCNN).

In the face recognition module, the aligned image is passed through an EfficientNet-B3 backbone that generates 512-dimensional face embeddings. These embeddings are stored in the SQL database, and cosine similarity is used to match the extracted embedding with stored identities. In parallel, the emotion recognition module operates on the same aligned face by detecting the facial landmarks using the Dilb landmark detector. Node features are derived from EfficientNet-B3 feature maps and processed using a HoGAN to learn relational interactions among emotion-relevant facial regions. Then, identity and emotion recognition modules are optimized using a joint loss function. Finally, the system integrates the retrieved identity information with the predicted emotional state to generate real-time assistive feedback that efficiently supports prosopagnosia patients.

A. Dataset Description

In this study, two publicly available benchmark datasets are utilized to support the tasks of face identity recognition and face emotion recognition, as shown in Fig. 2. First, the VGGFace2 dataset [36] is utilized, which is a large-scale face dataset designed to capture substantial intra-class variations. The dataset includes 3.31 million images of 9131 subjects, with wide diversity in pose, age, illumination, ethnicity, and background conditions. This dataset is suitable for learning robust facial embeddings and provides accurate face recognition in unconstrained environments. For emotion recognition, the FER2013 dataset [37] is used to train the emotion recognition module.

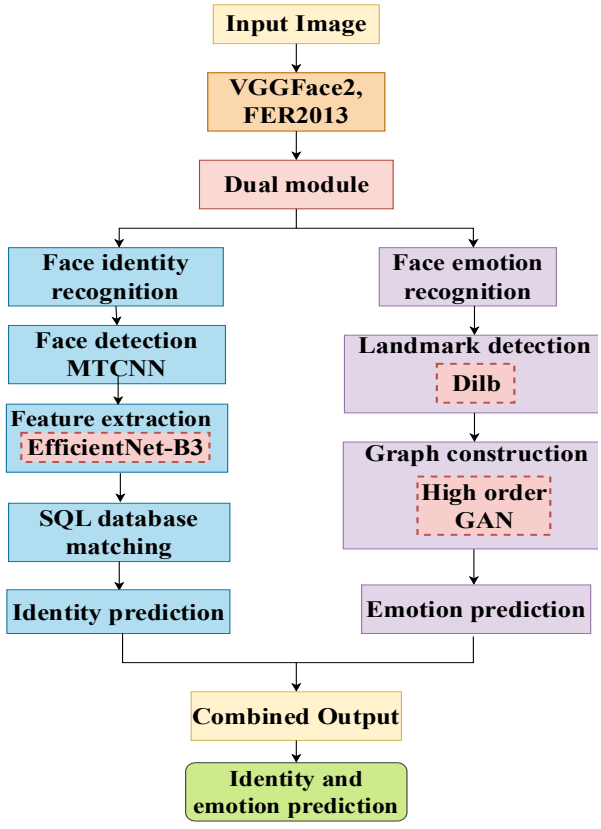

Fig. 1. Schematic representation of the proposed unified deep learning framework.

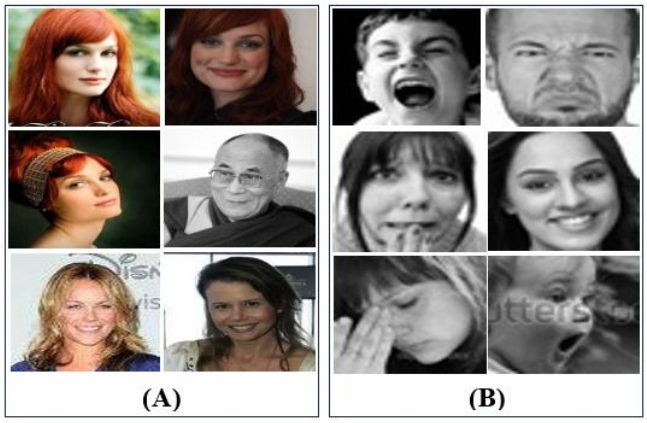

Fig. 2. Sample images from the dataset. (A) represents the sample images from the VGGFace2 dataset, and (B) represents the sample images from the FER2013 dataset.

The data consists of 48x48 pixel grayscale images of faces. The dataset consists of approximately 35,000 grayscale facial images, annotated into seven basic emotion categories: anger, disgust, fear, happiness, sadness, surprise, and neutral. The dataset includes images captured under diverse conditions with variations in facial expressions, occlusion, and illumination, making it suitable for learning generalized emotion representations. In this work, FER2013 is used only during the training phase to enable the model to learn emotion-specific facial patterns.

B. Face Detection and Alignment Using MTCNN

Face detection and alignment in the proposed framework are performed using the MTCNN [38], which consists of three parts: Proposal Network (P-Net), Refinement Network (R-Net), and Output Network (O-Net). The P-Net generates the image at multiple scales to generate a set of candidate face bounding boxes.

These bounding boxes are utilized to classify face and non-face windows, to estimate bounding box regression vectors for face location. R-Net rejects false candidates from the P-Net. Lastly, O-Net outputs five facial landmarks: the left and right mouth corners, the center of the nose, and the centers of the left and right eyes.

These landmarks are used to perform face alignment by estimating a similarity transformation that normalizes facial pose, scale, and rotation. The optimal transformation matrix T, is obtained by minimizing the alignment error between detected landmark positions P^*, as denoted in Eq. (1).

$$min \sum_{k=1}^{5} ||T(i_k, j_k) - (i_k{}^*, j_k{}^*)||_2^2 \quad (1)$$

where, k denotes the index of facial landmarks and (i_k, j_k) represents the detected coordinates of the k-th facial landmark. The aligned face is then cropped and resized to a fixed resolution of 224×224 pixels. This process improves the stability and accuracy of subsequent identity and emotion recognition modules.

C. Face Identity Recognition Module

The face identity recognition module is employed to extract discriminative facial representations of faces and identify individuals in unconstrained environments. It utilizes EfficientNet-B3 to generate facial embeddings. This matched against a stored identity database using cosine similarity to predict known or unknown identities.

1) Feature extraction through EfficientNet-B3: In this study, we utilized an EfficientNet-B3 [39] to extract deep features in the aligned images, as illustrated in Fig. 3. The pretrained model used is trained on ImageNet and is utilized as the convolutional backbone with all its parameters frozen. This increases a network's breadth, depth, and resolution and scales each dimension. The performance of models is improved when each size is scaled. EfficientNet-B3 uniformly balances network depth, width, and input resolution, as expressed in Eq. (2) – (4).

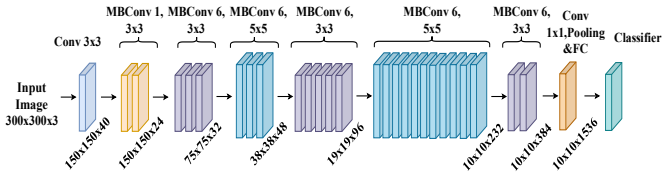

Fig. 3. Architecture diagram of the EfficientNet-B3.

$$depth_d = \alpha\theta \quad (2)$$

$$width_w = \beta\theta \quad (3)$$

$$resolution_r = \gamma\theta \quad (4)$$

where, $\alpha.\beta^2, \gamma^2$, where θ controls the overall model size and α, β, γ are scaling coefficients. The network is composed of Mobile Inverted Bottleneck Convolution (MBConv) blocks augmented with squeeze-and-excitation (SE) attention. This enhances channel-wise feature recalibration. For an intermediate feature map $X \in R^{H*W*C}$, the MBConv block first expands the channel dimension using a pointwise convolution. Then, a depth-wise convolution is used to efficiently model spatial information. Channel importance is then computed through global average pooling, as denoted in Eq. (5).

$$g = \frac{1}{hw} \sum_{u=1}^{h} \sum_{v=1}^{w} X(u, v) \quad (5)$$

where, g denotes the channel-wise descriptor vector, h denotes the height of the feature map X, and w denotes the width of the feature map X. The SE module generates channel attention weights, as mentioned in Eq. (6).

$$SE = \delta(W_2 \vartheta(W_1 g)) \quad (6)$$

where, δ and ϑ denotes the ReLU and sigmoid activation functions, respectively. W_1 and W_2 denotes the weight matrix of the fully connected layer. These weights are used to recalibrate the feature map, enabling the network to emphasize identity-relevant facial regions. The final convolutional feature maps produced by EfficientNet-B3 are aggregated using global average pooling to generate a compact feature vector f. This vector is then projected through a fully connected layer to obtain a fixed-length 512-d embedding (emd), as expressed in Eq. (7).

$$emd = W_f f + b_f \quad (7)$$

where, $W_f f$ denotes the learnable weight matrix and b_f signifies the corresponding bias vector. This encodes high-level facial characteristics suitable for identity discrimination. These embeddings serve as robust feature representations for subsequent identity matching and emotion analysis, balancing accuracy and efficiency in real-time facial recognition tasks.

2) SQL database matching for identity prediction: After extracting the 512-dimensional facial embedding from the EfficientNet-B3 feature extractor, identity prediction is performed through a SQL-based identity database [40]. During the enrolment phase, embeddings corresponding to known individuals are computed and stored in the database along with unique identity labels. During inference, the embedding obtained from a query face is compared against all stored embeddings e_s in the database using cosine similarity. The maximum similarity score is selected, and if it exceeds a predefined open-set threshold τ, the corresponding identity is assigned. The optimal threshold was selected by minimizing the Equal Error Rate (EER). This ensures a balanced trade-off between false acceptance and false rejection rates. Based on this analysis, τ was fixed at 0.65, which provided the best separation between known and unknown identities while maintaining stable real-time performance. Otherwise, the face is labeled as unknown. The identity associated with the maximum similarity score is selected as the predicted identity. The SQL database enables efficient storage, indexing, and retrieval of identity embeddings. This allows scalable and real-time identity matching. This structured matching mechanism allows reliable identity prediction while supporting dynamic updates, making it suitable for practical assistive applications for prosopagnosia patients.

D. Face Emotion Recognition Module

The face emotion recognition module is employed to identify the emotional state of an individual. It utilizes a landmark-based graph construction through Dilb and a HoGAN to capture spatial and relational dependencies among facial regions. This enables accurate real-time emotion classification to support prosopagnosia patients.

1) Facial landmark detection using Dilb: In the facial emotion recognition module, the proposed system performs landmark detection using the Dilb facial landmark detector [41]. This identifies 68 anatomically consistent key points distributed across critical facial regions. The detected landmark set is represented in Eq. (8).

$$L = \{(a_x, b_x)\}_{x=1}^{68} \tag{8}$$

where, (a_x, b_x) represents the two-dimensional coordinates of the x-th landmark. These landmarks capture subtle geometric variations in facial muscle movements that are strongly associated with emotional expressions. This normalization ensures consistency across faces of different sizes and orientations. This provides a stable geometric representation for subsequent graph-based emotion recognition.

2) Graph construction through high-order graph attention network (HoGAN): HoGAN [42] extends the conventional Graph Attention Network by modeling higher-order interactions that capture long-range dependencies across the graph. In this study, the facial landmark graph $G = (V, E)$, where V denotes the nodes and E denotes the edges, with node features $h_x \in \mathbb{R}^G$ for each landmark x, a standard attention mechanism computes pairwise attention coefficients between directly connected nodes, as denoted in Eq. (9).

$$e_{xy} = \text{LeakyReLU}(\text{w}^\top[\text{Mh}_x \parallel \text{Mh}_y]) \tag{9}$$

where, M denotes the learnable linear transformation, w represents the attention weight vector, and $\parallel$ signifies the concatenation. These coefficients are normalized using a SoftMax function over the neighborhood $\mathcal{N}_x$ of node x, as denoted in Eq. (10). This allows the network to adaptively weight the contribution of neighboring landmarks based on their relevance.

$$\sigma_{xy} = \frac{\exp(e_{xy})}{\sum_{k \in \mathcal{N}_x} \exp(e_{xk})}, \tag{10}$$

where, attention is extended to capture information from multi-hop neighborhoods by aggregating features from k-order neighbors. This enables the network to model complex facial muscle interactions across distant regions of the face. The high-order feature representation of the node x is computed as in Eq. (11).

$$\text{H}_i^{(k)} = \alpha\left(\sum_{y \in \mathcal{N}_x{}^k} M^k \, h_y\right) \tag{11}$$

where, $\mathcal{N}_x{}^k$ represents the set of nodes reachable within k hops, $\sigma_{xy}{}^k$ denotes the high-order attention coefficients, and $\alpha(.)$ represents the nonlinear activation function. Multiple attention heads are employed to stabilize learning and enhance representational capacity. The HoGAN effectively captures both localized and global facial dynamics that are critical for emotion expression. This capability is particularly beneficial for facial emotion recognition, as emotional cues are often distributed across multiple, spatially distant facial regions. Consequently, the high-order graph attention mechanism enables more discriminative and robust emotion modeling.

E. Joint Learning Strategy through Loss Functions

The proposed framework adopts a joint learning strategy to simultaneously optimize face identity recognition and facial emotion recognition within a unified DL framework. The model formulated the training dataset as D, where a_x represents the input facial image, b_x^{id} denotes the identity label, and b_x^{em} signifies the emotion label. Identity learning is formulated as a metric learning problem using triplet loss ($\mathcal{L}_{tr}$), as expressed in Eq. (12).

$$\mathcal{L}_{tr} = \sum_{i=1}^{N} \max\left(0, \| f(a_x^u) - f(a_x^p) \|_2^2 - \| f(a_x^u) - f(a_x^n) \|_2^2 + \alpha\right) \tag{12}$$

where, $f(\cdot)$ denotes the identity embedding function, N denotes the total images, and a_x^u, a_x^p, and a_x^n represent anchor, positive, and negative samples, respectively, with a margin α. Emotion recognition is optimized using a categorical cross-entropy loss ($\mathcal{L}_{cross}$), as denoted in Eq. (13).

$$\mathcal{L}_{cross} = -\sum_{c=1}^{C} b_c \log(\hat{b}_c) \quad (13)$$

where, C represents the number of emotion classes, b_c signifies ground-truth label, and $\hat{b}_c$ denotes predicted probability. The overall objective function is formulated as a weighted sum of both losses, as shown in Eq. (14).

$$\mathcal{L}_{total} = \lambda_1 \mathcal{L}_{tr} + \lambda_2 \mathcal{L}_{cross} \quad (14)$$

where, $\lambda_1$and λ_2 balance the contribution of identity and emotion tasks. This joint optimization enables the network to learn shared facial representations, improving generalization while ensuring efficient convergence for real-time assistive applications.

IV. Results and Discussion

This section presents the experimental performance of the proposed unified DL framework. The performance is assessed using quantitative metrics, qualitative visualizations, ablation analysis, and comparative analysis to demonstrate the effectiveness of the proposed system.

A. Hyperparameter Settings and Complexity Analysis

The proposed model finetunes hyperparameters to strike a balance between model performance and computational efficiency, as demonstrated in Table II. The proposed unified DL framework results in a balanced computational complexity for the proposed system. EfficientNet-B3 has a computational complexity of approximately $O(H \times W \times D)$, where H and Wdenote the spatial dimensions and D represents the channel depth. The emotion recognition module operates with a complexity of $O(K \times N^2)$, where $N = 68$ landmarks and K denotes the number of attention heads. This makes it suitable for real-world assistive applications for prosopagnosia patients.

TABLE. II. Hyperparameter Details of the Proposed Framework

Component	Hyperparameter	Value
MTCNN	Scale factor	0.709
	Number of landmarks	5
EfficientNet-B3	Dropout rate	0.3
	Embedding dimension	512
Dilb	Number of landmarks	68
HoGAN	Number of layers	3
	Attention heads	8
	Hidden dimension	128
	High-order hops	2-hop
Training Settings	Optimizer	Adam
	Learning rate	0.0001
	Weight decay	1×10^{-4}
	Batch size	32
	Epochs	10
	Triplet margin	0.2
	Loss weights (λ_1, λ_2)	1.0, 1.0

B. Performance Analysis of the Proposed Model

This section presents the performance analysis of the proposed unified deep learning framework, as illustrated in Table III. The performance was analyzed through the metrics of accuracy, precision, recall, specificity, f1-score, Matthews Correlation Coefficient (MCC), False Positive Rate (FPR), False Negative Rate (FNR), Equal Error Rate (EER), Cohen's kappa, and AUC values. The results show that the proposed model attains a better performance in both face identity recognition and face emotion recognition. This shows the ability of the proposed model to efficiently support patients with prosopagnosia.

TABLE. III. Performance of the Proposed Unified Deep Learning Framework

Metrics	Face identity recognition	Face emotion recognition
Accuracy (%)	99.58	99.02
Precision (%)	99.08	99.14
Recall (%)	99.11	99.09
Specificity (%)	99.58	99.39
F1-score (%)	99.09	99.21
MCC (%)	99.1	99.01
FPR	0.42	0.61
FNR	0.89	0.92
Equal Error Rate (EER)	0.45	0.87
Cohen's Kappa (%)	99.1	98.9
AUC (%)	99.8	99.5

C. Face Identity Recognition

Fig. 4 shows the results of MTCNN-based face detection and alignment. MTCNN detects faces across different subjects with variations in pose, illumination, facial appearance, and background. The five-point facial landmarks are used to align the faces that are detected, ensuring consistent positioning of key facial components such as the eyes, nose, and mouth. The visual results indicate the improved representation of the facial region following the alignment. This normalization significantly reduces intra-class variations and provides a stable input for the identity recognition module. The findings ensure that MTCNN is effective in preprocessing. This is essential in enhancing the accuracy of recognition in unconstrained and real-time assistive cases.

Fig. 4. Results of face detection and alignment through MTCNN. The first row denotes the original images of the VGGFace2 dataset, and the second row denotes the facial detection images.

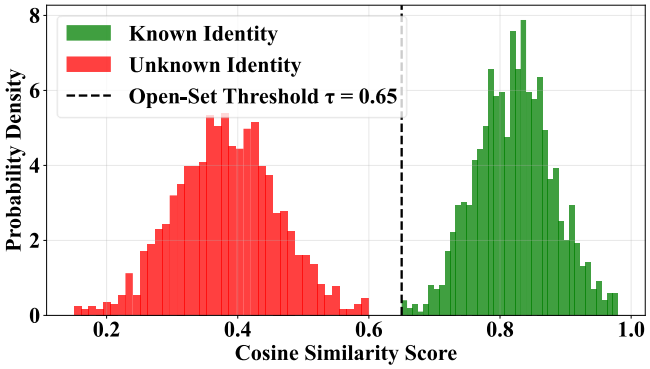

Fig. 5. Distribution of cosine similarity scores for known and unknown identities.

Fig. 5 illustrates the distribution of cosine similarity scores obtained during the identity matching process. The green histogram represents similarity scores for known identity pairs, which are concentrated at higher values. The red histogram corresponds to unknown identity pairs, which exhibit lower similarity scores. This reflects effective separation between different identities. The dashed line denotes the open-set decision threshold set at ($\tau = 0.65$), which serves as the boundary for distinguishing known and unknown identities. The minimal overlap between the two distributions demonstrates the discriminative power of the learned embeddings. This validates the effectiveness of the selected threshold in open-set identity recognition scenarios. This ensures reliable identity prediction while minimizing false acceptances and false rejections.

D. Emotion Recognition

Fig. 6 illustrates the results of facial landmark detection using the Dlib model. The green points represent the detected facial landmarks, which densely capture critical regions including the eyes, eyebrows, nose, mouth, and jawline. These precise geometric representations provide rich structural information, essential for modeling facial dynamics. This serving a reliable foundation for the subsequent graph-based emotion recognition module. This highlights its effectiveness in accurately localizing key facial features across different emotional expressions.

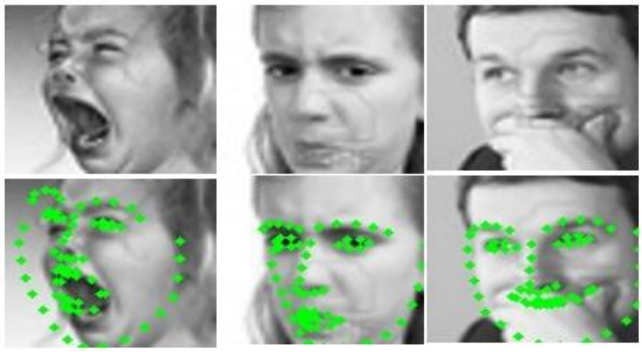

Fig. 6. Results of the facial landmark detector through Dilb. The first row denotes the original images of the dataset, and the second row denotes the facial landmark detection images.

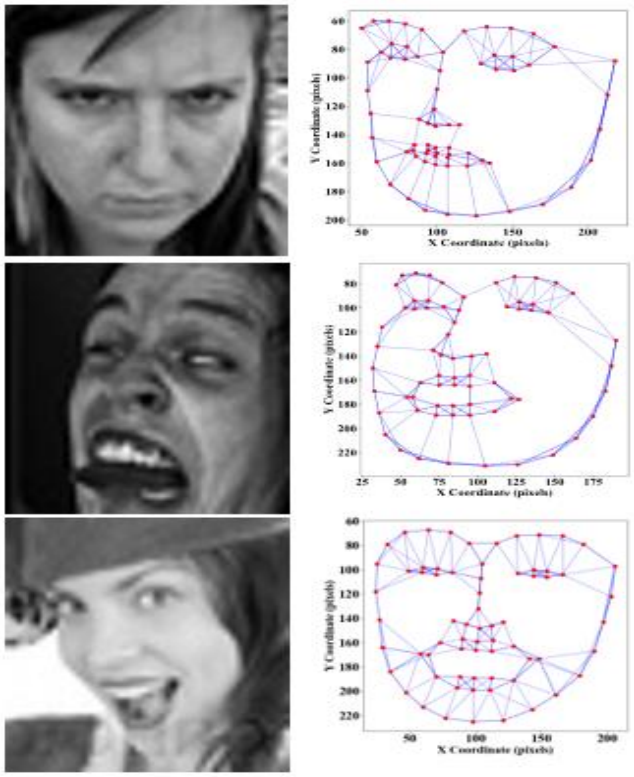

Fig. 7. Graph construction results through a high-order graph attention network.

Fig. 7 presents the graph construction results through HoGAN. The left column shows original facial images, while the right column illustrates the constructed facial graphs derived from the detected landmarks. Each red node represents a facial landmark, and the blue edges indicate the spatial and anatomical connections between landmarks used to form the graph structure. These structured graph representations enable to effectively capture of both local deformations and long-range dependencies between facial regions. This enhances the model's ability to discriminate subtle emotional cues. The visualization demonstrates that the proposed graph-based approach provides an interpretable and expressive geometric representation of facial dynamics.

E. Model Training Performance

Fig. 8 illustrates the training behavior and convergence characteristics of the proposed unified identity and emotion recognition framework. The accuracy curve shows a steady increase in classification accuracy as the number of training epochs progresses. The curve rises from approximately 60% in the initial epoch to nearly 99% by the final epoch. This consistent upward trend indicates effective feature learning and model convergence. This demonstrates that the network successfully captures discriminative facial representations with continued training. The rapid improvement in early epochs reflects efficient optimization, while the gradual saturation in later epochs suggests stable convergence without overfitting.

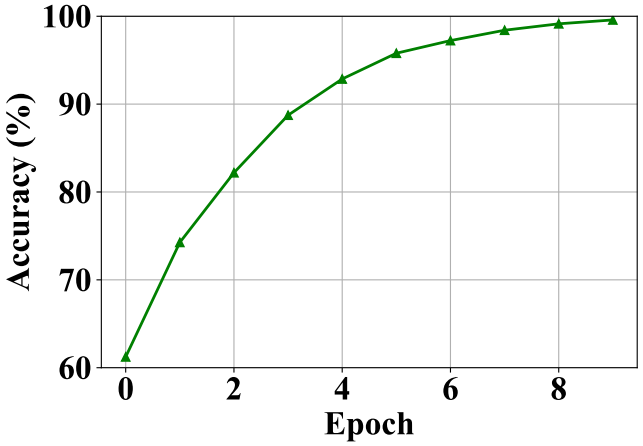

Fig. 8. Training accuracy of the proposed model across epochs, showing improvement and stable convergence during the learning process.

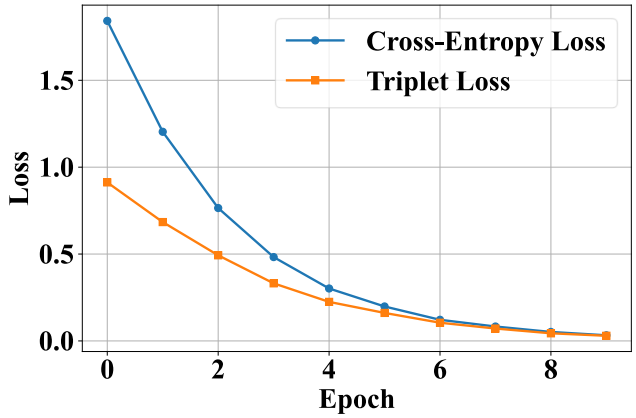

Fig. 9. Training loss curve of the proposed framework showing the reduction of cross-entropy loss for emotion recognition and triplet loss for face identity recognition across epochs.

Fig. 9 illustrates the loss function performance of the proposed framework. Both losses decrease across epochs, with cross-entropy loss reducing sharply during early training. Triplet loss gradually converges as embedding separability improves. The parallel decline of these losses highlights the effectiveness of the joint multi-task learning strategy, where identity and emotion objectives are optimized concurrently. These confirm that the proposed model achieves stable training, balanced optimization across tasks, and robust convergence. This supports its suitability for real-time cognitive assistance applications.

Fig. 10 illustrates the performance of the proposed facial emotion recognition module across seven emotion classes: Angry, Disgust, Fear, Happy, Sad, Surprise, and Neutral. Each emotion class achieves a high number of correct predictions. This indicates high classification accuracy and effective discrimination between emotional states. Misclassifications are minimal and primarily occur between visually similar emotions, such as fear and sadness or anger and disgust. This confirms the reliability and stability of the proposed emotion recognition module, validating its effectiveness for real-world cognitive assistance applications.

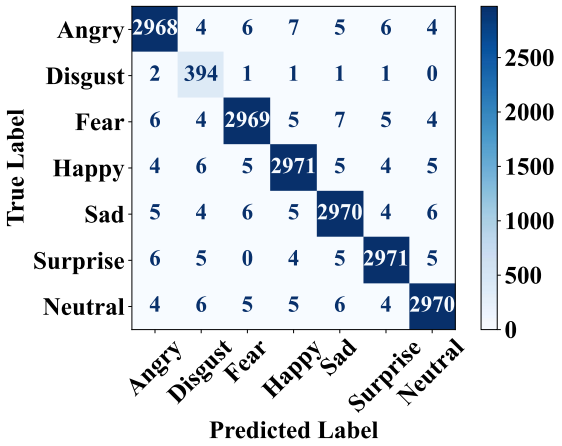

Fig. 10. Confusion matrix of the proposed framework.

Fig. 11. Results of the proposed prosopagnosia assistive system showing face identity and emotion recognition. This predicted identity labels and recognized emotional states.

Fig. 11 illustrates the results of the proposed prosopagnosia assistive system, showing its ability to simultaneously recognize face identity and facial emotion. Each shows an input image processed by the system, with the annotated output displaying the predicted identity label and the recognized emotional state. The examples highlight the system's robustness under varying conditions, including different lighting, facial poses, backgrounds, and emotional intensities. These results confirm the practical applicability of the proposed framework as a real-time cognitive assistance system. This helps to efficiently support individuals with prosopagnosia during everyday interactions.

F. Comparative Analysis

This section presents the comparative analysis of the proposed model, as represented in Table IV. The proposed framework is compared with the baseline models, MLBP-HOG-G, KNN, PNN, SVM, CNN, CLCM, and other approaches. The proposed model attained an accuracy of 99.58% and 99.02% in both modules. This shows that the proposed model attained a better accuracy compared to baseline models, and shows the efficiency in both face identity recognition and face emotion recognition.

TABLE. IV. COMPARATIVE ANALYSIS WITH BASELINE MODELS

Models	Face identity recognition			Face emotion recognition		
	Accuracy (%)	Precision (%)	F1-score (%)	Accuracy (%)	Precision (%)	F1-score (%)
MLBP-HOG-G	87.42	86.91	86.99	87.13	86.92	86.96
KNN	88.17	87.64	87.79	86.47	86.12	86.22
PNN	89.54	89.02	89.16	89.92	87.61	87.67
SVM	91.83	91.42	91.51	90.36	90.11	90.17
CNN	94.26	94.08	94.12	93.58	93.34	93.40
CLCM	96.48	96.31	96.35	95.94	95.81	95.85
GAT	98.12	98.01	98.03	97.61	97.49	97.52
Proposed	**99.58**	**99.08**	**99.09**	**99.02**	**99.14**	**99.21**

G. Discussion

This study presented a unified framework for face identity and facial emotion recognition aimed at addressing the real-world challenges faced by individuals with prosopagnosia. The experimental results demonstrate that integrating face detection and alignment with EfficientNet-B3-based identity feature extraction and landmark-driven HoGAN for emotion recognition leads to highly accurate performance. The joint learning strategy enables the model to exploit information between identity and emotion tasks. The study utilized the VGGFace2 and FER2013 benchmark datasets. They may introduce biases related to demographic distribution, illumination conditions, and expression diversity. VGGFace2 primarily contains celebrity images, which may not fully represent real-world population variability. FER2013 consists of low-resolution grayscale images that may limit fine-grained emotional representation. These dataset characteristics influence model generalization in practical deployments. To mitigate this, data augmentation and joint learning were employed to improve robustness. The strong separation observed in cosine similarity distributions indicates that the proposed system is well-suited for real-time assistive applications.

Although the proposed framework achieves very high performance across multiple evaluation metrics, it is important to critically consider potential overfitting effects. The high accuracy values may partially result from training and evaluation on benchmark datasets. To mitigate overfitting, regularization strategies including dropout, joint loss optimization, and validation monitoring were employed during training. The stable convergence behavior observed in training accuracy and loss curves suggests balanced learning. However, the proposed framework acknowledged some limitations. The study depends on publicly available datasets, which do not fully capture the diversity of real-world interactions experienced by prosopagnosia patients. Future work will focus on addressing these limitations by incorporating multimodal information such as speech, contextual cues, and physiological. This provides a foundation for intelligent assistive technologies for advancing cognitive support systems for prosopagnosia patients.

V. CONCLUSION

This study successfully developed a unified DL framework for face identity and facial emotion recognition to support individuals with prosopagnosia in real-world social interactions. The proposed model employed a dual module framework that simultaneously performs face identity recognition and face emotion recognition. The proposed system effectively captured both identity-specific and expression-related facial cues. The joint learning strategy enabled optimization of identity and emotion tasks, leading to high recognition accuracy, stable convergence, and strong generalization performance. The experimental results demonstrated that the proposed approach outperforms conventional task-specific models while maintaining real-time efficiency. The framework provides a scalable solution for cognitive assistance, offering an efficient identity and emotion framework to support the daily social interactions of individuals with prosopagnosia. In the future, we will extend the proposed framework under different real-world conditions, ensuring robust deployment in cognitive, practical assistive environments.

STATEMENTS AND DECLARATIONS

Author contributions: Both authors contributed to the conception of the problem setting, conceptualization, methodology, implementation, testing and writing the final manuscript.

Funding: No funding was received for conducting this study.

Availability of data and materials:

https://github.com/ox-vgg/vgg_face2
https://datarepository.wolframcloud.com/resources/FER-2013

Conflict of interest: The authors declare that they have no conflict of interest.

Ethical approval: The research is original, and the authors of this manuscript created all the figures and tables.

Consent to participate: Not applicable.

***Abstract*—Depression-related language on social media provides measurable signals for population-level mental-health research, yet model selection remains sensitive to evaluation protocol, domain shift, class imbalance, and computational constraints. This study benchmarks CNN, LSTM, and transformer encoders (BERT, RoBERTa, DistilBERT, and MentalBERT) for binary depression-indicative versus control classification on a unified corpus of 19,800 English posts/comments aggregated from three platforms (Reddit, Twitter, and Facebook) under a consistent preprocessing pipeline. We report two complementary evaluation protocols: (1) a fixed-split single-run baseline for a comparable snapshot, and (2) a five-seed repeated-run protocol with statistical testing (effect sizes and multiple-comparison correction) to quantify variability and reduce sensitivity to initialization effects. Under repeated-run reporting, MentalBERT achieves the best overall performance (F1 = 0.918 ± 0.005; AUC = 0.962 ± 0.002), while CNN/LSTM baselines show lower robustness under cross-platform transfer. Cross-domain experiments reveal a consistent performance drop relative to in-domain evaluation, confirming non-trivial platform shift and motivating robustness-aware reporting for deployment-oriented settings. In addition to predictive metrics, we report training time, inference latency, and derived throughput to support practical model selection for use cases such as moderation pipelines and screening/triage dashboards.**

I. Introduction

In modern society, depression has become an increasingly pressing public-health challenge, influencing not only individual well-being but also broader social and economic outcomes. According to the World Health Organization, depression affects approximately 332 million people worldwide (about 4% of the global population) and is a common mental disorder that can substantially impair daily functioning and, in severe cases, increase suicide risk [1]. In parallel, the rapid growth of digital footprints on social media platforms (e.g., Twitter, Reddit, Facebook) provides large-scale textual evidence where users may express emotional distress and related indicators, making text-based analysis a promising direction for population-level risk monitoring and research support. Prior work shows that linguistic signals in social-media text are associated with depression-related outcomes and can support NLP-based screening and monitoring in research settings [2], [3].

In recent years, there has been substantial progress in automated assessment of a person's psychological state through text analysis. Natural Language Processing (NLP), combined with machine-learning methods, provides computational tools for detecting depression-related signals from user-generated statements and other online textual traces [4]. Recent surveys and systematic reviews describe the evolution of this field from feature-engineered classifiers toward deep representation learning, including neural architectures and transformer-based approaches for text classification [5], [6]. In this context, NLP-based methods can support research-oriented screening and monitoring of depression and anxiety indicators; however, model outputs should be interpreted as risk signals rather than clinical diagnoses.

Early computational mental-health studies on online platforms often relied on bag-of-words or lexicon-based representations combined with linear classifiers (e.g., SVM, Naïve Bayes, logistic regression) as strong baselines for depression-related text classification. In community and forum settings, such approaches were evaluated on large-scale resources built from users' self-reported signals (e.g., self-reported diagnosis–based forum resources), which helped establish benchmark tasks for depression detection from language [7]. However, feature-engineered pipelines can struggle with subtle semantics, pragmatic cues, and longer-range context in noisy user-generated text, motivating deep representation learning. This shift promoted architectures that learn hierarchical and sequential representations directly from text, including CNN- and LSTM-based models that became strong baselines for sentence- and post-level classification tasks [8],[9]. More recently, transformer-based encoders and ensemble strategies have further improved contextual modeling for depression detection across social platforms, reinforcing the move toward attention-based architectures in modern benchmarks [10].

Transformer-based architectures have substantially advanced NLP by enabling global context modeling via self-attention mechanisms [11]. Building on this framework, BERT introduced deep bidirectional contextual representations and achieved strong performance across a wide range of language understanding and classification tasks, including text

*Corresponding author.

classification settings relevant to affective and mental-health NLP [12].

The present study provides a comparative assessment of CNN, LSTM, and BERT models in the context of depression detection from text-based data. All models were trained under identical conditions to ensure comparability. The analysis focuses on key performance metrics such as Accuracy, Precision, Recall, F1-score, and AUC, aiming to determine which architecture demonstrates the highest reliability in identifying depressive language patterns.

Despite the strong performance of CNN and LSTM baselines, recent work increasingly favors transformer-based encoders, particularly BERT and its variants, for mental-health–related text classification, due to their ability to model long-range context and bidirectional dependencies [12], [13]. More recently, several works have explored fine-tuning large language models for depression detection on social-media benchmarks and reported strong performance under their experimental settings [14]. In broader benchmarking and comparative studies, transformer-based encoders are frequently reported to be competitive on mental-health NLP tasks, including depression and anxiety detection [15]. However, statistical significance testing is sometimes omitted or misapplied in NLP benchmarking, which can lead to overconfident conclusions [16]. Practical deployment must still consider computational requirements, inference latency, and memory footprint compared to lighter neural architectures [17].

Despite substantial progress in neural text classification for mental health applications, the question of how different deep learning architectures compare under controlled and deployment-relevant conditions remains insufficiently explored. Existing studies often focus on a single model family, report results on a single dataset, or rely on one-off train–test splits without accounting for variability induced by random initialization and training dynamics. As noted in prior surveys and comparative reviews, comprehensive analyses that systematically contrast CNN, LSTM, and transformer-based models in depression-related text classification remain relatively scarce [15]. As a result, model selection is frequently based on isolated performance snapshots rather than on robust, reproducible evidence, complicating the identification of architectures that achieve a balanced trade-off between predictive accuracy and computational efficiency in real-world systems.

The purpose of this study is to conduct an empirical comparison of CNN, LSTM, and BERT architectures for binary classification of social media texts with respect to depressive versus non-depressive language. In addition to standard quality metrics (Accuracy, Precision, Recall, F1-score, and AUC), we quantify run-to-run variability under repeated training, report effect sizes with multiple-comparison control, and evaluate cross-platform transfer to better reflect deployment-oriented conditions.

Deployment motivation. The intended deployment setting is a post-level text classifier integrated into a decision-support workflow (e.g., a research screening dashboard or a content-moderation triage pipeline) where the model flags potentially depressive posts for human review. In such settings, the objective is not clinical diagnosis but reliable risk-sensitive prioritization under platform shift, bounded compute, and real-time throughput constraints.

In summary, this work (1) performs a controlled comparison of CNN, LSTM, and multiple transformer encoders under identical preprocessing and evaluation conditions; (2) evaluates both a single-run baseline and a repeated-run protocol with statistical testing to account for performance variability; and (3) complements predictive metrics with robustness (cross-platform transfer) and efficiency indicators (training time and inference latency) to support deployment-oriented model selection.

This study hypothesises that transformer-based encoders will outperform lightweight CNN/LSTM baselines on depression-indicative text classification because they model non-local context and subtle semantics. Although this direction is broadly expected, its magnitude, stability across random seeds, and robustness under cross-platform shift are not guaranteed and are often underreported in single-split comparisons. Therefore, the main novelty of this work is not architectural invention but a deployment-relevant evaluation design: we jointly analyze baseline accuracy, repeated-run stability, cross-platform degradation, and efficiency indicators under a unified preprocessing and training protocol.

The remainder of the study is organized as follows. Section II reviews related work and highlights methodological gaps in prior comparative studies. Section III describes the datasets, preprocessing pipeline, evaluation protocols, and statistical testing. Section IV reports experimental results, including baseline comparisons, transformer variants, and cross-platform transfer. Section V discusses deployment implications, limitations, and future research directions. Section VI concludes the study.

II. Related Works

Research on depression detection from text has evolved from feature-engineered machine-learning pipelines toward deep representation learning. Early studies relied on linear classifiers and handcrafted lexical and psycholinguistic features, but such approaches often struggled to capture compositional meaning and longer-range context in mental-health–related language, especially in noisy, user-generated social-media posts where context and pragmatics are hard to capture [4]. As deep learning became standard, neural baselines such as CNN and LSTM gained popularity due to their ability to learn task-relevant representations directly from data. CNN-based models are effective at extracting local n-gram patterns for sentence- and post-level classification [8], while recurrent architectures such as LSTM better capture sequential dependencies that may reflect evolving emotional framing in text [9].

Critical synthesis and gap. Many prior depression-detection comparisons are difficult to reconcile because they (1) use different label definitions (self-report vs symptom proxy), (2) mix platform-specific preprocessing and splits that may leak user timelines, (3) report a single train–test split without seed variability, and (4) omit efficiency reporting beyond point accuracy. Consequently, it is often unclear whether reported gains reflect model capability, data preprocessing choices, or favorable randomness. Domain-adaptive transformers such as

MentalBERT are frequently reported to outperform general-purpose BERT in mental-health language, but the magnitude varies across datasets. In our controlled benchmark, MentalBERT improves mean F1 by approximately 0.052 over standard BERT under Protocol B (Table IV), supporting the practical value of domain-adaptive pretraining when computational budgets permit. In addition, statistical testing protocols are often underspecified in NLP comparisons [16].

Comparative studies and systematic reviews often report that transformer-based encoders are competitive or superior to classical baselines on mental-health text classification benchmarks, although results depend on dataset construction and evaluation protocol [15]. At the same time, practical deployment must account for computational and memory costs of attention-based models, which motivates efficiency-oriented transformer variants and compact encoders when latency or footprint is constrained [17]. In addition, domain-adaptive pretraining (e.g., MentalBERT) aims to improve sensitivity to mental-health–specific language patterns and implicit distress markers. More recently, several works also explored fine-tuning large language models for depression detection, reporting strong performance on selected social-media benchmarks [14].

A complementary research direction focuses on domain-adaptive pretraining. MentalBERT is a representative example of a transformer pretrained on mental-health–related corpora (including content from mental-health communities), to increase sensitivity to psychologically salient cues and implicit distress markers. Such domain adaptation has been reported to improve performance over general-purpose encoders in settings where the target language includes community-specific vocabulary, self-referential statements, and non-standard phrasing. Beyond domain adaptation, integrative reviews emphasize that affective expression and linguistic markers in social-media text are consistently associated with mental-health–related outcomes, supporting emotion-aware feature analysis in computational mental-health research [18].

Datasets and evaluation campaigns have also expanded substantially. Classic corpora such as RSDD and platform-specific datasets enabled large-scale depression-related text classification and benchmarking [7], [19]. More recent resources emphasize richer supervision (e.g., DSM-oriented labeling), multi-task objectives, and evaluation designs that better reflect temporal dynamics and domain shift. For example, MentalHelp provides a multi-task dataset for mental-health objectives in social media [20], while ReDSM5 introduces depression detection labels aligned with DSM-5-oriented criteria on Reddit content [21]. In addition, user-level and multimodal datasets have been proposed to capture changes in behavior and language over time, enabling evaluation beyond isolated posts [22]. Community-driven shared tasks such as CLPsych encourage standardized protocols that emphasize robustness and longitudinal modeling in realistic scenarios [23]. Expanding beyond English and beyond a single platform is also an active direction; for instance, Arabic mental-health resources such as CARMA support cross-lingual and cross-cultural studies [24].

Overall, prior work indicates that realistic deployment-oriented evaluation should consider not only in-domain accuracy but also robustness under repeated runs, cross-platform transfer, and computational constraints. However, controlled comparisons that jointly analyze predictive quality, repeated-run stability, cross-platform robustness, and practical efficiency indicators under a unified pipeline remain limited [17]. Moreover, many studies report single-split results without repeated-run variability, which complicates robust model selection for deployment-oriented settings. This motivates the comparative and deployment-oriented analysis performed in the present study, as well as the consideration of early-risk prediction setups such as CLEF eRisk, which emphasize longitudinal evidence and early detection under constrained information [25].

III. Materials and Methods

A. Data

To conduct a comparative analysis, we relied on publicly available research corpora originating from multiple social media platforms, which helps capture variation in writing style, message length, and the way depressive states may be expressed in different online communities. The following datasets were used:

1) Reddit Self-reported Depression Diagnosis (RSDD): A user-level corpus derived from Reddit timelines where users self-report a depression diagnosis, paired with matched control users. The original resource covers posts from approximately 9,000 diagnosed users (with a larger set of matched controls) [7]. For the present experiments, we derive a post-level binary classification subset by sampling posts from the corresponding user timelines under a fixed protocol and applying filtering and normalization. Because the source dataset is user-level, we enforce user-disjoint train/validation/test splits to prevent leakage, ensuring that posts from the same user appear in only one split.

2) Twitter-based depression dataset (Twitter-STMHD): A user-level benchmark resource for mental-health analysis on Twitter [19]. From this dataset, we derive a post-level experimental subset of approximately 6,500 English tweets for binary depression-indicative versus control classification after filtering and normalization. As Twitter-STMHD is provided at the user level, we construct the post-level subset by sampling tweets from user timelines while enforcing user-disjoint splits to prevent user overlap across train, validation, and test.

3) Facebook comments corpus: Following Islam et al. [26], we use a Facebook comments corpus derived from publicly accessible pages and labeled into two categories (depression-indicative vs non-depressive) under the authors' labeling procedure. The source study reports 7,145 labeled comments (4,149 depression-indicative; 2,996 non-depressive). After applying our preprocessing and filtering pipeline (e.g., removing empty/duplicate entries and non-English fragments), we retain 4,300 instances for controlled experiments while preserving the original label mapping. In addition, to keep the merged corpus prevalence consistent with the overall non-depressive majority observed across sources (Table I), we subsampled the retained Facebook data without changing label definitions. Due to platform policy and data-sharing

constraints, we report only aggregated results and do not redistribute raw Facebook text.

Overall, the unified dataset comprises 19,800 post-level instances spanning all three platforms (9,000 Reddit posts, 6,500 tweets, and 4,300 Facebook comments). We use a fixed stratified split into training, validation, and test sets (80%/10%/10%). For user-level sources (RSDD and Twitter-STMHD), splits are user-disjoint to avoid leakage across a user's timeline; for Facebook, comments are split at the instance level while preserving class balance.

TABLE I. PLATFORM-WISE CLASS DISTRIBUTION AFTER PREPROCESSING

Platform	Total (N)	Depressive, n (%)	Non-depressive, n (%)
Reddit	9,000	3,600 (40.0%)	5,400 (60.0%)
Twitter	6,500	2,400 (36.9%)	4,100 (63.1%)
Facebook	4,300	1,800 (41.9%)	2,500 (58.1%)
Total (all platforms)	**19,800**	**7,800 (39.4%)**	**12,000 (60.6%)**

Across platforms, depressive posts are less frequent overall (Table I). We tested whether class proportions differ across platforms using a chi-square test of independence and found statistically significant, but small, differences ($\chi^2(2) = 28.96$, $p = 5.14e\text{-}07$; Cramér's $V = 0.038$). These supports treating platform shift as a meaningful factor when interpreting cross-platform transfer results.

The merged corpus exhibited a moderate skew toward non-depressive posts. To mitigate potential bias during training without distorting evaluation, we applied a conservative balancing strategy after performing the train/validation/test split and only on the training split. Specifically, we used mild random under sampling of the majority class and semantic-preserving text augmentation for the minority (depressive) class, while keeping the validation and test splits unchanged. This approach increases exposure to depressive patterns during learning while preserving a realistic evaluation setting and preventing leakage from synthetic text into evaluation.

All datasets used in this study are publicly available research corpora or publicly accessible social-media text collections described by prior work and used under their respective terms and platform constraints. In our local processing, we removed or masked user handles, mentions, URLs, and other explicit identifiers where present, and we used the data strictly for aggregated modeling and evaluation rather than any individual-level inference.

B. Text Preprocessing

Social-media text is typically noisy and informal, containing emojis, URLs, mentions, hashtags, non-standard spelling, and grammatical deviations. To reduce noise while preserving emotionally informative patterns, we applied a multi-stage preprocessing pipeline designed for user-generated posts. The process included six interrelated stages (Fig. 1) that transform raw posts (raw post text) into model-ready inputs while preserving linguistically and affectively informative cues.

1) Cleaning: We removed purely technical tokens (URLs, @mentions, and obvious HTML artifacts) and normalized whitespace. Importantly, we preserved punctuation patterns that may convey affect (e.g., ellipses "...", repeated exclamation marks "!!!", and expressive repetition) when they functioned as emotional markers rather than boilerplate. Emoji handling was conservative to avoid discarding affective cues.

2) Tokenization: To ensure comparability across model families, we used word-level tokenization for CNN/LSTM baselines and subword tokenization for transformer encoders using the official pretrained tokenizers (e.g., WordPiece for BERT). This design prevents tokenization mismatch from confounding architecture comparisons.

3) Lemmatization: Lemmatization was applied conservatively with part-of-speech constraints to avoid semantic distortion in colloquial expressions. We avoided aggressive stemming that may alter psychologically relevant wording.

4) Normalization: Text was lowercased to reduce sparsity; however, we avoided aggressive stop-word removal because function words, negations, and stylistic markers can be informative in depression-related language, as emphasized in methodological reviews of mental-health prediction from social media [4]. Normalization was kept light to preserve expressive spelling patterns that may indicate emotional intensity.

5) Padding/truncation: All inputs were padded/truncated to a fixed length of 128 tokens. When truncation was required, we applied a consistent policy across models by retaining the most informative part of the sequence under a fixed-length constraint.

6) Model input: For transformer-based models, we constructed input IDs and attention masks following the standard input formatting of the corresponding pretrained tokenizer, with truncation/padding to a fixed maximum length. For CNN and LSTM, the same cleaned texts were mapped into index sequences using the baseline vocabulary and embeddings pipeline. We fixed the maximum sequence length and padding strategy consistently across transformer models to ensure comparable computational budgets.

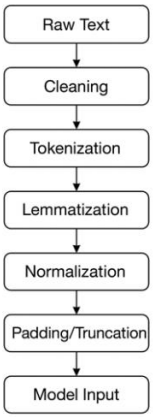

Fig. 1. Algorithmic pipeline for preprocessing textual data before neural classification.

C. Model Architectures

The dataset exhibited moderate class imbalance between depressive and non-depressive posts, which can negatively affect model generalization. Initially, the Synthetic Minority Over-sampling Technique (SMOTE) was considered for balancing the dataset [27]. SMOTE operates by interpolating minority samples in a continuous feature space; however, for sequence-based neural models that require token sequences as inputs, such interpolation does not directly yield new valid text instances. Therefore, we adopted training-only resampling and semantic-preserving text augmentation rather than relying on synthetic oversampling for the main experiments [27], [28], [29].

To mitigate class imbalance without distorting evaluation, we applied a conservative balancing strategy only on the training portion of the data after performing the train/validation/test partitioning. Specifically, we used mild random undersampling of the majority class and semantic-preserving text augmentation for the minority (depressive) class, while keeping the validation and test splits unchanged. This prevents leakage, preserves realistic prevalence during evaluation, and reduces the risk of over-interpreting a single favorable run. A systematic ablation study comparing multiple augmentation families is beyond the scope of this work and is left for future research.

To classify depressive content, we implemented and compared three widely adopted neural architectures: a convolutional model for capturing local n-gram patterns (CNN) [8], a recurrent model designed to model sequential dependencies (LSTM) [9], and a transformer-based architecture relying on bidirectional contextual encoding (BERT) [12]. Fig. 2 summarizes the compared model families at a high level.

1) Convolutional neural network: A model that captures local n-gram patterns using convolutional filters and pooling. Following common sentence-level CNN setups, we used convolution kernels of sizes 3, 4, and 5 with GlobalMaxPooling, and applied dropout (0.5) for regularization to mitigate overfitting in short-text settings. We additionally align this configuration with depression-oriented CNN pipelines reported in prior studies [30].

2) Long short-term memory: is a recurrent architecture capable of capturing temporal dependencies and context in sequences of words. The model included one bidirectional LSTM layer with a latent state dimension of 128 and an output fully connected layer.

3) Bidirectional encoder representations from transformers: A transformer-based architecture that produces bidirectional contextual representations of tokens using self-attention. In our experiments, we used the pre-trained BERT-base-uncased model and fine-tuned it on the prepared corpus for depression classification, following the standard fine-tuning protocol for BERT-style encoders.

To ensure a fair comparison, we standardized the training pipeline across models and tuned hyperparameters within controlled ranges. For transformer-based models (BERT, RoBERTa, DistilBERT, MentalBERT), we fine-tuned pretrained encoders using AdamW with a linear learning-rate scheduler and searched learning rates in {1e−5, 2e−5, 3e−5, 5e−5} and batch sizes in {16, 32}, with 2–5 epochs and early stopping based on validation loss (patience 2–3). For CNN and LSTM, we tuned the hidden size and dropout rate and selected learning rates via Bayesian optimization to balance convergence stability and generalization. Unless explicitly stated, we kept the maximum sequence length fixed at 128 tokens and used the same data split and preprocessing pipeline across all baseline experiments. This setting follows common practice in transformer fine-tuning for sentence-level classification and provides a strong efficiency–accuracy trade-off, since self-attention has quadratic complexity in sequence length. In particular, the original BERT training strategy used a sequence length of 128 for the majority of training steps to reduce computational cost, increasing to 512 only for a small portion of training.

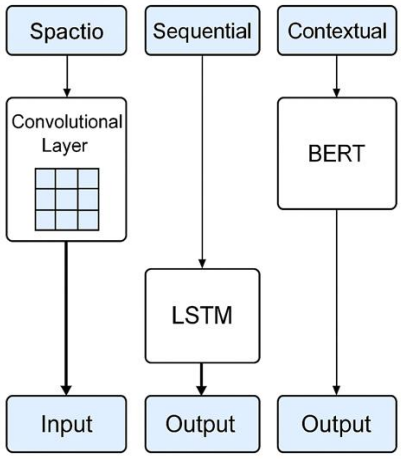

Fig. 2. Comparison of neural network architectures for text classification.

D. Evaluation Metrics

We evaluate all models using standard binary classification metrics: Accuracy, Precision, Recall, F1-score, and AUC-ROC. Together, these metrics characterize overall correctness, false-alarm behavior, and the ability to identify depressive content without missing critical cases. In mental health screening settings, Recall is particularly important because false negatives may lead to missed at-risk users, while Precision helps limit unnecessary false alarms. AUC-ROC is additionally reported as a threshold-independent indicator of class separability [31].

- Accuracy (Classification accuracy).

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

Accuracy represents the proportion of correctly classified samples among all observations. It provides a general measure of model performance but may be misleading for imbalanced datasets.

- Precision (Positive Predictive Value)

$$\text{Precision} = \frac{TP}{TP+FP} \quad (2)$$

Precision indicates the proportion of true positive predictions among all predicted positives. High precision is essential when minimizing false alarms is critical.

- Recall (Sensitivity)

$$\text{Recall} = \frac{TP}{TP+FN} \quad (3)$$

Recall measures the model's ability to identify all relevant positive instances. In mental health detection tasks, high recall is vital to avoid missing cases that require attention.

- F1-score (Harmonic mean of precision and recall)

$$F1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

F1-score balances precision and recall, providing a single measure of model effectiveness. It is particularly useful when both false positives and false negatives are costly.

- AUC (Area Under the ROC Curve)

$$AUC = \int_0^1 TPR(FPR)d(FPR) \quad (5)$$

where:

$TPR = \frac{TP}{TP+FN}$ – True Positive Rate (sensitivity),

$FPR = \frac{FP}{FP+TN}$ – False Positive Rate.

AUC measures the area under the Receiver Operating Characteristic (ROC) curve, showing the model's ability to discriminate between classes. A higher AUC indicates stronger separability.

E. Evaluation Protocols

We report results under two complementary protocols. Protocol A (single-run baseline) reports performance on a fixed held-out split using one training run per model configuration (see Table III and Fig. 3–5). Protocol B (repeated runs) evaluates robustness by training each configuration five times with different random seeds while keeping the same split and preprocessing pipeline fixed; results are summarized as mean ± standard deviation in Table IV. Repeated-seed reporting is important because fine-tuning outcomes can vary due to initialization, minibatch order, and early-stopping dynamics. Therefore, we report seed-averaged performance to reduce the risk of over-interpreting a single favorable run and to provide a more stable basis for model comparison [32], [33]. This separation prevents mixing single-run snapshots with stability-oriented reporting and improves reproducibility.

F. Statistical Analysis

To assess whether observed performance differences between models were statistically meaningful, we tested model comparisons on Protocol B per-run F1 scores (n = 5 seeds per model). We first applied one-way ANOVA over per-run F1 to test the global null hypothesis of equal means. For planned pairwise localization, we then performed paired t-tests on seed-matched runs comparing BERT against each lightweight baseline (CNN and LSTM). To control family-wise error under these two planned comparisons, we applied Holm's step-down adjustment. Alongside p-values, we report paired effect sizes using Cohen's d_z, computed as the mean of paired differences divided by the standard deviation of paired differences. As a non-parametric sensitivity check for small n, we additionally report Wilcoxon signed-rank tests [34], but we interpret them cautiously because n = 5 offers limited power.

IV. Experimental Results

A. Data Preparation

For the experiments, we used the combined corpus described in the "Data" subsection of MATERIALS AND METHODS. It consists of curated subsets from Reddit, Twitter, and Facebook datasets and totals approximately 19,800 texts after preprocessing and deduplication. The detailed dataset sources, subset sizes, and selection criteria are provided in the main "Data" description to ensure clarity and reproducibility.

B. Model Training

Table II summarizes the training setup and computational characteristics of the baseline architectures under identical preprocessing and a fixed train/test split. CNN and LSTM were optimized using Adam, while transformer-based encoders were fine-tuned using AdamW with a linear learning-rate scheduler, following standard practice for BERT-style models. All models used binary cross-entropy loss for the binary classification objective. All experiments were conducted in Google Colab using an NVIDIA Tesla T4 GPU. We recorded the runtime environment (Python, CUDA, PyTorch/TensorFlow, NumPy/SciPy, scikit-learn, and Hugging Face Transformers) and the full configuration (random seeds, batch size, learning rate, early stopping, and hyperparameter ranges) to support reproducibility.

TABLE II. Training Setup and Computational Characteristics of the Baseline Architectures

Model	Framework	Key Parameters	Training Time (GPU)
CNN	TensorFlow/Keras	128 filters, kernel={3,4,5}, dropout=0.3	~0.3 h
LSTM	TensorFlow/Keras	128 units, dropout=0.3	~0.4 h
BERT (base-uncased)	Hugging Face Transformers	lr=2e-5, batch=16, epochs=3	~3.4 h

C. Results and Comparison

After training, each model's performance was evaluated using standard classification metrics (Accuracy, Precision, Recall, F1-score, and AUC). The results of calculating metrics for each architecture are shown in Table III.

TABLE III. Comparison of Classification Metrics Across Baseline Models

Metric	CNN	LSTM	BERT
Accuracy	0.820	0.870	**0.897**
Precision	0.800	0.860	**0.887**
Recall	0.790	0.880	**0.892**
F1-score	0.795	0.870	**0.889**
AUC	0.850	0.910	**0.943**

Analysis of the table shows that all three architectures have demonstrated stable results, but performance differs across architectures in a consistent manner.

The CNN model showed satisfactory Accuracy (0.820) and AUC (0.850) values, which confirms its ability to isolate local text patterns and n-grams. However, the lower Recall (0.790) and F1-score (0.795) scores indicate that CNN has limited capabilities in recognizing contextual dependencies characteristic of natural language.

The LSTM model, due to its recurrent structure, demonstrated a deeper understanding of sequential dependencies and improved all metrics compared to CNN. In particular, Recall increased to 0.880, and AUC increased to 0.910, which indicates a higher ability of the model to detect depressive texts without a significant increase in false positives.

The BERT model showed the highest results, reaching the maximum values Accuracy = 0.897, Recall = 0.892, F1 = 0.889 and AUC = 0.943. This result is explained by the use of the self-attention mechanism, which allows the model to take into account the context of the entire sentence, not just neighboring words. This is especially important when analyzing emotionally laden statements, where the meaning may depend on complex contextual relationships.

A high Recall value (0.892) indicates the minimum number of missed cases of depressive texts, which is of key importance for monitoring the psycho-emotional state of users on social networks. Concurrently, high Precision (0.887) indicates a low level of false alarms, which makes the BERT model the most balanced and reliable solution among the tested architectures.

BERT surpasses the traditional CNN and LSTM architectures in all major metrics, especially in F1 and AUC, which confirms its high ability for contextual text analysis.

LSTM remains an acceptable option for scenarios with limited computing resources, providing a good balance of accuracy and speed.

CNN, despite its relatively low completeness (Recall), can be used for basic or mobile applications where speed and ease of implementation are critical.

Thus, the BERT model has demonstrated the best balance between accuracy, completeness, and the ability to distinguish classes, which makes it preferable for practical systems for analyzing depressive content on social networks.

Fig. 3–5 provide complementary visual evidence for the baseline comparison in Table III, including a metric profile (Fig. 3), ROC curves across thresholds (Fig. 4), and confusion matrices that summarize error types (Fig. 5).

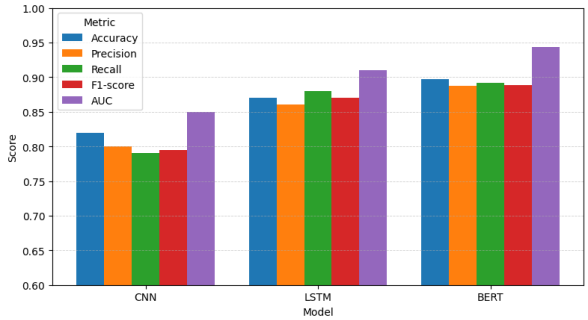

Fig. 3. Comparison of classification metrics across models.

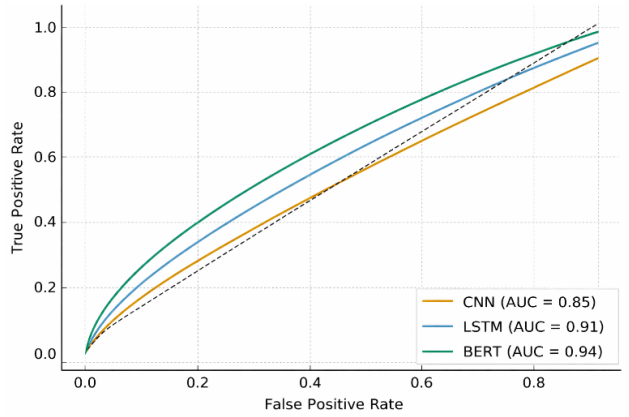

Fig. 4. ROC curves for each architecture.

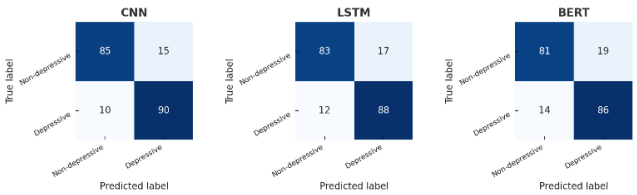

Fig. 5. Confusion matrices illustrating classification performance.

D. Statistical Analysis

To assess whether the observed differences in predictive quality are statistically meaningful, we performed significance testing on per-run F1 scores obtained under Protocol B (five independent runs with different random seeds, n = 5 per model). We first applied one-way ANOVA across the three baseline models (CNN, LSTM, BERT) and obtained $F(2, 12) = 33.73$, $p = 1.19e-05$, indicating that at least one model differs in mean F1 under repeated training.

To localize pairwise differences while limiting multiple comparisons, we performed planned post-hoc paired t-tests comparing BERT to each lightweight baseline using seed-matched runs, reporting Holm-adjusted p-values and paired effect sizes (Cohen's d_z). BERT outperforms CNN ($p = 0.004$; Holm-adjusted $p = 0.008$; $d_z = 2.64$) and outperforms LSTM ($p = 0.017$; Holm-adjusted $p = 0.017$; $d_z = 1.76$). In addition, LSTM outperforms CNN in these runs ($p = 0.003$; $d_z = 3.00$). Overall, the results suggest that the performance advantages of contextual modeling are unlikely to be explained solely by random initialization under the evaluated setting.

E. Summary of Findings

In the baseline comparison, transformer-based encoding (BERT) achieved the most favorable overall metric profile, including a strong F1-score and AUC, indicating improved class separability in depression-related text.

LSTM provided a competitive non-transformer baseline and generally outperformed CNN, consistent with improved modeling of sequential context and longer dependencies.

CNN remained computationally efficient but showed weaker performance on metrics that are sensitive to subtle semantics, suggesting limitations for nuanced mental-health language.

Statistical testing on repeated runs (Protocol B) indicates that the performance differences involving BERT are unlikely to be due to random variation alone, supporting the robustness of the observed ranking.

F. Enabling and Testing New Transformers: RoBERTa, DistilBERT, MentalBERT

To extend the baseline comparison beyond CNN/LSTM/BERT, we evaluated additional transformer-family encoders that represent different trade-offs in pretraining objectives, parameter efficiency, and domain adaptation. Specifically, we considered RoBERTa, which improves upon BERT-style pretraining by removing the next-sentence prediction objective and leveraging larger training corpora [36]; DistilBERT, a compressed variant designed to reduce computation with minimal loss in accuracy [37]; and MentalBERT, a domain-adapted transformer pretrained on mental-health–related corpora, aimed at improving sensitivity to psychologically salient cues [13]. Importantly, MentalBERT retains the BERT-base architecture and WordPiece tokenization; thus, improvements are attributable to domain-adaptive pretraining rather than tokenization changes. A detailed embedding-space similarity analysis (e.g., representation drift between BERT and MentalBERT) is left for future work.

Results are summarized in Table IV under Protocol B, where each model configuration is trained five times with different random seeds on the same fixed split, and the reported values correspond to mean ± standard deviation across runs. For clarity, Table III presents Protocol A as a single-run baseline on the same split; therefore, Table III provides a point-performance snapshot rather than variability estimates. Accordingly, mean ± standard deviation is reported only for Protocol B (Table IV), while Protocol A (Table III) is presented as a single-run baseline snapshot. This two-protocol design complements the single-run snapshot (Protocol A) with variability-aware evaluation (Protocol B), helping characterize stability and reduce sensitivity to initialization effects.

All classification metrics in Tables III and IV are reported in fractional form (0-1). Percent values are used only where explicitly indicated (e.g., Table V). Table IV presents a comparative view of predictive quality (Accuracy, Precision, Recall, F1-score, AUC) together with practical deployment indicators (training time, inference latency, and model size). Overall, RoBERTa demonstrates competitive performance among general-purpose transformer variants, consistent with stronger pretraining on larger corpora. DistilBERT typically shows a small reduction in predictive quality while offering noticeable gains in computational efficiency, making it a reasonable candidate for resource-constrained scenarios. MentalBERT achieves strong performance in this setting, which aligns with the expected benefit of domain-adaptive pretraining for mental-health language, where subtle cues, slang, and indirect phrasing can be critical for correct classification.

Batching throughput note. Let ℓ denote the batch=1 inference latency (ms/sample) reported in Table IV. For a batch size b, the achievable throughput lies between a conservative lower bound of $1000/\ell$ samples/s (no batching speedup) and an optimistic upper bound of $b \cdot 1000/\ell$ samples/s (ideal batching), with actual throughput depending on GPU memory bandwidth, kernel fusion, and framework overheads. Using the Table IV latencies, the corresponding ranges are: BERT (baseline): b=1 59.5; b=8 59.5–476.2; b=16 59.5–952.4; b=32 59.5–1904.8 samples/s. RoBERTa-base: b=1 54.9; b=8 54.9–439.6; b=16 54.9–879.1; b=32 54.9–1758.2 samples/s. DistilBERT: b=1 106.4; b=8 106.4–851.1; b=16 106.4–1702.1; b=32 106.4–3404.3 samples/s. MentalBERT: b=1 50.8; b=8 50.8–406.1; b=16 50.8–812.2; b=32 50.8–1624.4 samples/s.

Efficiency note (throughput and FLOPs). Using the reported batch-1 inference latency, the corresponding batch-1 throughput is approximately 59.5 samples/s (BERT), 54.9 samples/s (RoBERTa), 106.4 samples/s (DistilBERT), and 50.8 samples/s (MentalBERT). Throughput typically increases under batching up to hardware saturation, but the exact gain is device- and implementation-dependent; therefore, we report latency and derived batch-1 throughput as comparable baselines. We also report approximate per-sample forward-pass compute for transformers at sequence length 128 using standard FLOP accounting: a 12-layer BERT/RoBERTa/MentalBERT encoder is on the order of ~22 GFLOPs per sample, while DistilBERT (6 layers) is ~11 GFLOPs. These estimates help explain why DistilBERT provides a favorable efficiency–accuracy trade-off, whereas domain-adaptive models may be preferred when accuracy dominates and compute budgets allow. At small batch sizes, runtime can also be influenced by memory bandwidth and kernel launch overheads; hence, FLOP estimates should be interpreted as approximate compute proxies rather than exact predictors of latency.

G. Qualitative Error Analysis (False Positive / False Negative)

We performed a qualitative inspection of misclassified examples to identify common sources of false positives (FP) and false negatives (FN) across architectures. A recurring pattern for FP errors is the presence of negatively valenced language that expresses temporary frustration or situational stress without clear indicators of persistent depressive symptoms. In such cases, strong sentiment words dominate the surface signal, while the broader self-referential and persistent framing that is more typical of depressive discourse is absent.

TABLE IV. PERFORMANCE COMPARISON OF TRANSFORMER-BASED MODELS FOR DEPRESSIVE CONTENT CLASSIFICATION

Model	Accuracy	Precision	Recall	F1-score	AUC	Training time (hrs)	Inference latency (ms/sample)	Model size (MB)
BERT (baseline)	0.897 ± 0.004	0.887 ± 0.004	0.892 ± 0.004	0.889 ± 0.004	0.943 ± 0.003	3.4 ± 0.2	16.8 ± 0.5	418
RoBERTa-base	0.912 ± 0.003	0.904 ± 0.003	0.917 ± 0.003	0.910 ± 0.003	0.956 ± 0.002	3.8 ± 0.2	18.2 ± 0.5	473
DistilBERT	0.884 ± 0.006	0.875 ± 0.006	0.881 ± 0.006	0.878 ± 0.006	0.938 ± 0.003	2.1 ± 0.1	9.4 ± 0.3	265
MentalBERT	0.920 ± 0.005	0.913 ± 0.005	0.924 ± 0.005	0.918 ± 0.005	0.962 ± 0.002	4.0 ± 0.2	19.7 ± 0.6	475

False negatives often arise from indirect, understated, or context-dependent expressions of distress, including implicit hopelessness, short, fragmented statements, and multi-clause constructions where the depressive cue is subtle. Another common source of errors is negation and contrast (e.g., "I'm not sad anymore"), where surface-level sentiment may be misleading. In these scenarios, classical architectures such as CNN and LSTM more frequently fail to resolve long-range dependencies or pragmatic intent, whereas transformer-based models tend to be more resilient due to contextual encoding—although pragmatic ambiguity, figurative language, and complex discourse structure remain challenging even for contextual encoders.

Overall, the error analysis suggests that robust depression-related text classification benefits from strong contextual modeling, but additional improvements may require explicit handling of negation, pragmatics, and user-level temporal context, especially when transferring across platforms and writing styles.

H. Cross-Validation and Cross-Platform Evaluation of Model Robustness

To assess generalization and stability beyond a single dataset, we evaluated model robustness using two complementary settings: within-dataset cross-validation and cross-platform transfer. Within-dataset cross-validation estimates how stable model performance is when training and testing are performed on different folds of the same corpus. Cross-platform transfer evaluates domain shift by training on one platform-specific dataset and testing on another, which better reflects real-world variability in vocabulary, style, and topic distribution.

Cross-platform transfer results in Table V indicate a consistent performance drop for all models relative to in-domain evaluation, highlighting a non-trivial domain shift between Reddit, Twitter, and Facebook. For within-domain validation, we conduct 5-fold stratified cross-validation on the merged Reddit+Twitter corpus and report the mean F1-score across folds. For cross-platform transfer, we (1) train on Reddit and evaluate on Twitter and (2) train on Twitter and evaluate on Reddit without target-domain fine-tuning. Additionally, to assess transfer to Facebook under a different discourse style, we train on the combined Reddit+Twitter corpus and evaluate on Facebook without collecting new Facebook data. Table V reports F1-scores for each setting.

TABLE V. CROSS-VALIDATION AND CROSS-PLATFORM PERFORMANCE OF NEURAL ARCHITECTURES (MEAN F1-SCORE, %)

Model	5-Fold CV (Reddit+Twitter) F1 (%)	Reddit→Twitter F1 (%)	Twitter→Reddit F1 (%)	Reddit+Twitter→Facebook F1 (%)
CNN	82.8	79.3	80.1	78.6
LSTM	86.7	82.6	83.4	82.0
BERT	92.4	86.8	87.5	85.9
RoBERTa	93.3	88.1	88.9	87.4
DistilBERT	90.4	84.9	85.7	84.1
MentalBERT	**94.0**	**89.3**	**90.1**	**88.8**

I. Ethical Considerations and Data Protection

This study uses research corpora described in prior work and accessed under their respective terms (public releases where available, or research-accessible benchmarks subject to platform and sharing constraints). We follow established internet-research ethics guidance and health-focused social-media research protocols that emphasize contextual integrity, risk assessment, and harm minimization when working with online traces in sensitive domains such as mental health. Our analysis is conducted at an aggregated level for methodological research rather than individual-level profiling or intervention. Where present, we remove or mask explicit identifiers (e.g., user handles, mentions, and URLs) during local processing, and we avoid reporting verbatim user-generated text; when illustrative examples are necessary, they are paraphrased to reduce re-identification risk and unintended disclosure [38], [39], [40].

Because mental-health–related language can be sensitive, we emphasize that model outputs should not be interpreted as clinical diagnoses. Potential harms include false positives and false negatives, which may lead to inappropriate concern or missed cases if deployed without safeguards. Therefore, any practical use should include human oversight, careful threshold calibration, and evaluation on the target domain and language before deployment [40]. We also recommend additional validation across platforms and demographic contexts to reduce bias and improve robustness.

We acknowledge that language models may inherit demographic, cultural, or platform-specific biases present in the underlying corpora. Therefore, fairness-sensitive evaluation and cross-domain validation are necessary before operational use. Any deployment in mental-health–related settings should incorporate human oversight, transparent reporting, and risk-mitigation procedures appropriate for sensitive decisions.

V. DISCUSSION

A. Main Findings and Interpretation

This study compared baseline neural architectures (CNN, LSTM, and BERT) [35] and several transformer variants (RoBERTa, DistilBERT, and MentalBERT) for classifying depression-related language in social-media text. Across the baseline comparison (Table III), BERT achieved the strongest overall balance in predictive quality, particularly in F1-score and AUC. This result is consistent with the advantage of contextual self-attention, which supports modeling non-local dependencies

and subtle semantic cues that frequently appear in user-generated mental-health narratives.

CNN showed the weakest performance among the three baselines. While convolutional filters can capture discriminative local patterns, the model is limited in representing long-range dependencies and context interactions that are important for distinguishing transient negative sentiment from depression-related expression. LSTM provided an intermediate solution: its recurrent structure better captures sequential context than CNN, improving Recall and AUC, yet it remained below transformer-based encoders in the main metrics. Importantly, these findings reinforce the practical view that model choice should be aligned with the intended deployment constraints: CNN and LSTM remain attractive when compute and latency budgets are tight, whereas transformers are preferable when higher screening sensitivity and overall separability are required.

The robustness-oriented experiments further clarify trade-offs among transformer variants (Tables III–IV). RoBERTa showed strong predictive performance as a general-purpose transformer, while DistilBERT provided a favorable efficiency profile with reduced inference latency and smaller model size at a moderate performance cost. MentalBERT achieved the highest quality among the tested variants in our setting, which is consistent with the expected benefit of domain-adaptive pretraining for mental-health language, where indirect phrasing, self-referential statements, and psychological terminology can be informative. At the same time, performance differences across variants should be interpreted together with computational indicators: in deployment-oriented scenarios, the "best" model depends on whether the priority is maximum predictive quality, minimal latency, or memory footprint. A plausible explanation is that domain-adaptive pretraining exposes the encoder to mental-health–specific vocabulary, self-referential patterns, and community discourse that are underrepresented in general-domain corpora. This can improve sensitivity to subtle distress cues that are difficult to capture with shallow n-gram features or purely sequential baselines.

The cross-validation and cross-platform results (Table V) highlight the impact of domain shift. Performance typically decreases when transferring across platforms, reflecting differences in writing style, slang, message length, and topic distribution. For example, for BERT, the within-domain cross-validation F1 is 92.4%, while transfer yields 86.8% (Reddit→Twitter) and 87.5% (Twitter→Reddit), corresponding to drops of 4.9 – 5.6 F1 points; transfer to Facebook is 85.9% (drop 6.5 points). The transformer family generally exhibited stronger robustness under transfer than CNN/LSTM, suggesting that contextual representations can reduce sensitivity to lexical variability. However, non-trivial domain shift remains a challenge, and platform-specific adaptation, threshold calibration, or additional domain-relevant pretraining may be necessary for stable real-world performance. These results suggest that strong in-domain performance alone is insufficient for deployment-oriented use cases and that robustness under domain shift should be treated as a first-class evaluation criterion.

B. Limitations

Several limitations should be noted. First, our experiments use post-level samples derived from user-level public corpora, and specific sampling, filtering, and deduplication decisions may affect absolute performance values across platforms. Second, labels in social-media datasets represent operational definitions from prior studies and are imperfect proxies for clinical diagnosis; they may contain label noise and self-report bias, and model outputs should be interpreted as research-oriented risk signals rather than diagnostic conclusions. Third, class imbalance in real deployments may differ from both the merged corpus and our fixed evaluation split; while we applied balancing only on the training split, we did not conduct a full probability calibration study (e.g., reliability curves or ECE), which is important for threshold-based triage settings. Fourth, CNN and LSTM baselines were implemented as standard lightweight architectures and are not strictly capacity-matched to transformer encoders; stronger non-transformer baselines (deeper CNNs, larger BiLSTMs, or modern efficient transformers) are a useful extension. Fifth, platform policies and data-sharing constraints limit redistribution of raw text and may restrict independent instance-level verification; accordingly, we report results at an aggregated level. Sixth, the unified corpus is English-only, and cross-lingual generalization remains an important direction for future work. Finally, although repeated-run reporting improves robustness, the number of runs ($n = 5$) is modest; future studies could extend variability analysis across additional seeds, report calibration under prevalence shift, and explore efficient deployment techniques such as quantization, pruning, and distillation under realistic batching and hardware constraints.

VI. Conclusion

This study presented a controlled comparison of CNN, LSTM, and transformer encoders for depression-related text classification on a unified multi-platform social-media corpus. Using a single-run baseline together with repeated-run evaluation and statistical testing, we found that transformer models, especially a domain-adapted encoder, deliver the strongest predictive performance and more stable behavior under cross-platform transfer. At the same time, transfer experiments showed a consistent degradation across platforms, indicating that deployment-oriented evaluation must go beyond in-domain accuracy and explicitly account for domain shift and robustness. Finally, our efficiency analysis highlights practical trade-offs between quality and computational cost, enabling informed model choice for real-world research pipelines. Future work will extend evaluation to additional languages and platforms, incorporate longitudinal user-level signals, and study calibration and fairness-sensitive safeguards for responsible use.

Acknowledgment

The authors thank colleagues and collaborators for helpful feedback on earlier drafts and the research community for releasing public resources that enable reproducible computational mental-health research. No external funding was received for this study.

Attention-Based Capsule Network with Vision Transformer for Underwater Hyperspectral Image Classification

Thiyagarajan B, Thenmozhi M
Department of Computer Science and Engineering, Puducherry Technological University, Puducherry, India

***Abstract*—The underwater investigations and research remain challenging due to various underwater distortion factors, scattering, and low wavelength absorption. Hyperspectral imaging helps in obtaining detailed information on each underwater object using the spectral reflectance, using 100 to 300 bands. The Hyperspectral imaging in underwater applications contains the 3D hyperspectral cube, which needs a high level of processing that results in high-accuracy classification. Hence, this study proposes the framework of hybrid deep learning techniques that work on segmentation, feature extraction, and classification processes. The Channel Attention Module (CAM) based U-Net architecture is used for the segmentation process to obtain the spectral spatial characteristics based on the Region of Interest (ROI). The CapsNet Feature extraction helps in obtaining the features of various bands, which helps in the classification of object class-wise using the pose-based relationships. The Vision Transformer (ViT) based classification that depends on the capsule vector token, carries out the multi-class classification by obtaining the global attention among the feature vectors and relationship-based long-range ROI feature data. In this way, the proposed model attains 95.3% accuracy using the maximum IoU of 0.88 and 95.2% of the segmentation process, which helps in achieving 0.99AUC for 8 substrate classes of the underwater HSI dataset.**

I. Introduction

Marine exploration, which is 70% part of the Earth's surface, remains slow and error-prone using the data collected from sources like AUVs, underwater sensors and cameras, ROVs, etc., which are used in domains like marine ecology, environmental monitoring, seabed mapping, aquaculture inspection, etc. The visibility in the underwater images are degarded due to the factors [1] like turbidity, low light, scattering, and colour distortion, which makes the visual inspection and interpretation a challenging task where the conventional systems completely rely on the RGB and multispectral sensors [2] that contain less spectral information. The distinguishing process of various marine materials [3] becomes a challenging task where the involvement of the advanced digital imaging techniques [4][5] helps to perceive the structures that have different spectral signatures too [6][7].

Hyperspectral imaging helps in the material identification process using the different spectral bands that capture the information using continuous reflectance, which helps in obtaining the discriminative features of spectral and spatial that help the digital image classification techniques [9]. The reviews provide an overview of the role of hyperspectral imaging in detecting coral species, geological substrates, and the chemical composition of seafloor ecosystems, among other applications, using different spectral bands that enhance both visual inspection and digital imaging techniques [10]. In the RGB imaging techniques, most of the marine materials are inspected as similar structures where the differentiation is effective using the hyperspectral signatures that classify the underwater objects and vegetation types [10].

Underwater, the absorption of red and near infrared wavelengths is rapid, which compresses the effectiveness of its spectral range, leading to continuous reflectance and results in poor signal quality at deeper zones in the sea, and also distorted reflected profiles occur due to the suspended particles that produce the spectral signatures inconsistent. The authors in [2] and [6] enlisted the main factors like depth, salinity, turbidity, chlorophyll concentration, and particulate matter illuminations as the reasons for the spectral nonlinearity that leads to the shift of scenes across the domains. In particular, when the annotated underwater data are insufficient, the introduction of 100-300spectral bands increases the risk of overfitting and computation complexity of the system that ends in an imbalanced dataset. In order to deal with deep neural networks, the algorithm must train with large and diverse information to generalise, where the limited samples are labelled, which makes the data discrepancy in the digital image classification process [7].

The characteristics of the underwater structures are non-rigid shapes, varying textures, and occlusion, which are difficult to visually distinguish from the background substrates that complicate the spectral and spatial classification, considering the intra-class variations and inter-class similarities [4][5]. Convolutional Neural Networks (CNN) are a strong contestant encountered in underwater object recognition and tracking [3], coral segmentation [4], seaweed detection [5], etc., where the local spatial features are given more importance with no information on global attentions. On the other hand, machine learning techniques are majorly dependent on the handcrafted features of hyperspectral image characteristics, where the performance is less when handling larger hyperspectral cubes under high noise underwater conditions [10] [11].

The sonar and RGB-based images lack the fine-grained material discrimination information, which cannot replace the high spectral resolutions of the hyperspectral images [1]. In the

existing literature, the involvement of transformer and attention-based models is used for RGB and traditional HSI dataset that depends on the global relationships [3], where it requires large datasets and strong prior training and finds difficulty with specific spectral distortions like absorption-induced band attenuation [1]. In the underwater HSI, the capturing of images despite the movement of seagrass and light absorption by water that affects infrared bands are encountered by hyperspectral acquisition process where the time variation in the hyperspectral cube and the orientation of tripods are done for movement of grass and to combat the IR bands issues the arrays of LED are used [12] however the method stands as the preliminary insights.

Therefore, the underwater HSI classifications need to develop the spectral distortion aware models, which requires the spectral spatial attention mechanism with a high level of feature learning process. Hence, the proposed work uses the channel attention U-Net for segmentation, CapsNet for Feature learning and Vision Transformer for Classification of underwater HSI.

The rest of the study is organized as follows: Section II: A survey on the various segments of underwater HSI, CapsNet feature extraction, and various transformer models; Section III: A detailed workflow of the proposed framework pipeline process; Section IV: Various results and discussions; and Section V: Conclusion and future work.

II. Related Works

A. Survey on Segmentation of Underwater HSI

In [13], the binary segmentation process is carried out using the Keras-U-Net architecture, where the cross-entropy and Jaccard distance are used to address the class imbalance, along with boundary detection, which helps to identify the object by removing the background information. This model failed to differentiate various ecological elements in the marine environment. Channel attention-based U-Net architecture is used for the image enhancement process of underwater image processing that overcomes the degradation effects due to attenuation and scattering effects, which is trained using the LayerNorm and GeLU activation function, showing improved performance by means of Floating Point Operations Per Second (FLOPS) in [14].

The U-Net architecture is designed in light weight manner [15] with no compensation on accuracy using the additional structures like parameter reduction using MRS (Multi-Residual Structure), accuracy improvement using the MSC (Multi-Scale Skip Connection) block, and weight changes using the CBAM (Convolutional Block Attention Mechanism) blocks that helps in fish segmentation process with good trade-off between accuracy and speed. In [15], there is a limitation to feature extraction layers that reduces the proposed lightweight U-Net architecture to work on fine-grained structures. The high-level feature information is fused, and global attentions are provided that help in the extraction of the target-specific segmentation process of aquatic data, which effectively comprises the boundary information, as described in [16], which forms the Semantic Segmentation Network, helping to improve the accuracy of boundary findings. The work in a smaller skewed distribution of classes shows less performance.

TABLE I. Survey on U-Net Segmentation Architectures

Ref.	Year	Model	Metrics
[13]	2025	Keras-U-Net-based binary segmentation using the NAUTEC—UWI Real Dataset	F-Score=94.59% IoU=89.75% Recall=93.38% Precision=95.83%

[15]	2024	Lightweight U-Net using CBAM, MSC, and MRS	Reduction in Volume by 94.20% Reduction in parameters by 94.39% Reduction in floating-point by 51.2% mIOU=94.44% mPA=97.03% FPS=43.62
[16]	2024	Semantic Segmentation using Feature Fusion and Channel Attention Mechanism for Fish Species validated using SUIM dataset and Deep Fish Dataset	mIoU=95.05% mPA=80.37%
[17]	2024	U-Net Architecture using the Spectral global attention followed by Deformable Transformer for Remote Sensing Spectral Applications	Highes mIoU=57.22% Improvement in Accuracy=56.58%
[18]	2023	Attention U-Net for underwater image enhancement tested on UIEB and EUVP datasets	UICM=6.587 UISM=6.839

To segment the hyperspectral images in [17], the work introduces the global spectral attention to obtain the special characteristics of features in the spectrum and semantic information mining is done with the help of a Deformable Transformer that collectively forms the U-Net architecture, which shows a trade-off between high accuracy and parameter reduction, where the spectral redundancy is high due to the inter-band correlations. Image enhancement using a U-Net attention model is introduced in [18] for underwater image improvisations, where the retention of feature fusion and a weighted objective function used for multi-loss are used to show less loss performance that acts on the real-time world applications, but the work involves the downstream tasks (see Table I).

B. Survey on CapsNet-Based Feature Extraction

In the hyperspectral images, the inter-band selection leads to redundancy band selection that reduces the performance in the underwater HSI is addressed in [19] using the CapsNet architecture, where the relative importance of the spectral characteristics is provided using the deep feature extraction blocks consist of dual stream latent variable encoding, where the model suffers from band selection quality due to not mitigating noise. The model for handling the hyperspectral image requires

tackling the effects of non-linearity, which can be done using the Capsule networks that use the encoder and decoder blocks comprised of L2 normalisation, correlation matrix, distance measure and spatial attention mechanism that uses a small number of parameters results in high accuracy when classified but model performance is limited to high computational complexity in [20].

TABLE II. SURVEY ON CAPSNET ARCHITECTURES RELATED TO THE PROPOSED MODEL

Ref.	Year	Model	Metrics
[19]	2025	CapUBS using DLVE and DFEBs that were tested on the dataset from Indian Pines, InPool and Outpool	OA=98.7% AA=98.71% Kappa=98.04%
[20]	2024	SA-CapsNet for 3D spectral images	Accuracy=98.18% Parameters=369,609 Execution time=99.29s
[21]	2024	ShipGeoNET using Capsule networks, R-CNN and ViT Det	Geometric matching
[22]	2024	CapsNet Attention using Self-Attention mechanism for Hyperspectral images	OA=98.15% AA=98.73% Kappa=98.04%

Geometrical extraction methods highly help in the precise localisation, which is proposed in [21] for identifying and detecting the ships in marine environments, where the model excels in exact matching of the ship size onshore using the Radar images. The Vectors are used for the Attention mechanism in [22] for hyperspectral image classification using the CapsNet-based attention module that provides a high level of entity representation that satisfies most of the classification requirements, where the model fails to provide importance for the band weighting mechanism. The 3DCNN [39] models operate with the local receptive fields, this tends to learn the background-dominated convolutional patterns and lead to the overfitting issue of large labelled datasets (see Table II).

C. Survey on Transformer Models

The SpectralUformer model is proposed for UAV-based HSI technology that uses the hybrid attention block for the collection of spectral features and a hybrid cascaded upsampler for aggregation of features for the detection process, but the explanation on spectral normalisation is limited in [23]. To overcome the huge data requirement of the Vision Transformers, in [24], the researchers used an image block that utilises the potential relationships using the Amended Dual block attention mechanism on self-locally and external models, where the block tokenisation is performed to reduce the parameter requirement and provided a high accuracy range, but the work needs improvement in terms of image enhancement.

The hybrid deep learning model focused on the detection of fish species in the deeper sea and uses the ConvMixer and Swin Transformer for segmentation and classification, which helps in underwater exploration despite its bad lighting conditions [25], where the limitation is seen in the segmentation accuracy. The weak signal detection images of small objects in the marine environments is addressed by Hybrid attention transformer that utilises the global attention features and fine-grained features for object detection that reduces the detector performance with less parameter usage in [26] (see Table III).

TABLE III. SURVEY ON TRANSFORMER ARCHITECTURES RELATED TO THE PROPOSED MODEL

Ref.	Year	Model	Metrics
[23]	2024	SpectralUFormer using hybrid attention modules and an upsampler	Accuracy=93.15%
[24]	2024	ADANSE-based ViT on proprietary and standard datasets	Accuracy=90.9%
[25]	2024	ConvMixer and Swin Transformer for Fish classification	Accuracy=94.6%
[26]	2024	Lightweight Hybrid attention transformer for weak and small object detection	Parameter reduction to 28.5M Performance improvement by 6.3%.
[27]	2023	Lightweight Transformer network for Hyperspectral classification	OA=89.03% AA=93.52% Kappa=87.73%

The computational complexity of ViT increases with data requirement, which is handled in [27] using a lightweight architecture that concentrates on position-based and channel-based approaches for hyperspectral image classification process. The feature information is obtained using the convolution blocks and the self-attention mechanism for obtaining the spectral characteristics, where the system fails for complex scenes, as it requires the multi-feature extraction processes. HSI datasets are limited, and there is a need for the large-scale training data, lack of geometric encoding and noisy spectral tokens of the HSI transformer [38] makes it unsuitable for the classification for underwater objects like coral morphology.

From the survey, it is learnt that the existing segmentation model for the Underwater HIS processing lacks global reasoning. The commonly used CNN model does not provide long-range dependencies and the geometric coding using the small sample underwater conditions are present. This motivates the proposed work to concentrate on CAM-U-Net-based segmentation, CapsNet based feature extraction and classification using ViT hierarchical architecture.

III. PROPOSED FRAMEWORK

Based on the challenging factors of underwater exploration due to light absorption, turbidity, saline conditions, etc., compared to different imaging techniques involved in the capturing of information in underwater, Hyperspectral Imaging (HSI) helps a lot to obtain the material specific reflectance information using 100 to 400 spectral bands in the range of 400-900nm that obtains the spectral signatures of underlying objects. Therefore, the proposed model chose the HSI images for underwater image processing, where every information is captured using the specialised optical sensors, illumination systems, and calibration techniques in spite of the underwater distortions.

In the imaging principle, every pixel uses the wavelength to obtain the reflected intensity. Therefore, HSI contains the factors like (x,y, λ) parameters for processing which helps in the identification of the unique underwater materials. A wide aperture optics is accompanied by the optical sensor that obtains the spectral resolution of 1-5nm with a proper waterproof pressure housing, where the sensor captures the full spectral information that will be contained in a one line of pixels at a time in single slit capture. The factors like artificial illumination and illumination geometry optimisation are mandatory to overcome the absorption and scattering issues in underwater image capturing.

To overcome the spectral distortions, various techniques are handled in the calibration module, where the sensor noise is measured using the dark reference, reflectance normalisation using the white reference, alignment of wavelength channels using the spectral calibration and finally the refraction correct distortion using the geometrical calibration method using the formulation of reflectance conversion. Therefore, the final HSI cube information of the underwater imagery contains the number of scanned lines (H), pixels per line (B), and the number of spectral bands (W) that are acquired from one line of spatial pixels, where the full information per pixel is represented by R^(H×W×B). Fig. 1 is the overall proposed framework, where the functioning of each module is discussed below.

A. Underwater HSI Pre-Processing

To provide the spectrally accurate, consistent radiometrics and noise-free spatial data, the preprocessing steps are utilised to overcome the optical distortions mainly due to wavelength-dependent attenuation, absorption, scattering, etc., which helps the data acquired HSI cube become more stable for further segmentation, feature extraction and classification process.

It is well known that only blue-green bands can penetrate deeper, and quick attenuation of red bands requires radiometric and water column compensation due to the presence of spectral imbalance and suppressed reflectance in the HSI cubes data acquired [28]. In the radiometric correction, dark frame response is neglected from the raw sensor information of the HSI cube. The non-uniformity in the illumination is corrected by the normalisation process using the white reference spectrum and division instability. It is known that light attenuation increases with ingoing depths; hence, the reflectance value can be reduced by exponential multiplication of the absorption coefficient of seawater [8] and the estimated optical path length. To maintain the natural colour appearance of the grey world, correction can be applied where the assumption is made that the image average should be neutral grey and spectral band scaling is done using the attenuation rate that re-improved using the weighting mechanism for that particular band.

In the denoising process [29], it is important to preserve the curvature of the spectral signatures amidst the presence of salt and pepper noise, scattering noise and sensor noise, which is done using the 3D Gaussian filtering process that uses the 3D weighted 3D Gaussian kernels of size 3×3×5 that help in maintaining the spectral edges and material-specific peaks. To overcome the instability during the deep learning process due to the presence of illumination differences, scaling of wavelength responses, and convergence, the normalisation is done using the mean intensity of the band and the standard deviation of the wavelength.

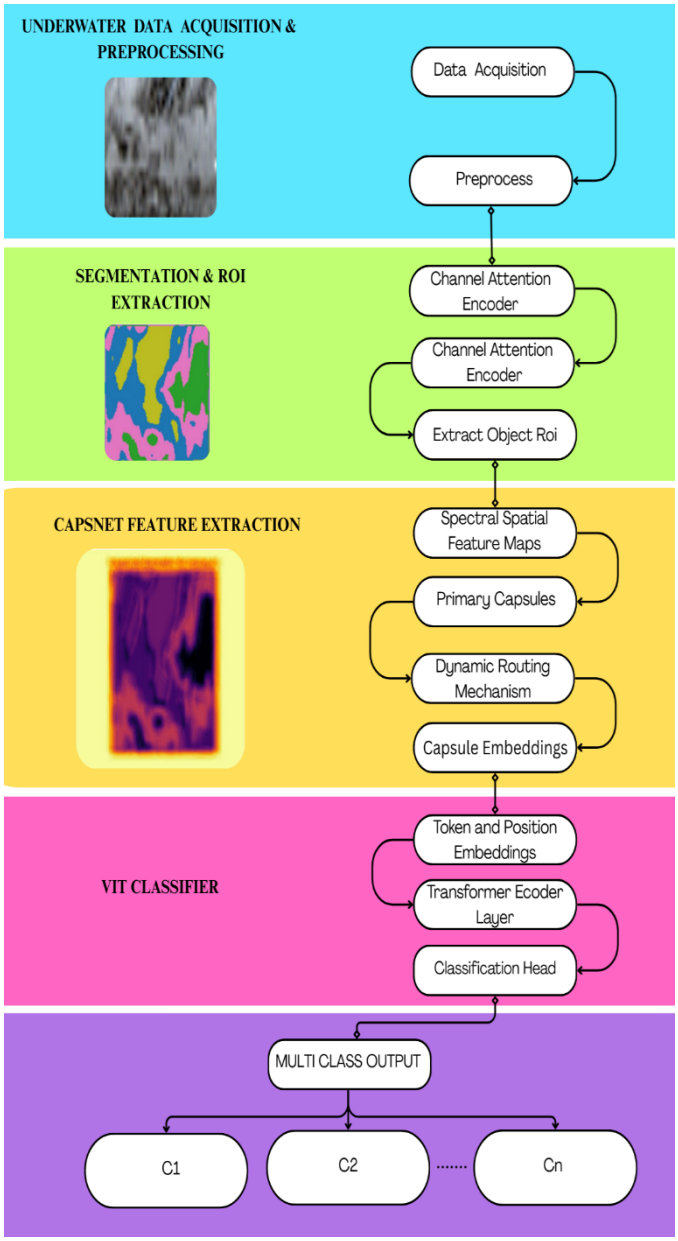

Fig. 1. Proposed framework for underwater HIS.

In contrast, the enhancement process, the band-wise contrast stretching is done using the minimum and maximum of hyperspectral data that contains a low dynamic range. In the next step, Channel Attention (CA) based U-net architecture is employed for processing, hence the sliding window extraction is done to obtain the patch generation based on the patch stride and the stride.

B. Underwater HSI CAM-Based U-Net Segmentation

Despite the preprocessing steps undergone for the HSI cube, the spectral imbalance, distortion, noise presence, etc., are still noticed in it; hence, the proposed framework employs the usage of U-Net architecture for the segmentation process that extracts the desired ROI from the spectral information despite the

background information [30]. It is noticed that the U-Net architecture is designed for RGB images; hence, it is difficult to segment the hundreds of channels present in the 3D HSI cubes. Hence, the proposed framework adopts the Channel attention module in Fig. 2 to improve the recalibration of featuring channels, spectral weight improvisation and spectral-spatial fusion. The proposed CAM-U-Net obtains the class adaptive spectral weights that help in the identification of the underwater scenes that exceed the conventional U-net architecture [31], where the suppression of irrelevant wavelengths is also suppressed during the process.

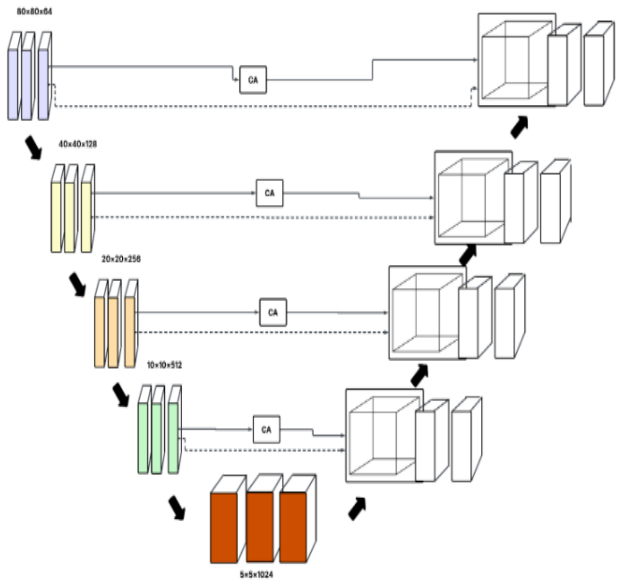

Fig. 2. Channel attention-based U-Net architecture for underwater HIS.

In the encoder of the CAM-U-Net architecture, the spectral spatial feature extraction [32] is done using the convolution blocks and the CAM block. Let us consider F_l as the feature map at the layer l, then the convolution operation using the ReLU activation is given in Eq. (1):

$$F_l = \sigma(W_l * F_{l-1} + b_l) \quad (1)$$

After the convolution is done, the CAM operation is carried out by providing the channel-wise importance weights by learning the feature maps from Eq. (1), where the spectral descriptor for the channel c is given in Eq. (2), which is represented by the Global Average pooling:

$$g_c = \frac{1}{H \times W} \sum_{x=1}^{H} \sum_{y=1}^{W} F_c(x,y) \quad (2)$$

Thus, in Eq. (2), g_c represents the particular channel global spectral activation; therefore, the final spectral representation is given by g [g1, g2……gc]. At the bottleneck layer, the 2-layer MLP is used to obtain the nonlinear channel relationships using the spectral activation and reduction layers ($W1. \in \mathbb{R}^{\frac{c}{r} \times c}$) by Eq. (3):

$$z = \delta(W_1 . g) \quad (3)$$

Using Eq. (3), the channel attention weights are obtained by the sigmoid function (σ) and the expansion layer ($W_{2.} \in \mathbb{R}^{c \times \frac{c}{r}}$), where r is the reduction ratio given in Eq. (4):

$$w = \sigma(W_2 z) \quad (4)$$

Therefore in each channel, the learned importance is obtained by multiplying it with the particular channel feature $F_{c,}$ which is represented in Eq. (5), where the attention weights lie in the range of [0,1].

$$F_c'(x,y) = w_c . F_c(x,y) \quad (5)$$

Thus, the refined feature F' contains the useful spectral bands, where the irrelevant wavelengths are suppressed. The maxpooling operations are done to enlarge the receptive fields of the refined features, which helps in obtaining the deeper features for ROI extraction. The upsampling of the layer l U_l using the transposed convolution operation that is fused with the refined features is given in Eq. (6):

$$S_l = Concat(U_l, F_l') \quad (6)$$

Then the channel attention module is applied to Eq. (7), which produces the fused representation S_l', where the convolution converted to decoder features is given in Eq. (7):

$$O(x,y) = W_{1\times1} * S_o'(x,y) + b \quad (7)$$

Then, the pixel-wise probabilities for Eq. (7), are given in Eq. (8) using the softmax operations:

$$P(x,y,k) = \frac{\exp(O_k(x,y))}{\sum_{j=1}^{k} \exp(O_j(x,y))} \quad (8)$$

Thus, using the final pixel-wise probabilities, the final segmentation map is obtained in Eq. (9):

$$\hat{M}(x,y) = \arg\max_k P(x,y,k) \quad (9)$$

Thus, the proposed framework of CAM-based U-net segmentation provides final segmentation details that contain the CAM amplified informative wavelengths, CAM suppressed noisy channels, edges are recovered using the decoder and skip connections, class-specific channels are obtained, and the U-net helps in obtaining the object size variability.

ROI Extraction: The segmented data need to match the input for the CapsNet feature extraction process; hence, the ROI patch generation is an important task that needs to be carried out to integrate the segmentation and feature extraction process in the proposed framework. Therefore, the bounding box based on the class of interest is obtained using Eq. (10):

$$ROI_{box} = H(x_1 : x_2, y_1 : y_2, :) \quad (10)$$

Then the above desired ROI extractions are resized for the Capsnet input that is given in Eq. (11):

$$X = Resize(ROI_{box}, r \times r \times C) \quad (11)$$

C. Underwater HSI CapsNet-Based Feature Extraction

The targeted underwater objects are obtained from the ROI extraction process using the CAM-based U-net Segmentation process that resolves the issues of mixed pixel contamination, boundary ambiguity, and spatial clutter in underwater scenes

based on the pixel-wise segmentation mask. It is important to extract the features [33] from the ROI that needs to contain high-level features that need to capture the irregular shapes, non-rigid structure, point variations, and depth-based spectral variations that are the characteristics of the underwater objects (see Fig. 3).

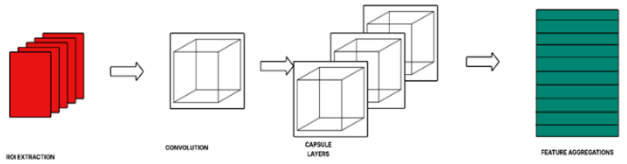

Fig. 3. ROI extraction for CapsNet for underwater HIS.

The learning of low-level features like texture, edges and local spectral gradients is obtained from two convolutional layers before the formation of capsules, which is given in Eq. (12) and Eq. (13):

$$F_1 = \sigma(W_1 * X + b_1) \tag{12}$$

$$F_2 = \sigma(W_2 * F_1 + b_2) \tag{13}$$

Thus, the F_2 contains the capsule formation that contains information about underwater object features. The capsule output [34] for each that is reshaped using the convolution feature maps is given in Eq. (14):

$$s_i = \sum_p W_{ip} . F_2(p) \tag{14}$$

The capsule vector is computed using the squash function that helps in providing the nonlinear vector length given in Eq. (15):

$$\hat{u}_{j|i} = w_{ij} u_i \tag{15}$$

The dynamic routing mechanisms help in mapping the parent node to the child node with the help of the coupling coefficients given in Eq. (16), where the nonlinear capsule outputs are produced in the vector form using the squash function that is represented in Eq. (17):

$$s_j = \sum_i c_{ij} \hat{u}_{j|i} \tag{16}$$

$$v_j = squash(s_j) \tag{17}$$

The transformational relationships help in capturing the coral reefs' curvature, texture, contour shapes, orientation variations based on the water movement, etc., which are represented in the Fcaps shown in Eq. (18), that is, actually the penultimate capsule output, where the softmax is not used, provides the deep features information.

$$F_{caps} = [v_1, v_2, \ldots . v_U] \tag{18}$$

D. Underwater HSI Vision Transformer-Based Classification

The HSI classification for underwater is done using the Vision Transformer that provides the long-range relationships to the spectral-spatial relationship, where the global attentions are provided to the capsule vectors obtained from Eq. (19):

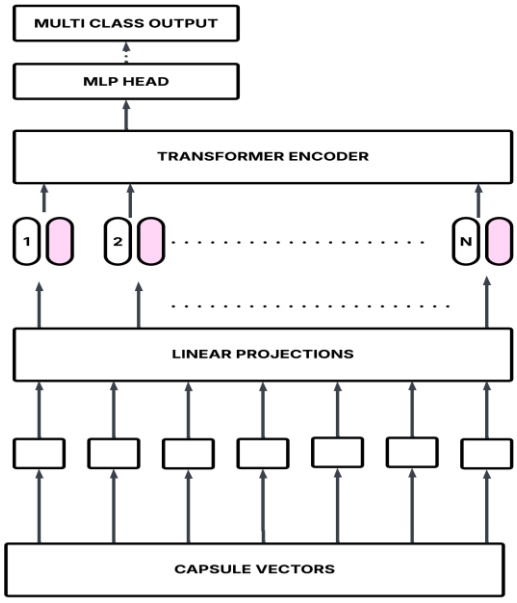

Fig. 4. ViT-based classification for underwater HIS.

$$u_i = squash(s_i) \tag{19}$$

The predictions are shared using the primary capsules for the higher level capsules using the formulation in Eq. (16).

The input of the ViT [35] requires a fixed level of dimension tokens; hence, the capsule vectors in straight act as the tokens, which is followed by the linear transformations [36] that are given in Eq. (20), which contains the learnable projection matrix Wp, and bias b.

$$L_i = W_p v_i + b_p \tag{20}$$

Now the tokenisation is given by T [L1, L2….LU]. Now the positional encoding is added to help the final classification process, which is done using the additions of the CLS token to the patches that are represented in Eq. (21):

$$Z_i^{(0)} = CLS + L_i + PE_i, \ \omega\eta\varepsilon\rho\varepsilon \ \iota = 1,2,,,,,,Y. \tag{21}$$

Now the self-attention is applied in the transformer block, where the neural network contains the query, key, and Value functions that extract the global and long-range dependency of the data. The value function extracts the actual object information present in ROI based features, the Query collects the information where the data contains the object-based information, and the Key collects the information that the query is trying to identify. The Query and Key parameters help to identify the classification pattern highlighted in the Value function using the attention formula given in Eq. (22):

$$A_i = \text{softmax}\left(\frac{Q_i K_i^T}{\sqrt{D}}\right) . V_i \tag{22}$$

The above attention values are obtained from the multi-heads of the transformer, to which the residual and layer normalisation are carried out. At the end using the CLS token that represents the entire patch is used for classification using the feed-forward neural network. Thus, the ViT helps in

handling the class ambiguity, irregular object shapes, which are common in underwater environments, and feature loss due to scattering.

IV. Results and Discussion

A. Implementation

The proposed framework is tested on the dataset Taxonomically annotated underwater hyperspectral and coral images of coral reef transects [37] that contains the hyperspectral images of underwater using the wavelength (400-750nm) using the 100-300spectral bands under the natural water illumination. The dataset contains the hyperspectral cubes and is annotated with detailed labelling of coral leaf substrates, corals, algae, sponges, sand, and rubble. Table IV provides the attributes of the datasets.

TABLE IV. HIS Dataset Attribute

Parameters	Value
No of Hyperspectral cubes	*120*
RGB images	*240*
Hyperspectral Cube Size	*512×512×(100-300) bands*
Spectral range	*400-750nm*
Mean annotated classes	*8*
Depths of transects	*5-30m*
Spatial resolution	*1-3mm/pixel*
ROI patches	*3730*

B. Data Preprocessing

The dataset contains the HSI cubes of size 512×512×no of bands, undergoes data preprocessing to reduce the noise and spectral distortion, which helps in the stable learning of the deep learning techniques involved in the proposed framework. At the initial stage, to reduce the spectral bias among the wavelengths, radiometric correction is done using the sensor-level dark current frames and white reference calibration for compensation purposes. Exponential absorption model is used for water column attenuation, and the normalisation is carried out using the z-sore among the cross-band illumination differences. The 3D Gaussian filters are used to suppress the shot noise and scattering distortions without disturbing the spectral gradients using the 3×3×5 spatial window filter size. The redundant information of spectral bands is reduced by the use of a 1×1 convolutional filter that compresses the channels to 16, which is followed by contrast stretching for improving the boundary visibility.

C. Segmentation

The encoder stage contains the augmented process of the U-net architecture and the CAM module using the four downsampling blocks, using 3×3 convolution per block, followed by the global average pooling and two MLPs, where the reweighting of the spectral channels is carried out using the CAM block. The connection between the encoder and decoder is maintained using the skip connections that help to maintain the spatial details, which are distorted due to the turbidity present in the underwater environment. The transpose of convolution upsampling takes place in the decoder, and the pixel-wise probabilities are obtained from the softmax operation using a 1×1 convolution operation. Now the mask of resolution 256×256 that is segmented for the classes of Pocillopora, Porites, Acropora, Macroalgae, sponge, and sand.

D. Feature Learning

The segmented masks are resized to a 64×64 bounding box that forms the ROI patches for the CapsNet feature extraction process. The two convolution layers provide the 9×9 kernel filters for extracting the low-level spectral and spatial features that are reshaped to 8-dimensional capsules for primary capsules that extract the high-level feature extraction that is concatenated into 10-digit capsule layers by a dynamic routing mechanism using the coupling coefficients. The features contain the capsule vector encoded geometry, orientation, and spectral reflectance patterns of similar coral taxa.

E. Classification

The capsule vectors act as the tokens that help in the tokenisation process, which are linearly projected for transformations followed by positional encoding. The 8 transformer layers with 6 Multi-Head Self-Attention and GeLU-activated feed-forward neural network are used for classification. The prediction of coral substrate classes is identified using the two-layer MLP using the CLS from the final layer.

This architecture combination ensures that the spatial relationships preserved by the capsules are effectively interpreted through the transformer's global context. By utilizing multi-head attention, the model selectively focuses on the intricate coral textures and geometric patterns that distinguish various substrate types. The feed-forward layers further refine these features, allowing for high-dimensional representations that remain resilient against underwater noise and lighting variations. As the data passes through the final transformer stage, the CLS token aggregates the most salient information required for a definitive categorization. Consequently, the two-layer MLP serves as a precise decision-making head, mapping these complex embeddings into distinct categorical probabilities with high accuracy. This integrated approach significantly enhances the model's ability to differentiate between the subtle morphological variations inherent in various coral species. The trainable parameter counts are estimated to be 15M, with the inference time of 30ms/ROI and Peak GPU memory of 3.5GB.

F. Implications

The visualization of Class Activation Maps (CAM) across the 10-band spectral data provides profound insight into the model's localized focus during the segmentation phase. By leveraging a U-Net architecture integrated with Channel Attention mechanisms, the network effectively filters out underwater backscatter while prioritizing the most discriminative morphological features of the coral substrates. Each feature map serves as a diagnostic window, revealing how the multi-band input—extending from visible light to specific spectral wavelengths—enables the system to bypass the inherent limitations of traditional RGB imagery. This high-dimensional feature extraction ensures that the boundaries of complex, overlapping coral colonies are delineated with high fidelity, significantly reducing false positives in heterogeneous seafloor

environments. Integrating 10-band spectral data with Channel Attention enables the U-Net to isolate critical morphological features while suppressing underwater noise, as demonstrated in the CAM visualizations (Fig. 4), for autonomous benthic mapping in complex seafloor environments.

Fig. 5 is the illustration of segmentation visualisation using the CAM-based U-net architecture for 10 bands, where the different band level shows different feature representation that helps in obtaining the informative bands. The higher bands 7 to 10 show good performance with more stable activations, which help in identifying the class-specific spectral characteristics using the channel attention recalibrations. The Gaussian-like activation regions are noted in the feature bands 3 to 6 that show more reliable reflectance structure for coral and benthic surfaces. In bands 1 and 2, the discriminative performance of the proposed framework has been obtained due to the strong attenuation for shorter wavelengths. Fig. 6 helps in obtaining the ROI extraction, where the mask was generated for band 3, which shows the high activation region, spatially coherent clusters, and segmentation contour overlay. Fig. 7 is the mean activation intensity of the segmentation process, which shows bands 7 to 9 have dominating spatial discriminations, which helps in obtaining the prioritised spectral channels. Table V presents the simulation parameters.

The bands 1, 3, and 10 have low values, indicating less involvement in the segmentation process. This selective prioritization not only streamlines the computational load during feature extraction but also enhances the signal-to-noise ratio by de-emphasizing the blue-dominated backscatter typically found in bands 1 and 3.

Consequently, the segmentation process becomes significantly more robust against the variable turbidity and lighting conditions common in deep-sea environments. Such channel-level optimization is pivotal for ensuring that the subsequent classification stages receive a refined, highly representative input, ultimately leading to superior identification of subtle coral substrate variations. This data-driven channel selection validates the use of multispectral imaging as a superior alternative to conventional three-band systems for complex biological mapping.

TABLE V. SIMULATION PARAMETERS

Parameters	Values
CAM-U-Net Architecture	
Input size	**256×256×16**
Encoder	4
Filter per level	64,128,256,512
Convolution	3×3, stride 1, padding 1
Activation	Relu
Pooling	Maxpooling 2×2
Channel attention reduction ratio	R=8
Decoder upsampling	Transposed convolution
ROI EXTRACTION	
Mask threshold	ARGMAX
Bounding box method	Contour based
Resize	Bilinear interpolation
Roi size	64×64×16
CAPSNET FEATURE EXTRACTOR	
Conv layer 1 and 2	256 filter, 9×9 kernel
Primary capsules	32 capsules × 8d vectors
Class capsules	10d ×16d vectors
Routing iterations	3
Capsule dim output	16d per class capsule
VIT CLASSIFIER	
Token dimension	**128**
No f token from Capsnet	32
Projection layer	16D→128D
Transformer layers	6
Attention heads	8
MLP DIM	256
CLS	Enabled
TRAINING SETUP	
Framework	PYTORCH
Optimiser	ADAM
Learning rate	1E-4
Batch size	16
Dropout	0.1

Regularization	1E-5

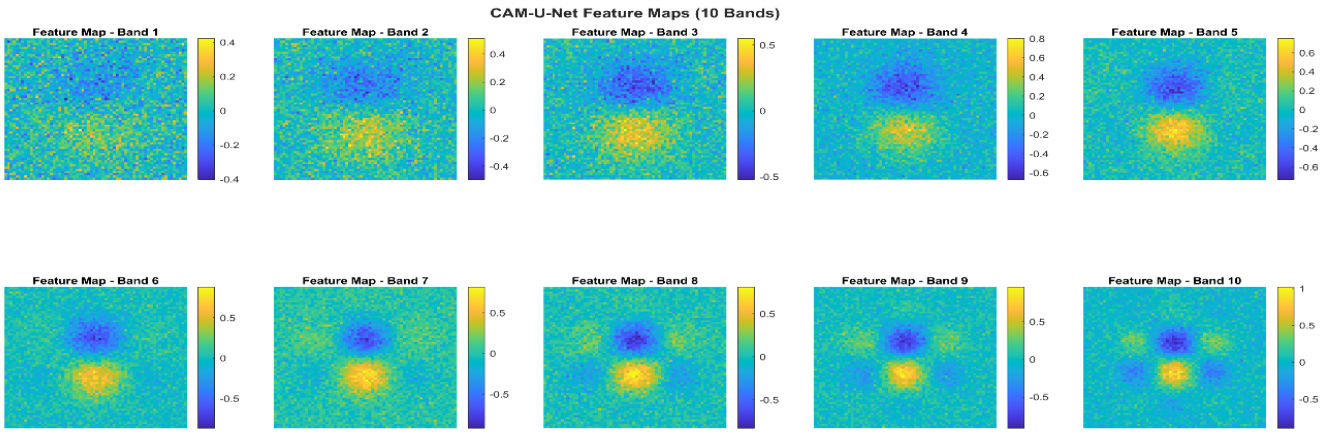

Fig. 5. CAM-based U-Net segmentation visualisation feature map for 10 bands.

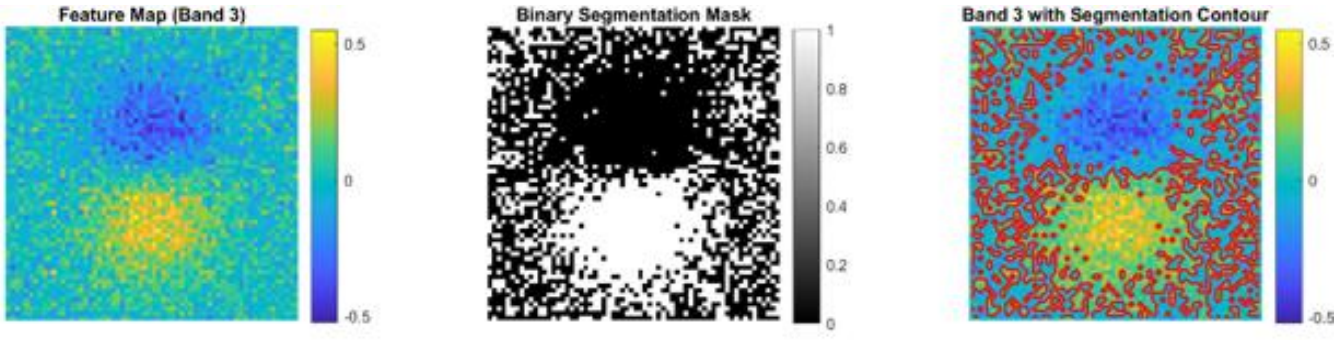

Fig. 6. CAM-based U-Net segmentation visualisation feature map and mask.

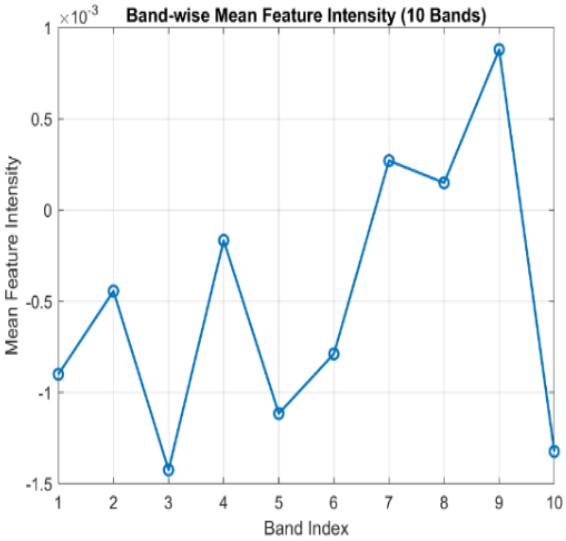

Fig. 7. Bandwise mean feature intensity for 10 bands using CAM-based U-Net segmentation visualisation.

Table VI is the CAM-based U-Net architecture for segmentation of substrate classes using the Intersection Over Union (IoU) to measure the overlapping, precision used for identifying the predicted positive pixels, recall helps to know the capturing most of the object, F scores helps in false negatives and positives and pixel segmentation helps in correctness that are manipulated using True positive (TP), True Negative (TN), False Positive (FP) and False Negative (FN).

The highest IoU is seen in the sand that has different texture patterns and unique spectral reflectance, where the coral class Acropora preserves the good boundary conditions with the IoU of 0.82. In the overall estimation, the strong segmentation performance is noted by the IoU value between 0.72 and 0.88 among the substrate classes. It is important to obtain a false positive rate that is minimal, which is estimated using the precision calculation, showing a range from 0.80 to 0.93. The recall helps in obtaining the features of class regions, where 0.91 is at maximum and helps in calculating the trade-off F-score that shows consistent segmentation performance across different classes of spectral bands. Thus, the ROI patches have sharper boundaries, region consistency, and confident segmentation output, which is indicating highly discriminative and uniform characteristics.

TABLE VI. CAPSNET FEATURE EXTRACTION METRICS

Class	*Capsule Mean Length*	*Capsule Variance*	*Spread*
Acropora coral	0.862	0.041	0.203
Pocillopora coral	0.835	0.049	0.221
Porites coral	0.812	0.052	0.238
Soft coral	0.778	0.067	0.265
Macroalgae	0.902	0.036	0.184
Turf algae	0.791	0.059	0.249
Sponge	0.804	0.055	0.232
Sand	0.918	0.029	0.162
Acropora coral	0.862	0.041	0.203

Table VI is the CapsNet feature extraction performance on the ROI extracted data from the segmentation modules, where the factors like capsule mean length, capsule variance and spread help in the statistical analysis of capsule outputs. To know the presence of a feature, the capsule length can be used from the analysis of the sand, and the macroalgae show the highest identity of spectral-spatial features. To measure the stability of the capsule across various classes of ROI extraction, capsule variance is used, where the higher variance of soft coral has a higher 0.067 because of the greater intra-class variability based on the textures and spectral mixing. The capsule activation among the intra-class dispersion is noted using the spread function, where the soft coral shows a high of 0.265.

Table VI provides a comprehensive statistical analysis of the performance of CapsNet in feature extraction from region-of-interest (ROI) data derived from the segmentation modules. A comprehensive understanding of how well the capsule network reflects spectral–spatial features across several aquatic classes is provided by the analysis, which focuses on capsule mean length, capsule variance, and spread. By displaying the strength, stability, and dispersion of capsule activations, these measures provide deeper interpretation beyond classification accuracy.

Within each class, the feature existence confidence is directly shown by the capsule mean length. Stronger and more reliable activation of class-specific spectral-spatial characteristics is implied by higher values. Because of its

relatively homogeneous texture and low spectral mixing, sand has the highest capsule mean length of 0.918 in the data. In underwater photography, macroalgae have a high mean length of 0.902, which reflects their unique spectral response and unusual spatial patterns.

The statistical analysis in Table VI indicates that CapsNet proficiently captures substantial and interpretable spectral–spatial data, especially for classes exhibiting consistent visual traits. In order to improve global contextual knowledge, complementary mechanisms like attention and transformer-based modules are required, as evidenced by the observed variance and spread in complex biological classes. These results confirm that capsule-based feature modelling is a solid basis for classifying underwater images.

Alongside class-specific statistical results, the capsule-based study underscores CapsNet's capacity to maintain the spatial hierarchies intrinsic to underwater objects. Capsule representations capture both the existence and instantiation properties of features, in contrast to traditional CNN feature maps. This is especially useful in underwater environments where illumination, scale, and orientation vary greatly. Because of this feature, CapsNet can continue to provide discriminative representations even in the face of extreme optical aberrations. Compact capsule distributions with longer mean lengths indicate better separability in the latent space from the standpoint of categorization, which directly promotes trustworthy decision boundaries. The statistical compactness found in substrate-dominant groups like macroalgae and sand suggests that CapsNet can accurately and minimally confuse low-texture regions. On the other hand, the network's capacity to encode part-whole interactions, including branching, folding, or layered structures, is advantageous for biologically rich classes.

Furthermore, the segmentation-driven ROI extraction approach is indirectly validated by the capsule statistics. The segmented regions maintain important object-level information while decreasing irrelevant background noise, as demonstrated by stable capsule activations across several classes. The whole framework's resilience is strengthened by the synergy between segmentation and capsule-based feature extraction.

Global contextual awareness is required to further resolve ambiguities among visually overlapping classes, even while CapsNet excels at local structure preservation. Consequently, a solid empirical foundation for integrating attention mechanisms and transformer-based modelling in subsequent trials is provided by the capsule feature behaviour seen in Table VI.

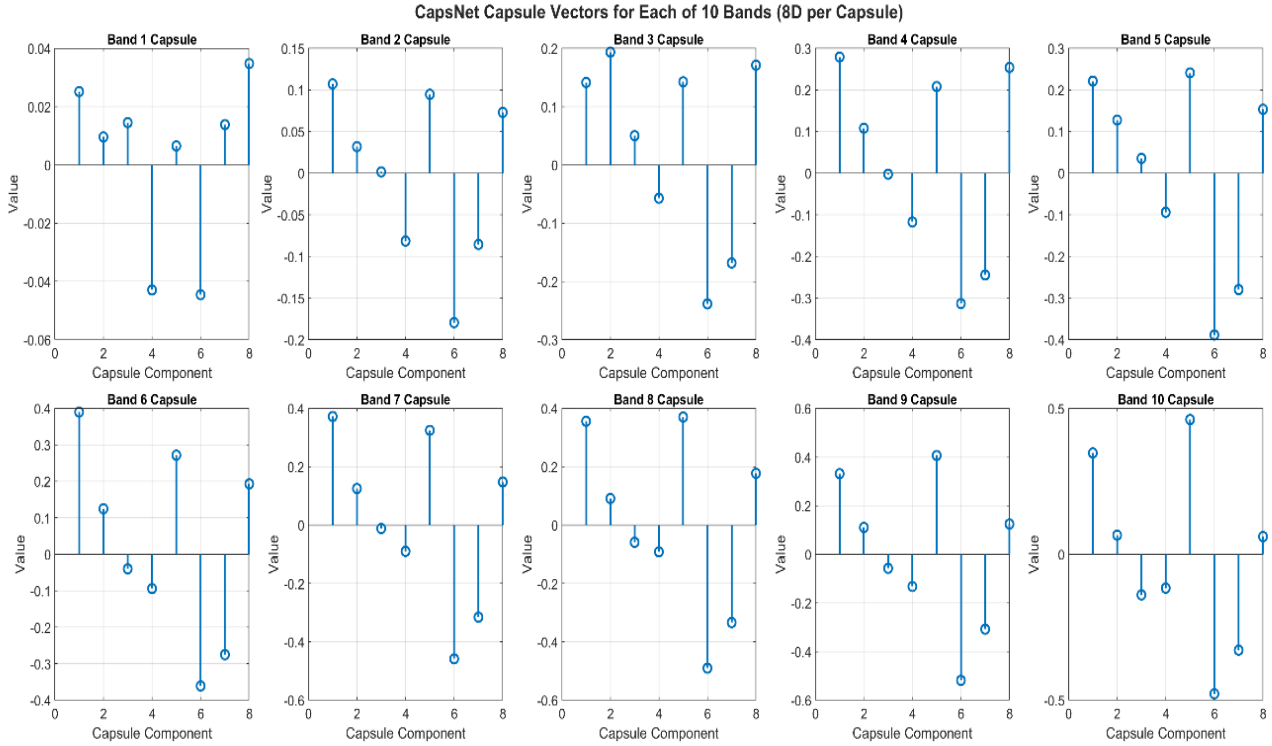

Fig. 8. Capsule vector for 10 bands based on the ROI extracted patches from the segmentation process.

Fig. 8 is the depiction of the CapsNet feature extraction projections using the ROI patches extracted from the segmentation process, which shows the effective multi-band feature abstraction with both positive and negative vectors indicating the spatial relationships based on the pose and magnitude-based features. The band 10 outputs are obtained from the 8-dimensional feature representation helps in exhibiting the spectral spatial characteristics among the bands. In the sensitive underwater imaging, the bands 3,6,7,8, and 10 help in the identification of corals, algae, sand, etc., classes present in the HSI cubes based on the higher vector components that capture the band-specific spatial spectral characteristics. Less dominance is noticed in the spectral bands of 4, 5 and 9 that contain the structured activations with informative spectral information. The shorter wavelengths showed low performance at bands 1 and 2, mainly due to the attenuation factor under the

sea, which showed weak capsule activations. These findings show that the capsule network creates discriminative pose-aware representations by efficiently utilizing informative spectral bands, which directly enhances class separability. In complex underwater sceneries, the predominance of mid-to-long wavelength bands allows for robust recording of object borders and texture variations. Stronger capsule activations in these bands are therefore associated with improved physiologically varied class recognition. The significance of choosing reliable spectral regions underwater is further highlighted by the diminished impact of shorter wavelengths. All things considered, the band-wise capsule behaviour shows that CapsNet is appropriate for spectral-spatial feature learning in difficult underwater hyperspectral situations.

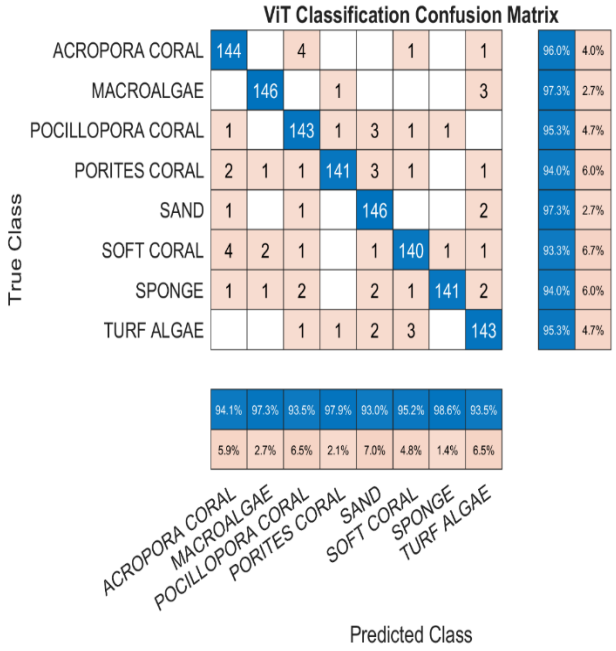

Fig. 9. Confusion matrix from ViT classification.

Fig. 9 is the confusion matrix obtained for the 8 substrate classes of the dataset of underwater HSI, which are preprocessed and segmented using CAM CAM-based U-net architecture and CapsNet-based feature extraction. The confusion matrix produces the cues for true class and predicted class for 8 substrates. The proposed framework highly classifies the sand class with 97% efficiency because of its fine-grained texture patterns that are effectively segmented and feature extracted.

The overall range is between 93 and 98% for all the classes of substrates in the underwater HSI datasets. This shows the preservation of spectral spatial characteristics by the proposed segmentation, features collection by CapsNet feature extraction, and classification, which obtains global attention based on range dependencies among the classes. The misclassification is noted in the coral taxonomy due to the similar structural patterns and spectral overlaps. Based on the confusion matrix, the proposed work plots the accuracy and error curves for 100 epochs, where the accuracy stood on average at 95% with an error percentage of 5%. The proposed method shows consistent learning activity till 60 epochs and saturates after that, as depicted in Fig. 10.

Fig. 11 is the depiction of AUC curves for 8 substrate classes that help to show the proposed framework's performance robustness for true negative and false positive rates. All the classes shown above 0.99 had the highest AUC values of macroalgae due to the distinctive spectral signatures for various hyperspectral bands. Table VII discusses the various ViT classification hybrid models, where the proposed combination framework shows higher performance.

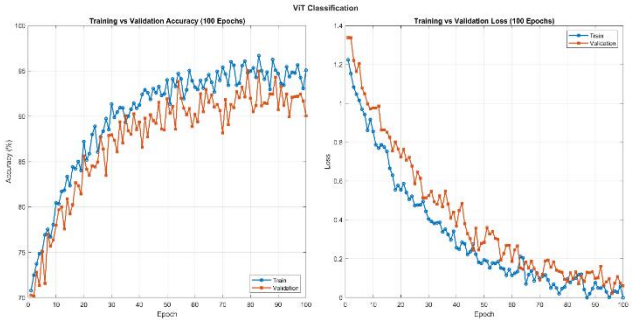

Fig. 10. ViT classification of underwater HSI based on CapsNet feature extraction and CAM-based U-Net segmentation.

The training curves' constant convergence behaviour demonstrates how stable the suggested learning framework is in challenging underwater environments. While the saturation after 60 epochs shows that the model achieves an ideal representation without overfitting, the progressive decrease in error rate during early epochs reveals efficient feature learning from segmented ROI patches. This characteristic is especially crucial for undersea hyperspectral data, as significant spectral redundancy and a lack of labelled samples can otherwise impair generalization.

The robustness of the suggested framework in differentiating between visually and spectrally similar categories is further demonstrated by the good AUC performance across all substrate classes. Reliable underwater scene interpretation depends on the model's capacity to maintain a favourable balance between true positive and false positive rates, which is confirmed by the nearly flawless AUC values. Macroalgae achieves the highest AUC due to its distinctive spectral reflectance and spatial continuity, enabling clearer decision boundaries within the feature space.

Common morphological traits and overlapping spectral responses are the main causes of misclassification within coral taxonomy, particularly between branching and large coral taxa. However, by maintaining spatial hierarchies while concurrently modelling long-range relationships, the network is able to reduce these ambiguities through the merging of capsule-based representations with transformer-driven global context. In difficult situations where local texture alone is insufficient, this dual representation capability enhances differentiation.

The channel attention mechanism suppresses redundant or noise-prone channels and highlights useful spectral regions to further improve feature selection. This selective amplification stabilizes categorization results across epochs and enhances learning efficiency. The Vision Transformer, CapsNet, and channel attention modules work together to acquire complementary information at various representation levels.

Overall, the performance trends show that the suggested hybrid design successfully strikes a compromise between global contextual understanding and local structural awareness. The framework's appropriateness for underwater hyperspectral image classification is validated by its good classification accuracy, robust convergence behaviour, and consistently high AUC values. These findings demonstrate that the suggested approach can function as a trustworthy basis for sophisticated mapping of marine habitats and automated substrate analysis.

Additionally, the integrated design shows tolerance to illumination variability and spectrum disturbance that are frequently found in underwater conditions. More accurate feature discrimination across diverse substrates is made possible by the combined learning of spectral context and spatial structure. For complicated benthic classes, where minute characteristics affect classification results, this is especially advantageous. Strong generalization ability across several ROI samples is shown by the observed performance consistency. As a result, the suggested architecture provides an efficient and well-rounded solution for underwater hyperspectral classification problems.

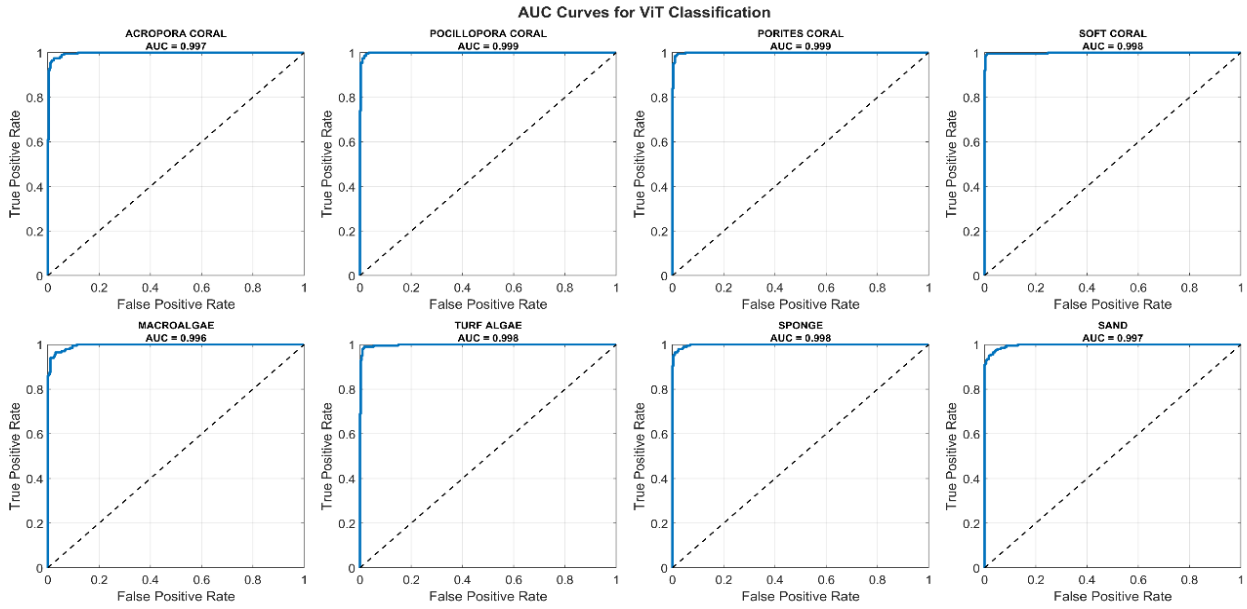

Fig. 11. AUC curves for 8 classes of underwater HSI using ViT classification.

TABLE VII. COMPARATIVE STUDY BASED ON THE PROPOSED MODELS

Ref	Year	Models	Accuracy
[23]	2024	SpectralUFormer using hybrid attention modules and an upsampler	93.15%
[24]	2024	ADANSE-based ViT on proprietary and standard datasets	90.9%
[25]	2024	ConvMixer and Swin Transformer for Fish classification	94.6%
[27]	2023	Lightweight Transformer network for Hyperspectral classification	89.03%
Proposed Model (CAM-based U-Net+Capsnet+ViT)			**95.3%**

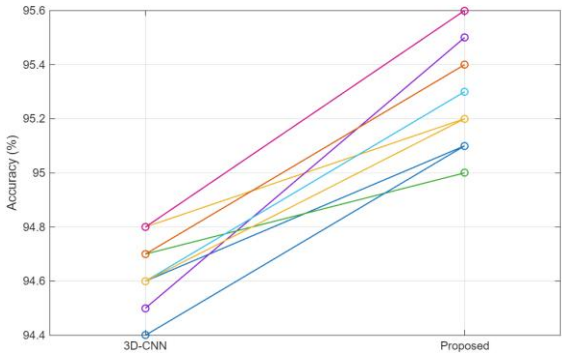

Fig. 12. Paired runs test for 3DCNN with the proposed model.

The statistical analysis is carried out using the paired runs with the 3D CNN [39] and the proposed framework against the measure of accuracy. It is seen that the baseline accuracy range is approximately 94.5% with the proposed accuracy range of 95.5% that shown the improvement per run to 0.4% to 0.9% (see Fig. 12).

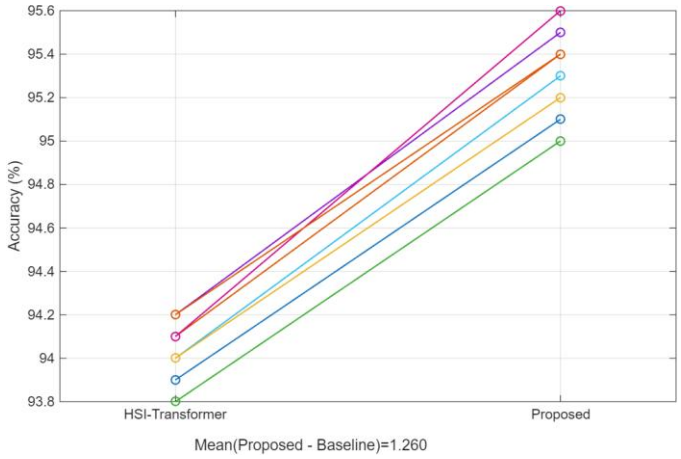

Fig. 13. Paired runs test for the HSI transformer with the proposed model.

Fig. 13 depicts the paired run test for the HIS transformer and the proposed framework. The proposed work shows stable gain using the channel attention-based segmentation, capsule features that provide pose-aware and the context based global transformer with a baseline accuracy range of 94.5% accuracy approximately and a mean improvement of +1.26%.

V. Conclusion

The advanced hybrid deep learning techniques that utilise the CAM-based U-et architecture for segmentation, CapsNet-based Feature Extraction, and ViT classification for Underwater Hyperspectral Image classification are framed and obtained the accuracy of 95.3% with AUC 0.99. The proposed framework obtains the region of interest from the hyperspectral images from 10 bands input by channel attention, which helps the U-net architecture to spatially and spectrally characterise multi-band hyperspectral images. The CapsNet features extract the pose and spatial relationships using the capsules and dynamic routing mechanism from the ROI extraction of segmented bands. The VitClassification uses the capsule vectors for identifying the global relationships using the query, key, and value in the transformer heads that provide range relationships among the features to identify the classes of substrates. The proposed framework achieved pixel accuracy of 95.2% with a maximum IoU of 0.88. In future works, as follows: a) The scalability of the proposed work applies to all hyperspectral image-based applications. b) Band-wise classification enhancement using the advanced generative models to improve the performance of the overall systems, and c) The proposed framework suffers from computational complexity; hence, the lightweight models need to be incorporated.

Conflict of Interest

The authors declare that there is no conflict of interest related to the research.

Effectiveness of Capsule Networks in Detecting Deepfakes Instead of Traditional CNNs

M. C. Weerawardana, T. G. I. Fernando
Department of Computer Science, University of Sri Jayewardenepura, Nugegoda, Sri Lanka

***Abstract*—As artificial intelligence has advanced, computer-generated fake content has become increasingly prevalent. Deepfake is an advanced fake creation generated using deep learning-based technologies, and deepfake images, videos, and voices have spread rapidly. The distinction between real and fake content is very hard for the naked eye, making reliable detection essential. Existing deepfake detection methods have achieved success, but still face limitations in keeping pace with the rapid evolution of deepfake generation techniques. In particular, CNN-based approaches may require a large number of parameters and may not fully capture spatial hierarchies. In this research, we investigate whether Capsule Networks can provide an effective and parameter-efficient alternative for deepfake detection. We proposed four different Capsule Network architectures by altering the size, complexity, and configuration. A comparative analysis is conducted against state-of-the-art Capsule models and CNN models across various datasets, utilizing AUC% and the number of parameters as evaluation criteria. For transparency, we note that some baseline CNN and Capsule models follow the training protocols and datasets reported in their original studies, which may differ across implementations. Our experimental results show that the proposed Capsule Network models achieved over 98% AUC% on the evaluated datasets while using fewer parameters than several CNN-based models. These findings suggest that Capsule Networks exhibit greater efficacy in detecting deepfakes compared to traditional CNN-based methods and represent a promising direction for future research.**

***Keywords*—Deepfake; deep learning; capsule network; convolutional neural network**

I. Introduction

Currently, we are exposed to a new generation fueled by artificial intelligence (AI). Day-by-day, AI generates novel creations that become integrated into the world. AI-related applications and tools play different roles in social media, websites and the Internet. Among many applications in AI, deepfake [2] is a significant and critical technology. Deepfakes involve digitally reenacting and manipulating facial appearances, utilizing deep neural networks to swap faces [1] with someone else's likeness. Deepfakes are generated in a complex process using deep neural networks. At present, lots of deepfake-generated tools like GAN [3], FaceSwap-GAN [4], FaceApp [5], Face2Face [6], and DeepFake [7] are available freely. Deepfake generates fake images, voices, and videos. The speciality of these deepfake-generated forgeries is as real as seen by the naked eye. Deepfake creation tools have been developed with new technologies and release highly accurate and quality outputs. The produced fake information can mislead society by spreading fake news, defaming celebrities and public figures, creating pornographic videos for blackmail, or perpetrating financial fraud [2].

The challenge lies in the fact that the human eye may struggle to discern between real and fake content within deepfakes. So, deepfake detection is a big challenge because synthetic forgeries are deceiving the naked eye. Many researchers have presented different approaches to detecting deepfakes during the last few years. These methods can be categorized into several technologies like feature-based [8], artifacts [9], inconsistencies of physiological signals [10], [21] and deep convolutional approaches [11], [12], [13]. These existing deepfake detection methods have achieved success but come with significant limitations. The key limitation in existing deepfake detection research is the insufficient examination of cross-dataset generalization. Many prior studies report performance primarily under intra-dataset train-test splits, which may lead to overly optimistic estimates of real-world effectiveness. In practical scenarios, however, detection must handle previously unseen manipulation techniques, varying compression levels, and diverse data distributions. The existing detection methods have failed to respond to the new technologies with the rapid evolution of deepfake creation, leaving a gap where deepfakes outpace detection techniques. Additionally, there are no flawless detection methods, particularly in Convolutional Neural Network (CNN)-based approaches. To avoid this situation, we moved to a new way rather than traditional methods.

The increasing realism of deepfakes poses significant challenges to digital security and misinformation control. Traditional CNN-based detection methods often struggle to capture subtle structural inconsistencies in manipulated content. Motivated by the need for more robust detection methods, this study explores the potential of Capsule Networks, which are better suited to model spatial and hierarchical relationships, to improve deepfake detection performance. This experimental protocol enables a rigorous analysis of robustness to domain shift.

The main contribution of this study is the development and comparative evaluation of multiple Capsule Networks for deepfake video detection, demonstrating that Capsule Networks are more effective than traditional CNN-based models. We conduct a comparative analysis of the performance of the proposed Capsule Network models against state-of-the-art Capsule models, and traditional CNN-based models across various datasets utilizing AUC% and the number of parameters as the criteria for comparison. So, to achieve this target, we utilized multiple Capsule Network models for the experiment,

altering several parameters, changing size, complexity, and configuration, etc. For the comparison, we selected five existing CNN methods. They were MesoNet [15], Head Pose [17], Visual Artifact [8], XceptionNet [16], and Multitask-learning [19] architectures, which were fine-tuned on the 140K Real and Fake Faces Kaggle dataset [20]. These models have been implemented on several technologies. We used five different datasets: UADFV [17], DF-TIMIT [21], FaceForensics++ [22], DFDC [23][24], and Celeb-DF [25]. To address the generalization problem, we conduct systematic cross-dataset evaluations by training the proposed models on a single dataset and assessing the performance across multiple unseen datasets.

Our study is structured as follows: in the first part, we present a brief introduction about deepfakes, along with their background, problem, motivation, and contribution, and outline the structure of our study. The second part represents a literature summary on deepfake detection methods and Capsule Networks. Next, we detail our methodology, including our proposed Capsule models and datasets used. In section four, we explore our implementations and detail the results obtained throughout the experiment. Lastly, we summarize the conclusions drawn.

II. Related Work

Under the related works, we cover the existing best deepfake detection methods and explore the improvements and unique advantages of the Capsule Network models on deepfake detection.

A. Deepfake Detection Methods

Recently, deepfake is a more concerned phenomena due to the rapid spread of various deepfake creations [2]. Deepfake generation and detection are developing in parallel. From 2018 onwards, there has been increased socialization of forgery arts, applications, fake video creations, and deepfake generation tools. At the same time, financial frauds, revenge on politicians and popular people, pornographic videos of celebrities and blackmails, etc. started to increase gradually [2]. With the growth of misleading information, attention has been drawn to finding deepfake detection methods. Recently, a considerable number of research publications regarding deepfake detection have been available.

Numerous researchers have proposed various approaches for deepfake detection, including feature-based [8], artifact analysis [9], inconsistencies in physiological signals [10], [21], and deep convolutional methods [11], [12], [13]. Deep convolutional approaches may be quite reliable because they do not depend on feature limits. XceptionNet architecture [16] has been successfully used in many approaches [22], [26], [27]. In 2020, Kumar et al. [28] presented a successful model with an accuracy of 99.2% on the CelebDF dataset using XceptionNet architecture as a feature extractor. Several papers have presented deepfake video detection methods using Recurrent neural networks [30], [32] or LSTMs [31], [33]. Lima et al. [29] combined several 2D and 3D convolutional layers in their model to leverage the temporal dimension. Very recently, Google has presented a watermark-based detection tool called SynthID [34] to identify AI-created images. But our opinion is that the Watermark technique is not very successful because the sources of image creation are varied. This method is not valid for widespread usage because it is restricted only to limited resources like Google Cloud and some specific customers, such as Vertex AI [34].

Deep learning methods, machine learning methods, computer vision methods, multimodal and scalable techniques can be used for deepfake detection. The problem lies in deepfake creation, which continuously evolves with new technologies and advances day-by-day. Therefore, the state-of-the-art deepfake detection methods may fail in the face of new technical advances. Recently, a few researchers in the domain of deepfakes have explored the use of Capsule Networks.

B. Capsule Network Models and Their Advantages

According to the literature, Capsule Networks are not a novel concept in the field of deepfake detection. Hinton et al. [35] first introduced the concept of the Capsule Networks in 2011. Then again, Hinton et al. [36] introduced the training and propagation of capsules using the routing by agreement algorithm in 2017. Capsule Networks are composed of vectorial units that encode information in multiple dimensions, including pose information, unlike scalar units in Convolutional Neural Networks. Fig. 1 presents the general architecture of the Capsule Network employed in this work. The model processes the input through a primary capsule layer that encodes local features as vector representations. These capsules are then aggregated in a higher-level capsule layer using a routing mechanism to model hierarchical relationships. The resulting capsule outputs are used in the decision stage, and the final predictions are obtained at the output layer.

Through experiments, it has been shown that Capsule Networks could improve upon the limitations of traditional CNN methods in detecting deepfakes. Hinton et al. [35] have found some drawbacks in the use of a pooling layer in a CNN architecture. Mainly, the authors [35] mentioned that information like the position of an object is lost in the pooling layer. In the CNN model, neural networks strongly consider key elements like the eyes of a face rather than its position because the pooling layer deletes other information like position. But position is very important to increase the accuracy of the method. On the other hand, vectors help to collect more information about the object, like position, color, texture, and skewness, etc. and help to get more accurate predictions. In 2018, Shahroudnejad et al. [37] identified an additional drawback: the need for more training data when employing CNN architectures with a pooling layer. Also, the authors in [37] described that CNNs require longer duration training data and Capsule Networks need a wider range of training data. Recent research has also explored transformer-based and hybrid architectures for deepfake detection. Transformer backbones such as Swin Transformer have been proposed to capture global context and spatial consistency, improving robustness across datasets in deepfake video classification [44]. Furthermore, hybrid models integrating CNNs with vision transformers have been developed to leverage local feature extraction and global attention mechanisms for enhanced detection efficacy [45]. However, these approaches often require large-scale training data and substantial computational resources, which can limit their practical development.

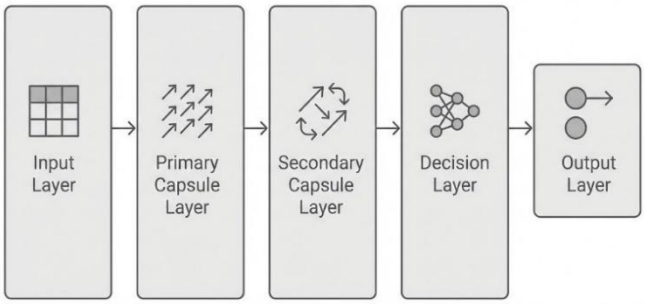

Fig. 1. Common architecture of the capsule network.

Jindong et al. [38] have presented the advantages and disadvantages of the Capsule Network architecture. Advantages are the ability to generalize, a small number of parameters needed, various transforms applied to the image and resistance to attacks. According to the authors [38], the disadvantages are that the capsules have limited learning capabilities and sometimes Capsule Networks show poorer assessment than traditional CNNs on large datasets like ImageNet [39].

Recently, Nguyen et al. [40] have improved a Capsule-Forensics Network [40], [41] for deepfake video detection. This method has shown higher performance compared to the state-of-the-art methods while utilizing less training data, a smaller number of parameters and lower computational cost, etc. [40], [41]. These superior advancements across multiple domains have motivated them to turn towards the Capsule Networks.

C. Improvements of the Capsule-Forensics Architecture

In 2019, Nguyen et al. [40] improved the Capsule-Forensics architecture for deepfake video detection. In the following paragraph, we briefly described the configuration and shortcomings of the Capsule-Forensics architecture.

Capsule-Forensics architecture has been configured along with a part of the pre-trained VGG-19 model [14], which has been used to extract the features and has been transformed into primary capsules. The authors [40] have included a 'stat pooling layer' to calculate the mean and standard deviation for filters. The Capsule-Forensics architecture has utilized from 3 to 10 primary capsules, each with 8 features, to extract relevant features. Next, the architecture was configured along with a dynamic routing algorithm. Here, the dynamic routing algorithm performs two iterations, calculating the sum of output vectors from the primary capsules. The authors [40] have used two output capsules (for deepfake and real with 4 x 1 vectors). The resulting vector has passed through the SoftMax layer. The authors [40] used an average function to predict the probability values of deepfakes. Capsule-Forensics architecture has used 3.9 million parameters for the whole network. Nguyen et al. [40] showed 93.11% accuracy on binary classification with FaceForencis++ dataset. Tolosana et al. [42] utilized the same architecture and demonstrated a 99.52% AUC on the FaceForensics++ dataset and 82.46% AUC on the Celeb-DF dataset. This architecture has exhibited superior performance by utilizing fewer parameters, a smaller amount of training data and lower computational costs compared to state-of-the-art methods. Hence, many research domains have started incorporating Capsule Networks, particularly within the field of deepfakes.

But we identified that the Capsule-Forensics architecture [40], [41] has several shortcomings. The authors [40], [41] and [42] utilized a small number of primary capsules, typically ranging from 3 to 10. It appears that their configuration might be considered weak since primary capsules hold significant importance in computing the values of secondary capsules. Additionally, the authors of [40] and [42] employed only 2 iterations for the dynamic routing algorithm. A higher number of iterations can significantly impact the accuracy of the final prediction. The Capsule-Forensics architecture also incorporated the 'statistical pooling layer.' According to the principles of Capsule Networks, the pooling layer's function involves discarding a considerable amount of valuable information, potentially leading to a decrease in the performance of the capsules. We believe that this architecture has the potential to achieve higher performance by addressing these existing shortcomings and implementing necessary improvements.

III. Methodology

In the research carried out in this study, our primary objective was to implement multiple Capsule Network architectures for detecting deepfake videos, addressing the existing shortcomings of the Capsule-Forensics architecture. We aimed to compare their performances and evaluate the effectiveness of modifications introduced to address the earlier discussed shortcomings. To achieve this, we centered our attention on the Capsule-Forensics architecture introduced in 2019. While retaining the fundamental elements of the Capsule-Forensics network, we made essential modifications necessary to implement diverse Capsule Network architectures for deepfake detection. We altered the size, complexity, and configuration of each Capsule architecture from its original specifications. Furthermore, we conducted a comparative analysis of the performance of Capsule Network models and CNN models for deepfake detection. Our objective was to demonstrate that Capsule Networks possess greater efficacy in detecting deepfakes compared to traditional CNN methods.

We configured four different Capsule Network models for the analysis, elaborated upon in detail in the following section. During experimentation, the DFDC dataset was utilized for training the Capsule models. To compare the performance, we employed five state-of-the-art CNN models: specifically, the MesoNet [15], Head Pose [18], Visual Artifact [17], XceptionNet [16], and Multitask-learning [19] architectures. All these models are feature-based deepfake video detection methods. They were initially pre-trained on the ImageNet dataset [39], and their output layers were subsequently replaced with fully connected decision layers for the purposes of this study. Initially, we fine-tuned and retrained these models using the 140K Real and Fake Faces Kaggle dataset during the training phase. To conduct a comparative analysis, we assessed the performance of the mentioned CNN models across five datasets: UADFV, DF-TIMIT, FaceForensics++, DFDC, and Celeb-DF dataset. Subsequently, we analyzed the results and compared the performance of each Capsule model with that of the state-of-the-art CNN models in detecting deepfake videos. The Area Under Curve (AUC) values are presented in the results and discussion section for comparison analysis.

A. Proposed Capsule Network Architecture

Our primary objective was to demonstrate that Capsule Networks possess greater efficacy in detecting deepfakes compared to traditional CNN methods. For this task, we need to implement a better Capsule Network architecture and to show better performance instead of the state-of-the-art CNN methods. We tried to rectify the few shortcomings present in the state-of-the-art Capsule models for detecting deepfake videos. We started with the state-of-the-art Capsule-Forensic architecture [40], enhancing identified shortcomings, and subsequently assessed various Capsule Network architectures listed below to enhance their performance. While keeping the fundamental elements of the Capsule-Forensics architecture utilized in [40] as the basis, we made some necessary modifications to our Capsule Network architectures described as follows.

We modified their size, complexity, and configuration as necessary. We require an existing pretrained model to extract the necessary features for the primary capsules in our Capsule models. We chose the VGG-19 CNN architecture [14] as a pretrained model. In the model configuration, the larger models were set up with the initial 8 convolutional layers and totaled around 1.6 million parameters. The smaller models were composed of the initial 3 convolutional layers, resulting in a total of around 0.4 million parameters. The authors of [40] and [42] utilized a limited number of primary capsules, typically ranging from 3 to 10. Their configuration appears weak because primary capsules play a crucial role in computing output values for the secondary capsules. Secondary capsules are of great importance to predict the correct values. We assumed that a large number of primary capsules may eliminate noise and prevent poor predictions. Thus, we conducted experiments with varying numbers of primary capsules, starting from 1,800 primary capsules.

Initially, we used two secondary capsules for each class. Later, we conducted tests with different quantities of secondary capsules for each class. In most instances, there were 16 capsules of 16x1 dimensions used. The fully connected decision layer was used to distinguish real and deepfakes. The number of iterations in the dynamic routing algorithm plays a role in determining the weights assigned to the secondary capsules. The better weights of the secondary capsules ensure better accuracy of the predictions. The authors of [40] and [42] have used only 2 iterations in their research. Instead of using only 2 iterations, we implemented a broader range of iterations in the dynamic routing algorithm, employing a minimum of 3 and a maximum of 5 iterations. Finally, we obtained a comparative analysis of each architecture's performance in comparison to the state-of-the-art methods. Below is the list of all the implemented Capsule Network models used in our experiment. Fig. 2 shows a graphical representation of the architectural configuration of each model.

- Capsule Network model 1: This model was configured with 1,800 primary capsules, each consisting of 8 dimensions, and 2 secondary capsules, each comprising 16 dimensions.
- Capsule Network model 2: This model was designed with 7,200 primary capsules, each having a length of 8, and 10 secondary capsules, each with a length of 16. Additionally, a fully connected layer was incorporated as the decision maker.
- Capsule Network model 3: This specific Capsule Network model comprised 1,568 primary capsules, each having a length of 8, and 16 secondary capsules, each with a length of 16. During the training process, the dynamic routing algorithm utilized 3 and 5 iterations. Additionally, a fully connected layer was included for decision-making purposes.
- Capsule Network model 4: This model shares similarities with Capsule Network model 3, except for model 4, which includes 8 secondary capsules instead of 16.

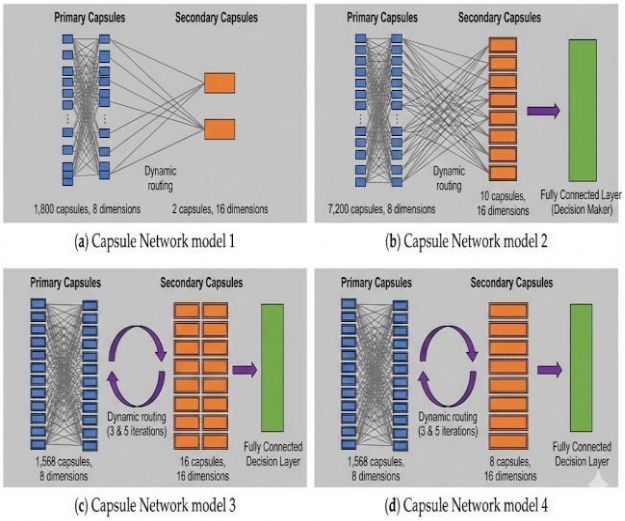

Fig. 2. Proposed capsule network architecture.

B. Dataset Used

When selecting a dataset for deepfake detection, several crucial characteristics should be considered, including short video length (10-15 seconds), focus on close-up human faces, confirmation of consent from actors involved, the total number of videos available, and the overall quality of the video content. These factors are most affected in determining the accuracy and reliability of a deepfake detection method. Currently, many open-source free deepfake datasets are available. We chose five distinct datasets that were very suitable for our experiment: UADFV, DF-TIMIT, FaceForensics++, DFDC, and Celeb-DF. The dataset contained both real and deepfake video clips, each lasting around 5 to 10 seconds in duration. We need to break them down into individual frames for further analysis and processing. Each frame is fed into the detection architecture. To create frames, we selected multiple video clips from both real and deepfake sources found within the DFDC, UADFV, DF-TIMIT, FaceForensics++, and Celeb-DF datasets.

When selecting video clips, we specifically targeted those that provided better focus on the face region. This consideration was crucial since deepfakes primarily manipulate and alter facial features. We employed "Windows Movie Maker" to split the video clip into individual frames. The first 256 frames of each video clip were extracted and resized to 299x299. Thus, we aimed to exclusively extract the facial regions from each frame. For our experiment, after splitting the video, we adopted an

appropriate preprocessing pipeline as follows to extract the necessary features from each frame. Initially, we performed face detection, followed by detecting facial landmarks, eliminating the background, and ultimately resizing the image as part of our preprocessing pipeline. These steps were repeated for all 256 frames within each of the selected video clips. Here, we utilized DLib-ml [43] for detecting the face region and identifying facial landmarks. DLib-ml is a machine learning based toolkit designed for face detection, developed by King in 2009 [43]. We applied DLib-ml for every frame, extracting 68 landmarks from each frame. The resulting landmarks were then mapped onto a standard 3D facial landmark model consisting of 68 points.

We used two datasets for the training process. The 140K Real and Fake Faces Kaggle dataset was used for the CNN models, while the Deepfake Detection Challenge (DFDC) dataset served as the dataset for the Capsule Network models. The DFDC dataset was chosen for training the Capsule Network models because its video-based deepfake samples capture complex spatial relationships, pose variations, and manipulation artifacts that align with the Capsule Network's ability to model hierarchical part–whole representations; therefore, DFDC enables the Capsule Network to exploit its architectural advantages more fully, while the 140K Real and Fake Faces Kaggle dataset remains more suitable for CNNs that perform effectively on static image classification tasks. Below are the six distinct datasets we selected for our research:

- UADFV dataset: This dataset includes 49 original videos collected from YouTube and 49 fake videos generated using deep neural networks.
- DF-TIMIT dataset: This dataset includes 640 real and fake videos. Deepfake videos were generated using FaceSwap-GAN. This dataset is divided into the DF-TIMIT-LQ and DF-TIMIT-HQ datasets.
- FaceForensics++ (FF++) dataset: This dataset consists of 1,000 videos from both real and fake sources. Real videos were collected from YouTube, and Deepfake videos were generated using FaceSwap.
- Deepfake Detection Challenge (DFDC) dataset: This dataset encompasses 4,113 fake videos, which were generated using 1,131 real videos. DFDC used 66 individuals of diverse age, gender, and culture.
- Celeb-DF dataset: This dataset contains 590 real videos and 5,639 fake videos, which were generated using FaceSwap technology.
- 140K Real and Fake Faces Kaggle dataset: This dataset consists of 140,000 human face images, including 70,000 real faces and 70,000 fabricated faces, which were generated using StyleGAN. This dataset is segmented into three subsets: 100,000 images for training, 20,000 for testing, and 20,000 for validation purposes.

C. Model Training

Our primary purpose was to evaluate the effectiveness of both Capsule Network models and modified versions thereof in comparison to state-of-the-art CNN methods regarding their performance. We conducted repeated training and testing of the models with the intention of achieving higher accuracy.

In the training process, we utilized the DFDC dataset for the Capsule models. We selected 10^{-3} as the learning rate value, maintaining a learning rate decay factor within the range 0.5 and 0.8. For the model training, we opted for 15 epochs, utilized the Adam optimizer, set a batch size of 16, and employed 3 and 5 iterations for the dynamic routing algorithm as the required parameters.

We selected five established state-of-the-art CNN models, which were previously pretrained on the ImageNet [39] dataset. During our experiment, we fine-tuned these models in accordance with our specific requirement of classifying real and fake videos. Here, we trained the CNN models on the 140K Real and Fake Faces Kaggle dataset, with a fixed learning rate of $5x10^{-4}$, a learning rate decay factor set to 0.92, running for 10 epochs and utilizing the Adam optimizer with a batch size of 64. Also, we selected Binary Cross-Entropy as the loss function.

In scripting the programs, we utilized Jupyter notebooks with Python. Google Collaboratory was instrumental in executing all our notebooks. In managing the extensive dataset, we opted to partition it into three distinct categories to facilitate training, testing and validation. Specifically, we allocated 100,000 images for the training set and reserved 20,000 images each for the testing and validation sets. These images were drawn from the 140K Real and Fake Faces Kaggle dataset and the DFDC dataset. Saved models were evaluated with five distinct datasets and compared their performance using the Area Under the Curve (AUC%) values.

IV. Results and Discussion

We used Windows Movie Maker to split the video clip into the first 256 frames. Each frame was processed using the "DLib-ml" tool to detect the face region and facial landmarks, marking 68 landmarks of each frame. The resultant landmarks were subsequently mapped onto a standard 3D facial landmark model consisting of 68 points. Fig. 3 shows the detected facial landmarks identified by the "DLib-ml" tool. In Fig. 3, the original real image is shown in Image (A). Image (B) displays the facial landmarks (indicated by red dots) of the central face region of the real face, while Image (C) displays the facial landmarks (indicated by blue dots) of the entire face region of the real face. All frames have been resized to 299x299. The first 256 frames of every video clip underwent this process.

Image (A) – Original Image (B) – Red dots Image (C) – Blue Dots

A. Performance of the Different Deepfake Video Detection Methods

In this research, our objective is to conduct a comparative analysis of the performance of the proposed Capsule Network models against state-of-the-art Capsule models and CNN models across various datasets. We aim to utilize AUC% and the number of parameters as the criteria for comparison.

Firstly, we determined the superior performance of the Capsule Networks over traditional CNN models. Secondly, we evaluated whether our Capsule Network models could achieve comparable or superior performance compared to state-of-the-art Capsule Network (CapsNet) models [41], [42] and CNN models. In this experiment, AUC% values were employed for evaluating the performance of each model. Table I showcases the results obtained from the four proposed Capsule Network models alongside the selected state-of-the-art CNN methods, evaluated across five distinct datasets. The proposed Capsule Network model 1, as depicted in Table I, attained the highest AUC% score of 99.55% on the FaceForensics++ dataset, outperforming existing CNN-based approaches and other models. Table I reveals that all detection methods, apart from Capsule Network models, encounter the most significant challenge in detecting deepfakes within the Celeb-DF dataset. Their performance rates with this dataset have remained below 70% to date. However, the proposed Capsule models outperform others, specifically on Celeb-DF. The following Fig. 4 enhances the clarity of the results in Table I.

Fig. 4 shows the grouped bar chart illustrating the performance of proposed Capsule Network models and state-of-the-art CNN models across different datasets. The graph shows the AUC% values of each model on the y-axis and the datasets on the x-axis. Fig. 4 clearly visualizes the higher AUC% values of the proposed Capsule models 1 and 2 across the five different datasets.

The Capsule Network models 3 and 4 were not tested on the UADFV, DF-TIMIT and DFDC datasets. The Capsule Network models 3 and 4 were designed specifically for comparison to the state-of-the-art CapsNet models and other proposed models. Therefore, models 3 and 4 were solely tested on the FaceForensics++ and Celeb-DF datasets, as shown in Table II.

Moreover, the difficulty levels in detecting fakes using the aforementioned methods vary across different datasets, such as DFDC and Celeb-DF. This suggests that the contents of recently developed datasets are still difficult to detect due to the varying collection of deepfake videos. Among the CNN-based models listed in Table I, XceptionNet exhibited the best performance across all datasets, attaining a notable accuracy of 99.0% with the FaceForensic++ dataset. Nonetheless, the proposed Capsule models we tested exhibited impressive AUC% scores, surpassing 99% on the FaceForrensics++ dataset, with some even exceeding 99.5%.

Based on Table I, it's evident that the proposed Capsule Network models achieve competitive performance over the existing CNN models across the datasets evaluated in this study.

Table II shows the AUC% values of the proposed Capsule models and state-of-the-art Capsule models on both the FaceForensics++ and Celeb-DF datasets. We evaluated the performance using AUC% and the number of parameters. According to Table II, it is noticeable that the majority of Capsule Network models, including both our experimental models and state-of-the-art models, have reached an AUC% score exceeding 95%. Capsule Network model 1 has achieved an AUC% score of 99.55%, surpassing the AUC% scores of existing Capsule Network approaches on the FaceForensics++ dataset. Further, except for Capsule Network model 1, the proposed Capsule Network models showed better performance compared to state-of-the-art Capsule Network architectures on the Celeb-DF dataset.

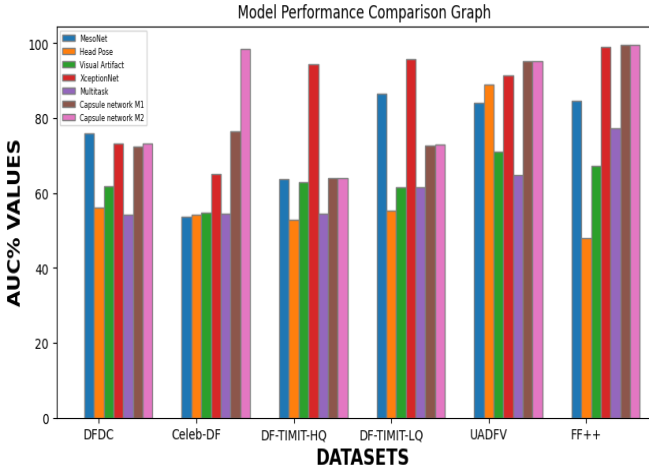

Fig. 4. Comparative performance of proposed capsule network models and CNN models across different datasets.

TABLE I. COMPARATIVE ANALYSIS BETWEEN THE PROPOSED CAPSULE NETWORK MODELS AND STATE-OF-THE-ART CNN-BASED MODELS ACROSS MULTIPLE DATASETS FOR PERFORMANCE EVALUATION

Model	Dataset					
	DFDC	*Celeb-DF*	*DF-TIMIT*		*UADFV*	*FF++*
			HQ	*LQ*		
MesoNet [15]	76.0	53.7	63.8	86.5	84.2	84.5
Head Pose [18]	56.0	54.3	52.8	55.3	89.0	47.9
Visual Artifact [17]	61.8	54.9	63.0	61.5	71.0	67.2
XceptionNet [16]	73.2	65.1	94.3	95.8	91.3	99.0
Multitask [19]	54.1	54.5	54.6	61.6	64.9	77.2
Capsule Network model 1 (Our model)	72.5	76.43	63.9	72.8	95.1	99.55
Capsule Network model 2 (Our model)	73.1	98.4	64.0	72.9	95.2	99.51

TABLE II. COMPARATIVE ANALYSIS BETWEEN THE PROPOSED CAPSULE NETWORK MODELS AND THE STATE-OF-THE-ART CAPSULE NETWORK MODELS ON THE FACEFORENSICS++ AND CELEB-DF DATASETS

Model	AUC %		No. of parameters
	FaceForensics++	Celeb-DF	
Nguyen et al- CapsNet [41]	93.11	57.50	3.9 M
Tolosana et al- CapsuleNet [42]	99.52	82.46	3.9 M
Capsule network model 1	99.55	76.43	5 M
Capsule network model 2	99.51	98.40	16 M
Capsule network model 3: 3 iterations	98.40	97.76	6 M
Capsule network model 3: 5 iterations	99.00	99.00	6 M
Capsule network model 4	98.31	97.46	4 M

Tolosna et al. [42] introduced an architecture that attained 82.46% AUC% on the Celeb-DF dataset and 99.52% on the FaceForensics++ dataset. In contrast, our proposed Capsule model 3 demonstrated the best performance of 99% on the Celeb-DF dataset and 99% on the FaceForensics++ dataset.

Tolosna et al. [42] introduced an architecture that attained 82.46% AUC% on the Celeb-DF dataset and 99.52% on the FaceForensics++ dataset. In contrast, our proposed Capsule model 3 demonstrated the best performance of 99% on the Celeb-DF dataset and 99.00% on the FaceForensics++ dataset.

Fig. 5 illustrates the grouped bar chart showing the AUC% values of proposed Capsule Network models and state-of-the-art Capsule Network models on the FaceForensics++ and Celeb-DF datasets. The graph shows the AUC% values of each model on the y-axis and the datasets on the x-axis.

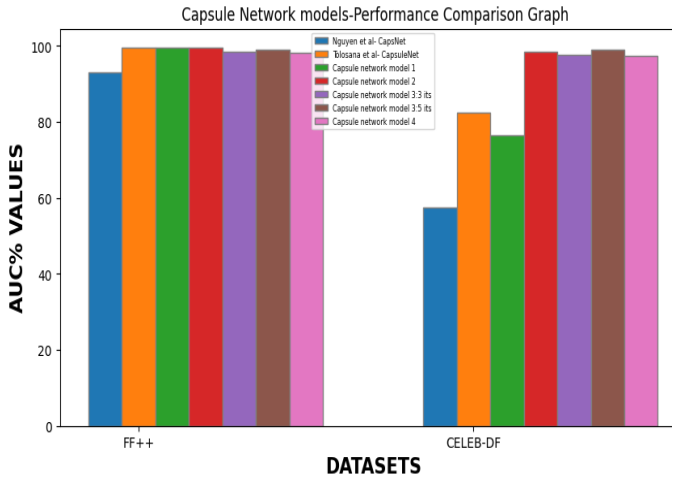

Fig. 5. Comparative performance of proposed capsule network models and state-of-the-art capsule network models on the faceforensics++ and celeb-DF datasets.

Fig. 5 shows a clear comparison of the performance of each model on each dataset. According to Fig. 5, the AUC% values of our proposed Capsule models display higher values than state-of-the-art Capsule models on both the FaceForensics++ and Celeb-DF datasets.

Additionally, we experimented with several iterations of the dynamic routing algorithm. Increasing the number of iterations in the Capsule Network can lead to higher performance. For instance, in Capsule Network model 3, transitioning from 3 iterations to 5 iterations within the same architecture enhanced the performance from 98.40 to 99.00 on the faceForensics++ dataset and from 97.76% to 99.00% on the Celeb-DF dataset, respectively. Nevertheless, a higher number of iterations also leads to increased prediction time, rendering it unsuitable for real-time tasks.

In addition, we conducted an experiment that demonstrates the superiority of Capsule Networks over Convolutional Networks. For instance, Capsule Network models 3 and 4 utilized 6 million and 4 million parameters, respectively, whereas the CNN models employed over 10 million parameters. Despite processing fewer parameters, the Capsule Network models achieved results with over 97% AUC%, surpassing the performance of the CNN models. Through experimentation, we found that maintaining over 1.9 million parameters in each Capsule Network model allowed them to achieve superior performance compared to CNN models.

The following Fig. 6 shows the line chart comparing the number of parameters used for the Capsule models and CNN models. The graph will illustrate the model complexity and resource requirements between the two types of models. Capsule Networks achieve consistently high AUC scores across all parameter sizes, demonstrating strong performance even with fewer parameters. In contrast, CNN models show a gradual improvement in AUC as the number of parameters increases, indicating a higher dependence on model size. Notably, CNNs require substantially more parameters to approach the performance level of Capsule Networks. These results highlight the superior parameter efficiency and robustness of Capsule Networks compared to conventional CNN architectures.

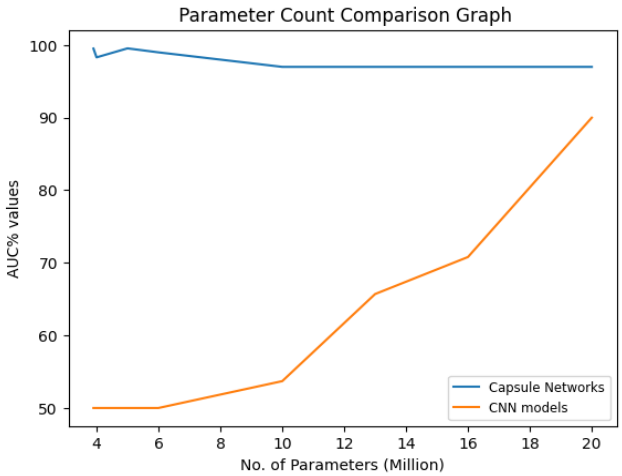

Fig. 6. Comparison of the number of parameters used for both capsule network models and CNN models.

The reported results are presented as single-run AUC values obtained under a fixed and consistent experimental protocol. Although additional statistical validation, such as repeated trials or confidence interval estimation, would further strengthen the robustness assessment, the observed performance trends remain

stable across five cross-dataset evaluations. All models were tested on the same five unseen datasets to assess generalization; Capsule Networks were trained on the DFDC dataset, while CNN models were trained on the 140K Real and Fake Faces Kaggle dataset due to experimental design considerations. Consequently, the observed performance improvements reflect empirical results under the current experimental setup rather than a strict isolation of architectural superiority or generalization capability. Future work will include controlled experiments and extended statistical analysis to more rigorously evaluate architectural generalization and performance stability.

We encountered several challenges during the model training process, particularly in terms of the amount of time it takes to train the models. Achieving higher accuracy requires more than 100,000 data points for training, which may be time-consuming. The time required for successful training can vary depending on factors such as hardware resources, computational cost, size of the dataset, number of training epochs, and type of neural network architecture of the detection model. In our experiment, we used Google Collab online for training and for the evaluation process. We used Windows Movie Maker for the frame extraction. While this tool is not conventional for research, the frame extraction procedure was consistent across all videos, ensuring that the experimental results are reproducible. For future studies, the same extraction procedure can be implemented using standard tools such as OpenCV, which would provide fully reproducible frame sequences.

V. Conclusion

Deepfake-generated fake images, voices, and videos are rapidly spreading across various social media platforms and websites. The deepfake creation tools are highly recommended for their output accuracy, as the synthetic forgeries they produce can appear indistinguishable to the naked eye. Detecting deepfakes poses a significant challenge due to the high accuracy of these fabricated creations.

Through this study, we aimed to present a novel and robust approach to deepfake detection distinct from existing state-of-the-art methods. We identified that Capsule Networks have more effective power in detecting deepfakes instead of traditional CNN-based methods. According to our results, despite having fewer parameters, the Capsule Network models achieved results with over 98% AUC%, showing stronger performance. Our proposed Capsule Networks exhibited reduced performance degradation compared to traditional CNNs and existing Capsule (CapsNet) models, indicating improved generalization capability. We emphasize the following points and present the summarization of the research as follows.

- For the model training, we employed 15 epochs for Capsule models and 10 epochs for CNN models. However, the proposed Capsule Network models outperformed the CNN models, completing the training process in a shorter period.
- Capsule Networks can retain more information compared to traditional CNNs, even with less training data.
- Capsule Networks demonstrated stronger performance under the given experimental configuration.
- As the number of iterations of the dynamic routing algorithm increases, the performance of the Capsule models also improves, even with a smaller number of parameters.
- Existing CNN-based deepfake detection methods have shown lower accuracy, often falling below approximately 65%, primarily due to the generalizability problem. Capsule Networks, however, offer a solution that avoids the generalizability problem.

Our results show that Capsule Networks exhibit greater efficacy in detecting deepfakes compared to traditional CNN-based methods. Therefore, Capsule Networks are better suited for deepfake detection due to their capacity for generalization, utilization of fewer parameters, and the ability to handle image rotation, transformation, and dimensionality. These qualities make Capsule Networks an ideal choice for deepfakes detection. Novel methods within Capsule Networks for deepfake detection should be further improved in the near future. These findings will be a significant step forward for the new researchers in the deepfake domain.

***Abstract*—Accurate characterization of wind resources is essential for reliable energy yield estimation and wind farm planning, particularly in regions with limited long-term measurements. This study presents a machine-learning–assisted probabilistic wind assessment in Sechura, Peru, based on multi-year hourly wind data obtained from the NASA POWER database. A representative Typical Meteorological Year (TMY) was constructed to preserve seasonal and diurnal variability while enabling standardized annual energy production (AEP) calculations. Wind speed distributions were modeled using empirical distributions, kernel density estimation (KDE), the Weibull distribution, and Gaussian mixture models (GMM). Statistical evaluation indicates that KDE and GMM reduce the annual RMSE by more than 50% compared to the Weibull model, achieving coefficients of determination above 0.98. Annual energy production is estimated at approximately 1.88 GWh, with differences below 0.3% among probabilistic models. The corresponding capacity factor is approximately 0.25 for a utility-scale wind turbine. The results demonstrate that advanced probabilistic models substantially improve wind speed representation while having a limited impact on integrated annual energy estimates, highlighting the importance of model selection for variability and seasonal analysis rather than for annual yield estimation.**

***Keywords*—Wind resource assessment; probabilistic modeling; machine learning; kernel density estimation; Gaussian mixture model; annual energy production; capacity factor**

I. Introduction

Reliable characterization of the wind resource is a fundamental prerequisite for accurate annual energy production (AEP) estimation, optimal site selection, and robust planning of wind-power projects. Traditionally, wind-speed variability has been modeled using parametric probability density functions, with the two-parameter Weibull distribution being the most commonly employed due to its mathematical simplicity and the availability of closed-form expressions for wind power density and related energy metrics. However, numerous studies have shown that the Weibull distribution can present significant shortcomings when representing wind regimes characterized by skewness, intermittency, strong seasonality, or multimodal behavior. Comparative studies at regional and global scales have demonstrated that no single parametric model can universally capture the complexity of wind-speed distributions across different climatic contexts, particularly in coastal areas and complex terrain [1], [2]. Such limitations may lead to biased estimates of wind power density and, consequently, of AEP [3]–[5].

In response to these limitations, more flexible statistical approaches have been developed and applied. Kernel density estimation (KDE) has emerged as a prominent nonparametric alternative, capable of reconstructing the probability density function directly from observed data without imposing a predefined functional form. Several studies report that KDE systematically outperforms Weibull models in goodness-of-fit metrics and distributional distances, especially when advanced bandwidth-selection strategies and bias-correction techniques are applied [6]–[8].

At the same time, mixture models offer an effective parametric compromise by representing complex distributions as weighted combinations of simpler component distributions. Weibull mixtures and Gaussian mixture models have shown superior capability to capture wind multimodality and to provide more realistic uncertainty estimates for energy production [9]–[15]. These approaches have been extensively used both for wind-resource assessment and for analyses of variability and energy-related risk.

In regions lacking long in-situ measurement records, atmospheric reanalysis products have become an established and reliable data source for wind-resource evaluation. In particular, the NASA MERRA-2 reanalysis has been extensively validated and demonstrated to provide surface and near-surface wind fields suitable for energy applications [6], [16]. Platforms such as NASA POWER facilitate access to these data and have been widely used in studies of wind potential and turbine selection [17]– [22].

This study combines a regional case study (Sechura, Peru) with a differentiated methodological approach. Sechura is a coastal area with high wind potential that has been little explored using advanced methods. Recent studies indicate that wind energy in Peru remains underdeveloped and its potential is not yet fully exploited [23]. In this context, our research provides original value by applying advanced probabilistic techniques, assisted by machine-learning approaches, to characterize the local wind resource. Specifically, we employ an unsupervised Gaussian mixture model (GMM) to identify wind regimes in Sechura, which, to the best of our knowledge, has not been widely documented in the local literature.

Within this context, the present work develops a machine-learning–assisted probabilistic assessment of the wind resource for Sechura, Piura (Peru), using hourly MERRA-2 reanalysis data. We systematically compare empirical distributions, kernel density estimation, the Weibull distribution, and mixture

models, evaluating their statistical performance and their impact on wind power density estimation, annual energy production, and capacity factor. The objective is to provide a rigorous methodological perspective to improve wind-resource characterization in arid coastal environments, where wind variability and multimodality are critical factors.

II. METHODOLOGY

A. Study Area and Data

The study area is located in Sechura, Province of Sechura, Piura, Peru, on the northern Pacific coast of South America (latitude −5.99°, longitude −81.08°). The region is characterized by arid climatic conditions, low surface roughness, and relatively flat terrain, making it suitable for wind resource assessment. The local wind regime is influenced by southeast trade winds and land–sea breeze circulations, which contribute to pronounced seasonal and diurnal variability.

Hourly wind speed data at 50 m above ground level were obtained from the NASA POWER database, based on the MERRA-2 reanalysis [16]. The dataset spans the period from December 2014 to January 2026 and includes wind speed, wind direction, and surface pressure. The average elevation of the corresponding grid cell is approximately 31.65 m above sea level.

Due to the absence of long-term in situ wind measurements in Sechura, MERRA-2 reanalysis data were used as the primary data source. Reanalysis products combine historical global observations with numerical atmospheric models through data assimilation techniques, providing temporally consistent, long-term wind datasets with global coverage. Such datasets are widely employed in preliminary wind resource assessments, particularly in regions lacking ground-based measurements.

Nevertheless, previous studies have reported that reanalysis data may present biases in coastal environments, including potential underestimation of wind speeds due to spatial resolution and surface parameterization limitations [24]. Therefore, the results presented here should be interpreted as a probabilistic assessment based on large-scale atmospheric reanalysis data. Future work should incorporate local meteorological mast measurements to validate and calibrate the probabilistic models developed in this study.

The NASA POWER wind-speed data used in this study correspond to a nominal measurement height of 50 m above ground level. For consistency, no vertical extrapolation or wind-shear correction was applied to adjust the wind speeds to the turbine hub height. The selected Gamesa G58/850 turbine typically operates at hub heights slightly above this level (approximately 55–65 m), and the study area is characterized by flat terrain and low surface roughness. Under these conditions, the expected wind-speed difference between 50 m and the hub height is limited. Nevertheless, the use of 50 m wind speeds directly in the energy calculations represents a simplifying assumption. A more detailed site-specific assessment could apply logarithmic or power-law vertical wind profiles to explicitly account for wind shear effects.

Wind-speed and surface-pressure data were obtained from the NASA POWER reanalysis and updated through January 2026. Hourly series were downloaded manually from the NASA POWER portal and then processed using a Python pipeline that performs chronological concatenation of hourly records and basic quality control: nonphysical values (e.g., negative wind speeds) are clipped or removed, and remaining gaps are handled during aggregation. Derived quantities (e.g., air density) are computed from the cleaned time series, and a Typical Meteorological Year (TMY) was constructed by averaging all available observations for each calendar hour. This workflow supports straightforward manual updates as new data becomes available and thus facilitates frequent refreshes of the resource assessment.

B. Typical Meteorological Year Construction

To enable standardized AEP calculations while preserving long-term variability, a Typical Meteorological Year (TMY) was constructed from the multi-year dataset. For each calendar hour defined by month, day, and hour, the representative wind speed was computed as the arithmetic mean of all available observations corresponding to that time slot across the full record. Leap-day observations (29 February) were excluded to maintain a total of 8760 hourly values.

This procedure reduces the influence of anomalous years while retaining essential seasonal and diurnal variability, and is a widely accepted practice in wind and solar resource assessments [17], [20].

The Typical Meteorological Year (TMY) was constructed by averaging the multi-year hourly wind-speed series for each hour of the calendar year, rather than applying the Finkelstein–Schafer (FS) method, which selects representative months based on statistical goodness-of-fit criteria [25]. The hourly averaging approach produces a continuous and temporally homogeneous climatological year, avoiding potential discontinuities that may arise when concatenating months from different years.

Although the FS technique is widely applied in solar energy studies, the present wind-focused analysis prioritizes the temporal smoothness and long-term mean representativeness of the multi-year hourly average. This averaged TMY is appropriate for the comparative probabilistic assessment conducted in this study. Nevertheless, future research could evaluate a TMY constructed using the FS methodology to quantify potential differences in estimated energy production.

C. Probabilistic Wind Speed Models

1) Empirical distribution: The empirical probability density function (PDF) was obtained directly from the TMY wind speed data using normalized histograms and serves as the reference distribution for model comparison.

2) Kernel Density Estimation (KDE): KDE was employed as a nonparametric method to estimate the wind-speed PDF. Several bandwidth-selection strategies were considered, including normal-scale rules and cross-validation-based methods, which have demonstrated superior performance in wind-energy applications [6], [7], [8], [27].

The KDE of wind speed v is defined as

$$f_{KDE}(v) = \frac{1}{nh}\sum_{i=1}^{n} K\left(\frac{v - v_i}{h}\right) \quad (1)$$

where, n is the sample size, h is the bandwidth, and $K(\cdot)$ is a Gaussian kernel. Two bandwidth selection methods were considered: a normal-scale rule (KDE-NS) and least-squares cross-validation (KDE-LSCV), the latter being shown to provide superior performance in wind energy applications [4].

3) Weibull distribution: The two-parameter Weibull distribution was used as the parametric reference model. Shape and scale parameters were estimated via maximum likelihood following standard practice in the literature [1], [2], [5], [28].

The Weibull PDF is given by

$$f_W(v) = \frac{k}{c}\left(\frac{v}{c}\right)^{k-1} \exp\left[-\left(\frac{v}{c}\right)^{k}\right] \quad (2)$$

where, k is the shape parameter and c is the scale parameter. Maximum likelihood estimation was used to estimate the parameters. Despite its widespread use, the Weibull distribution may inadequately represent multimodal or highly variable wind regimes [1], [2].

4) Gaussian Mixture Model (GMM): To capture possible multimodal behaviour, mixture models were applied, including Weibull mixtures and Gaussian mixture models (GMMs). These models represent the overall PDF as a weighted sum of individual component distributions and have demonstrated superior capability to describe complex wind regimes and to quantify energetic uncertainty [9]–[15].

The GMM represents the wind speed PDF as a weighted sum of Gaussian components:

$$f_{GMM}(v) = \sum_{j=1}^{M} \pi_j \frac{1}{\sqrt{2\pi}\sigma_j} \exp\left[-\frac{(v-\mu_j)^2}{2\sigma_j^2}\right] \quad (3)$$

where, M is the number of components, π_j are the mixing weights, and μ_j, σ_j are the mean and standard deviation of each component. A three-component GMM was selected based on model parsimony and interpretability, consistent with previous wind energy studies using mixture models [9].

Although the applied techniques correspond to classical statistical learning rather than deep learning, both kernel density estimation and Gaussian mixture models are formally categorized as unsupervised machine-learning methods.

The use of the term 'Machine-Learning–Assisted' is justified because the analysis incorporates an unsupervised machine-learning algorithm within the probabilistic modeling framework. Specifically, we employ a Gaussian Mixture Model (GMM) [26], which assumes that the wind-speed distribution arises from a weighted combination of multiple Gaussian components. Model parameters are estimated through the expectation–maximization (EM) algorithm, enabling the automatic identification of latent wind regimes without prior labeling. This unsupervised clustering approach captures multimodal characteristics of the wind-speed distribution that cannot be adequately represented by single-parameter models such as the Weibull distribution. Therefore, although the framework does not rely on supervised predictive learning, the integration of automated data-driven clustering techniques supports the use of the term 'machine-learning–assisted' in this study.

The optimal number of mixture components was determined using statistical information criteria. Models with varying numbers of clusters were fitted, and both the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC) were computed for each configuration. The criteria exhibited a minimum (or clear elbow point) around k=3, indicating that three components provide an adequate balance between model goodness-of-fit and complexity. In addition, the selection of three clusters is physically consistent with the local wind-resource characteristics, where it is plausible to distinguish low-, medium-, and high-wind regimes. This approach avoids overfitting while ensuring a parsimonious yet flexible probabilistic representation of the wind-speed distribution.

To avoid heuristic selection of the number of mixture components, models with different values of k were evaluated using the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC). Both criteria reached their minimum at k=3, indicating that three components provide the optimal trade-off between model fit and complexity. The large ΔAIC relative to the Weibull model further supports this selection.

D. Statistical Performance Metrics

Model performance was assessed using a combination of goodness-of-fit metrics and distributional distance measures commonly adopted in wind-speed probabilistic modeling. These include the root mean square error (RMSE), mean absolute error (MAE), the Kolmogorov–Smirnov (KS) statistic, the Kullback–Leibler (KL) divergence, the Hellinger distance, and the one-dimensional Wasserstein distance, which together provide a comprehensive evaluation of both pointwise errors and global distributional discrepancies [3], [4].

The R^2, RMSE and MAE were computed as:

$$R^2 = 1 - \frac{\sum_{i=1}^{n}\left(f_{\text{emp},i} - f_{\text{model},i}\right)^2}{\sum_{i=1}^{n}\left(f_{\text{emp},i} - \overline{f_{\text{emp}}}\right)^2} \quad (4)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(f_{emp,i} - f_{model,i}\right)^2} \quad (5)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|f_{emp,i} - f_{model,i}\right| \quad (6)$$

The Kolmogorov–Smirnov statistic was used to quantify the maximum absolute deviation between the empirical and modeled cumulative distribution functions (CDFs):

$$KS = \sup_{v} \left| F_{emp}(v) - F_{model}(v) \right| \tag{7}$$

Kullback–Leibler divergence

$$D_{KL}(f_{emp} \| f_{model}) = \sum_{i} f_{emp,i} \ln \left(\frac{f_{emp,i}}{f_{model,i}} \right) \tag{8}$$

Hellinger distance

$$H = \frac{1}{\sqrt{2}} \sqrt{\sum_{i} \left(\sqrt{f_{emp,i}} - \sqrt{f_{model,i}} \right)^2} \tag{9}$$

Wasserstein distance (1D, discrete form)

$$W = \sum_{i} \left| F_{emp}(v_i) - F_{model}(v_i) \right| \Delta v \tag{10}$$

E. Wind Power Density Estimation

Wind power density (WPD) was computed from each modeled PDF, incorporating air density estimated from surface pressure data. Annual energy production and capacity factor were calculated by mapping wind speeds to the power curve of a representative commercial wind turbine and integrating the resulting hourly power time series according to standard procedures [17]– [22].

Wind power density (WPD) was calculated from each modeled PDF as:

$$WPD = \frac{1}{2} \rho \int_{0}^{\infty} v^3 f(v) dv \tag{11}$$

where, ρ is air density, computed from surface pressure data under standard atmospheric assumptions.

F. Energy Production and Capacity Factor

Hourly electrical power output was obtained by mapping wind speeds to a commercial-scale wind turbine power curve. The annual energy production (AEP) was computed as:

$$E_{annual} = \sum_{i=1}^{8760} P_i \Delta t, \qquad \Delta t = 1\,\text{h} \tag{12}$$

The mean annual power was calculated as:

$$\bar{P} = \frac{E_{annual}}{8760} \tag{13}$$

The capacity factor (CF) was defined as:

$$CF = \frac{\bar{P}}{P_{rated}} \tag{14}$$

Seasonal energy production and capacity factors were computed analogously by integrating over the corresponding seasonal subsets of the TMY dataset.

Reference wind turbine. A commercial horizontal-axis wind turbine, Gamesa G58/850, was selected as the reference machine for energy production and capacity factor calculations, with technical specifications obtained from TheWindPower.net [29]. The turbine has a rated power of 850 kW and a three-bladed rotor with a diameter of 58 m (swept area = 2,642 m²). Cut-in, rated, and cut-out wind speeds are 3.0 m/s, 12.5 m/s, and 25.0 m/s, respectively. Maximum rotor speed is 30.8 rpm (tip speed ≈ 94 m/s). Rotor blades are fiberglass/epoxy composites. This turbine model was used to map probabilistic wind speed distributions to electrical output via the manufacturer's power curve for AEP and CF estimation [29].

G. Computational Implementation and Cost

To assess practical computational costs, bandwidth selection via leave-one-out least-squares cross-validation (LSCV) was compared against a simple rule-of-thumb (Silverman's rule). Using our Python implementation (vectorized operations and peak memory tracking via tracemalloc), the following empirical results were obtained: the LSCV bandwidth search required ≈ 1.06 s with a peak Python allocation of ≈ 32.03 MB, whereas KDE evaluation on the fine integration grid (using either the Silverman bandwidth or the LSCV-selected bandwidth) completed in ≈ 0.33 – 0.35 s with negligible allocation peaks (≈ 0.11 MB). All benchmarks were executed on the author's workstation: Intel Corporation Core(TM) i5-7200U @ 2.50 GHz (2 physical cores, 4 logical processors) with 17,060,569,088 bytes (≈ 15.89 GB) RAM. These results indicate that the dominant computational overhead arises from the repeated evaluations inherent to LSCV bandwidth selection rather than from KDE evaluation once the bandwidth is fixed. For practical applications, we therefore recommend: 1) subsampling or parallelization when applying LSCV to large datasets; 2) using rule-of-thumb bandwidths (Silverman/Scott) or approximate KDE implementations (KD-tree, FFT/binning) for very large n or latency-constrained settings; and 3) complementing tracemalloc with system-level monitoring tools (e.g., psutil) when total process memory usage is required. Table I summarizes the measured execution times and peak Python allocation on the reference workstation.

TABLE I. BENCHMARK RESULTS (EXECUTION TIME AND PEAK PYTHON ALLOCATION

Metric	Time (s)	Peak allocation (bytes)	Peak (MB)
LSCV bandwidth search	1.0621	32033025	30.54
KDE evaluation (Silverman)	0.3499	119464	0.11
KDE evaluation (LSCV bandwidth)	0.3341	119424	0.11

Note: Reference workstation: Intel Corporation Core(TM) i5-7200U CPU @ 2.50 GHz — 2 physical cores (4 logical processors); 17,060,569,088 bytes (≈ 15.89 GB) RAM. Measurements performed on the author's machine; memory values report Python allocation peaks captured by tracemalloc.

Execution times and memory usage depend on hardware and system configuration (e.g., multithreaded BLAS).

III. Results and Discussion

The performance of probabilistic wind speed models was evaluated using both statistical and distributional metrics on the Typical Meteorological Year (TMY) dataset for Sechura, Peru. The models analyzed include empirical histograms, kernel density estimation with normal and least-squares cross-validation bandwidths (KDE-NS and KDE-LSCV), a two-parameter Weibull distribution, and a three-component Gaussian mixture model (GMM(3)). The main objective of this section is to compare these models in terms of fit accuracy and to interpret their implications for wind resource assessment.

A. Annual PDF Fitting Accuracy

Fig. 1 compares the annual empirical wind speed distribution with the fitted PDFs and CDFs obtained using KDE, Weibull, and GMM models. The KDE-LSCV closely follows the empirical distribution across the entire wind speed range, while the Weibull model exhibits noticeable deviations, particularly in the tails, explaining its poorer goodness-of-fit metrics reported in Table II.

Table II summarizes the annual goodness-of-fit metrics for each model. The empirical distribution serves as a perfect reference, as expected, with zero error across all metrics.

Among the fitted models, KDE-LSCV achieves the best overall performance, with the highest coefficient of determination (R^2 = 0.98) and the lowest values in the Kolmogorov–Smirnov statistic (KS = 0.02), RMSE, MAE, and distributional distance measures (Hellinger, Kullback–Leibler, and Wasserstein). This confirms that KDE-LSCV accurately represents both the central tendency and the tails of the wind speed distribution, which is critical for wind energy applications where tail behavior influences extreme events and energy yield predictions [6]– [8], [23].

Similar conclusions regarding the superiority of kernel-based approaches have been reported in recent studies employing advanced and adaptive bandwidth KDE techniques. For example, Chau et al. [30] demonstrated that hybrid adaptive KDE formulations significantly improve wind speed representation across diverse climatic conditions, while Ning et al. [31] showed that KDE-based probabilistic modeling provides robust performance even in highly variable and extreme wind regimes. Although the present study employs classical LSCV bandwidth selection, the results are consistent with these findings and confirm the strong suitability of KDE for wind resource assessment.

In contrast, the Weibull distribution exhibits substantially poorer performance, with R^2 = 0.62 and the largest error and distance metrics (e.g., Wasserstein = 0.37). This indicates a significant mismatch with the empirical distribution, especially in the tails. These findings align with previous comparisons showing that fixed parametric models such as Weibull can be inadequate in complex wind regimes [1]– [5].

The GMM(3) model improves significantly upon the Weibull distribution and yields results comparable to KDE-NS, demonstrating that mixture distributions are effective in capturing multimodal wind speed structures. Previous studies likewise highlight the advantages of mixture models for improved uncertainty representation in wind energy modeling [9]– [15]. Nevertheless, GMM(3) remains slightly inferior to KDE-LSCV across most evaluation metrics, reflecting the superior flexibility of non-parametric density estimation methods.

TABLE II. Annual PDF Fit Metrics

Model	R^2	KS	RMSE	MAE	Hellinger	KL	Wasserstein
Empirical	1.00	0.00	0.00	0.00	0.00	0.00	0.00
KDE-NS	0.95	0.03	56.56	31.43	0.06	0.01	0.05
KDE-LSCV	0.98	0.02	39.35	23.07	0.04	0.01	0.02
Weibull	0.62	0.11	154.00	95.00	0.18	0.12	0.37
GMM (3)	0.94	0.03	59.70	36.49	0.07	0.02	0.05

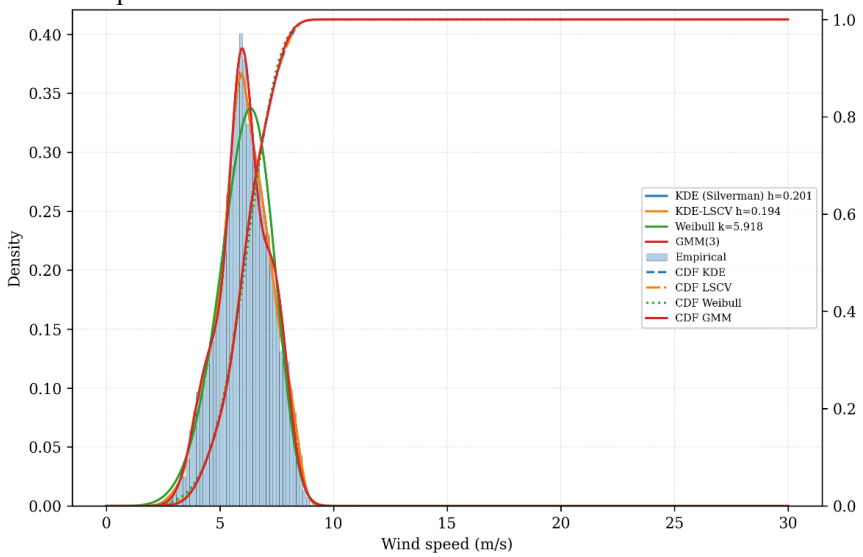

Fig. 1. Comparison of annual wind speed probability density functions (PDFs) and cumulative distribution functions (CDFs) for Sechura using empirical data, KDE, Weibull, and GMM models.

B. Seasonal Probabilistic Fitting Performance

Fig. 2 presents the seasonal empirical wind speed distributions together with the fitted probability density functions (PDFs) and cumulative distribution functions (CDFs) for Summer, Autumn, Winter, and Spring. Across all seasons, the KDE-LSCV model closely follows the empirical distribution, accurately capturing both central tendencies and tail behavior. In contrast, the Weibull distribution exhibits noticeable deviations, particularly during Winter and Summer, where multimodal features are evident in the empirical data. The GMM(3) model provides an improved representation of multimodality compared to Weibull, although it remains slightly less accurate than KDE-LSCV in terms of overall distributional agreement.

Seasonal performance for Summer, Autumn, Winter and Spring is shown in Table II. KDE-LSCV consistently achieves the highest R^2 and the lowest KS, RMSE, MAE, and distance metrics across all seasons, indicating robustness in capturing seasonal wind speed variations.

The GMM(3) model exhibits intermediate performance, consistently outperforming the Weibull distribution across most evaluation metrics. In particular, the Weibull model performs poorly during extreme seasonal regimes (e.g., summer and winter), as evidenced by elevated Kolmogorov–Smirnov statistics and large error values. This behavior indicates a limited ability to adapt to seasonally varying distribution shapes and tail characteristics. These observations are consistent with findings in the literature, which report that simple parametric assumptions frequently fail in environments characterized by complex and highly variable climatic patterns [3]– [5].

Table III lists the seasonal PDF fit metrics for the selected wind-speed models (KDE-LSCV, GMM(3) and Weibull). The table reports R^2, Kolmogorov–Smirnov (KS) statistic, RMSE, MAE and three distributional distances (Hellinger, KL and Wasserstein) for Summer, Autumn, Winter and Spring.

As shown in Table III, KDE-LSCV consistently delivers the best seasonal goodness-of-fit, with $R^2 \approx 0.97$–0.98 and the lowest KS, RMSE and distributional distances across all seasons. GMM(3) produces competitive, intermediate results (typically $R^2 \approx 0.95$), while the Weibull model performs poorly ($R^2 \approx 0.60$–0.65) and exhibits the largest errors and distributional discrepancies, especially in Winter and Summer. These seasonal patterns confirm the robustness of non-parametric and mixture approaches for capturing changing wind regimes (Table III).

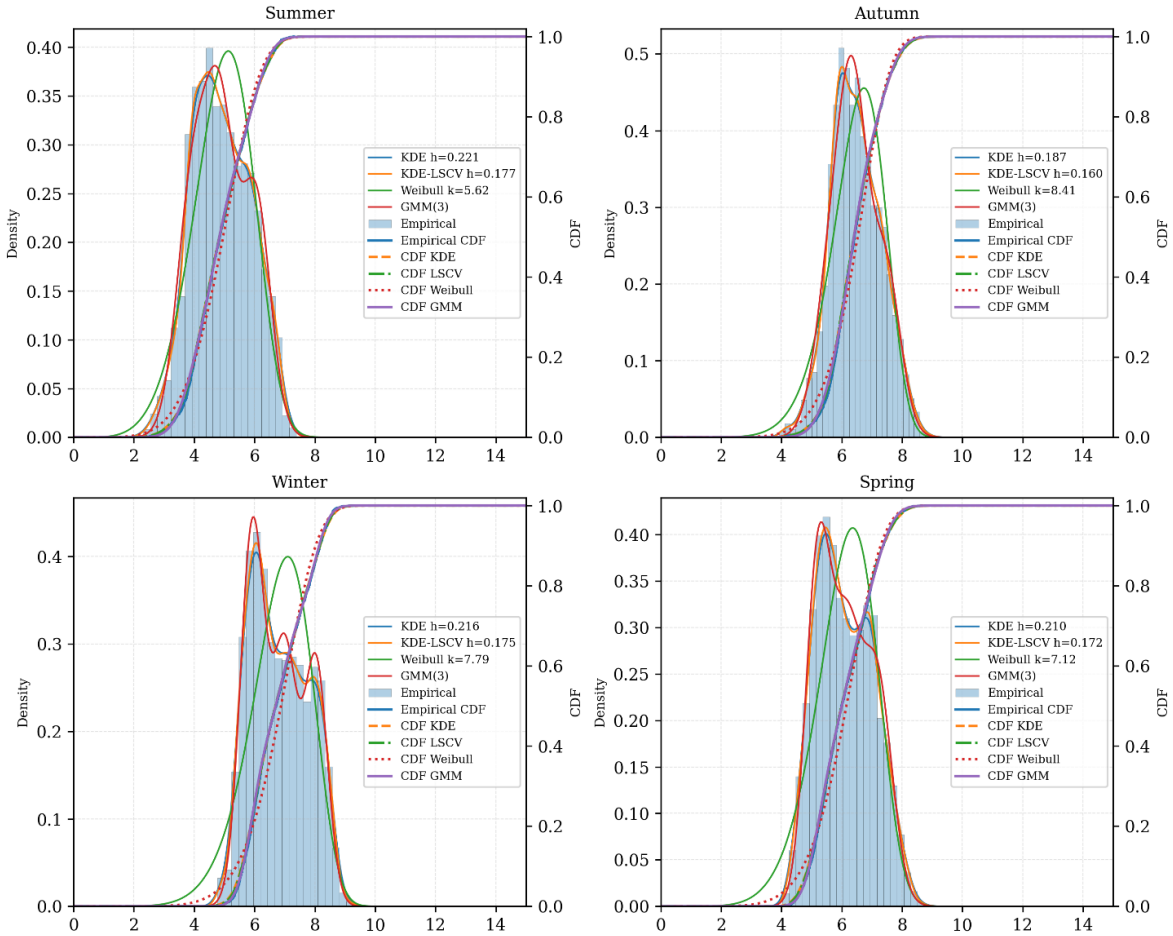

Fig. 2. Seasonal empirical wind speed distributions and fitted PDFs and CDFs for Summer, Autumn, Winter, and Spring using KDE, Weibull, and GMM models.

TABLE III. SEASONAL PDF FIT METRICS FOR SELECTED WIND SPEED MODELS

Season	Model	R^2	KS	RMSE	MAE	Hellinger	KL	Wasserstein
Summer	KDE-LSCV	0.97	0.02	45.12	25.99	0.04	0.01	0.02
	GMM (3)	0.95	0.03	52.33	30.44	0.05	0.01	0.05
	Weibull	0.61	0.11	160.23	98.11	0.19	0.13	0.39
Autumn	KDE-LSCV	0.98	0.02	35.99	21.46	0.04	0.00	0.02
	GMM (3)	0.96	0.03	49.12	29.25	0.05	0.01	0.04
	Weibull	0.65	0.10	140.99	85.12	0.17	0.11	0.36
Winter	KDE-LSCV	0.97	0.02	40.46	23.35	0.04	0.01	0.02
	GMM (3)	0.95	0.03	55.68	34.12	0.06	0.01	0.06
	Weibull	0.60	0.12	170.46	105.68	0.19	0.14	0.41
Spring	KDE-LSCV	0.97	0.02	42.33	24.57	0.04	0.01	0.02
	GMM (3)	0.95	0.03	57.00	36.79	0.06	0.01	0.06
	Weibull	0.61	0.12	165.12	100.23	0.19	0.13	0.40

C. Impact on Energy Production and Capacity Factors

Table IV presents the seasonal mean power output, annual energy production (AEP), and capacity factor estimated using the different probabilistic models. Although substantial differences are observed in the quality of the wind speed distribution fitting, the resulting integrated energy metrics remain remarkably consistent across models. Specifically, deviations in AEP and capacity factor are below 0.3%, indicating that long-term energy estimates are relatively insensitive to moderate discrepancies in probability density representation.

This behavior can be attributed to the smoothing effect of turbine power curves and the dominance of mid-range wind speeds in the energy contribution, which reduces sensitivity to distributional differences in the tails. Similar findings have been reported in previous wind energy studies, where parametric and non-parametric models yield comparable long-term energy outputs despite notable differences in statistical performance metrics [17]– [22].

Nevertheless, accurate probabilistic modeling remains critical when the scope extends beyond aggregated annual indicators. Applications such as uncertainty quantification, risk assessment, seasonal forecasting, and turbine selection or optimization require faithful representation of the full wind speed distribution, particularly in the tails, where extreme events and variability play a decisive role.

TABLE IV. SEASONAL ENERGY PRODUCTION AND CAPACITY FACTOR

Season	Model	Mean power (kW)	AEP (MWh)	CF
Summer	Empirical	115.87	250.28	0.14
	KDE-NS	116.39	251.40	0.14
	KDE-LSCV	116.20	251.00	0.14
	Weibull	116.62	251.91	0.14
	GMM (3)	115.87	250.28	0.14
Autumn	Empirical	246.28	537.88	0.29
	KDE-NS	246.60	538.58	0.29
	KDE-LSCV	246.52	538.39	0.29
	Weibull	246.27	537.86	0.29
	GMM (3)	246.29	537.91	0.29
Winter	Empirical	282.67	624.13	0.33
	KDE-NS	283.06	625.00	0.33
	KDE-LSCV	282.93	624.70	0.33
	Weibull	283.65	626.31	0.33
	GMM (3)	282.67	624.13	0.33
Spring	Empirical	211.47	466.92	0.25
	KDE-NS	211.88	467.84	0.25
	KDE-LSCV	211.75	467.54	0.25
	Weibull	212.11	468.35	0.25
	GMM (3)	211.49	466.96	0.25

Note: AEP and CF were computed using the power curve of the Gamesa G58/850 wind turbine (rated power: 850 kW; rotor diameter: 58 m; cut-in / rated / cut-out wind speeds: 3.0 / 12.5 / 25.0 $m \cdot s^{-1}$). Technical specifications were obtained from TheWindPower.net [29].

Fig. 3 compares the seasonal energy production estimated using the different probabilistic wind speed models. Despite the substantial differences observed in the statistical fitting accuracy of the distributions, the resulting seasonal energy estimates are remarkably consistent across all models. For all seasons, deviations in AEP remain very small, confirming that integrated energy metrics are weakly sensitive to moderate discrepancies in wind speed probability density modeling. This behavior is mainly attributed to the smoothing effect of turbine power curves and the dominance of mid-range wind speeds in energy production.

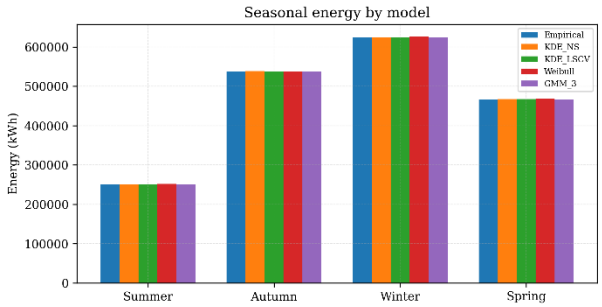

Fig. 3. Seasonal energy production estimated using different probabilistic wind speed models.

TABLE V. ANNUAL GENERATED ENERGY AND CAPACITY FACTOR FOR DIFFERENT PROBABILISTIC WIND MODELS

Model	Generated Energy (Wh)	Capacity Factor
Empirical	1,879,199,060	0.25
KDE-NS	1,882,521,226	0.25
KDE-LSCV	1,882,318,322	0.25
Weibull	1,883,887,128	0.25
GMM(3)	1,879,320,489	0.25

As shown in Table V, the estimated annual energy production varies by less than 0.3% among the considered probabilistic models, resulting in capacity factors close to 0.25 for all cases. Although advanced probabilistic models significantly improve the representation of wind speed distributions, their impact on integrated annual energy production is limited, as evidenced by the results in Table V. This confirms that annual energy yield is primarily driven by the mean wind regime, whereas model selection becomes more relevant for variability, extremes, and seasonal analysis.

From a methodological perspective, the results highlight the effectiveness of data-driven and machine-learning-based probabilistic models for wind resource characterization. Although the applied techniques belong to classical statistical learning rather than deep learning, both kernel density estimation with data-adaptive bandwidth selection and Gaussian mixture models can be formally classified as unsupervised machine learning approaches. Their superior performance relative to classical parametric models confirms the value of machine learning tools for capturing complex wind speed distributions.

These statistical indicators quantify the degree of divergence between wind-speed probability distributions, which directly translates into differences in the estimated annual energy production (AEP). From an energy perspective, low values of KS, KL divergence, or Hellinger distance (approaching zero) indicate highly similar distributions, implying that AEP estimates derived from alternative models would differ only marginally. Conversely, higher metric values reveal substantial discrepancies in the representation of wind regimes, particularly in the tails of the distribution, which disproportionately influence power output due to the cubic dependence of wind power on velocity.

In particular, divergence-based measures such as KL and Hellinger are sensitive to distributional shape differences, including multimodality and tail behavior, which can lead to meaningful variations in AEP when inadequately modeled. The Wasserstein distance provides an intuitive interpretation, as it measures the average displacement required to transform one distribution into another in the wind-speed domain; larger values therefore indicate greater shifts in effective wind regimes and potentially greater deviations in energy yield. Overall, these metrics provide a quantitative bridge between statistical goodness-of-fit and the reliability of energy production estimates.

As a potential extension of this work, the probabilistic framework developed here could be used to estimate P50 and P90 energy production levels. This would involve generating multiple synthetic wind-speed realizations from the fitted probabilistic model (e.g., via Monte Carlo sampling) and computing the corresponding annual energy production (AEP) for each realization. The resulting AEP distribution would allow direct extraction of production percentiles such as P50 and P90. Alternatively, analytical integration of the estimated joint probability density could be explored to derive production quantiles. Although beyond the scope of the present study, this extension would enable explicit quantification of production uncertainty and improve risk assessment in wind-energy project evaluation.

IV. CONCLUSIONS

This study presented a comprehensive probabilistic assessment of the wind resource at Sechura, Peru, based on a Typical Meteorological Year derived from long-term reanalysis data. Empirical distributions, kernel density estimation, Weibull fitting, and Gaussian mixture models were systematically compared using classical goodness-of-fit metrics, distributional distance measures, and energy-based indicators at both annual and seasonal scales.

The results demonstrate that non-parametric kernel density estimation with least-squares cross-validation (KDE–LSCV) provides the most accurate representation of the wind speed distribution. At the annual scale, KDE–LSCV consistently achieved the highest coefficient of determination and the lowest Kolmogorov–Smirnov statistic, RMSE, and distributional distances (Hellinger, Kullback–Leibler, and Wasserstein). These findings confirm its superior ability to reproduce both the central tendency and the tails of the empirical distribution.

Seasonal analyses further reinforced these conclusions. KDE–LSCV outperformed all alternative models in Summer, Autumn, Winter, and Spring, exhibiting stable performance across contrasting wind regimes. In particular, the Winter season revealed pronounced limitations of unimodal parametric models, where the Weibull distribution failed to capture the observed complexity of the wind regime, resulting in very poor goodness-of-fit metrics. In contrast, Gaussian mixture models demonstrated strong seasonal robustness, especially during Winter, indicating their suitability for representing multimodal wind patterns.

Despite the substantial differences observed in statistical goodness-of-fit metrics, annual and seasonal energy production estimates remained remarkably consistent across models, with deviations generally below 0.3 %. Electrical efficiency and capacity factor values were virtually unchanged, indicating that energy-based indicators are less sensitive to moderate distributional discrepancies under the conditions examined. Nevertheless, accurate probabilistic modeling remains essential for applications involving risk analysis, extreme wind assessment, and turbine selection, where misrepresentation of distribution tails can have significant consequences.

Overall, the results show that reliance on a single Weibull distribution may lead to systematic mischaracterization of wind regimes in coastal sites with complex seasonal variability. KDE–LSCV is recommended as the primary modeling approach for wind resource characterization at Sechura, while Gaussian mixture models provide a valuable parametric alternative when

compact analytical representations are required. The combined use of distributional distance metrics and energy-based indicators is strongly recommended for robust wind energy assessments.

Future work should focus on validating these findings using in situ measurements, extending the analysis to hub-height extrapolation and uncertainty quantification, and evaluating the implications of probabilistic model choice on long-term economic performance and grid-integration studies.

***Abstract*—The agricultural supply chain plays a critical role in ensuring food security and sustainability; however, it continues to face challenges related to data fragmentation, limited transparency, and insufficient trust among participating stakeholders. Existing supply chain systems are primarily based on centralized identity and data management models, which introduce single points of failure, restrict auditability, and raise privacy concerns. More critically, the absence of decentralized and stakeholder-controlled identity mechanisms limits accountability and verifiable governance across agricultural ecosystems. In this work, we present Ziraai SSI, a blockchain-based self-sovereign identity (SSI) prototype designed to support identity-centric governance and trust establishment in agricultural supply chains. The proposed approach integrates blockchain-based trust anchoring with self-sovereign identity principles using decentralized identifiers (DIDs) and verifiable credentials (VCs). Through this integration, stakeholders retain direct control over their digital identities while enabling cryptographically verifiable and privacy-preserving interactions across organizational boundaries. The system architecture follows a multi-layered design that addresses identity management, credential lifecycle handling, authentication, access control, and governance. To move beyond conceptual analysis, the framework is realized as a functional research prototype using standardized SSI technologies and an agent-based architecture. The implemented system supports end-to-end credential workflows, including secure connection establishment, credential issuance, selective disclosure, and proof-based verification, without reliance on centralized identity providers or authentication authorities. Experimental validation conducted in a controlled environment confirms correct execution of identity and credential lifecycles, decentralized authentication, and privacy-preserving verification. The evaluation focuses on functional validation within a controlled prototype environment and does not include large-scale scalability benchmarking. These results demonstrate the feasibility of identity-centric governance mechanisms in agricultural supply chains using standardized SSI technologies.**

Keywords*—Blockchain; self-sovereign identity (ssi); agricultural supply chain; verifiable credentials; decentralized identity; privacy-preserving authentication

I. Introduction

The agricultural supply chain (ASC) plays a fundamental role in global food systems by linking producers, processors, distributors, and consumers through a sequence of interdependent activities that ensure food availability, quality, and safety. Despite its critical importance, the ASC continues to face persistent challenges related to traceability, data integrity, and trust among participating entities [1]. In practice, these challenges are exacerbated by fragmented information flows and limited mechanisms for independently verifying stakeholder actions across organizational boundaries. Traditional supply chain management systems, which are predominantly centralized and fragmented, often fail to provide end-to-end visibility, thereby limiting the ability to verify product authenticity and ensure compliance with quality and safety standards. Moreover, information asymmetry and data silos across stakeholders significantly hinder transparency and impede effective coordination throughout production, logistics, and distribution stages [2].

Issues related to identity verification and data authenticity are particularly pronounced in agricultural supply chains. Farmers, cooperatives, logistics providers, and certification bodies often rely on third-party intermediaries for authentication, certification, and market access. While such intermediaries simplify coordination, they also concentrate trust and control within centralized entities, increasing operational overhead and introducing privacy and accountability risks. Consequently, the absence of a unified, tamper-resistant, and stakeholder-centric identity mechanism represents a major barrier to the development of transparent, equitable, and verifiable agricultural value chains [3]. These traceability failures and certification disputes in agri-food systems further highlight that transparency without verifiable stakeholder identity remains insufficient for ensuring accountability and timely dispute resolution [4], [5].

Blockchain technology has been widely recognized as a promising approach to addressing several of these challenges. By maintaining a distributed, immutable ledger of transactions, blockchain enables auditability, data integrity, and tamper-resistance without requiring centralized control [6]. However, blockchain-based transparency alone does not guarantee trust if the identities of participating entities cannot be reliably verified or held accountable [7]. In parallel, Self-Sovereign Identity (SSI) has emerged as a paradigm in digital identity management that enables individuals and organizations to create, own, and manage their digital identities independently of centralized authorities. SSI systems rely on decentralized identifiers (DIDs) and verifiable credentials (VCs) to support cryptographically verifiable and selectively disclosable identity assertions [8]. The convergence of blockchain and SSI technologies, therefore, offers a complementary mechanism for managing both

*Corresponding author.

transactional data and stakeholder identities in a decentralized and verifiable manner.

Within agricultural supply chains, such an integration has the potential to empower stakeholders, particularly smallholder farmers, by granting them direct control over their digital identities and credentials, while simultaneously enabling verifiable, privacy-preserving data exchange across the supply chain [9]. Prior research has demonstrated the applicability of blockchain for enhancing traceability and transparency in agri-food logistics [10], [11]. Nevertheless, most existing solutions emphasize product-centric traceability and transactional logging, with limited attention to decentralized identity management, stakeholder authentication, and governance. Similarly, although SSI frameworks have been extensively explored in domains such as finance, healthcare, and education [12], their systematic application to agricultural supply chains remains comparatively underexplored. Beyond theoretical promise, the effective adoption of blockchain-enabled SSI solutions in agriculture requires practical validation through implemented systems that demonstrate real operational workflows [5],[13]. Without such validation, proposed frameworks risk remaining abstract and disconnected from deployment-level considerations, including identity lifecycle management, credential exchange, user consent, and interoperability among heterogeneous stakeholders.

Motivated by this research gap, this study not only proposes a blockchain-based self-sovereign identity framework but also realizes the proposed design through a functional research prototype, referred to as Ziraai SSI. The implemented system operationalizes decentralized identifiers, verifiable credentials, and privacy-preserving authentication mechanisms using agent-based SSI technologies. As a result, farmers, issuers, and verifiers can interact through secure, standards-compliant credential workflows without relying on centralized identity providers. Accordingly, this work addresses the limitations of existing approaches by developing a blockchain-based self-sovereign identity framework tailored to agricultural supply chains. The framework leverages blockchain-based trust anchoring to ensure data integrity and auditability, while SSI principles aim to decentralize identity control and authentication. The main contributions of this study are summarized as follows:

- The design of a multi-layered blockchain–SSI framework that explicitly centers on stakeholder identity, authentication, and governance within agricultural supply chains.
- The formulation of a credential lifecycle mechanism encompassing issuance, selective disclosure, verification, and governance processes aligned with agricultural traceability requirements.
- The practical implementation and validation of the proposed framework, through the Ziraai SSI research prototype, demonstrate end-to-end decentralized identity and credential management for agricultural stakeholders.
- A prototype-level evaluation emphasizing functional feasibility and security-property realization within a controlled environment.

The remainder of this study is organized as follows. Section II reviews related work on blockchain- and SSI-based approaches in supply chain contexts and identifies key research gaps. Section III presents the proposed Blockchain-Based SSI framework and its architectural components. Section IV describes the system design and implementation details of the Ziraai SSI prototype. Section V discusses the experimental results and validation outcomes. Finally, Section VI concludes the study and outlines directions for future research.

II. Related Work and Motivation

The agricultural supply chain (ASC) has historically relied on centralized information systems for data management, certification, and identity verification. Siloed databases, manual record-keeping processes, and limited interoperability across organizational boundaries are typically characteristic of such systems. As a consequence, trust is often established procedurally rather than cryptographically, making verification dependent on institutional authority rather than on independently verifiable evidence. These limitations expose agricultural ecosystems to data inconsistencies, unauthorized modifications, and operational inefficiencies, ultimately undermining trust among supply chain participants [1]. In particular, the absence of a unified, verifiable digital identity framework for stakeholders—such as farmers, processors, distributors, and regulators—amplifies risks of fraud, accountability gaps, and asymmetric information sharing within agricultural ecosystems.

A. Traditional Traceability and Identity Systems

Conventional agricultural traceability mechanisms have primarily relied on study-based documentation or centralized databases that record transactions at isolated points in the supply chain [14]. While these approaches provide some oversight, they lack real-time synchronization and are vulnerable to data loss, manipulation, and delayed verification. In centralized architectures, trust is concentrated in a single authority, creating single points of failure and increasing exposure to security breaches and unauthorized access [15]. From a governance perspective, such architectures also constrain independent auditing, as verification processes remain tightly coupled with the system operator.

Efforts to digitalize agricultural operations—through enterprise resource planning (ERP) systems, cloud-based farm management platforms, and centralized certification portals—have partially addressed traceability concerns. However, these systems often suffer from limited interoperability and opaque auditing mechanisms, leading to fragmented data ownership and asymmetric access to information [16]. Moreover, identity verification within these platforms typically relies on username–password credentials or centralized authentication services, which provide limited assurance regarding the real-world legitimacy of participating entities and introduce risks related to credential compromise, privacy leakage, and misuse of personal data [17].

B. Blockchain for Agricultural Traceability

Blockchain technology has emerged as a promising approach for enhancing transparency and integrity in supply chain systems by enabling distributed, immutable record-

keeping among mutually untrusted entities. Numerous studies have explored blockchain-based approaches for improving agricultural traceability, food safety, and quality assurance. For example, Kamble et al. [6] proposed a blockchain-enabled model to enhance provenance tracking and operational efficiency in agricultural supply chains, while Feng et al. [3] demonstrated the potential of smart contracts for automating quality assurance processes. Zhao et al. [9] provided a comprehensive synthesis of blockchain applications in agri-food value chains, highlighting improvements in accountability and auditability.

Despite these advances, blockchain-based agricultural systems frequently treat identity as an implicit or external assumption rather than as a first-class design concern. In many implementations, identity verification is either delegated to centralized authorities or represented through application-specific identifiers that lack cryptographic portability across systems. It weakens the overall trust model, as the integrity of on-chain data ultimately depends on the authenticity and accountability of off-chain actors who generate it [11].

C. Evolution of Self-Sovereign Identity (SSI)

Self-Sovereign Identity (SSI) represents a paradigm shift in digital identity management by emphasizing user autonomy, decentralization, and privacy preservation [18]. SSI frameworks are built on decentralized identifiers (DIDs) and verifiable credentials (VCs), enabling individuals and organizations to control their identity attributes and selectively disclose information without relying on centralized identity providers [19]. A defining characteristic of SSI systems is privacy by design, in which sensitive identity data remains under the control of the credential holder and is shared only via cryptographically verifiable proofs [20].

SSI has gained significant traction in domains where trust, privacy, and regulatory compliance are paramount, including finance, healthcare, and education [21]. In contrast, its application within agricultural supply chains remains comparatively limited [13]. This gap is particularly notable given the multi-actor, cross-organizational, and trust-fragmented nature of agricultural ecosystems, where stakeholders often lack shared identity infrastructure or centralized governance mechanisms [22].

D. Combining Blockchain and SSI for Secure Supply Chains

The integration of blockchain and SSI technologies offers complementary benefits for building decentralized trust infrastructures. Blockchain provides immutability, transparency, and distributed consensus, while SSI enables user-centric identity ownership and selective credential disclosure [23]. Together, these technologies support identity-aware trust architectures in which entities can interact securely without dependence on centralized intermediaries.

Several studies have examined partial integrations of blockchain and SSI across different application domains. Shehu et al. [24] discussed the role of SSI in enabling interoperable and verifiable identity ecosystems when combined with distributed ledgers. Khoualdi et al. [25] investigated the challenges associated with integrating SSI, IoT, and blockchain for traceability applications, identifying scalability and standardization as key obstacles. Ahmed et al. [26] further emphasized the potential of blockchain-based identity management to enhance transparency and governance in future supply chains. However, most existing works remain limited to architectural discussions or small-scale experimental demonstrations. In particular, they provide limited insight into complete system realization, end-to-end credential workflows, and implementation-level validation within agricultural environments [27].

E. Research Gaps and Motivation

Based on the reviewed literature, several research gaps can be identified:

- Limited integration of decentralized identity mechanisms within agricultural blockchain systems, with most solutions focusing primarily on transactional traceability.
- Insufficient empirical validation of SSI-based approaches in agricultural contexts, despite their demonstrated applicability in other regulated domains.
- Lack of identity-centric governance models capable of supporting heterogeneous stakeholders without centralized control.
- Scarcity of implementation-level studies demonstrating complete issuer–holder–verifier workflows using standardized SSI protocols.

Notably, there is a lack of research demonstrating a complete and operational SSI-based agricultural identity system that explicitly supports issuer, holder, and verifier roles using standardized SSI protocols and evaluates these interactions through implemented, end-to-end workflows. As a result, much of the existing literature remains either conceptual or limited to partial demonstrations that do not fully address identity lifecycle management and governance requirements. This gap motivates the design and implementation of Ziraai SSI as an identity-centric, standards-compliant prototype tailored specifically to agricultural supply chain governance. To further clarify the positioning of the proposed approach, Table I provides a comparative analysis of Ziraai SSI against representative categories of existing agricultural traceability systems, blockchain-based solutions, and SSI frameworks. The comparison highlights that most existing approaches either focus on transactional traceability without decentralized identity support or explore SSI concepts without domain-specific, implementation-level validation. In contrast, Ziraai SSI integrates blockchain-based trust anchoring with self-sovereign identity mechanisms, delivering a functional research prototype that supports complete, end-to-end credential workflows in an agricultural context.

TABLE. I. COMPARISON OF ZIRAAI SSI WITH EXISTING BLOCKCHAIN- AND SSI-BASED APPROACHES

Approach Category	Blockchain	SSI	DID	VC	Selective Disclosure	Prototype
Conventional agricultural traceability systems	x	x	x	x	x	✓
Blockchain-based agricultural traceability	✓	x	x	x	x	Partial
SSI frameworks (non-agricultural domains)	x	✓	✓	✓	✓	✓
Blockchain –SSI conceptual models for supply chains	✓	✓	✓	✓	✓	x
Ziraai SSI (this work)	✓	✓	✓	✓	✓	✓

While decentralized systems improve transparency and privacy, they require more coordination between participating organizations and can be more complex to deploy than centralized identity systems. Scalability and secure wallet key management are also important practical considerations in real-world implementations [28].

III. PROPOSED BLOCKCHAIN-BASED SSI FRAMEWORK FOR AGRICULTURE

This section presents the conceptual and architectural design of the proposed blockchain-based self-sovereign identity (SSI) framework for agricultural supply chains. The framework is intended to address persistent challenges related to stakeholder authentication, data integrity, transparency, and trust in decentralized agricultural ecosystems. Rather than treating identity as a supporting component of traceability, the proposed framework positions identity as a foundational element of supply chain governance. By combining blockchain-based trust anchoring with SSI principles, the framework establishes a generalizable model for identity-centric supply chain interactions that is independent of specific implementation technologies. While the framework is presented at an abstract level to ensure reusability across different agricultural contexts, its design is explicitly informed by practical deployment considerations, and it directly guides the concrete realization described in Section IV.

A. Design Objectives

The design of the proposed blockchain-based self-sovereign identity (SSI) framework is guided by a set of objectives derived from the structural characteristics, trust relationships, and governance requirements of agricultural supply chains. These objectives aim to address limitations observed in existing centralized and semi-decentralized identity and traceability systems, while ensuring compatibility with standardized SSI ecosystems. The following design objectives therefore guide the framework:

- Decentralized Identity Control: Empower agricultural stakeholders to manage their own digital identities using decentralized identifiers (DIDs) and verifiable credentials (VCs), without reliance on centralized identity or certification authorities. This objective reflects the need for stakeholder autonomy and for identity to be long-term portable across organizational and institutional boundaries [29].
- Tamper-Resistant Identity and Data Management: Ensure that identity-related metadata, credential schemas, and verification artifacts are anchored on a decentralized ledger, providing integrity, authenticity, and accountability for identity-linked interactions without dependence on mutable centralized databases or trusted third parties.
- Privacy and Selective Disclosure: Enable entities to disclose only the minimum necessary identity attributes during verification processes through selective disclosure mechanisms and cryptographic proof-based credential presentation. This objective is particularly critical in agricultural contexts, where stakeholders may be reluctant to share sensitive personal or organizational information [30].
- Transparency and Auditability: Provide stakeholders and oversight entities with verifiable and independently auditable identity-related records, while ensuring that sensitive credentials and personal information remain under the exclusive control of their respective holders [25].
- Scalability and Interoperability: Support integration with existing agricultural platforms and interoperability with consortium-based or multi-network identity infrastructures. This ensures that the framework can adapt to heterogeneous deployment environments and evolving governance models [20].

Together, these objectives define the conceptual scope of the proposed framework and guide the architectural and implementation choices discussed in subsequent sections.

B. Framework Overview

The proposed framework adopts a multi-layered architectural design that separates identity management, authentication, access control, data interaction, and governance concerns. This separation of concerns enables modularity and extensibility, allowing individual layers to evolve independently while preserving cryptographic trust guarantees across the system. Within this framework, blockchain technology is employed primarily as a decentralized trust anchor rather than as a general-purpose transaction execution platform. Specifically, the blockchain component anchors decentralized identifiers (DIDs), credential schemas, credential definitions, and governance-related metadata, enabling verifiable identity resolution and long-term auditability. This design deliberately avoids unnecessary on-chain transaction overhead while retaining tamper resistance for identity-critical information. The

framework is structured into five logical layers that collectively support secure, privacy-preserving interactions in the agricultural supply chain. Each layer addresses a distinct functional responsibility, ranging from stakeholder identity representation to governance and trust management.

C. Layer 1 – Stakeholder Identity and Credential Layer

This foundational layer defines how digital identities are created, represented, and managed within the agricultural supply chain.

- Each stakeholder (e.g., farmer, cooperative, distributor, certification authority, regulator) is associated with a decentralized identifier (DID) compliant with W3C standards.
- Authorized entities issue verifiable credentials (VCs) that attest to stakeholder attributes, certifications, or roles.
- The holder controls the credentials and can present them selectively for verification.
- Credential revocation and status information are conceptually supported by publicly verifiable registries, enabling detection of expired or invalid credentials.

By decoupling identity ownership from centralized authorities, this layer establishes accountability while preserving stakeholder autonomy.

D. Layer 2 – Data Recording and Verification Layer

This layer governs how supply-chain events and identity-linked actions are recorded and verified.

- All interactions are cryptographically bound to verified identities.
- Data submissions are accepted only after successful credential validation.
- Immutable records enable retrospective auditing and compliance verification.

Rather than prioritizing transaction throughput, this layer emphasizes the integrity and authenticity of identity-bound data, which is particularly critical in agricultural governance and certification scenarios.

E. Layer 3 – Trust and Authentication Layer

The trust and authentication layer ensures that all interactions occur between verified participants.

- Mutual authentication is performed using cryptographic proofs derived from DIDs and VCs.
- Selective disclosure mechanisms enable attribute-level verification without revealing full credentials.
- Authentication policies prevent unauthorized access to identity-protected resources.

This layer enables privacy-preserving trust establishment across heterogeneous agricultural stakeholders without requiring shared identity infrastructure.

F. Layer 4 – Access Control and Policy Layer

This layer defines how access permissions and disclosure policies are enforced.

- Access control decisions are based on credential attributes rather than static roles.
- Stakeholders retain control over what data is shared, with whom, and under what conditions.
- Policy enforcement is auditable and aligned with regulatory requirements.

By decoupling identity from application-specific logic, this layer supports flexible and context-aware governance models.

G. Layer 5 – Governance and Consensus Layer

The governance layer defines the rules under which identities and credentials are recognized as trustworthy.

- Credential schemas and issuer policies are governed collectively.
- Regulatory authorities can participate as oversight entities without assuming centralized control.
- Trust anchors ensure long-term verifiability of identity claims.

This layer enables institutional trust without centralization, which is a key requirement in multi-stakeholder agricultural ecosystems. In the current prototype, governance follows a consortium-based trust model in which authorized issuers are pre-approved before registering credential schemas on the ledger. Schema registration requires prior agreement among consortium participants before activation. Disputes related to credential validity are addressed through revocation registry updates and publicly verifiable status checks. Formal on-chain voting or automated consensus mechanisms were not implemented in this prototype; however, the architecture allows such mechanisms to be incorporated in future extensions.

H. Framework Workflow

At a conceptual level, the framework supports the following workflow:

- Stakeholder identity establishment through decentralized identifiers (DIDs)
- Credential issuance by authorized entities
- Identity-bound data interaction across supply chain stages.
- Selective disclosure and cryptographic verification.
- Auditability and compliance validation.

This abstract workflow directly informs the concrete realization described in Section IV.

I. Security Considerations

The proposed framework addresses core security requirements, including integrity, authentication, confidentiality, non-repudiation, and unlinkability, through cryptographic identity mechanisms rather than centralized

enforcement. These properties are derived from decentralized identifiers, verifiable credentials, and proof-based authentication, ensuring distributed trust, resilience to compromise, and reduced reliance on centralized authorities.

IV. System Design and Implementation Details

This section describes the practical realization of the proposed blockchain-based self-sovereign identity framework through the Ziraai SSI research prototype. In contrast to the conceptual focus of Section III, this section details how the framework is instantiated using standardized self-sovereign identity technologies, thereby validating its feasibility under realistic interaction and governance assumptions. The implementation is intentionally designed as a research prototype and prioritizes standards compliance, architectural traceability, and workflow correctness over production-scale optimization.

A. Implementation Environment

The Ziraai SSI platform is implemented using an agent-based SSI architecture aligned with current industry and standards-body specifications. The selected implementation environment reflects explicit design decisions motivated by interoperability, modularity, and alignment with widely adopted SSI ecosystems.

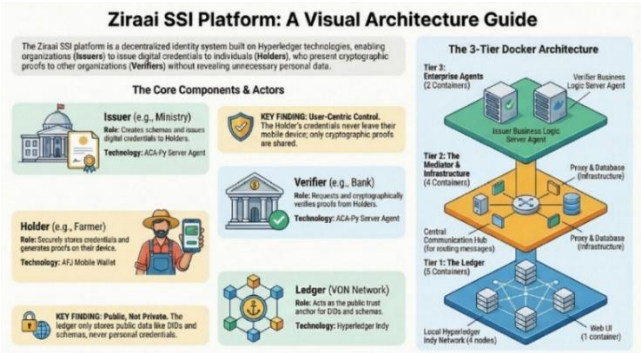

Fig. 1. Ziraai SSI Platform visual architecture.

- Identity ledger: Hyperledger Indy (local development network), used exclusively as a decentralized trust anchor for DIDs, credential schemas, and definitions
- SSI framework: Hyperledger Aries, implemented through ACA-Py agents and Aries-compatible wallets
- Communication protocol: DIDComm, enabling secure, peer-to-peer agent communication
- User interfaces: Web-based dashboards for issuer and verifier roles, and a mobile wallet application for farmers and credential holders
- Deployment: Containerized microservices orchestrated using Docker to support modular experimentation and reproducibility

The choice of Hyperledger Indy and Aries enables strict separation between identity anchoring, credential exchange, and application logic, which is essential for evaluating identity-centric architectures. Fig. 1 provides a visual architecture of the Ziraai SSI platform.

B. System Architecture and Modules

The system architecture mirrors the layered framework described in Section III while introducing concrete implementation components.

- SSI agents implement identity and credential logic for each stakeholder.
- Application controllers mediate interactions between user interfaces and agents.
- Wallet components provide secure credential storage and user-controlled disclosure.
- Verification services enable proof validation and audit support.

Each implementation module maps directly to a corresponding conceptual layer of the proposed framework, ensuring architectural consistency and traceability between design intent and system realization. Fig. 2 shows the architecture of the Ziraai SSI platform and the modules.

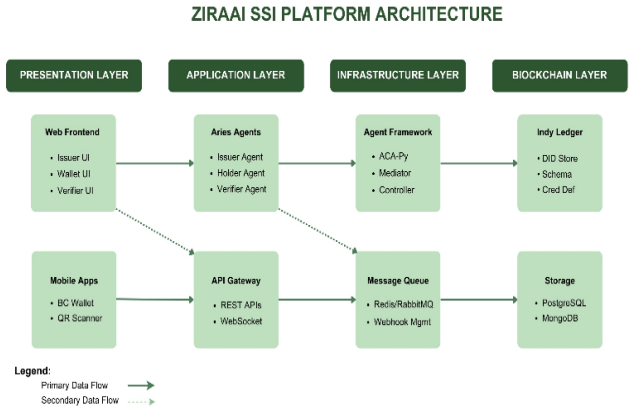

Fig. 2. Architecture and layers of the Ziraai SSI platform.

C. SSI Credential Lifecycle and Workflow

Ziraai SSI implements a complete SSI credential lifecycle consistent with standardized SSI protocols.

- Secure connection establishment using agent-mediated invitations
- Credential issuance with explicit holder consent
- Credential storage within a holder-controlled wallet
- Privacy-preserving credential verification through selective disclosure

The issuance and verification processes follow established SSI interaction patterns, ensuring compatibility with external SSI agents and minimizing reliance on application-specific extensions. The sequence of interactions shown in Fig. 3 demonstrates how issuer, holder, and verifier roles collaborate through standardized SSI protocols to support an end-to-end, trust-preserving credential lifecycle.

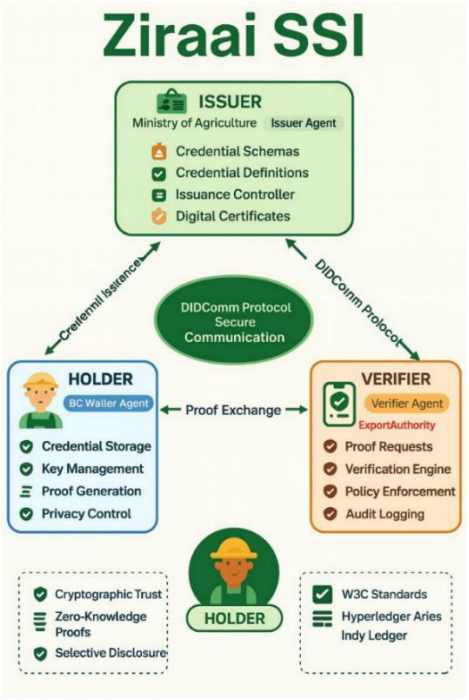

Fig. 3. Modules of the Ziraai SSI platform.

1) Credential issuance workflow: The process of issuing a verifiable credential (VC) involves the farmer (Holder), the issuer, and their respective agents as specified in Algorithm 1.

Algorithm 1: Credential Issuance

1. Issuer Admin (Web UI): Clicks "Create Invitation".
2. Issuer Controller: Calls ACA-Py agent to create a connection invitation.
3. Issuer Agent: Generates invitation and returns it.
4. Issuer Controller: Displays invitation as a QR code on the UI.
