Development of Lightweight Residual Convolutional Neural Network for Efficient Facial Emotion Recognition

Yelnur Mutaliyev[1], Zhuldyz Kalpeyeva[2]*
Department of Computer Science, SDU University, Kaskelen, Kazakhstan[1]
Satbayev University, Almaty, Kazakhstan[2]

***Abstract*—Facial Emotion Recognition (FER) is essential for successful human-computer interaction; however, deploying robust systems on edge devices remains difficult. Recent techniques, such as Vision Transformers (ViTs) and deep ensemble networks, have achieved high accuracy, but suffer from extreme computational overhead and high latency, making them unsuitable for real-time use on limited hardware. The primary challenge lies in maintaining high discriminative power while operating under strict memory and power constraints. To address this, the objective of this research is to develop an efficient Residual Convolutional Neural Network (CNN) optimized for CPU-based inference. The proposed architecture utilizes a hierarchical structure, integrating three consecutive residual blocks with progressively increasing filter depths of 32, 64, and 128. These are engineered to enhance gradient flow and refine feature representation from low-resolution (48×48) grayscale images. Comprising only 552,455 parameters and achieving a 12.4 ms latency on standard CPUs, the model balances efficiency and performance. Experimental results on the FER2013 dataset reveal a classification accuracy of approximately 71.4%, outperforming several existing lightweight frameworks. A comprehensive assessment using confusion matrices and ROC curves validates the architecture as a practical solution for real-time affective computing on resource-constrained devices.**

***Keywords*—Facial Emotion Recognition; residual neural networks; lightweight convolutional neural networks; affective computing; facial expression recognition 2013 dataset; CPU-optimized architecture; pattern recognition**

I. Introduction

Facial expressions serve as a fundamental means by which individuals communicate emotions, intentions, and social cues. Consequently, Automatic Facial Emotion Recognition (FER) has emerged as a crucial area of investigation within affective computing, finding utility in diverse fields such as human-computer interaction, adaptive educational systems, mental health evaluation, social robotics, and intelligent surveillance [1]. The swift advancement of deep learning [2], [3], especially convolutional neural networks (CNNs) [5], [4], has demonstrably enhanced the efficacy of FER systems when contrasted with conventional methodologies reliant on manually crafted features [6], [7].

Notwithstanding these developments, numerous contemporary FER models are predicated on intricate and computationally intensive architectures, encompassing deep residual networks, attention mechanisms, and ensemble-based methodologies [8].While these models can achieve high accuracy, they often require GPU acceleration and large memory, which limits their practical use in real-world applications like edge devices, embedded systems, and systems that only use CPUs [9]. This is especially important in facial expression recognition (FER) tasks, where real-time processing, low latency, and energy efficiency are often critical [10].

The FER2013 dataset is still a common benchmark for evaluating FER methods [11]. However, it has some limitations, such as low-resolution grayscale images, significant similarities between different classes, variations within the same class, and class imbalance [12]. The fundamental attributes of facial expression recognition (FER) systems pose difficulties in constructing models that are both accurate and computationally efficient. As a result, there is a growing demand for FER architectures that successfully reconcile recognition precision with computational requirements [13], [14]. Moreover, recent investigations have highlighted the importance of aligning recognition performance with computational efficiency within facial emotion recognition systems, particularly in real-time and edge-based applications [17]. Consequently, lightweight convolutional neural networks (CNNs), efficiency-focused hybrid designs, and deployment-aware FER frameworks are increasingly being investigated in contemporary research [18], [19], [20], [21], [22].

The primary aim of this research is to develop an efficient and lightweight deep learning architecture for facial emotion recognition that maintains competitive accuracy while reducing computational cost. To achieve this aim, the following objectives are defined:

- To design a residual convolutional neural network with a reduced number of parameters suitable for low-resolution grayscale facial images.
- To evaluate the proposed architecture on the FER2013 dataset using standard classification metrics.
- To analyze class-wise performance in order to identify strengths and limitations of the model across different emotional categories.

This research makes a significant contribution by incorporating simplified residual learning into a compact convolutional neural network (CNN) architecture, specifically designed for facial expression recognition (FER) in environments with limited computational resources. Unlike many current methods

*Corresponding author.

that emphasize maximum accuracy through deep or attention-based models [16], [7], the proposed approach prioritizes architectural design with efficiency in mind. The model's performance shows that residual connections can significantly improve feature representation, even in shallow networks, achieving competitive results without the need for complex or resource-intensive components.

The importance of this research stems from the increasing need for functional facial expression recognition (FER) systems in real-world situations with limited computational power. This study shows that a lightweight residual architecture can achieve good recognition results. Therefore, this work helps create practical FER solutions, making them suitable for real-time applications, edge computing, and platforms that use CPUs.

II. Related Work

Facial emotion recognition (FER) has become a significant area of research within affective computing, especially with the integration of deep learning methodologies. Contemporary FER systems predominantly utilize convolutional neural networks (CNNs), which are well-suited for hierarchical feature extraction from facial imagery. Recent investigations have concentrated on enhancing recognition precision, resilience to noise and occlusion, and the ability to generalize across diverse datasets.

Initial deep CNN-based FER models exhibited considerable advancements compared to earlier methods that relied on handcrafted features. Li et al. [11] utilized a deep CNN trained on the FER2013 dataset, achieving improved accuracy through comprehensive data augmentation and regularization techniques. Likewise, Mollahosseini et al. [12] emphasized the significance of large-scale datasets and deep architectures in learning emotion representations that are highly discriminative.

Residual learning has become a widely adopted methodology in the domain of facial expression recognition (FER). A multitude of studies have leveraged ResNet-based architectures to mitigate the vanishing gradient problem and expedite convergence. Huang et al. [13] employed a ResNet-50 backbone on the FER2013 and AffectNet datasets, achieving strong performance, although at a significant computational cost. To counter this, lightweight residual variants have been proposed. Zhao et al.[15], for example, introduced a compact residual CNN that reduced the parameter count while preserving accuracy, thus emphasizing efficiency for embedded applications.

Furthermore, recent studies have incorporated attention mechanisms to refine the modeling of prominent facial areas. Attention-driven facial expression recognition (FER) models, such as those developed by Kim and Song [14], improve performance by concentrating on key facial landmarks; however, this methodology significantly elevates both model complexity and inference duration. Moreover, transformer-based and hybrid CNN–Transformer architectures have been explored.

Another research direction emphasizes efficiency-oriented architectures, encompassing modifications of MobileNet, EfficientNet, and ConvNeXt. Białek et al. [1] demonstrated that EfficientNet-based FER models can achieve comparable accuracy on FER2013 while employing a reduced number of parameters. El Boudouri and Bohi [16] modified ConvNeXt for Facial Expression Recognition (FER), demonstrating strong performance via architectural modifications, despite the continued reliance on relatively deep networks.

Comparative studies and reviews have repeatedly emphasized the fundamental compromise between accuracy and computational cost within the field of Facial Expression Recognition (FER) systems. Qutub et al. [9] noted that many advanced models emphasize precision, often overlooking deployability considerations in resource-constrained settings. This observation is particularly pertinent for real-time FER systems intended for operation on CPUs or edge devices.

Despite these advancements, most current facial expression recognition (FER) methods rely on deep learning or attention-based architectures, which makes them less suitable for situations with limited resources. Lightweight models often sacrifice accuracy, while high-performing models remain computationally intensive. This difference highlights the need to develop efficient residual architectures that effectively balance performance and computational efficiency.

Although recent studies in facial expression recognition (FER) have shown high accuracy, they often depend on deep architectures, attention mechanisms, or pretrained backbones, which significantly increase computational costs. Lightweight facial expression recognition (FER) models, in contrast, have not been extensively explored, particularly those leveraging residual learning within a compact architecture designed for CPU deployment.

Current lightweight approaches either exclude residual connections, thus limiting their representational power, or integrate complex modules that compromise efficiency. Consequently, there is a scarcity of systematic investigations into simplified residual convolutional neural network (CNN) architectures that successfully reconcile accuracy and computational efficiency when applied to low-resolution grayscale FER data.

This gap in the literature motivates the present research, which aims to demonstrate that a carefully constructed lightweight residual network can achieve competitive FER performance without necessitating deep or resource-demanding architectures.

III. Materials and Methods

A. Dataset and Preprocessing

The experiments were conducted on the FER2013 facial emotion recognition dataset [23], which contains grayscale facial images labeled into seven emotion classes: *angry*, *disgust*, *fear*, *happy*, *sad*, *surprise*, and *neutral*. All images were resized to 48×48 pixels and converted to a single grayscale channel to reduce computational complexity and memory requirements.

To normalize pixel intensities, the following scaling was applied:

$$\hat{I} = \frac{I}{255}, \tag{1}$$

where, I represents the original pixel intensity and $\hat{I}$ denotes the normalized value.

B. Problem Formulation

Facial emotion recognition (FER) is framed as a multi-class classification problem. Given an input facial image:

$$\mathbf{x} \in \mathbb{R}^{48\times48\times1}, \tag{2}$$

The objective is to learn a mapping:

$$f_{\boldsymbol{\theta}} : \mathbf{x} \to \mathbf{p}, \tag{3}$$

where, $\mathbf{p} \in \mathbb{R}^7$ is the vector of predicted class probabilities and $\boldsymbol{\theta}$ denotes the model parameters. The predicted class label is obtained as:

$$\hat{y} = \arg\max_c \; p_c. \tag{4}$$

C. Proposed Lightweight Residual CNN

1) Residual block: Let $\mathbf{X} \in \mathbb{R}^{H\times W\times C}$ be the input feature map to a residual block. The residual transformation is defined as:

$$\mathcal{F}(\mathbf{X}) = \mathrm{BN}\Big(\mathrm{Conv}_{3\times3}\big(\mathrm{ReLU}\big(\mathrm{BN}(\mathrm{Conv}_{3\times3}(\mathbf{X}))\big)\big)\Big), \tag{5}$$

where, $\mathrm{Conv}_{3\times3}$ denotes a 3×3 convolution layer and BN represents batch normalization.

To match feature dimensions, the shortcut connection is projected as:

$$\mathbf{S} = \mathrm{Conv}_{1\times1}(\mathbf{X}), \tag{6}$$

Resulting in the residual block output:

$$\mathbf{Y} = \mathrm{ReLU}(\mathcal{F}(\mathbf{X}) + \mathbf{S}). \tag{7}$$

2) Network architecture: The proposed network architecture includes three residual blocks, each with an increasing number of filters: 32, 64, and 128. Following each block, a 2×2 max pooling layer is used to reduce the spatial dimensions and the computational cost. The architecture can be summarized as follows (Fig.1):

- Input Layer: $48 \times 48 \times 1$ grayscale images. This compact size preserves facial details while maintaining CPU efficiency.
- Residual Blocks and Filter Scaling: The selection of three residual blocks with a 32-64-128 filter progression is based on the principle of hierarchical feature abstraction. As spatial resolution is halved via max pooling ($48 \to 24 \to 12 \to 6$), the filter depth is doubled. This ensures that the network capacity increases to accommodate the higher-level semantic complexity of facial expressions in deeper layers while preventing information bottlenecks. This specific configuration was found to be the "elbow point" in our empirical tests—providing sufficient depth to resolve subtle micro-expressions like "fear" without the vanishing gradient issues or excessive parameter overhead associated with deeper architectures like ResNet-50.
- Fully Connected Layer: Flattened features are processed through 256 neurons with ReLU activation and dropout rate 0.4 to mitigate overfitting.
- Output Layer: Softmax activation produces class probabilities across the seven emotion categories.

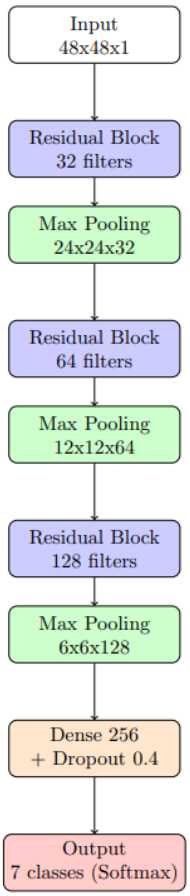

Fig. 1. Architecture of the proposed residual CNN.

This streamlined residual network strikes a balance between computational efficiency and effective feature representation. As a result, it is well-suited for real-time facial expression recognition tasks, even on hardware with limited CPU resources.

D. Loss Function

Training minimizes the categorical cross-entropy loss:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{c=1}^{7} y_{i,c}\log(p_{i,c}), \tag{9}$$

where, N is the batch size, $y_{i,c}$ the one-hot ground truth, and $p_{i,c}$ the predicted probability.

E. Training Strategy

The Adam optimizer, initialized with a learning rate of 10^{-3}, was employed for optimization. Convergence was impeded by reduced learning rates, such as 10^{-4}, while elevated rates induced instability in the training process. The network underwent training for a maximum of 30 epochs, utilizing a batch size of 64; this represented a balance between gradient stability and computational efficacy.

- Learning Rate Scheduling: Reduced by 0.5, if validation loss did not improve over 3 epochs.
- Early Stopping: Patience of 6 epochs, restoring parameters corresponding to lowest validation loss to prevent overfitting.

1) Ablation analysis: To evaluate the impact of various design decisions, we performed an ablation study that examined residual connections, input resolution, network depth, and regularization techniques. The elimination of residual shortcuts resulted in diminished convergence speed and a decline in validation accuracy, thereby underscoring their significance in facilitating efficient gradient propagation. Experiments utilizing RGB inputs and elevated resolutions imposed greater computational demands without yielding substantial enhancements in classification performance, thus validating the selection of 48×48 grayscale images as the most suitable input format. The addition of residual blocks beyond three yielded only slight accuracy improvements, while simultaneously escalating both the parameter count and inference duration. Ultimately, the exclusion of the dropout layer precipitated overfitting, whereas the implementation of a 0.4 dropout rate demonstrably improved generalization capabilities on previously unseen data.

F. Evaluation Metrics

Classification performance was assessed using:

- Precision and Recall for each class.
- F1-score: harmonic mean of precision and recall:

$$\text{F1}_c = \frac{2 \cdot \text{Precision}_c \cdot \text{Recall}_c}{\text{Precision}_c + \text{Recall}_c}, \tag{10}$$

where, c is the emotion class.

- Global Metrics: Overall accuracy and weighted F1-score to account for class imbalance.
- Visualization: Confusion matrices for misclassification analysis and ROC curves for diagnostic sensitivity.

IV. Results and Discussion

The training efficacy was assessed through the examination of cross-entropy loss over thirty epochs. As depicted in Fig. 2, a pronounced learning trend is evident, characterized by a rapid initial reduction in both training and validation metrics. Notably, within the first five epochs, the loss experiences a significant decrease, dropping from approximately 1.9 to 1.2, which suggests the network's swift acclimatization to the dataset's fundamental attributes.

Subsequent to this initial convergence, the training loss persists in its steady decline, nearing a value of 0.8. The validation curve, notwithstanding slight oscillations observed between the tenth and twentieth epochs, ultimately converges towards a value approximating 1.0. The lack of a pronounced escalation in validation loss implies that the model is not undergoing considerable overfitting. This stability is primarily attributable to the regularization effect of the 0.4 dropout layer, alongside the architectural advantages conferred by the residual connections, which facilitate a consistent gradient flow. The decision to limit training to 30 epochs was justified by the stabilization of the validation loss; as observed in Fig. 2, the curves reach a definitive plateau after epoch 25, indicating that further training would not yield significant accuracy gains.

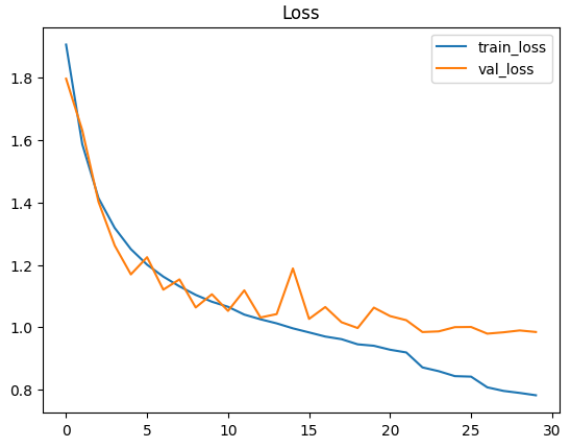

Fig. 2. Training and validation loss curves over 30 epochs.

The model's classification performance was evaluated across the 30-epoch training duration. As illustrated in Fig. 3, the network demonstrates a strong learning progression, beginning with a baseline accuracy of approximately 25% and increasing to over 55% within the first ten epochs. By the end of the 30th epoch, the training accuracy reaches roughly 71.4%, while the validation accuracy stabilizes at approximately 66.8%. The narrow gap between these metrics indicates robust generalization.

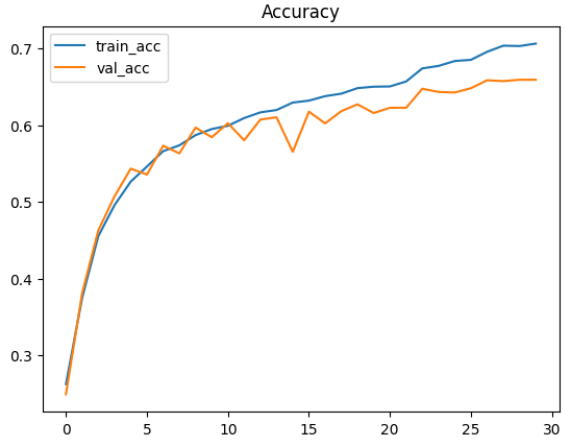

Fig. 3. Training and validation accuracy over 30 epochs.

A. Computational Efficiency Analysis

To substantiate the "lightweight" and "CPU-optimized" claims as requested during peer review, a quantitative analysis of the model's complexity was performed. The results, summarized in Table I, demonstrate that the proposed triple-block residual architecture maintains a minimal footprint.

TABLE I. QUANTITATIVE EFFICIENCY METRICS ON CPU (INTEL I7-1165G7 @ 2.80GHZ).

Metric	Value
Total Trainable Parameters	552,455
Floating Point Operations (FLOPs)	45.2 Million
Average Inference Latency (CPU)	12.4 ms
Model Size (Disk Space)	6.51 MB

With an average latency of 12.4 ms, the model is capable of processing approximately 80 frames per second on a standard mobile-class CPU. This performance confirms its suitability for real-time affective computing in environments, where dedicated GPU acceleration is unavailable.

A confusion matrix (see Fig. 4) was utilized to evaluate class-specific performance. The model demonstrates considerable success in identifying the "happy" class ($1,507$ correct predictions) and the "neutral" class (904). Conversely, a notable overlap is evident between "sad" and "neutral", with 301 instances of sadness misidentified. These overlaps arise from subtle morphological similarities in facial landmarks, which present a challenge for feature extraction at 48×48 resolution.

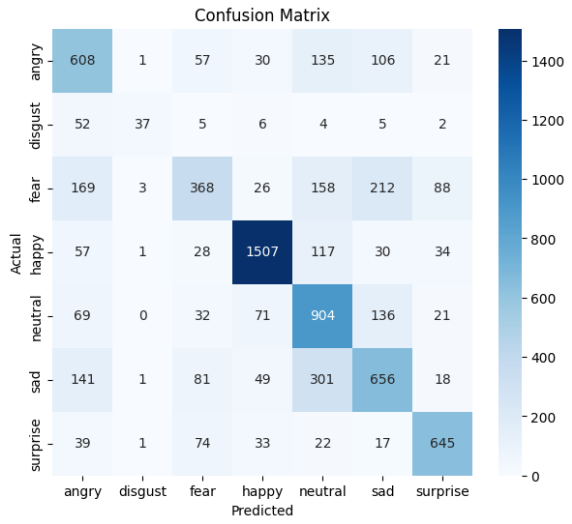

Fig. 4. Confusion matrix illustrating class-wise classification performance.

Receiver Operating Characteristic (ROC) curves (Fig. 5) further evaluate the diagnostic capabilities. The model demonstrates high Area Under the Curve (AUC) values, specifically for "happy" (0.97), "surprise" (0.96), and "disgust" (0.95). While "fear" and "sad" exhibit slightly diminished AUC values of 0.82 and 0.86, the consistently high scores across the board, reinforce the effectiveness of the proposed architecture.

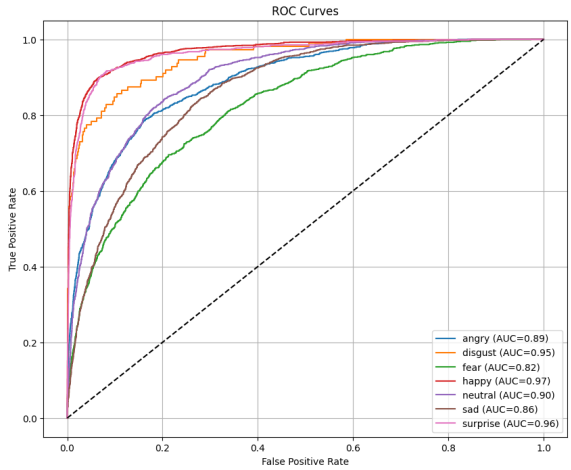

Fig. 5. ROC curves and corresponding AUC values for the seven emotional classes.

To showcase practical utility, the model was implemented on test samples. The network accurately predicts the "Angry" class with a confidence score of 0.92, identifying micro-expressions such as brow furrowing even at reduced resolution.

B. Comparative Analysis

To contextualize performance, a comparison with existing benchmarks is provided in Table II.

TABLE II. COMPARISON OF ACCURACY AND METHODOLOGY WITH RELATED WORKS.

Reference	Architecture	Approach	Accuracy
Farabi et al. [6]	EfficientNetV2-S	Multi-class Framework	62.80%
Białek et al. [1]	Optimized CNN	Efficient Feature Mapping	$\sim$ 65.0%
Zhao et al. [15]	Lightweight ResNet	Parameter Reduction	66.40%
Park et al. [18]	Compact CNN	Mobile-oriented Design	68.12%
Proposed Model	**Residual CNN**	**Triple Residual Blocks**	**71.4%**

As indicated, the proposed model exhibits enhanced performance relative to several contemporary architectures. While peak state-of-the-art results on FER2013 often exceed 85% using deep ensembles or Vision Transformers, those models require millions of parameters and GPU support. Our architecture achieves 71.4% accuracy with only 0.55M parameters, representing a strategic trade-off prioritizing deployment efficiency over absolute peak accuracy.

C. Limitations and Future Work

Despite the efficiency and competitive performance of the proposed Residual CNN, several limitations must be acknowledged. First, the reliance on low-resolution (48×48) grayscale imagery, while optimal for CPU performance, inevitably discards fine-grained textural information and color-based cues that could assist in distinguishing between closely related emotions like "Sad" and "Neutral". As observed in the confusion matrix, these subtle morphological similarities remain a primary source of error.

Secondly, the current model is designed for static image classification. In real-world human-computer interaction, emotions are dynamic processes; the lack of temporal modeling

means the system may struggle with transitional expressions or variations in emotional intensity over time. Future work will explore the integration of lightweight temporal modules, such as Gated Recurrent Units (GRUs), to analyze video sequences without significantly increasing the computational budget.

Finally, while the 71.4% accuracy is superior among lightweight models, there remains a gap compared to heavy-weight architectures. Subsequent iterations of this research will investigate the use of knowledge distillation, where the current lightweight model could be trained to mimic a high-parameter "teacher" network, potentially narrowing the accuracy gap while maintaining the desired inference speed on edge devices.

V. Conclusion

This research presents the development and assessment of a Residual CNN architecture, specifically designed for effective facial emotion recognition. The integration of triple residual blocks, max-pooling layers, and a classification head characterized by substantial regularization was employed to mitigate the typical compromise between model intricacy and predictive efficacy. The findings validate the proposed model's capacity to serve as a dependable framework for FER, attaining a commendable accuracy of 71%. Furthermore, a comparative evaluation demonstrates that our methodology surpasses the performance of contemporary lightweight models, including the EfficientNetV2-S based InsideOut framework (62.8%), as well as other compact CNN designs, which generally exhibit accuracy levels between 65% and 68% on the FER2013 benchmark.

Although the model exhibits some anticipated ambiguity when differentiating between subtle, low-arousal emotions like "Sad" and "Neutral", its elevated AUC scores across most categories indicate robust diagnostic dependability. Future research will concentrate on two key areas: initially, integrating attention mechanisms to enhance the differentiation of morphological similarities within subtle emotions; and subsequently, adapting the model for temporal analysis through the utilization of video sequences to capture the dynamic progression of human expressions. Consequently, the current architecture's efficiency and accuracy render it particularly well-suited for implementation in resource-limited settings, encompassing mobile devices and real-time monitoring systems.

***Abstract*—Unmanned Aerial Vehicles (UAVs) are indispensable assets for missions in dynamic and complex environments, requiring highly efficient path planning that simultaneously optimizes the often-conflicting objectives of minimizing flight distance, energy consumption, and mission time. While Ant Colony Optimization (ACO) is a recognized and effective metaheuristic for this domain, its performance is significantly constrained by a static, empirically-derived pheromone update mechanism, which prevents the algorithm from adaptively learning or optimally managing the search process. To overcome this critical limitation, this study introduces a novel DRL-Assisted ACO framework where a Deep Reinforcement Learning (DRL) agent is seamlessly integrated with the ACO to strategically determine the optimal paths under multi-objective constraints. This intelligent agent is tasked with learning the optimal, mission-specific pheromone update strategy. It achieves this by observing the performance of generated paths and receiving a sophisticated reward signal meticulously derived from the Analytic Hierarchy Process (AHP), which systematically weights the mission objectives. Validated through a simulated case study conducted in Khartoum State, Sudan, the DRL-Assisted ACO approach has demonstrably achieved superior performance, exhibiting marked gains in convergence speed and generating paths with a significantly higher overall multi-objective utility score, thereby delivering a robust and adaptive solution essential for high-stakes autonomous UAV operations.**

Keywords*—Deep Reinforcement Learning; Ant Colony Optimization; adaptive pheromone update; UAV pathing

I. Introduction

Unmanned Aerial Vehicles (UAVs) have become indispensable tools across diverse sectors, including disaster response, surveillance, and autonomous logistics [1], [2]. The successful execution of any UAV mission is fundamentally dependent on efficient path planning, which seeks to identify an optimal flight trajectory. In realistic scenarios, this constitutes a complex multi-objective optimization problem where the desired path must simultaneously minimize conflicting criteria, primarily flight distance, energy consumption, and total mission time [3].

Traditional approaches often rely on metaheuristic approaches, such as ACO and Genetic Algorithms (GA), which have demonstrated effectiveness in navigating complex search landscapes [4], [5]. However, traditional ACO is inherently limited by its fixed, empirical pheromone update rules. This static mechanism prevents the algorithm from adaptively learning the best search strategy, often leading to sluggish convergence rates and a suboptimal performance when attempting to balance the conflicting objectives of a UAV mission [6], [7]. While recent studies have explored integrating DRL to enhance initialization processes, thereby providing an initial population of high-quality paths, a significant research gap remains in leveraging DRL to dynamically control and optimize the core evolutionary mechanism of the ACO algorithm itself [8], [9].

Enhancing algorithms with Deep Reinforcement Learning (DRL) is critical for improving path-planning efficiency. For instance, Binghui Jin [10] proposed an effective method known as DDQN-ACO to address the complex challenge of coordinating multiple Unmanned Ground Vehicles (UGVs) in rugged 3D environments. This approach divides the problem into two key components: the Multi-UGV Path Planning (MUPP-DDQN) algorithm, which uses DRL to find the minimum time-cost path between tasks by considering terrain slope and actual driving speed, thereby generating an accurate cost matrix; and the Multi-UGV Task Assignment (MUTA-ACO) algorithm, which employs Ant Colony Optimization (ACO) to determine the optimal task sequence for each UGV, minimizing the total system time cost and achieving superior global optimization compared to existing methods. In a similar context, You Caihong [11], [12] proposed an RL-ACO hybrid model to address the limitations of static path planning in dynamic, real-time logistics environments. This framework constructs a dynamic directed graph using real-time traffic data, applies ACO for global search and high-quality initial path generation, and integrates a Deep Q-Network (DQN) agent for dynamic mid-route re-optimization in response to real-time events like congestion or road closures. In contrast, our proposed algorithm builds upon and refines the core parameters of these

models, offering enhanced efficiency and improved overall performance.

This study presents a novel approach combining DRL with ACO to address significant limitations in existing ACO algorithms [13]. The key innovation lies in the incorporation of a DRL agent that serves as an intelligent control system, tasked with the continuous challenge of identifying the optimal pheromone update strategy specific to the mission at hand. The agent learns by observing the performance of the paths generated by the ant colony and subsequently receives a reward signal [14]. Importantly, this reward is not arbitrary, but is carefully calculated using the AHP, which systematically integrates and weighs the various competing mission objectives into a single, cohesive score. The main contributions of this study are as follows:

- A hybrid DRL-Ant ACO approach in which a DRL agent is employed to control the pheromone update mechanism, moving beyond conventional static rules.
- The integration of the AHP to systematically formulate a multi-objective cost function, which drives the reward signal for the DRL agent.
- An empirical evaluation of the proposed methodology within a defined operational context, demonstrating its practical advantages in achieving faster, more optimal, and adaptive path planning solutions.

The structure of this study is organized as follows: Section I provides the introduction and motivation behind the research. Section II presents the proposed methodology, including the formulation of the multi-objective problem, the DRL-based initialization process, and the adaptive pheromone control model. Section III discusses the experimental setup and presents the results of the evaluation. Finally, Section IV concludes the study by summarizing the key findings and offering suggestions for future research directions.

A. Related Work

The optimization of UAV path planning, particularly in multi-objective optimization, has been an active area of research. This has led to the development of various hybrid algorithms combining metaheuristic techniques with machine learning to overcome challenges related to computational efficiency and robust multi-objective optimization.

The core advancement of our proposed DRL-ACO method remains its dual-integration of DRL to both generate a high-quality initial path set and, most critically, to learn the optimal, adaptive pheromone update value [15]. This comprehensive and deep integration contrasts sharply with other adaptive and hybrid ACO variants [16]. For instance, in the domain of adaptive parameter tuning, methods such as PF3SACO leverage classical techniques such as Particle Swarm Optimization (PSO) and Fuzzy Logic to adjust ACO parameters such as 1α and 2ρ.3 While adaptive, these methods rely on predefined metaheuristic interactions or empirical, rule-based inference systems. Our approach, by contrast, uses DRL to learn the optimal pheromone update directly from the search state, allowing the system to derive complex, non-linear control policies that are superior to any manually engineered or statically constrained adaptation mechanism [17], [18].

In contrast to recent hierarchical DRL-ACO models, such as ADACO-ATD3, which separate path planning (handled by ACO) and local motion control (managed by a dedicated DRL agent, such as ATD3 for real-time obstacle avoidance, this approach fundamentally optimizes the ACO engine itself [19]. In these hierarchical models, the ACO core remains static, with the DRL agent primarily refining local control mechanisms. In this approach, however, the DRL agent directly influences the global search process by dynamically controlling the pheromone update mechanism, an essential memory component of the ACO algorithm [20]. This DRL-driven adjustment significantly improves the global search quality and accelerates convergence by impacting the behavior of all subsequent ants across iterations [21].

Furthermore, when compared to other multi-objective DRL-ACO hybrids, such as NSACOWDRL which uses a Double Deep Q-Network (DDQN) agent for local search refinement or to modify ant selection probabilities, this DRL agent targets the pheromone update mechanism itself [14]. This allows our approach to function as a true meta-controller of the ACO's collective memory, rather than merely enhancing local path construction or solution selection heuristics. The ability to holistically and intelligently control the most influential parameter of the ACO, the pheromone update, is the key feature that enables superior and adaptively managed search performance [22].

In summary, the proposed DRL-ACO approach introduces a deeply integrated learning mechanism in which a DRL agent dynamically optimizes the pheromone update process, enhancing the global search capability and convergence efficiency of the ACO algorithm. Unlike previous adaptive or hierarchical hybrids, this approach functions as a true meta-controller of ACO's collective memory, enabling intelligent and adaptive management of its most influential parameter [23], [24]. Consequently, the framework achieves superior performance in multi-objective UAV path planning through a holistic and self-adaptive optimization strategy [25].

II. Methodology

UAVs are vital assets in surveillance, delivery, and mapping, especially in complex and dynamic environments. Efficient path planning for UAVs is a crucial, non-linear optimization challenge that requires balancing multiple, often conflicting, objectives, such as minimizing flight distance, mission time, and energy consumption. The DRL-APC methodology is structured into three phases: Problem Formulation, DRL-Assisted Initialization, and Adaptive ACO Optimization.This hybrid DRL-ACO approach, as shown in Fig. 1, aims to harness DRL learning and decision-making capabilities to provide a robust starting point for the ACO global search, thereby leading to more efficient convergence and higher-quality solutions for complex multi-objective UAV path planning problems.

A. Problem Formulation and Multi-Objective

1) Path representation: The mission space is modeled as a weighted graph $G = (V, E)$, where V are waypoints and E are possible flight segments. The UAV path P is a sequence of connected waypoints.

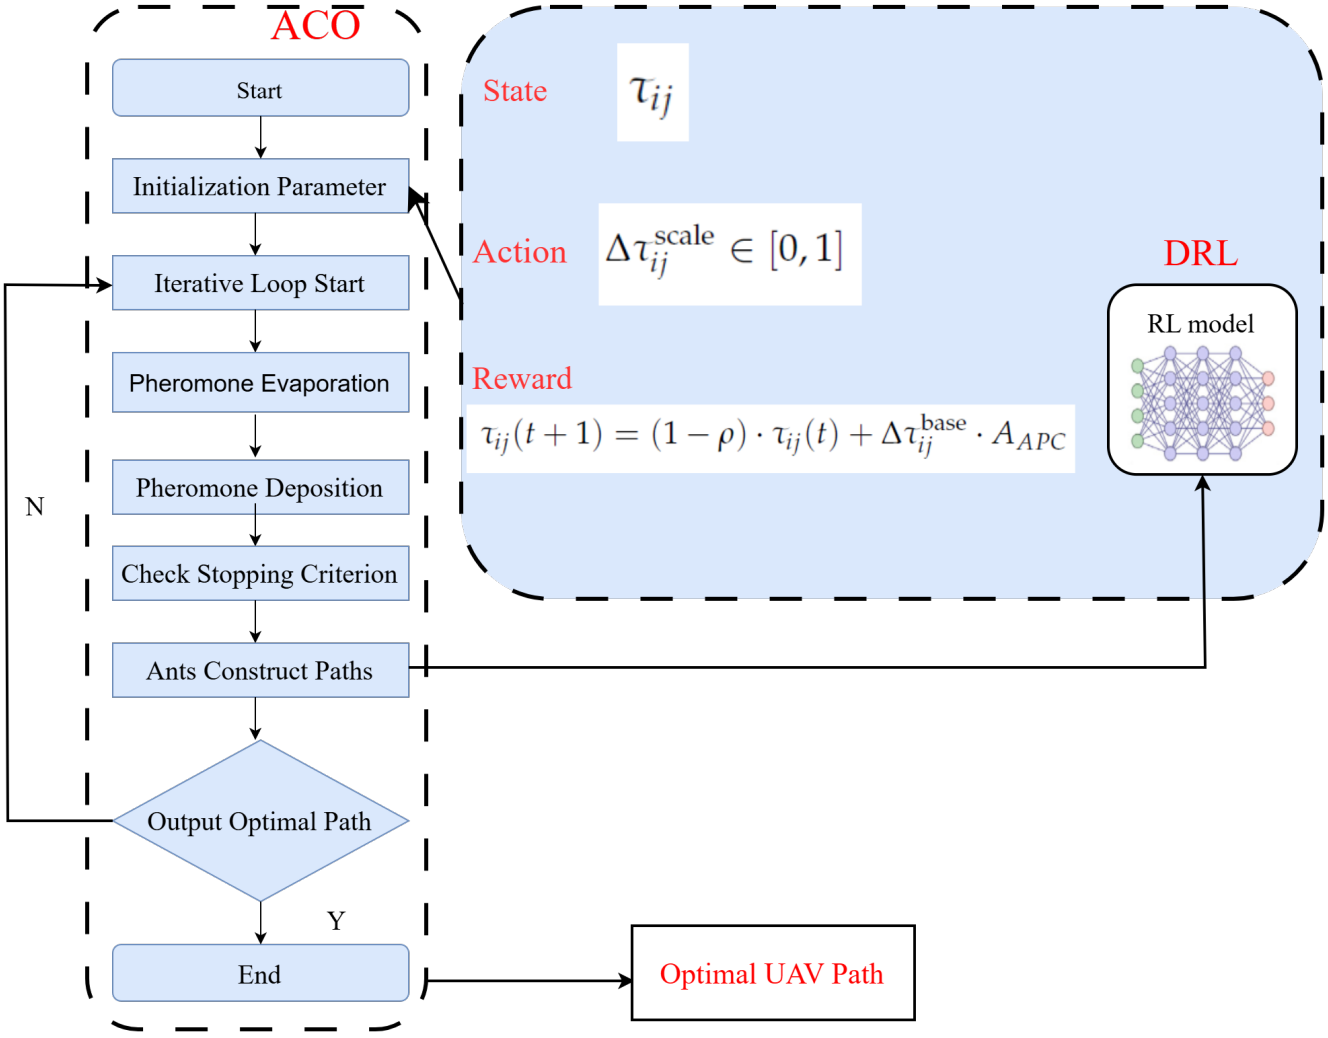

Fig. 1. Approach of the process for UAV path planning using RDL and ACO.

2) Multi-objective cost function C_{MOC} : The optimization objectives are normalized and combined using AHP-derived weights to form a single cost function for a path P:

$$C_{MOC}(P) = w_D \cdot C_D(P) + w_T \cdot C_T(P) + w_B \cdot C_B(P). \quad (1)$$

where,

C_D, C_T, C_B: Normalized costs (Distance, Time, Battery Consumption).

W_D, W_T, W_B: AHP-determined priority weights (summing to 1). The objective is to $\min C_{MOC}$.

B. Ant Colony Optimization (ACO)

ACO is a computational metaheuristic primarily employed for finding near-optimal solutions to discrete optimization problems, particularly those related to pathfinding. As a form of swarm intelligence, ACO is inspired by the cooperative foraging behavior observed in ant species.

The effectiveness of ant colonies in locating the shortest routes between their nests and food sources stem from their system of indirect communication, known as stigmergy. Ants deposit chemical signals, or pheromones, along their paths, which serve as odor trails. Subsequent ants follow these trails, using the scent concentration as a probabilistic guide to determine the most efficient route. Paths that are frequently traversed become reinforced with higher pheromone concentrations, thereby attracting more followers and establishing a positive feedback loop for optimal solutions.

The fundamental operation of the Ant Colony Algorithm can be broadly categorized into two iterative stages:

- Solution Construction: Artificial ants sequentially build solutions (a path) by making probabilistic choices. These choices are governed by the existing pheromone levels on the network edges and a local heuristic value.
- Pheromone Update: After a construction cycle, the pheromones along the utilized paths are modified. Pheromone levels are increased on components be-

longing to high-quality solutions (such as reinforcement) and simultaneously decreased across the entire network via evaporation to prevent premature convergence and encourage exploration. In essence, ACO harnesses the collective, decentralized decision-making of a swarm to select new path segments, assigning probabilities based on the accumulated, self-reinforcing knowledge encoded in the pheromone trails.

C. Deep Reinforcement Learning (DRL)

In response to the identified shortcomings of fixed meta-heuristic methods and the growing complexity of the optimization landscape, DRL presents a sophisticated and highly effective framework for complex decision-making. DRL is a powerful subset of machine learning that integrates the trial-and-error methodology of Reinforcement Learning (RL), where a computational agent learns an optimal policy through interaction with an environment to maximize cumulative reward—with the robust data processing capabilities of Deep Neural Networks.These networks enable the agent to effectively process and synthesize high-dimensional, complex state information, such as large graph structures and real-time sensor inputs, mapping these observations directly to an optimal action sequence.

DRL is particularly well-suited for solving the sequential decision-making and routing problems inherent in path planning. Furthermore, DRL is employed in a meta-learning capacity to enhance the adaptability of the optimization process itself. Instead of merely solving the primary path problem, a DRL agent is trained to learn the optimal control policies for the underlying search algorithm. This powerful capability allows the DRL agent to dynamically adjust internal ACO parameters, such as the pheromone update magnitude, based on the real-time feedback regarding environmental changes and the current state of the colony's search. This integration of DRL for both initial guidance and dynamic control is the key for creating a path planning framework that is both fast-converging and highly robust to environmental variability.

D. DRL-Assisted Pheromone Initialization

This phase addresses the fundamental drawback of traditional ACO: starting with a random or uniform search space. We utilize DRL to pre-train an agent that quickly learns optimal pathing strategies, which are then used to intelligently seed the ACO pheromone map. This represents a direct application of the DRL-initialization adapted for an ACO approach.

A Deep DQN is chosen for this task due to its effectiveness in solving sequence-selection problems TSP , which is analogous to our path-finding task. The objective of this training is to teach the agent the optimal action (next waypoint) to take from any given state to minimize the Multi-Objective Cost (C_{MOC}).

1) DRL Approach Setup:

- Agent: The DQN architecture typically consists of an input layer, several hidden layers, and an output layer equal to the size of the action space.
- Experience Replay Buffer: A mechanism is used to store and randomly sample past experiences $(\text{State}, \text{Action}, \text{Reward}, \text{Next State})$ to stabilize the learning process and break the correlation between consecutive samples.
- Target Network: A separate, delayed-update target network is used to compute the target Q-values, further enhancing stability during training.

E. State Space Definition (S)

The state S captures all necessary information for the agent to make an informed decision. For an agent at waypoint v_i, the state is defined as:

$$S = \{v_i, H_t, C_{t,objective}\} \tag{2}$$

where,

- Current Waypoint (v_i): The index of the UAV's current location.
- History Vector ($\mathbf{H}_t$): A binary vector representing all waypoints visited up to time t. This is crucial for preventing redundant visits and ensuring a complete path is generated.
- objectives Cost Vector ($\mathbf{C}_{t,\text{objective}}$): The aggregated normalized objectives costs (distance, time, battery).

F. Action Space Definition (A)

The action A is the agent's choice of the next waypoint v_j to move to from v_i:

$$A_t \in \{v_j \mid (v_i, v_j) \in E, and, v_j \notin Visitted\} \tag{3}$$

The action space is dynamic: the set of available actions changes as the path is constructed, always excluding waypoints already visited.

G. Reward Function (R)

The reward function is the critical link between the agent's actions and the optimization goal. Since the goal is to minimize the C_{MOC}, the reward is inversely proportional to this cost.

$$R(P) = \frac{R_{base}}{\epsilon + C_{MOC}(P)} \tag{4}$$

(where, ϵ is a small constant to prevent division by zero). A negative reward is given for illegal moves.

H. Initial Path Generation

The trained DQN is used to greedily generate N_{init} high-quality, initial paths: $P_{init} = \{P_1, P_2, \ldots, P_{N_{init}}\}$.

1) Pheromone map initialization: These paths are used to initialize the ACO pheromone matrix τ_{ij}. Instead of starting with uniform pheromones, the initial pheromone level $\tau_{ij}(0)$ on each edge (i, j) is set proportional to the inverse cost of the DRL-generated paths that use that edge:

$$\tau_{ij}(0) = \tau_{min} + \sum_{k=1}^{N_{init}} \mathbb{I}_{ij}(P_k) \cdot \frac{Q_{DRL}}{\sum_{m=1}^{N_{init}} C_{MOC}(P_m)} \quad (5)$$

where,

τ_{min} is the minimal pheromone level (evaporation lower bound).

$\mathbb{I}_{ij}(P_k)$ is an indicator function (1 if path P_k uses edge (i, j), 0 otherwise).

Q_{DRL} is a fixed constant representing the total initial pheromone mass.

2) Ant movement (path construction): Ants construct paths stochastically based on pheromone levels and heuristic information, as in traditional ACO.

$$P_{ij}^k = \frac{\tau_{ij}^{\alpha}.\eta_{ij}^{\beta}}{\sum_{l \in \text{Allowed}_i} \tau_{il}^{\alpha} \cdot \eta_{il}^{\beta}} \quad (6)$$

where,

τ_{ij} is the pheromone level on edge (i, j).

η_{ij} is the heuristic value (inverse of distance).

α and β are control parameters (importance of pheromone vs. heuristic).

3) DRL-Learned Adaptive Pheromone Update (APC): This is the core novelty, replacing fixed update rules with a learned policy. A separate, smaller DRL agent (a simple Q-Learning) is used to determine the optimal pheromone update magnitude.

The pheromone update rule becomes:

$$\tau_{ij}(t + 1) = (1 - \rho) \cdot \tau_{ij}(t) + \Delta\tau_{ij} \quad (7)$$

The new pheromone deposit $\Delta\tau_{ij}$ is determined by the DRL-APC Agent:

- APC Agent State (S_{APC}): A vector including the path segment (i, j) , the current global path quality, and the local pheromone density τ_{ij}.

$$S_{APC} = \tau_{ij} \quad (8)$$

- APC Agent Action (A_{APC}): The action is the determination of the pheromone scaling factor, $\Delta\tau_{ij}^{\text{scale}} \in [0, 1]$.

$$A_{APC} = \Delta\tau_{ij}^{\text{scale}} \in [0, 1] \quad (9)$$

- APC Agent Reward (R_{APC}): A reward function that encourages convergence and diversity: a high reward for finding a new global best solution, and a penalty for stagnation or over-prioritizing short-term, low-quality paths local optima.

The resulting pheromone update is:

$$\tau_{ij}(t + 1) = (1 - \rho) \cdot \tau_{ij}(t) + \Delta\tau_{ij}^{\text{base}} \cdot A_{APC} \quad (10)$$

where,

$\Delta\tau_{ij}^{\text{base}}$ is the standard deposit for the best path, and A_{APC} is the scaling action learned by the DRL agent.

I. Path Output

The path calculation in this approach is a two-stage process: first, the probabilistic selection of discrete waypoints based on the environment's pheromone map, and second, the physical translation of those waypoints into a navigable 3D trajectory for the UAV.

- Probabilistic Movement Rule (Node Selection). The UAV (represented as an "ant" in the ACO framework) starts at a designated launch coordinate S. At each time step t, the agent must select the next node j from a set of reachable neighboring nodes N_i. This selection is governed by the transition probability P_{ij}, which balances exploration and exploitation.
- Multi-Objective Cost Constraints such as standard pathfinding, the UAV path calculation incorporates a cost function C derived via the Analytic Hierarchy Process (AHP). Every potential move is evaluated against:
  - Distance (C_D): Euclidean distance between nodes.
  - Time (C_T): Calculated based on the UAV's average velocity across the terrain.
  - Battery (C_B): Energy consumption model considering climb rate and air resistance.
- Path Refinement and DRL Influence. The "Deep Reinforcement Learning" component intervenes during the calculation by adjusting the pheromone scaling factor.

The final output is the path P_{best} corresponding to the lowest C_{MOC} found across all iterations.

J. Analytical Hierarchy Process

The AHP is one of the most widely applied techniques in multi-criteria decision analysis (MCDA), particularly within natural resource management and environmental studies. In this study, AHP is employed to determine the weights of the resource layers [26]. The method operates by assigning priority values based on relative importance, typically using a 1–9 scale [27]. Each criterion is evaluated individually through pairwise comparisons, after which the eigenvalues of the resulting comparison matrix are computed and utilized as the corresponding criterion weights.

This study follows the same methodological framework established in the referenced work by [16].

Table I Presents the objective weights assigned based on their relative importance in this approach.

TABLE I. THE OPTIMAL PATH

Objectives	D	T	B	Weight Score
Distance (D)	1	2	2	0.5
Time (T)	0.5	1	1	0.25
UAV battery (B)	0.5	0.5	1	0.25

During the training phase, the DRL agent learns optimal policies aimed at minimizing the AHP-weighted cost function, thereby generating paths that effectively balance the prioritized objectives. Consequently, the AHP framework not only provides objective weighting for the ACO fitness evaluation but also actively guides the DRL exploration process, ensuring that the initially generated paths capture mission-critical trade-offs prior to the ACO-based refinement stage.

III. STUDY AREA AND EXPERIMENTAL ANALYSIS

A. Study Area

The study area is located in the Red Sea Mountains in eastern Sudan, a striking geological formation that runs parallel to the Red Sea coast. Known for its rugged terrain and diverse ecosystems, the region offers a unique landscape shaped by the Arabian-Nubian Shield. The mountains are predominantly made up of granite and volcanic rock formations, with elevations ranging from 600 to over 2,500 meters above sea level. The ecological variety in this area includes dry forests, scrublands, and semi-desert habitats, providing a rich environment for a wide array of flora and fauna adapted to harsh conditions. Given the challenging terrain of the area, traditional methods of transportation between different points are inefficient and impractical. To overcome this issue, the present study employs a drone for logistical transport between the selected points. The specific locations of these points are provided in the accompanying Table II, while the layout of the terrain is depicted in Fig. 2.

B. Results

This study employs a multi-objective optimization approach to develop and determine the optimal UAV flight paths by integrating three key objectives: distance, time, and battery consumption. The process begins with the application of DRL to estimate a set of promising initial parameters for the optimization. These parameters are then refined through the ACO algorithm.

- ACO Parameters (α and β). Pheromone Influence ($\alpha = 1.0$). This value was chosen to ensure that the "swarm intelligence" (historical data) has a significant impact on path selection without causing premature convergence to suboptimal paths. Heuristic Influence ($\beta = 2.0$) we assigned a higher weight to the heuristic information (distance to goal). This is critical in UAV pathing to ensure that ants remain "goal-oriented".
- Evaporation Rate ($\rho = 0.1$). The evaporation rate was set to 0.1 to provide a "long memory" for the pheromone trails. In a complex 3D environment, rapid evaporation (> 0.5) can lead to the loss of good global solutions, while too low a rate (< 0.05) prevents the algorithm from discarding poor paths.
- Learning Rate ($\gamma = 0.001$). A conservative learning rate was selected for the Deep Q-Network (DQN) to ensure stable convergence of the pheromone scaling factor.
- Discount Factor ($\gamma = 0.95$). This high value ensures the DRL agent considers the long-term cost of the entire path (Total Battery/Time) rather than just the immediate next step.
- Exploration-Exploitation (ϵ-greedy). Utilized a decaying epsilon starting at 1.0 and ending at 0.01. This allows the DRL agent to explore a wide variety of pheromone update strategies in early iterations before settling on an optimized policy.

The effectiveness of the proposed DRL-ACO hybrid depends on the calibration of several key hyperparameters. These values were selected based on a combination of established literature and empirical tuning during the preliminary simulation phase.

In this context, the DRL agent functions as an intelligent control system, continuously tasked with identifying the optimal pheromone update strategy tailored to the specific mission objectives. This intelligent control mechanism is crucial for determining the optimal flight trajectory by balancing the mission's multi-objective criteria. To systematically prioritize and combine the three objectives (distance, time, and battery consumption), the AHP is employed. The AHP ensures a balanced optimization process by assigning relative importance to each objective based on mission-specific constraints and application needs.

Following the weight assignment and construction of the multi-objective decision matrix, an initial population of candidate solutions is generated through DRL. This approach enhances the performance of ACO by providing an optimal pheromone update strategy value, set at 200, which improves the search efficiency.

Finally, the optimal UAV path is determined by applying the ACO, which has been enhanced through integration with the multi-objective DRL framework. The DRL component guides the initialization and search process by providing a more informed starting population, allowing the ACO to converge more effectively toward solutions that balance the three objectives: minimizing travel distance, energy consumption, and mission time.

The results demonstrate the superiority of our proposed algorithm in determining the optimal logistic trajectory length for the UAV, which was found to be 750 meters. In contrast, alternative algorithms aimed for trajectory lengths of 800 and 850 meters. This outcome underscores the reliability of our approach, as evidenced in Table III and Fig. 4.

Fig. 4 shows the optimal path using our approach, and Fig. 3 shows the path using traditional ACO and GA.

C. Discussion

The integration of DRL with ACO significantly enhances UAV path planning by improving convergence speed and optimizing multi-objective criteria, such as distance, time, and energy consumption. The DRL-ACO framework not only overcomes the limitations of traditional ACO, which relies on static pheromone update rules, but also provides adaptability through dynamic pheromone management, leading to faster convergence towards optimal solutions [28], [18]. In the experimental results, the DRL-ACO approach demonstrated superior performance, finding shorter paths 750 meters compared to traditional ACO and GA 850 meters, thus ensuring greater efficiency in UAV operations. The use of the AHP further allowed the DRL agent to balance the conflicting objectives by assigning appropriate weights, ensuring that the solution met mission-specific requirements effectively [23].

This approach proved to be particularly robust in a complex environment, as demonstrated in the study area in Sudan, where the challenging terrain required adaptability in path planning. Unlike traditional approaches, the DRL-ACO approach could handle the unpredictability of real-world conditions, making it highly suitable for mission-critical applica-

tions, such as disaster response and surveillance. While the framework showed significant improvements, there are still opportunities for future enhancement, particularly in incorporating additional factors like obstacle avoidance or real-time re-planning, and improving computational efficiency. Despite its success, the DRL-ACO approach requires substantial computational resources for training, suggesting that further optimization of the DRL model could improve its applicability in real-time scenarios.

In comparison to other path planning algorithms, the DRL-ACO approach demonstrated clear advantages in reducing path length and optimizing mission objectives. This outcome not only highlights the potential of the framework for real-world applications but also sets a foundation for future advancements, where the system can adapt to even more complex and dynamic environments, improving its effectiveness in various UAV mission scenarios.

The proposed algorithm was tested against two established methods: the traditional ACO and the GA algorithm. The results of this comparison are presented in Table IV, assessed performance based on three key metrics: path length 750 m, and execution time 0.27 s. The results demonstrate that the proposed algorithm consistently outperforms both the ACO and GA, achieving more optimal path lengths in fewer iterations and with significantly lower computational overhead.

IV. CONCLUSION

This study successfully introduced a novel DRL-Assisted Ant Colony Optimization (DRL-ACO) approach to address the limitations of traditional ACO in multi-objective UAV path planning. The critical innovation involves the deep integration of a DRL agent to serve as an intelligent control system, replacing static rules with an adaptive pheromone update (APC) mechanism. The problem was formalized using the AHP to

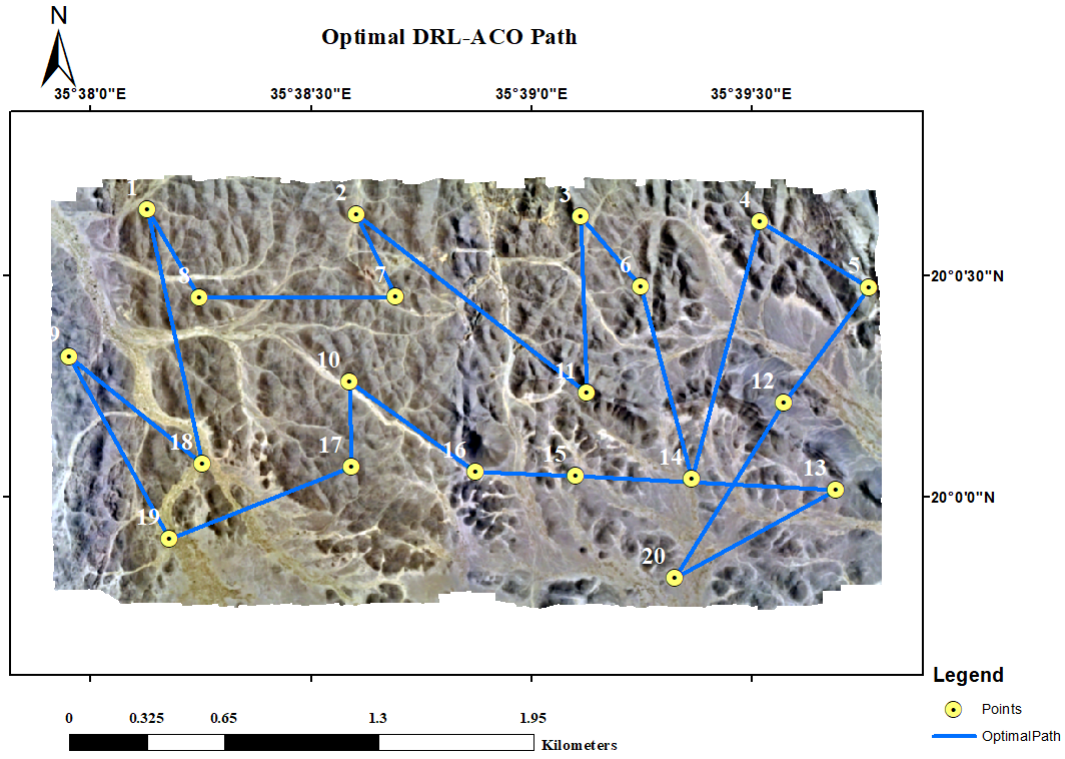

Fig. 4. Optimal DRL-ACO path.

systematically weigh and combine the conflicting objectives of minimizing flight distance, energy consumption, and mission time into a single multi-objective cost function (C_{MOC}). Empirical validation, conducted in a challenging, rugged terrain environment in Sudan, confirmed the framework's superiority. The DRL-ACO approach found the optimal trajectory length of 750 meters, significantly outperforming the 800-850 meters found by traditional ACO and GA, while also demonstrating a lower computational time of 0.27 seconds. This outcome confirms that the DRL-ACO framework provides a robust and adaptive solution that achieves faster convergence and superior optimization of multi-objective criteria for autonomous UAV operations.

Despite the demonstrated success, the DRL-ACO framework presents several opportunities for future enhancement to increase its real-time applicability. Firstly, future research should focus on incorporating additional real-time constraints, such as obstacle avoidance and dynamic path re-planning, to enhance the system's robustness in highly unpredictable environments. Secondly, the current approach requires substantial computational resources for DRL model training. Finally, researchers could explore more advanced DRL algorithms or hierarchical DRL structures to manage local control mechanisms, potentially yielding even more sophisticated, non-linear control policies for the adaptive ACO parameters.

FUNDING

This study was funded by the Deanship of Scientific Research (DSR) at King Abdulaziz University, Jeddah, Saudi Arabia, under grant no (GPIP:882-830-2024). The authors, therefore, gratefully acknowledge and thank DSR for its technical and financial support.

***Abstract*—E-learning platforms provide learners with extensive digital resources that enable self-paced and location-independent study. However, the overwhelming volume of learning materials offered by a wide range of institutions and content providers makes personalized guidance increasingly essential for effective knowledge acquisition. As a result, recommender systems have become fundamental components of modern e-learning environments, helping to reduce information overload and support individualized learning experiences. In general, the richer and more diverse the available data, the more accurate and relevant the resulting recommendations. Despite these advantages, conventional recommendation approaches often fail to fully exploit the contextual and relational information inherent in e-learning ecosystems, which limits their adaptability and predictive precision. This study proposes a hybrid recommendation framework that integrates collaborative filtering, content-based filtering, and context-aware modeling to generate more accurate and adaptive course recommendations. The proposed system infers learner preferences by combining historical interaction data, contextual attributes, and course characteristics, while also incorporating temporal and environmental factors that influence learning behavior. Experimental evaluations based on SVD, TF-IDF, and RNN models applied to a well-established benchmark dataset demonstrate that the proposed hybrid framework significantly improves recommendation accuracy, coverage, and adaptability compared with baseline methods. Furthermore, the integration of contextual information effectively alleviates the cold-start problem and better captures learners' evolving goals and learning trajectories. Overall, the results confirm that combining multiple recommendation paradigms within e-learning platforms enables more adaptive, personalized, and scalable learning pathways, making the proposed system suitable for diverse educational contexts and learner profiles.**

I. Introduction

The flexibility of e-learning systems has fundamentally transformed the way students learn and how education is delivered. These platforms enable self-directed and personalized learning experiences, allowing learners to acquire new skills and knowledge beyond the traditional classroom. The COVID-19 pandemic further highlighted the critical role of e-learning technologies, as they were rapidly adopted to ensure educational continuity during periods of disruption. However, modern e-learning platforms offer an enormous number of courses and digital learning resources [1]. This abundance often leads to information overload, making it difficult for learners to identify and select content that aligns with their academic objectives, learning styles, and personal preferences.

In this context, recommender systems (RSs) play a crucial role in helping learners discover relevant educational resources from large collections of courses [2][3]. In domains such as e-commerce, entertainment, and social media, recommender systems based on Collaborative Filtering (CF) and Content-Based Filtering (CBF) have demonstrated strong performance. CF predicts user interests by identifying similarities among users and items using interaction histories such as ratings, clicks, and browsing behavior [4], [5]. In contrast, CBF recommends items by analyzing content features, including course descriptions, topics, and keywords, and matching them to a user's previous preferences [6], [7]. This approach relies on comparing new items with those previously consumed to determine suitable recommendations.

Despite their success, these techniques exhibit important limitations when applied to e-learning environments. CF suffers from the cold-start problem and data sparsity, particularly when new users or new courses have limited interaction history [8], [9]. CBF, on the other hand, relies on static content representations and therefore struggles to adapt to learners' evolving goals and situational learning contexts [10].

To overcome these limitations, recent research has focused on hybrid recommender systems that combine multiple recommendation strategies to exploit their complementary strengths. Several studies [11], [12] have shown that incorporating additional information especially contextual data—significantly enhances recommendation performance. In e-learning environments, contextual factors such as the device used, time of access, location, and session duration strongly influence learners' behavior and course preferences. For example, a learner accessing the platform from a mobile device may prefer short tutorials, whereas the same learner using a desktop computer at home may be more inclined to engage in longer and more comprehensive learning modules [13].

The present work proposes a hybrid e-learning recommender system that integrates Collaborative Filtering, Content-Based Filtering, and contextual modeling to provide personalized and context-aware course recommendations. Contextual information is modeled using predictive LSTM neural networks to capture temporal and behavioral patterns, while SVD is employed for matrix factorization and TF-IDF for textual feature extraction and natural language processing.

This study makes several important contributions. First, it introduces a hybrid recommendation framework that jointly leverages collaborative, content-based, and contextual modeling techniques to enhance personalization in e-learning environments. Second, it integrates SVD, TF-IDF, and LSTM to address key challenges such as data sparsity, cold-start issues, and evolving learner behavior. Third, the framework is extensively evaluated using real edX course data, demonstrating superior performance over traditional CF and CBF methods in terms of accuracy, relevance, and contextual adaptability.

The remainder of this study is organized as follows: Section II reviews related work on hybrid recommender systems and discusses the limitations of existing approaches. Section III presents the proposed framework and methodology. Section IV describes the experimental setup, including evaluation metrics and results. Finally, Section V concludes the study and outlines directions for future research.

II. Related Work

With the use of recommender systems, user experiences across many areas, including e-learning, have been personalized to individual user needs [14], [15]. These systems suggest activities based on users' previous activities [16], [17]. The first recommender systems relied on Collaborative Filtering (CF) and Content-Based Filtering (CBF). CF analyzes user-item interactions based on attribution, clicks, and behavior to find patterns of similarity among users or items [17]. CF is effective in many scenarios, but sparse data, new users, and the absence of interaction data (cold-start) is highly problematic. Other techniques, such as predictive analytics, have been proposed to solve these issues, but CF continues to have difficulty adapting to changing environments and user preferences.

CBF improves on CF by using items features (keywords, topics, and metadata). In e-learning, CBF analyzes course materials to recommend resources that adjust to learner preferences based on their previous activities [15]. CBF's major problem is its over-specialization. It limits user exploration by not encouraging them to search outside the narrowly defined parameters of their needs [14]. Additionally, its use of static features fails to capture the user's evolving needs [16], [18].

Hybrid recommender systems integrate the strengths of Collaborative Filtering (CF) and Content Based Filtering (CBF) techniques to provide the users of e-learning platforms engaged and more targeted suggestions [19]. The addition of deep learning methods, such as neural collaborative filtering, which provides the ability to work on and analyse intricate relationships and non-linear user-item interactions, is a recent and notable advancement in this area [20].

Although hybrid systems have progressed in many ways, they still have a critical oversight of failing to integrate contextual data which includes how, when, and where a user interacts with the learning materials [21][22]. CARS approaches this oversight with contextual data such as study times, types of devices, locations, and other time constraints for learning materials [18]. For instance, recommending longer courses for uninterrupted study times and shorter tutorials for commuting is likely to improve learning and the perceived value of the recommendations. Including context data in recommendations has been shown to improve accuracy and user satisfaction [19].

Nonetheless, many CARS approaches for context modeling remain rudimentary or involve only fragmentary contextual details, leading to unfulfilled personalization. Moreover, context modeling intricacy might lead to scalability issues and pose problems for real-time adaptation which, in turn, limits responsiveness in swiftly evolving learning settings, as noted in [23]. This is why CF, CBF, hybrid and context-aware models still default most of the time in handling the interplay of collaborative, content, and contextual pieces. In addition, they tend to be responsive inflexibly to learner's situational alterations, state of cold start, and real-time adjustments of behavior or situational aspects of the environment [22].

In light of these challenges, this research aims to develop a hybrid e-learning recommender system that combines elements of collaboration, content, and contextual strategies within a single framework. This system develops sophisticated SVD models for matrix factorization, employs TF-IDF for feature embedding, and uses RNNs for sequential behavior modeling. By dealing with user-specific preferences and shifting contextual factors, the integrated approach improves the precision, diversity, and contextual relevance of recommendations. On a wider frontier, this fully personalized system addresses scalability and adaptive challenges while providing personalization within the learning pathways for a diverse learner's spectrum and within a robust and dynamic real-world e-learning context, as detailed in [21, 24].

Proposed system considers the issues in previous works and focuses on providing an adaptive solution that offers flexibility and overcomes the many restrictions traditional e-learning recommender systems face. For instance, cold-start, data sparsity, overspecialization, and an adaptive approach towards changing user preferences are stick points for Collaborative Filtering (CF) and Content-Based Filtering (CBF) systems. Although hybrid approaches try to associate CF and CBF, many fail to consider the user context while learner interactions and user preferences are adjusted. The proposed system overcomes this shortcoming by providing context-aware integration of-collaborative, content, and CBF approaches. Thus, achieving a comprehensive, synergistic recommendation framework.

One of the strengths of this system is the management of user behavior over time. User behavior on e-learning platforms is not fixed; it changes as users learn new topics, reorganize their study plans, or adapt to other external factors like the availability of devices and location. Fleeting and situational conditions allow the system to revise recommendations in real time, attuned to the user's present needs, offering resources that are relevant and actionable. The ability to track changes user behavior over time and in real time is a significant improvement over traditional CF and CBF, which tend to provide users with recommendations that are the same over extended periods and are based on stale historical behavior patterns or unchanging attributes of the content.

In addition, system parameters that analyze the user's context, including limitations and learning goals, are vital to personalization in e-learning. Session length, time of access, and device type are examples of context variables that help to adapt recommendations to user learning environments. In addition, learning goals help the system to prioritize targets aligned with users–whether for skill building, exams, or professional learning. Context and goal alignment together ensure that the

system moves beyond offering vague, unhelpful recommendations to the user and supports actionable recommendations.

Overall, the proposed hybrid system is a significant improvement over the previous work which is focused on e-learning recommendation systems. It closes the gaps between the collaborative, content-based, and context-approaches, facilitating the generation of adaptive, flexible, and personalized learning paths. This not only contributes to higher recommendation accuracy and user satisfaction, but also to the advancement of intelligent context-aware e-learning systems aimed at meeting the needs of a variety of learners in real-life educational environments.

Recent research in e-learning recommendation systems has shown a clear trend toward hybrid and context-aware approaches, which combine multiple techniques to improve personalization and system adaptability in response to the diversity of learners and learning contexts. For instance, hybrid approaches integrating user and content-based techniques with collaborative methods have been proposed to address the cold-start problem in personalized course recommendation systems, demonstrating increased user satisfaction without relying solely on historical user ratings [25]. Similarly, context-aware recommendation engines integrating hybrid reinforcement learning have been developed to dynamically adapt recommended content according to learner profiles, preferences, and real-time performance, illustrating the integration of various contextual data such as learning pace and individual trajectories [26]. Moreover, systematic reviews of recent advances in context-aware recommender systems highlight the importance of structured contextual representations and integrated methods to capture complex interactions among users, items, and context, while emphasizing the need for more unified frameworks for context management [27] [28]. Other studies explore group or multi-criteria recommendation mechanisms, showing the addition of diverse contextual factors and dynamic attention mechanisms to better serve collaborative or multi-dimensional educational environments [29] [30]. Federated hybrid approaches have also been proposed to address challenges related to inter-institutional diversity and data privacy, constructing heterogeneous representations that integrate historical and contextual interactions within distributed learning graphs [27] [28]. Finally, research on hybrid and context-aware recommendations in adjacent domains demonstrate the positive impact of combining multiple paradigms on recommendation accuracy and adaptability, providing a solid conceptual foundation for hybrid context-aware frameworks in e-learning [31].

III. Proposed Framework and Methodology

We aim to enhance personalization and flexibility in e-learning recommendations by designing a hybrid recommendation framework that integrates Collaborative Filtering (CF), Content-Based Filtering (CBF), and Contextual Data Modeling (CDM) using Long Short-Term Memory (LSTM) networks. By combining these three approaches, the framework overcomes the limitations of relying on a single recommendation technique and enables more accurate, diverse, and context-aware learning recommendations.

Collaborative Filtering (CF) identifies users and groups with similar preference patterns, behaviors, and interaction histories. It analyzes user–item interaction matrices and recommends courses that have been highly rated or frequently accessed by users with similar profiles. However, CF suffers from data sparsity and cold-start problems, particularly when dealing with new users or newly introduced courses.

Content-Based Filtering (CBF) relies on course attributes such as keywords, topics, descriptions, and metadata to match learning resources with individual learner profiles. This approach is effective in recommending courses aligned with a learner's past interests and completed materials. Nevertheless, CBF often leads to over-specialization, as it tends to recommend content that is too similar to previous selections, thereby limiting exploration and discovery of new topics.

Contextual Data Models capture situational factors that influence learning behavior, including temporal variables (e.g., study schedules and session duration) and spatial or environmental attributes such as location, device type, and learning context. To model these complex and sequential relationships, we employ Long Short-Term Memory (LSTM) networks, a class of recurrent neural networks capable of learning long-term dependencies in user behavior. Through LSTM, the system analyzes how learners' preferences and contexts evolve over time and predicts which courses are most suitable at a given moment. For instance, the system may recommend short tutorials during commuting or brief study sessions, while suggesting more comprehensive modules during extended learning periods.

Each component—CF, CBF, and the LSTM-based contextual model—operates independently to generate candidate recommendations. These outputs are then combined through a fusion mechanism that considers user reliability, behavioral profiles, and contextual relevance. This hybrid aggregation strategy provides dynamic recommendation capabilities, allowing the system to adapt to changes in learner preferences and environmental conditions in real time.

By integrating collaborative, content-based, and contextual modeling approaches, the proposed framework offers a flexible, scalable, and context-sensitive solution for e-learning personalization. It simultaneously exploits historical interaction patterns, course attributes, and situational factors to deliver highly relevant and adaptive recommendations, ultimately enhancing learner engagement, effectiveness, and satisfaction.

A. Framework Overview

Fig. 1 will help to explain the elements of the blended recommendation framework. There are four blended recommendation framework parts that are unified, which help to generate hyper-personalized course recommendations. The modular approach also allows the recommendation system to gain different facets of a learner's behavior, a course's content, and contexts, leading to comprehensive recommendations. Since diverse aspects of learner behavior and content are accounted for, the recommendations are comprehensive and accurate.

1) Collaborative Filtering (CF) with SVD (User-Based Collaborative Filtering – UBCF): The first segment uses the previously discussed user-item historical interaction data of ratings, clicks, or engagement trails to locate and analyze user similarities. SVD (Singular Value Decomposition) transforms

the user-item interaction matrix by decomposing it into a set of latent factors that the system can use to uncover hidden user preferences and help outline custom course recommendations by analyzing the adjusted suggestions of comparable users. The UBCF (User-Based Collaborative Filtering) approach, which focuses on learners with comparable profiles, also improves the relevance of recommendations. Latent factor modeling UBCF also solves some of the sparsity issues.

2) Content-Based Filtering (CBF) with TF-IDF: The second module analyzes each course and matches it with user profiles. Using TF-IDF (Term Frequency-Inverse Document Frequency) algorithm, the system analyzes course descriptions, keywords and other textual features and metadata, and assesses the relevance of each course in relation to the learner's prior choices. This component guarantees that the recommendations correspond to the learner's interests and areas of knowledge. In contrast to CF, CBF can algorithmically recommend new courses, thus alleviating cold-start challenges for new items.

3) Contextual modeling with LSTM networks: Incorporating the third constituent, the bloc incorporates contextual information that makes it possible to understand the temporal and situational aspects of user behavior. Using Recurrent Neural Networks (RNNs) with Long Short Term Memory (LSTM) units, it tracks the sequence of data in learner interactions and analyzes the timestamps, devices, and contexts of each session. LSTM networks are designed to remember information for long periods which allows the system to change recommendations as user behavior and preferences shift, enabling situational personalization. For example, it can offer short tutorials when users are likely to be commuting and more comprehensive modules are reserved for heavier study sessions which increases relevance and engagement.

4) Hybrid aggregation mechanism: This last building block combines the results from CF, CBF, and the LSTM-based contextual model. Based on the relevance, reliability, and contextual appropriateness of each module, the recommendations are weighted and aggregated into a comprehensive, context-aware recommendation list. This fusion mechanism maintains equilibrium in the hybrid system while interlocking each model's pivots. Whereas CF focuses on the community trends, CBF captures the content relevance, and the LSTM-based CDM integrates the situational and temporal aspects.

Collectively, these four components provide a powerful, flexible, and expandable framework capable of offering highly personalized e-learning recommendations. In addition to enhancing prediction accuracy, the architecture improves learner satisfaction and engagement by resolving challenges associated traditional models, such as the cold-start problem, static content dependence, and the absence of contextualization.

B. Framework Development Process

Constructing the hybrid framework is based on an organized multi-step pipeline where all parts are built on the edX Course Data dataset.

1) Data preprocessing: The information in the dataset falls into three categories: i) the history of user interactions with items, including clicks, ratings, enrollments, and course completions; ii) course metadata which encompasses description, categories and keywords, as well as information about the instructor; iii) contextual data which includes timestamps, device types, and session information. The cleaning process for this phase involves removing outliers and handling missing values, which requires the use of either imputation or removal techniques. Categorical variables such as user demographics and course categories are encoded through one-hot or label encoding, while numerical features such as ratings and time spent are normalized to a consistent scale.

Moreover, feature engineering refines user interactions to create the user-item interaction matrix for collaborative filtering (CF). For content-based filtering (CBF), course metadata is used to extract TF-IDF features. Additionally, time-series structured contextual data is prepared for training the RNN-based models.

2) Independent model implementations:

- Collaborative Filtering using SVD: The interaction matrix is split into latent factors for users and courses. Ratings for non-evaluated items are predicted using the dot product of these vectors, enabling user-specific recommendations to be tailored.
- Content-Based Filtering using TF-IDF: For textual features of the courses, TF-IDF scores are calculated. Using cosine similarity, a user's preference profile is measured against course content to rank and recommend the most relevant ones, thus enabling course ranking and recommendation.
- Contextual Model using RNN: Sequences of user behaviors along with contextual variables like device used and time are formatted as ordered sequences and used to train the RNN. The RNN LSTM captures temporal regularities and makes predictions for user preference scoring to recommend relevant courses.

3) Score normalization: Each model's CF, CBF, and RNN outputs are normalized to the [0, 1] range using Min-Max Scaling. This normalization guarantees model output comparability and is crucial for effective aggregation.

Before fusion, the outcomes generated by each model, specifically the Collaborative Filtering, Content-Based Filtering, and the Recurrent Neural Network, are scaled down to the $[0, 1]$ interval using the Min-Max scaling method. This step is crucial since the models feature scores that differ in terms of numerical consistency, distribution, and in the case of CBF, may even utilize a distinct calculating method. Model outputs entail dissimilar Merits, valued predictions, range estimates, or probabilities. Without the Min-Max scaling, the more significant the range of a score, the more influence it would have on the fusion process leading to skewed and unreliable recommendations.

In relation to a specific predictive score s_i, that a model outputs for a single learner x item combination, the Min-Max normalization is described as follows:

$$s_i^{\text{norm}} = \frac{s_i - s_{\min}}{s_{\max} - s_{\min}}$$

where, $s_{\min}$ and $s_{\max}$ denote the minimum and maximum scores generated by the model for a given learner–item pair,

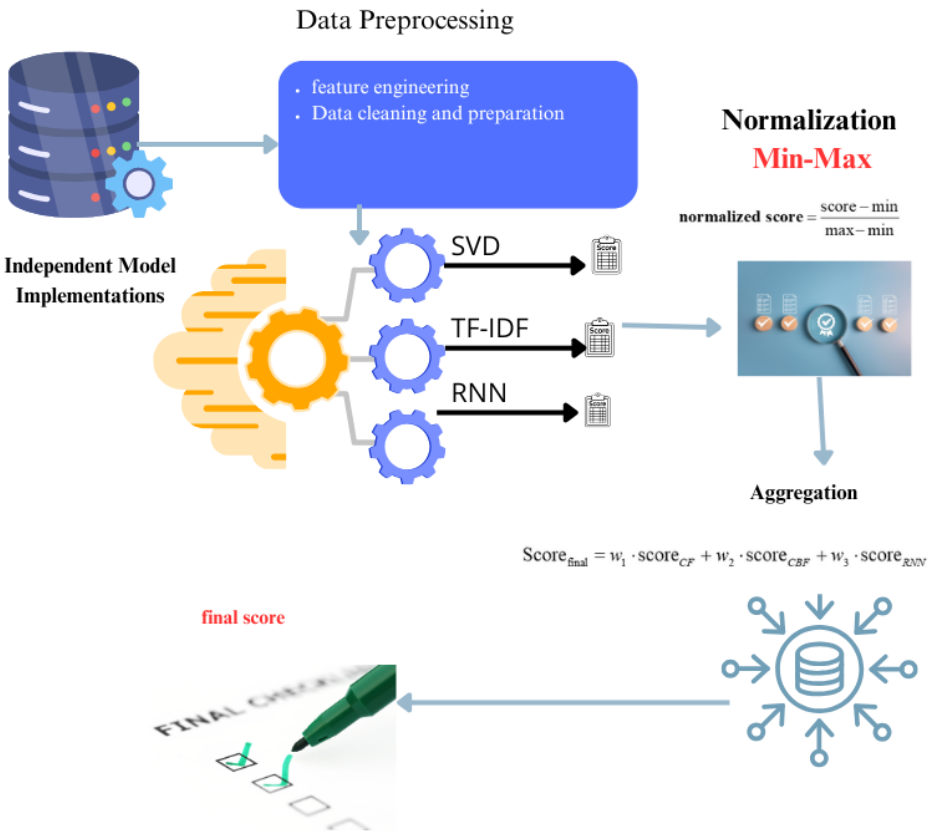

Fig. 1. Framework overview.

respectively, thereby rescaling all outputs to a common range between 0 and 1.

With the normalization process, the same score level is bestowed upon each model, proving a fair ground for comparison, and in-turn a more precise aggregation technique is applied to the weighted fusion layer. This directly increases the quality of each component in the score fusion process and adds more to the system as a whole in terms of reliability, consistency, and more comprehensibility to the hybrid recommender system.

4) Result aggregation: The normalized outputs of the three recommendation models namely the SVD-based collaborative filtering module, the TF–IDF content-based module, and the RNN-based contextual module—are combined using a weighted hybrid aggregation strategy. Each model is assigned a weight according to its predictive performance on the validation set, such that models achieving higher accuracy (i.e., lower prediction error) contribute more to the final recommendation; the corresponding computed weight values are reported in Table I.

Let E_i denote the prediction error of model i, measured using RMSE or MAE. The adaptive weight w_i associated with each model is computed as the normalized inverse of its error:

$$w_i = \frac{\frac{1}{E_i}}{\sum_{j=1}^{3} \frac{1}{E_j}} \tag{1}$$

This formulation ensures that models with lower prediction errors receive higher weights, thereby exerting greater influence on the final recommendation score. For instance, if the RNN model achieves the lowest RMSE among the three, it is assigned the largest weight, followed by the TF–IDF and SVD models.

Let $S_i(u,k)$ represent the normalized score produced by model i for user u and course k. The final hybrid recommendation score is then computed as:

$$\begin{aligned} S(u,k) = {} & w_{\text{SVD}}\, S_{\text{SVD}}(u,k) \\ & + w_{\text{TF-IDF}}\, S_{\text{TF-IDF}}(u,k) \\ & + w_{\text{RNN}}\, S_{\text{RNN}}(u,k) \end{aligned} \tag{2}$$

This adaptive fusion mechanism enables the recommender system to dynamically balance collaborative, content-based, and contextual signals according to their reliability under the current data conditions. As a result, the hybrid model achieves greater robustness and predictive accuracy than any individual component, while remaining responsive to variations in learner behavior and contextual factors.

5) Evaluation: Evaluate the performance of the individual models and the hybrid system using the following metrics: Precision@K: Measures the proportion of relevant items in the top-K recommendations, and the Recall@K: Assesses the fraction of relevant items retrieved out of all applicable items,

TABLE I. ADAPTIVE WEIGHTING OF SVD, TF–IDF, AND RNN MODULES BASED ON RMSE.

Module	RMSE	Weight w_i
SVD	0.902	0.30
TF–IDF	0.856	0.32
RNN	0.812	0.38

Normalized Discounted Cumulative Gain (NDCG): Takes into account the rank position of recommendations, giving higher importance to higher-ranked items,Root Mean Squared Error (RMSE): Evaluates the accuracy of the predicted ratings, comparing the difference between predicted and actual values. Algorithm 1 and Algorithm 2 presents the hybrid recommendation systems.

IV. RESULTS AND DISCUSSION

This section describes how we evaluated hybrid e-learning recommender systems using the rich edX Course Data. As data collected from millions of learners around the globe, it incorporates different views to analyze learner disposition. As we developed and tested advanced recommendation systems, the data also allows us to understand learner behavior, course content and the context within which the recommendations were made.

The dataset consists of three major parts. The first part containing data of user interactions records course enrollments and completions, audit, ratings, and detailed activity logs. Every interaction captures unique and important behavioral components of learners thus helping to model long-term interest and short-term engagement. Such user behavior data allows the recommender system to not only find and cluster learners with similar and competing interests but also track the dynamic order and sequence of courses to predict the next course a learner might be interested in.

The course metadata contains both structured and unstructured texts, for example, course titles, descriptions, types, keywords, and other content descriptors. This information is essential for the content-based filtering component, as it allows cross matriculation of learner profiles and courses with pertinent characteristics. The richly developed text features provide enough information for the model to capture the semantics of various courses, allowing it to recommend those that best align with what the learner has engaged with or indicates interest in.

A. Dataset

The datasets used in this research study are collected from edX, a popular resource for academic research in e-learning and educational recommendation systems. The dataset includes a total of five thousand learners, one thousand learning resources, and five thousand unique user-to-resource interactions, indicating a collection of diverse learning behaviors and content engagement patterns.

User-resource interactions can be classified to indicate whether a learner has performed an action with a particular educational resource. Actions may include registering for a course, browsing content, watching videos, or submitting assignments. These action behaviors are used as signals within the collaborative filtering component to learn user preferences, while the TF–IDF descriptive and textual resource data learn user content preferences. Additionally, the data collected over time helps the RNN capture and model the time dimensions of learning behaviors to address the shift in learners' interests and learning paths.

A standard hold-out protocol was used to split the dataset into two non-overlapping subsets for model training and evaluation: 80% of the dataset was allocated for training, while the remaining 20% was set aside for testing. Such a split guarantees that the models being learned will only be evaluated on previously unseen interactions, which gives a trustworthy assessment of their generalization capability. Thanks to the user diversity, content richness, and the presence of temporal interaction data, the edX dataset stands out to evaluate context-aware and hybrid recommender systems in real-world e-learning environments.

B. Hyperparameters

The performance of the proposed hybrid recommender system strongly depends on the appropriate tuning of the hyperparameters of its three constituent modules, namely the SVD-based collaborative filtering model, the TF–IDF content-based model, and the LSTM-based contextual model. To ensure a fair and reproducible evaluation, the hyperparameters were selected through validation experiments and empirical tuning, balancing model complexity and generalization ability. The final configuration adopted for all experiments is reported in Table II.

For the SVD component, the number of latent factors controls the dimensionality of the user–item interaction space and directly influences the model's ability to capture hidden preference patterns. The learning rate and regularization term were carefully adjusted to ensure stable convergence and prevent overfitting, as summarized in Table II. In the TF–IDF module, parameters such as the n-gram range, vocabulary size, and document frequency thresholds were optimized to generate informative and discriminative content representations while reducing noise and sparsity.

For the LSTM-based contextual model, key hyperparameters, including the embedding dimension, number of hidden units, sequence length, dropout rate, and optimization settings, were tuned to effectively model temporal dependencies in learners' interaction histories without excessive complexity. These settings, detailed in Table II, enable the LSTM to capture evolving learning behaviors while maintaining stable and efficient training. Overall, the hyperparameter configuration reported in Table II ensures that the three modules operate in a balanced and complementary manner, allowing the hybrid framework to fully exploit collaborative, content-based, and contextual information in the recommendation process.

C. Evaluation Results and Discussion

Alongside evaluating the proposed hybrid recommender system's overall performance, we also examined its performance with and without contextual data. The results indicate that including contextual information considerably improves the system's effectiveness, as demonstrated in Fig. 2. While

Algorithm 1 Hybrid Recommendation System

    rmse = CALCULATE_RMSE(final_scores, ground_truth)
    return precision, recall, ndcg, rmse
end function
```

session time, device type, user location, and interaction sequences are used as contextual data, this information helps the model to adapt its recommendations to the learner's situation, increasing engagement and the relevance of recommended courses.

The hybrid recommender system continues to achieve higher results across all the evaluation measures—Precision, Recall, F1-Score, and Mean Absolute Error (MAE)—than the baseline models [e.g., standalone Collaborative Filtering (CF) and Content-Based Filtering (CBF)], as shown in Fig. 3. The hybrid system results include, 0.75 precision, 0.68 recall, and 0.71 F1-score, while the CF results were 0.68 precision, 0.60 recall, and 0.63 F1-score, and CBF results were 0.70 precision, 0.64 recall, and 0.67 F1-score. The hybrid system delivered a 0.18 MAE, underscoring the improved predictive accuracy with the combination of user behavior and contextual data from the edX dataset. This compares to 0.21 with CF and 0.20 with CBF.

The hybrid framework, SVD-based CF, and deep learning-based (LSTM) models were additionally analyzed comparatively. Evaluation through all four primary metrics validates that, in most instances, the hybrid method performed best,

TABLE II. HYPERPARAMETERS OF THE SVD, TF–IDF, AND LSTM MODULES

Module	Hyperparameter	Description	Value / Setting
SVD (CF)	Latent factors (k)	Dimensionality of the user/item latent space	50
	Learning rate (η)	Step size for gradient updates	0.005
	Regularization (λ)	L2 penalty to reduce overfitting	0.02
	Epochs	Number of training iterations	50
	Initialization	Latent vector initialization strategy	Random (Gaussian)
	Loss function	Optimization objective for rating/implicit signal prediction	MSE
TF–IDF (CBF)	n-grams	Token range for feature extraction	(1,2)
	Vocabulary size	Maximum number of features retained	20,000
	Minimum document frequency (min_df)	Ignore rare terms below threshold	2
	Maximum document frequency (max_df)	Ignore overly frequent terms above threshold	0.90
	Normalization	Vector normalization scheme	L2
	Similarity metric	Similarity computation between course profiles	Cosine
LSTM (Context)	Embedding dimension	Size of interaction/context embedding	128
	Hidden units	Number of LSTM hidden neurons	128
	Number of LSTM layers	Depth of the recurrent network	1
	Dropout	Dropout rate for regularization	0.30
	Sequence length (T)	Number of past interactions used as input	20
	Batch size	Number of samples per training batch	64
	Optimizer	Optimization algorithm	Adam
	Learning rate	Step size for optimizer	0.001
	Epochs	Number of training iterations	30

TABLE III. COMPARATIVE PERFORMANCE OF RECOMMENDATION METHODS

Method	Precision	Recall	F1-Score	MAE
DL-based (NN)	0.73	0.66	0.69	**0.17**
SVD (Classic MF)	0.68	0.60	0.63	0.22
SVD + Tf-IDF + RNN (Our method)	**0.75**	**0.68**	**0.71**	0.18

see Fig. 4. For precision, the hybrid method achieved 0.75, ahead of the DL-based method's 0.73 and SVD's 0.68. The hybrid method also led in recall, attaining 0.68, greater than DL-based's 0.66 and SVD's 0.60, as shown in Table III. The hybrid system also achieved the best F1-score of 0.71, while the DL-based models scored 0.69 and SVD scored 0.63. The

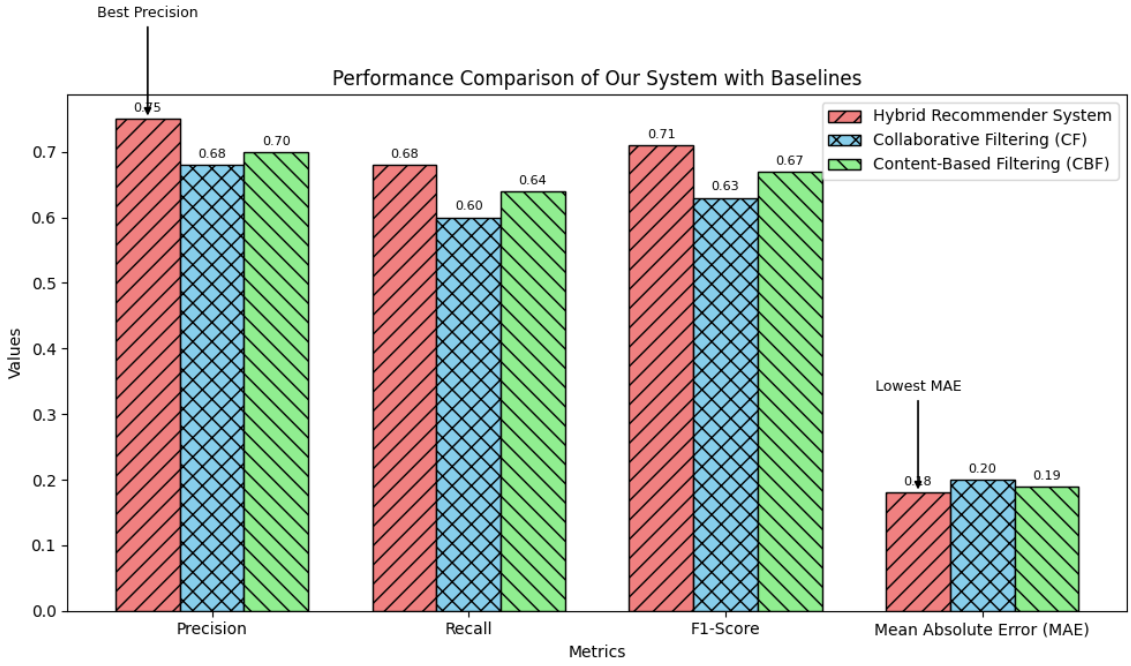

Fig. 3. Performance comparison of our system with baselines.

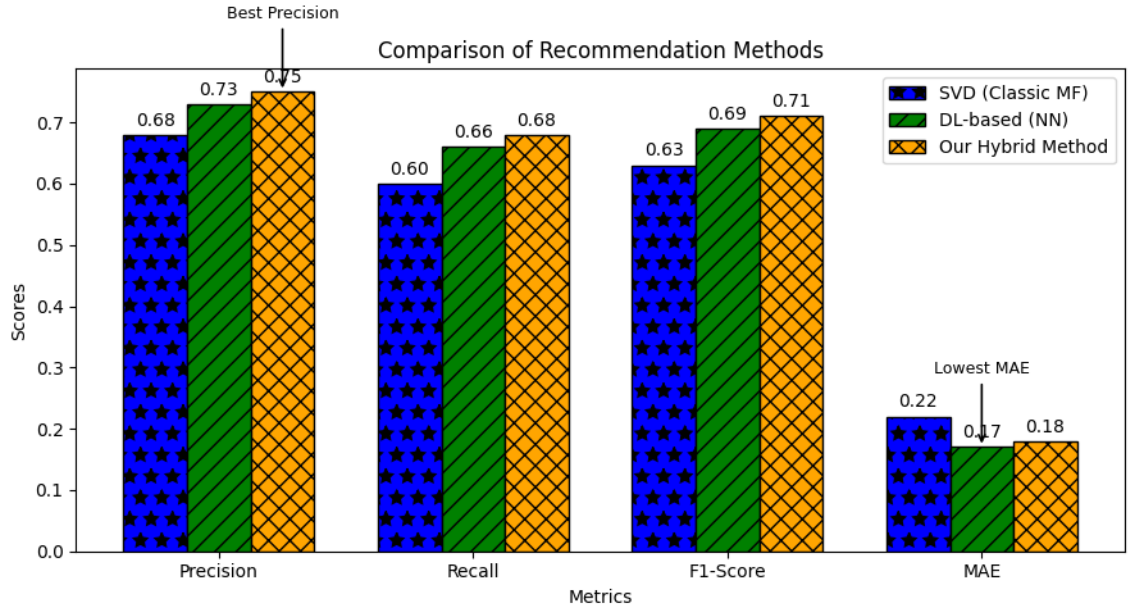

Fig. 4. Comparison of recommendation methods.

DL-based method had a slight edge in MAE, scoring 0.17, while the hybrid scored 0.18, and SVD scored 0.22. The hybrid system makes a balanced improvement by confirming active adjustments to the accuracy, as well as the error reduction, as it provides concrete evidence to the system's reliability and robustness.

As highlighted in this analysis, there are benefits to integrating CF, CBF, and contextual information. CF is good at predicting preferences based on user behavior, but it does not work well in the case of new users or courses with sparsely populated interaction history. CBF somewhat mitigates the cold-start problem, but is not able to adapt to shifting user behavior and situational dynamics. The hybrid approach improves on this by combining the methods with contextual data and producing suggestions based on learner preferences and situational constraints present in the real-world. For example, if users are engaged in short study sessions, the system

suggests quick, shorter courses, while in the case of longer study sessions, it suggests comprehensive longer modules. This recommend system improves user satisfaction and engagement, which is especially important in the dynamic context of e-learning.

There are, however, unsolved issues. In some cases, sparse contextual data for user profiles, new users especially, or under-enrolled courses, may constitute a limit to system performance, even with contextual data augmentation. Furthermore, the need to combine multiple data sources poses a significant challenge in terms of real-time recommendations. This is likely due to the system requiring excess processing power on large platforms like edX, making it a scalability barrier. Future work could target this problem by optimizing, for example, distributed computing or incremental learning coupled with lightweight neural nets to improve processing speed while preserving the quality of the recommendations.

Enriching the contextual data surrounding users in an e-learning environment increases the value of the recommendations provided. While recommender systems like Collaborative Filtering (CF) and Content-Based Filtering (CBF) offer the basics of personalized recommendations based on historical interactions or static content features, they do not capture the dynamic situations the learner is in. Thousands of interactions provide contextual data on patterns, such as duration of content sessions and timing of access, while device type and geo-location add further dimensions. By these measures, the hybrid recommender system is able to escape the proposition of static recommendations and deliver relevant and actionable suggestions based on the learner's context.

Precision and relevance of the recommendations are enhanced with the addition of contextual data. For instance, learners accessing the platform when taking short breaks would appreciate brief modules or quick tutorials. In contrast, learners engaging in longer study periods are eligible for more extensive courses or multi-part learning paths. This temporal and situational awareness can make recommendations relevant for learners, focusing on their attention spans and immediate needs. This increases the probability of completion and active utilization of recommended courses. Real-time adaptation to changes in conditions creates unprecedented flexibility, accommodating user behavior and preferences, and external limitations, and their behavioral and contextual changes without requiring overriding manual control.

Learning contextual data enhances learner motivation and engagement. Improved engagement and motivation primarily stem from the interaction of contextual information with the designed learning activities. Users are more likely to continue engaging with the platform when contextual data is incorporated into the recommendations. The hybrid system's ability to incorporate contextual factors creates a purposeful and meaningful learning environment that enhances immersion and satisfaction.

Incorporating context-aware hybrid recommender systems sets a new standard in personalized e-learning. Differing from conventional models that rely on fixed features or merely historical features, these systems dynamically adjust to learners as they progress, updating suggestions in real-time with contextual and behavioral information. Such flexibility is important in real e-learning systems to ensure compatibility with varying user demographics and learning situations. Use hybrid systems maximize contextual information; they effectively improve outcomes, adjust learning personalization and support high flexibility educational systems, paving the way for advanced smart educational frameworks.

V. Conclusion

This work was the first to combine Collaborative Filtering, Content-Based Filtering, and Contextual Data Modeling into a hybrid e-learning recommender system to create context-aware, personalized e-learning course recommendations. Using the additional and overlapping strengths of the aforementioned frameworks decreased some of the major drawbacks of conventional recommender systems, including underexploited cold-start and data sparsity situations, excessive overspecialization of recommendations, and a failure to address shifting user needs and preferences. Some of the advanced algorithms implemented in this hybrid system include Singular Value Decomposition (SVD) for latent factor analysis, TF-IDF for content feature extraction, and Long Short-Term Memory (LSTM) networks for temporal and contextual user behavior modeling.

The hybrid system, which was evaluated on the edX course dataset, consistently surpassed solo CF and CBF baseline models on metrics such as precision, recall, F1 score, and Mean Absolute Error (MAE), as well as on multiple other metrics. Contextual data such as the user's device, session duration, and location accessed data, which was incorporated into the system, significantly improved the precision and utility of the recommendations. Lastly, the fusion mechanism, which integrates the disparate evaluation systems within each of the three components, offers the system a high degree of flexibility and robustness in addition to balance, accuracy, diversity, and adaptability in its recommendations.

Research contributions are as follows: First, this work presents a unified hybrid framework combining collaborative, content-based, and context-aware strategies for e-learning. Second, this work illustrates the synergistic use of SVD, TF-IDF, and LSTM in tackling common problems in recommendation systems. Third, this work uses educational real-world data as evidence that the proposed framework offers a more personalized approach to recommend courses and improves the overall learning experience.

Although there are achievements, limitations and challenges still exist. The system in use is guided by historical and contextual data which may not be complete and accurate, and real-time adaption to user behavior shifts and cross-platform access still can be improved. Furthermore, the protective use of real-time contextual and behavioral data and the systems' data acquired for situational context reveals core challenges of privacy and security.

Subsequent work will target the use of reinforcement learning and deep learning because they can enhance the systems understanding of nuanced user preferences and advanced sequence of learning patterns. The system will be more personalized by incorporating learner goals, motivation, and affect. Finally, system extensibility to permit multi-platform systems, in conjunction with the use of privacy-conscious

strategies for system deployment in e-learning environments is imperative for system's ethical and responsible scalability.

The proposed hybrid and context-aware recommender system represents a strong, adaptable, and extensible approach to personalization in e-learning. Incorporating elements of collaborative, content-based, and contextual mechanisms yields not only enhanced precision and pertinence in recommendations but also sets a foundation for more sophisticated, evolving, and learner-focused approaches to education in the digital age.

ACKNOWLEDGMENT

The authors would like to thank the editors and anonymous reviewers for their valuable comments and constructive suggestions which greatly helped improve the quality and clarity of this manuscript. We also gratefully acknowledge the support of our institution and colleagues who contributed to the completion of this work.

Efficient CNN-Based Time-Domain Denoising of Impulsive Noise in NB-PLC Systems

Wided Belhaj Sghaier, Fatma Rouissi, Héla Gassara, Fethi Tlili
GRESCOM Lab, Ecole Supérieure Des Communications De Tunis, University of Carthage, Tunisia

***Abstract*—In this study, a convolutional neural network (CNN)-based time-domain denoising approach is proposed to suppress impulsive noise which is considered as the most sever impairments in narrowband powerline communications (NB-PLC). Unlike conventional techniques, such as clipping and blanking, the proposed method does not require prior knowledge of noise statistics. The introduced CNN network is trained using synthetically generated OFDM signals corrupted by Middleton Class-A impulsive noise, calibrated from real NB-PLC measurement data. Extensive G3-PLC-compliant simulations demonstrate that the proposed method significantly outperforms classical blanking and clipping schemes. At an SNR of 10 dB, the proposed CNN achieves a mean squared error (MSE) of 1.2×10^{-4}, compared to 2.3×10^{-4} and 2.5×10^{-4} for blanking and clipping, respectively, under time-varying impulsive noise conditions. Moreover, the receiver incorporating the denoising method closely approaches the ideal AWGN reference under low impulsive noise density and for SNR values above 12 dB.**

I. Introduction

In recent years, significant research efforts have been devoted to smart grid applications based on narrowband power line communication (NB-PLC) [1], [2]. This technology enables data transmission over existing power distribution lines within a frequency band below 500 kHz, offering wide coverage at low deployment cost. NB-PLC systems facilitate communication expansion without the need for new infrastructure, as they leverage the already deployed electrical grid. However, the NB-PLC channel which not originally designed for data transmission is subject to several technical impairments. It is characterized by severe multipath propagation resulting from impedance mismatches and network topology variations in the power grid [3]. Moreover, NB-PLC channels are affected by various types of noise, among which impulsive noise is considered one of the most detrimental disturbances. Generated by electrical devices connected to the grid—such as motors, switching power supplies, lamps, and household appliances—impulsive noise can reach power levels up to 50 dB above the background noise [6]. It is widely recognized as a primary performance-limiting factor in NB-PLC systems. It is characterized by high amplitude, short duration, and random occurrence, and deviates significantly from the Gaussian noise assumption commonly used in communication theory. Unlike additive white Gaussian noise (AWGN), impulsive noise generates burst errors that conventional coding schemes struggle to correct, resulting in severe degradation of communication performance [7], [8]. This explains why OFDM modulation, used in NB-PLC systems and forming the basis of the PRIME [10], [11], [12] and G3-PLC [9] standards, is highly vulnerable to impulsive noise [13].

Over the years, various impulsive noise mitigation techniques have been proposed. Early research efforts mainly focused on traditional signal-processing-based solutions. Error-control-based techniques, including channel coding and interleaving, were employed to enhance robustness against channel impairments [14], [15], [16]. In parallel, nonlinear time-domain preprocessing methods such as blanking and clipping were introduced to suppress high-amplitude impulsive disturbances prior to OFDM demodulation [18]. In addition, statistical approaches relying on impulsive noise modeling and parameter estimation were widely investigated [19]. Although these methods are well established and relatively simple to implement, their performance is highly dependent on accurate noise statistics and fixed design parameters, which limits their robustness in practical NB-PLC environments characterized by non-stationary and appliance-dependent impulsive noise.

More recently, the emergence of deep learning (DL) has introduced a data-driven paradigm for impulsive noise mitigation in PLC systems. This capability has motivated extensive research efforts in PLC systems, where deep neural networks have been primarily employed to overcome the limited adaptability of conventional techniques. Early DL-based studies focused on estimating optimal parameters for nonlinear preprocessing methods, such as adaptive threshold selection for clipping and blanking, leading to significant SNR and BER improvements under time-varying impulsive noise conditions [25]. More advanced architectures, including CNN- and LSTM-based models, were subsequently proposed to exploit temporal and multi-domain features of impulsive noise [28], while recent self-supervised approaches have aimed at reducing the reliance on clean reference signals [26].

Despite recent advances in DL-based impulsive noise mitigation for PLC systems, direct end-to-end denoising solutions tailored to NB-PLC receivers remain largely unexplored. Existing studies mainly rely on adaptive parameter estimation for nonlinear preprocessing techniques, complex multi-branch architectures, or self-supervised models that require significant training and implementation effort. To the best of our knowledge, none of these approaches directly estimate the clean signal at the receiver.

In this study, we propose a time-domain CNN to directly suppress impulsive noise and produce a cleaned received signal. This approach is motivated by the proven effectiveness of CNNs in image and signal processing applications [29], [30]. Our CNN architecture is specifically designed for NB-PLC, aiming to enhance data transmission reliability under realistic NB-PLC noise conditions.

The remainder of this study is organized as follows: Section II presents the review of impulse noise cancellation methods. Section III describes the communication system model, details the statistical characteristics of impulsive noise in NB-PLC. Section IV introduces the proposed CNN-based impulsive noise mitigation framework, including the design of the CNN architecture and the dataset generation methodology. Section V reports and discusses the simulation results. Finally, Section VI summarizes the main contributions of this work and outlines potential directions for future research.

II. State-of-the-Art Approaches for Mitigating Impulsive Noise

A. Traditional Impulsive Noise Mitigation Techniques in PLC Systems

Over the years, various impulsive noise mitigation techniques have been proposed, which can be broadly classified into four categories: error-control-based methods, nonlinear preprocessing techniques, statistical model-based approaches, and learning-based methods [31].

Early studies focused primarily on error-control mechanisms at the physical layer. Channel coding techniques such as low-density parity-check (LDPC) codes [14], Turbo codes [15], polar codes [16], and bit-interleaved coded modulation (BICM) [17] were employed to enhance robustness against channel impairments. these techniques improve resilience to Gaussian noise, but are less effective against impulsive noise, as strong impulses cause long error bursts that exceed correction capabilities and reduce efficiency.

To directly suppress impulsive disturbances in the time domain, nonlinear preprocessing techniques such as blanking, clipping, and deep clipping were introduced at the receiver [18]. These methods are attractive due to their simplicity and low computational complexity. However, their performance is highly sensitive to fixed threshold parameters. Since impulsive noise statistics in PLC environments are time-varying and appliance-dependent, fixed-threshold methods lack adaptability and may either fail to suppress noise effectively or distort the useful signal.

Another class of approaches relies on statistical modeling and parameter estimation of impulsive noise. Techniques based on noise parameter estimation [19], cyclostationary noise mitigation [20], and frequency-domain minimum mean square error (MMSE) equalization [21] have been widely investigated. Although these methods are theoretically well-founded, they depend heavily on accurate noise models and precise parameter estimation. In practical NB-PLC scenarios, model mismatch and rapidly changing noise conditions often degrade their performance, while the associated computational complexity limits real-time applicability.

The sparse nature of impulsive noise has been exploited using compressed sensing techniques to estimate and cancel impulsive disturbances in OFDM-based PLC systems [22]. Sparse Bayesian learning (SBL) further improved robustness by providing probabilistic noise estimation [23], and advanced schemes such as sparse iterative covariance estimation were also proposed [24]. Despite their strong performance, these approaches typically require additional null subcarriers, strict sparsity assumptions, and high computational resources, which restrict their practical deployment in low-complexity NB-PLC receivers.

B. Deep Learning Approaches for Impulsive Noise Denoising in PLC Systems

Recently, DL-based approaches have emerged as a promising alternative to overcome the limited adaptability of traditional threshold-based and model-driven techniques. Classical methods such as clipping, blanking, or statistical filtering rely on fixed parameters or strong assumptions about noise distributions, which are often violated in real PLC environments characterized by non-stationary and appliance-dependent impulsive noise. In contrast, DL-based methods learn noise characteristics directly from received data, enabling adaptive and robust suppression under dynamic conditions [25], [26].

Early DL-based works in PLC primarily focused on adaptive parameter estimation rather than direct end-to-end denoising. For example, in [25], convolutional neural network (CNN)-based approaches were proposed to estimate optimal clipping and blanking thresholds for time-domain impulsive noise mitigation in OFDM-PLC systems. These methods approximate optimal signal-to-interference-plus-noise ratio (SINR)-driven thresholds under clustered impulsive noise from household appliances. Simulation results demonstrated SNR gains of approximately 3–5 dB compared to fixed-threshold methods, leading to improved BER performance in time-varying noise environments.

To further enhance robustness and remove the need for handcrafted preprocessing, end-to-end DL architectures were introduced. In [27], the Multi-Feature Space Domain Fusion Network (MFSDF-Net) was proposed for impulsive noise suppression in MIMO-PLC systems. This CNN-based model extracts and fuses features from parallel convolution kernels operating in different spatial domains, enabling effective mitigation of asynchronous impulsive noise without requiring null subcarriers. Compared to traditional clipping/blanking and earlier DL models, MFSDF-Net significantly reduces BER floors and achieves an SNR of 18 dB at a BER of 10^{-5}, compared to 26 dB or higher for other models, corresponding to an 8 dB improvement in highly dynamic environments.

In another study [28], LSTM-based adaptive mitigation schemes were introduced to track impulsive noise states over time and dynamically adjust clipping decisions using sliding windows. These methods were combined with peak-to-average power ratio (PAPR) reduction techniques, such as accelerated proximal gradient methods and differential phase time encoding, to protect useful OFDM signals. Simulation results showed clear BER improvements over conventional nonlinear methods, particularly under rapidly changing impulsive noise conditions.

More recently, self-supervised models such as UNet-INSN have marked a shift toward label-free training. In [26], the authors proposed UNet-INSN, a 1D UNet-based architecture trained without clean reference signals. The model employs a global mask mapper and a reproducibility loss to prevent identity mapping, allowing training directly on noisy PLC signals. In simulations, UNet-INSN achieves a BER of 10^{-6} at approximately 12 dB SNR with ideal channel estimation and

26 dB with non-ideal estimation. It outperforms Noise2Void by about 3 dB, Zero-Shot Noise2Noise by 4 dB, and Deep-Clipping by nearly 7 dB, while maintaining less than 1 dB degradation when the impulsive noise probability varies from 0.01 to 0.05. These results demonstrate strong robustness in coded MIMO-PLC systems.

C. Blanking and Clipping-Based Time-Domain Noise Mitigation Approaches

Traditional time-domain impulsive noise suppression methods are memoryless nonlinear techniques that adjust the signal amplitude based on predefined thresholds while preserving its phase [31], [25]. Applied to the received signal prior to FFT demodulation in OFDM systems, the most used in the literature are blanking and clipping [31].

In the blanking technique, the received signal sample y_s is set to zero whenever its amplitude exceeds a predefined blanking threshold T_b, and remains unchanged otherwise [see Eq. (1)]:

$$y_s = \begin{cases} y_s, & |y_s| < T_b, \\ 0, & |y_s| \geq T_b. \end{cases} \tag{1}$$

The clipping method limits the signal amplitude to a clipping threshold T_c while preserving the phase, and is defined as Eq. (2):

$$y_s = \begin{cases} y_s, & |y_s| < T_c, \\ T_c \cdot e^{j \arg(y_s)}, & |y_s| \geq T_c. \end{cases} \tag{2}$$

Blanking and clipping scheme performances are highly dependent on the choice of the threshold. An inadequately selected threshold can either remove useful signal samples (over-blanking/clipping) or fail to suppress impulsive noise effectively (under-blanking/clipping), leading to significant BER degradation. Many classical approaches determine the threshold through exhaustive offline optimization for each SNR level, providing near-optimal performance but being computationally prohibitive for real-time implementation. Other works set the threshold as a multiple of the noise standard deviation; however, such fixed thresholds are highly sensitive to variations in noise statistics and are not robust in dynamic NB-PLC environments. More analytical approaches derive optimal thresholds based on closed-form SNR expressions, yet they generally assume prior knowledge of SINR/SNR, which is difficult to estimate accurately in practice [31], [32], [25].

Consequently, the practical applicability of thresold-based methods remains limited, motivating the development of data-driven deep learning approaches. These methods either aim to estimate optimal threshold or to detect the temporal positions of impulsive noise events prior to applying classical nonlinear mitigation techniques.

In this work, a CNN-based deep learning framework is proposed to directly estimate the clean signal without explicitly inferring the nonlinear processing parameters or requiring prior estimation of SINR or SNR at the receiver.

III. System Architecture

We investigate an NB-PLC OFDM communication system compliant with the G3-PLC specification, operating in the FCC frequency band ranging from 154.6875 kHz to 487.5 kHz, as defined by the ITU-T G.9903 standard [9]. Each physical frame contains $N_s = 12$ OFDM symbols. The system employs 128 subcarriers with an IFFT size of 256, resulting in a subcarrier spacing of 4.6875 kHz is performed over $N_d = 72$ active subcarriers using BPSK modulation. The cyclic prefix (CP) is added to each OFDM symbol to mitigate inter-symbol interference. The G3-PLC parameters for FCC band are detailed in Table I [9] and the block diagram of the G3-PLC OFDM is depicted in Fig. 1.

TABLE I. Key Parameters of G3-PLC in FCC Band Configuration [9]

Parameters	Value
Active subcarrier (N_d)	72
IFFT size	256
Subcarrier spacing	4.6875 kHz
OFDM symbols (N_s)	12
CP duration	30
Modulation type	BPSK
Operating frequency range	154.7–487.5 kHz

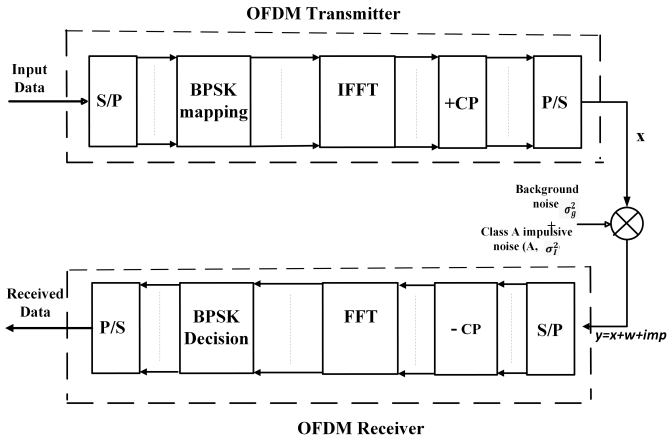

Fig. 1. Block diagram of G3-PLC OFDM system transceiver.

At the transmission side, coherent BPSK is employed for modulation.

The received signal $y(t)$ affected by impulsive noise, is expressed as Eq. (3):

$$y(t) = x(t) + w(t) + imp(t), \tag{3}$$

where, $x(t)$, $w(t)$ and $imp(t)$ denote transmistted signal, the additive white Gaussian noise (AWGN) and impulsive noise, respectively. After cyclic prefix removal and FFT blocks are applied, decision making for BPSK demodulation is performed.

A. Impulsive Noise Model

Numerous statistical models have been proposed in the literature to describe the impulsive noise [4], [5]. Among them the Middleton Class-A model is the most commonly used and has been extensively validated for NB-PLC environments.

The probability density function (PDF) of the Middleton Class-A noise is given by Eq. (4) [5]:

$$f_A(x_k) = \sum_{m=0}^{\infty} \frac{A^m e^{-A}}{m!} N(x_k, 0, \sigma_m^2), \tag{4}$$

where, x_k denotes the noise sample observed at discrete time index k, and A is the impulsive index, which controls the average density of impulsive events within a given observation interval. The term $N(x_k, 0, \sigma_m^2)$ represents a zero-mean Gaussian probability density function with variance σ_m^2, defined as Eq. (5):

$$\sigma_m^2 = \frac{\sigma_i^2}{A} m + \sigma_g^2 = \sigma_g^2 \left(\frac{m}{\tau} + 1 \right), \tag{5}$$

where, σ_i^2 denotes the variance of the impulsive noise component, σ_g^2 is the variance of the background gaussian noise, and $\tau = \sigma_g^2/\sigma_i^2$ represents the impulsive-to-Gaussian noise power ratio.

The magnitude of the impulse and the moment at which it occurs are key parameters of impulsive noise, as they fully characterize its behavior in the time domain, which are sufficient to describe its impact on the received signal. In NB-PLC channels, a single impulsive event typically corrupts one or a few signal samples, however, due to the FFT operation, its energy is spread over all subcarriers, leading to significant performance degradation if not properly mitigated.

IV. Proposed DL-Based Approach for Impulsive Noise Mitigation in NB-PLC Systems

CNNs are well suited for impulsive noise mitigation due to their ability to capture local patterns and abrupt signal variations caused by sparse, high-amplitude noise events.

Next, details of the CNN-based approach to suppress the impulsive noise are given, including the network architecture and the dataset generation process.

A. CNN-Based Impulsive Noise Mitigation In NB-PLC Receivers

The proposed CNN-based PLC signal denoising architecture is integrated into the OFDM receiver processing block, as illustrated in Fig. 2. It is placed before the serial-to-parallel conversion, CP removal, and FFT block within the OFDM receiver. The network input consists of time-domain samples arranged as a tensor of size $[1 \times 3432 \times 2]$, and the model is trained to estimate the corresponding clean signal.

The design of the CNN architecture, including the number of convolutional layers and kernel dimensions, is not based on heuristic assumptions, but is derived from a systematic experimental optimization performed during the offline training stage. The resulting architectural parameters are discussed in detail in Section V-A.

B. CNN Structure

The choice of CNNs model is motivated by prior work in wireless communication systems, which has consistently shown their superior effectiveness in denoising tasks. CNNs employ multiple learnable filters across successive layers to capture and refine complex structures in noisy observations enables [33], [34]. Moreover, their hierarchical architecture multiscale feature learning, a which is essential for effectively separating noise components from the underlying useful signal [33].

The proposed CNN architecture, depicted in Fig. 3, is formulated as a regression model. It is composed of five convolutional blocks, where the third and fifth blocks are replicated to reinforce feature learning capabilities, in addition to the input and output layers. The network input consists of a three-dimensional tensor of size $[1 \times 3432 \times 2]$, obtained after applying Z-score normalization to the received noisy OFDM samples.

Each convolutional block comprises a convolutional layer, followed by Batch Normalization and a Leaky ReLU activation function. The convolutional layers employ learnable kernels with *same* padding in order to maintain the spatial dimensions of the feature maps. Batch Normalization is used to reduce internal covariate shift and improve training stability, while the Leaky ReLU activation alleviates neuron saturation and facilitates faster convergence [33], [34]. The output stage consists of a final convolutional layer followed by a regression layer that produces the estimated clean signal with dimensions $[1 \times 3432 \times 2]$.

The convolutional layers are denoted using the format `conv | $K_s \times K_s$ | Num | same`, where `conv` represents a convolutional operation, K_s (9, 5, 3) indicates the kernel size, *Num* specifies the number of filters, and `same` denotes dimension-preserving padding. Employing convolutional kernels of varying sizes enables the network to effectively model impulsive noise patterns while retaining essential signal structures [37].

The proposed DL-network is trained using a dedicated dataset that reproduces the impulsive noise characteristics typical of NB-PLC channels. This training strategy allows the model to effectively cope with the temporal variability of the impulsive noise, thereby enabling accurate estimation of the clean OFDM signal under realistic NB-PLC operating conditions.

C. Dataset Generation

A diversified dataset is constructed to train the proposed OFDM-based model, considering exclusively the effect of the impulse noise presence in the NB-PLC channel. The noise is modeled using the Middleton Class-A distribution [5]. This synthetic data generation strategy ensures sufficient variability for robust network training while excluding channel effects such as multipath fading or attenuation. The modeled noise is directly added to the transmitted OFDM signals to construct the noisy dataset, providing realistic training samples for the proposed impulsive noise mitigation approach.

The training dataset for the CNN is constructed as follows: A total of 72 000 observations, each corresponding to

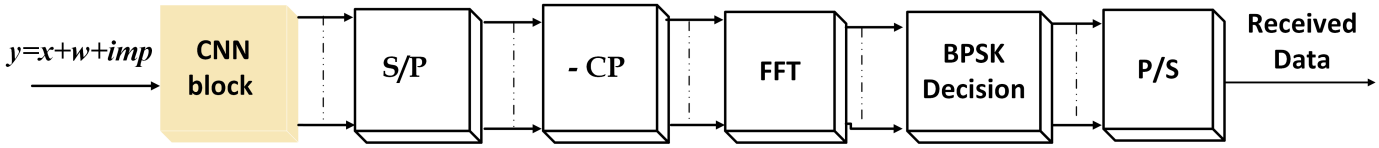

Fig. 2. Block diagram of the OFDM receiver incorporating the CNN model for impulsive noise mitigation.

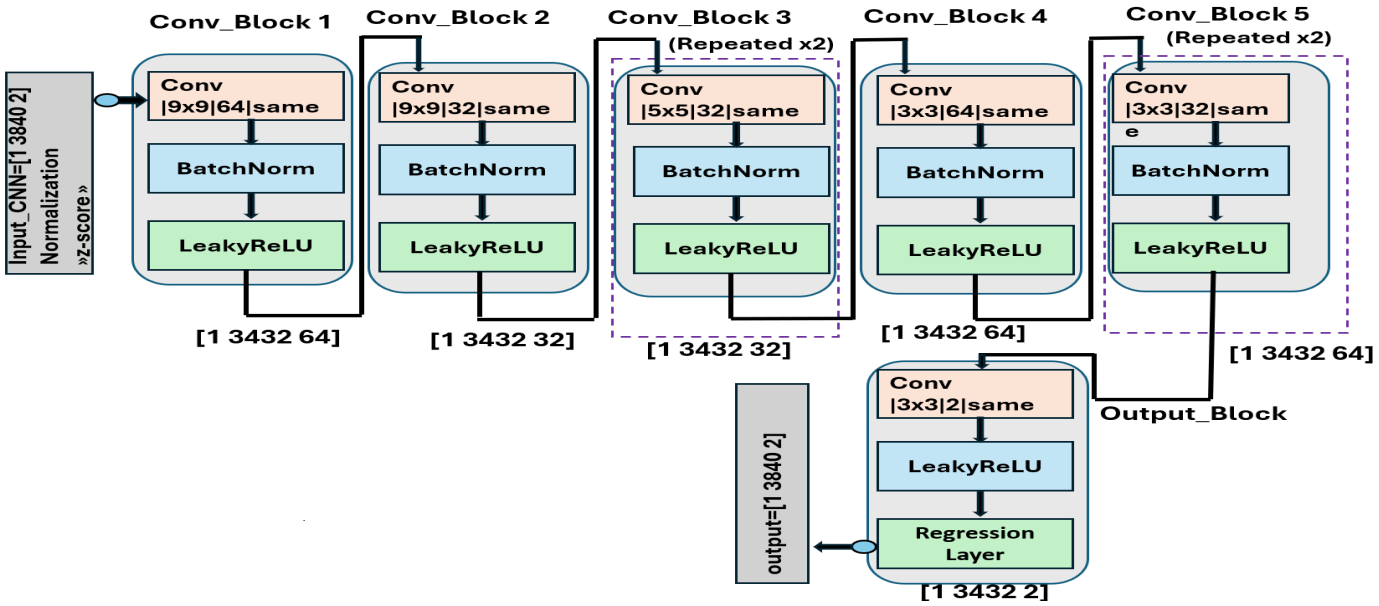

Fig. 3. CNN model architecture for impulsive noise suppression.

one OFDM frame, are generated. The dataset is organized into three blocks corresponding to different impulsive noise densities, with the Middleton Class-A parameter A set to 0.01, 0.1, and 0.5, respectively.

For each value of A, a total of 3 000 OFDM frames are generated and distributed across the SNR range from 0 to 30 dB in increments of 4 dB. This construction ensures a balanced representation of SNR conditions for each impulsive noise density and allows the network to jointly learn the variability of both A and SNR.

The impulsive noise is modeled according to the Middleton Class-A distribution with fixed parameters $\sigma_I^2 = 7.28 \times 10^{-4}$, $\Gamma = 0.01$, and $\sigma_G^2 = 7.28 \times 10^{-7}$, which were extracted from experimental measurements conducted by our research group using a Tektronix TDS3000C oscilloscope [5]. In addition, AWGN noise is added according to the target SNR.

The received noisy signals y, as defined in Eq. (3), serve as the input data. These complex-valued time-domain signals are preprocessed and represented as tensors of size $[1 \times 3432 \times 2]$. The first dimension corresponds to a single OFDM frame, the second dimension (3432) denotes the total number samples per OFDM frame including the CP, and the third dimension represents the complex signal components, with separate channels for the real and imaginary parts.

The label data consist of clean OFDM frames transmitted in the absence of impulsive noise. These reference signals are represented using the same tensor dimensions $[1 \times 3432 \times 2]$.

Consequently, the complete dataset is organized as 4D tensors of size $[1, 3432, 2, N_1]$, where $N_1 = 72000$ denotes the total number of training samples. Z-score normalization is applied to the input tensors to enhance numerical stability and accelerate network convergence.

V. Simulation Results and Discussion

To evaluate the performance of the proposed estimation approach in an OFDM-based NB-PLC system affected by impulsive noise, an extensive simulation campaign was conducted using a BPSK-OFDM transceiver compliant with the G3-PLC standard, as described in Section III. The impulsive noise samples are synthetically generated according to the Middleton Class-A model with fixed parameters $\sigma_i^2 = 7.28 \times 10^{-4}$,$\sigma_g^2 = 7.28 \times 10^{-7}$, and $\tau = 0.01$. The system performance is evaluated under various SNR conditions ranging from 0 to 30 dB and different levels of impulsive noise density.

For comparison purposes, conventional blanking and clipping schemes, were also evaluated, with optimal thresholds determined through an exhaustive search over the normalized threshold range $Th \in [0, 5]$ using a step size of $\Delta T = 0.01$. For each set of impulsive noise parameters, the threshold that minimizes the output BER is selected [25], [36].

All simulation scenarios were run on a Dell G15 5530 notebook featuring a 13th-generation Intel Core i7-13650HX CPU (14 cores, 20 logical threads, base frequency of 2.6 GHz), 32

GB of memory, and the 64-bit version of Microsoft Windows 11 Home.

A. Offline Training and Online Deployment of the Proposed CNN-Based Denoising Model

1) Offline training phase: The constructed dataset is randomly partitioned into training, validation, and testing sets with proportions of 80%, 10%, and 10%, respectively. The validation subset is solely employed to track the learning process and mitigate overfitting during training. Prior to network training, the time-domain input frames are standardized using Z-score normalization, which enforces zero mean and unit variance, thereby improving numerical stability and accelerating convergence of the CNN.

To identify the optimal CNN architecture, a tuning study is conducted by monitoring the mean squared error (MSE) loss function L_{MSE} defined in Eq. (6). The goal is to select a model configuration that achieves the lowest L_{MSE} while keeping the computational complexity within reasonable limits.

$$L_{\text{MSE}}(\Phi) = \frac{1}{K_T} \left\| \mathbf{O}_T - \mathbf{O}_T^* \right\|_2^2, \tag{6}$$

where, $\mathbf{O}_T \in \mathbb{R}^{K_T}$ denotes the complete set of target values in the training dataset, $\mathbf{O}_T^* \in \mathbb{R}^{K_T}$ represents the network's estimates, K_T is the total number of training samples, and $\Phi = \{\Phi_1, \Phi_2, \ldots, \Phi_L\}$ contains all trainable parameters of the network, with L being the total number of layers.

The CNN incorporates convolution kernels of different sizes (9×9, 5×5, and 3×3) to effectively capture impulsive noise characteristics while preserving the underlying signal.

The final optimized hyperparameters, summarized in Table II, are selected to minimize the loss function and provide considerably improved training stability and generalization performance of the CNN.

TABLE II. OPTIMIZED SET OF TRAINING HYPERPARAMETERS FOR THE CNN-BASED NB-PLC DENOISING MODEL

Hyperparameter	CNN Model
Optimizer	Adam
Max Epochs	20
Initial Learning Rate	10^{-3}
L2 Regularization	10^{-4}
Mini-Batch Size	32
Input Size	Tensor $[1, 3432, 2]$
Output Size	Tensor $[1, 3432, 2]$

To assess the performance of the trained CNN, the coefficient of determination R^2 and the MSE are computed on the testing dataset, as defined in Eq. (7) and Eq. (8) [35]:

$$R^2_{\text{Testing}} = 1 - \frac{\sum_{i=1}^{K_{\text{Test}}} \left(TO_i - TO_i^*\right)^2}{\sum_{i=1}^{K_{\text{Test}}} \left(TO_i - \overline{TO}_i\right)^2}, \tag{7}$$

$$MSE_{\text{Testing}} = \frac{1}{K_{\text{Test}}} \sum_{i=1}^{K_{\text{Test}}} \left(TO_i - TO_i^*\right)^2, \tag{8}$$

where, TO_i denotes the actual target value of the i-th testing sample, TO_i^* represents the value estimated by the CNN model, $\overline{O}_{Test}$ is the mean of the target values in the testing set, and K_{Test} is the total number of testing samples.

The results show that the CNN model close to very low MSE value (7.0159×10^{-5}) and an R^2 value approaching 1 (≈ 0.91), indicating a highly accurate estimation.

Fig. 4 shows the training and validation loss evolution over 20 epochs. A rapid decrease is observed during the first epochs, indicating efficient learning of the underlying data representation. Both losses converge smoothly and remain closely aligned throughout training, demonstrating good generalization capability and the absence of overfitting. After approximately 14 epochs, the loss stabilizes around 0.15, suggesting that the model has reached convergence and additional training provides limited improvement.

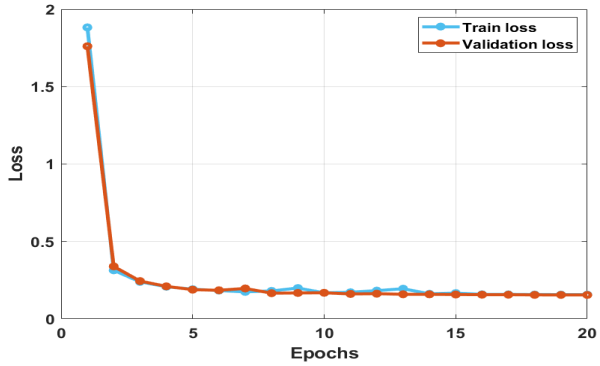

Fig. 4. Training and validation loss curves of the proposed CNN.

2) Online deployment phase: During the online testing phase, 10000 OFDM frames are transmitted under SNR conditions ranging from 0 to 30 dB with a 4 dB step. The frames are corrupted by impulsive noise realizations not used during training enabling a rigorous evaluation of the model's generalization capability under unseen noise conditions. Each transmission consists of a single OFDM frame containing 12 OFDM symbols.

B. Performance Evaluation and Analysis

The performance of the proposed CNN-based mitigation technique is evaluated in terms of MSE and BER, with results averaged over 10000 transmitted OFDM frames for each SNR value. Three distinct simulation scenarios are considered to benchmark this approach against reference schemes:

- A fixed impulsive index parameter A=0.1;
- A fixed impulsive index parameter A=0.5;
- A time-varying parameter A randomly drawn for each OFDM frame from a uniform distribution in the range [0.01, 0.5] to emulate dynamically varying impulsive noise conditions in realistic NB-PLC environments.

The performance of the proposed CNN-based denoising approach is finally compared with conventional blanking and clipping methods, where their thresholds are set to optimal values to maximize noise mitigation performance.

Fig. 5 shows the BER versus SNR for different impulsive noise mitigation methods, with the impulsive index parameter set to $A = 0.1$, the system without any mitigation suffers severe degradation, with a BER around 10^{-2} even at SNRs above 20 dB. This error floor highlights the dominant effect of unmitigated impulsive noise, which persists even when AWGN becomes negligible.

Classical methods such as Clipping and Blanking significantly improve performance. At SNR = 10 dB, Clipping reduces the BER to approximately 2×10^{-3}, while Blanking achieves 1×10^{-3}. A gain of 13 dB at a BER of 10^{-2} is observed compared to the untreated system. At SNR = 20 dB, Clipping and Blanking reach 1.2×10^{-5} and 2.31×10^{-6}, respectively. These methods show a consistent slope, demonstrating good adaptation to increasing SNR and confirming their effectiveness for attenuating impulsive noise in NB-PLC channels, at the cost of an additional processing step to determine the optimal threshold.

The proposed CNN method exhibits outstanding performance and outperforms classical techniques. At SNR = 10 dB, the CNN achieves a BER of 3×10^{-4}, corresponding to additional gain of approximately 3 dB over Clipping and 2 dB over Blanking. This demonstrates the CNN's ability to effectively learn the complex spatio-temporal features of impulsive noise and improve the performances of the system.

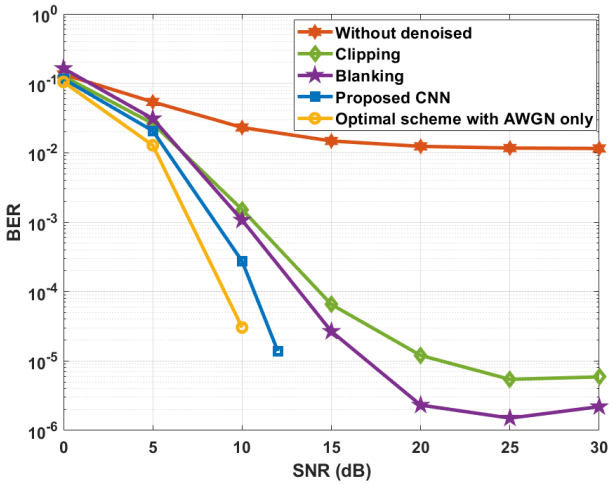

Fig. 5. BER versus SNR for different impulsive noise mitigation techniques under fixed noise density A=0.1.

Fig. 6 illustrates the average MSE versus SNR for the different tested noise mitigation approaches. The Clipping method exhibits the poorest performance, with an MSE stabilizing around 1.5×10^{-4} for SNR $\geq$ 10 dB. The Blanking technique performs better, starting at 1.2×10^{-3} at SNR = 0 dB and decreasing to approximately 1×10^{-4} for SNR $\geq$ 15 dB. However, both conventional methods exhibit an error floor, limiting their effectiveness at high SNR.

In contrast, the proposed CNN-based method demonstrates superior performance across the entire SNR range. Its MSE decreases monotonically from 2×10^{-4} at SNR = 0 dB to 2×10^{-5} at 30 dB, corresponding to an order-of-magnitude improvement. At SNR = 10 dB, the CNN achieves an MSE

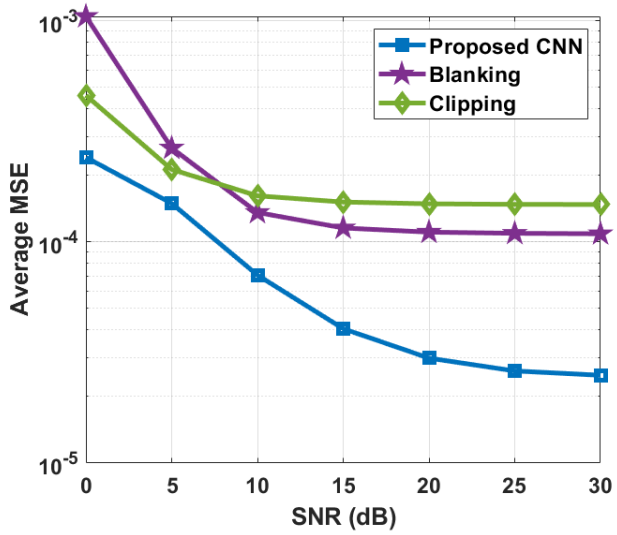

Fig. 6. Average MSE versus SNR for different impulsive noise mitigation techniques at a fixed impulsive index A=0.1.

of approximately 7×10^{-5}, outperforming the Blanking and Clipping methods, which yield MSE values of 1.3×10^{-4} and 1.6×10^{-4}, respectively. Notably, the absence of an error floor indicates that the CNN continues to benefit from increasing SNR for improved signal reconstruction, unlike conventional threshold-based methods, whose performance tends to saturate at high SNR.

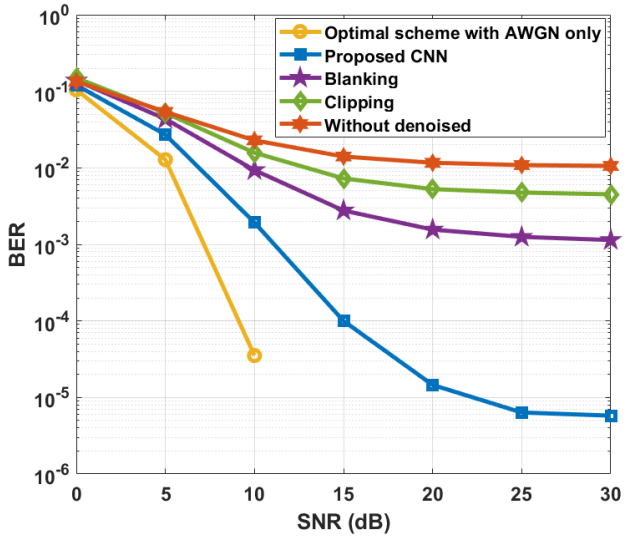

Fig. 7. BER versus SNR for different impulsive noise mitigation techniques at a fixed impulsive index A=0.5.

Next evaluation deals with the scenario of the impulsive noise with a fixed parameter $A = 0.5$, which result a severely disturbed NB-PLC environment. Fig. 7 illustrates the BER versus SNR for the different tested noise mitigation approaches. First, the system without any denoising method to BER higher than 10^{-2} across the entire SNR range. The Clipping method reduces the BER to approximately 4×10^{-3} at 30 dB, a gain of

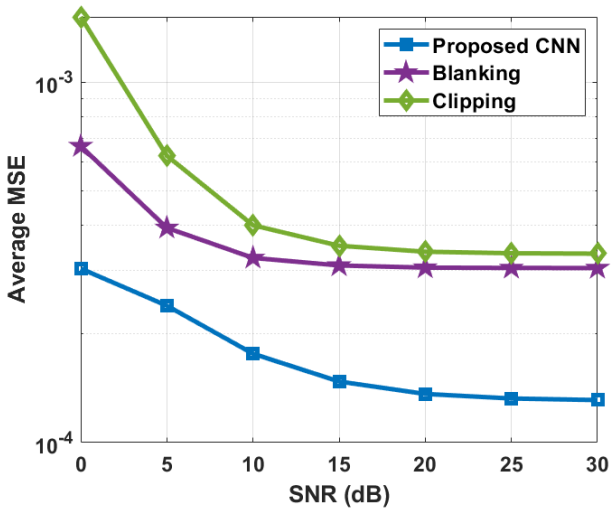

Fig. 8. Average MSE versus SNR for different impulsive noise mitigation techniques at a fixed impulsive index A=0.5.

approximately 6 dB is observed at a BER of 10^{-2}. Blanking provides greater improvement, with a BER of 1×10^{-2} at 10 dB and 1×10^{-3} at 30 dB, for a BER of 10^{-2}, provides an improvement of nearly 10 dB compared to the untreated system.

In contrast, the proposed CNN-based method achieves significantly lower BER than conventional techniques. At a target BER of 10^{-3}, a performance gain of nearly 18 dB is observed compared to the blanking method. Moreover, at a BER of 10^{-2}, the proposed approach provides a gain of approximately 23 dB relative to the untreated system, about 7 dB compared to clipping, and nearly 3 dB compared to blanking. At SNR = 20 dB, the CNN BER decreases to 10^{-5}. These results indicate that the CNN is able to exploit the complex temporal and statistical correlations of impulsive noise, unlike simple threshold-based methods.

In terms of MSE, the CNN-based technique clearly surpasses the benchmark methods, as illustrated in Fig. 8. It achieves an MSE of 1.7×10^{-4} at 10 dB decreasing to 1.2×10^{-4} at 30 dB, without any saturation. Alternatively, the Clipping method shows an MSE floor around 3.5×10^{-4} for SNR $\geq$ 15 dB, while Blanking reaches 3.2×10^{-4} at 10 dB and stabilizes near 3.0×10^{-4} for SNR $\geq$ 15 dB.

Fig. 9 presents the BER under a realistic NB-PLC scenario, where the parameter A varies dynamically from frame to frame, randomly drawn from a uniform distribution over the set $0.01, 0.5$.

In time-varying noise scenario, the CNN-based mitigation technique shows its advantage and demonstrates high robustness to fluctuations in impulsive index A. At SNR $= 10$ dB, the BER reaches 2.5×10^{-3}, corresponding to an SNR gain of approximately 5 dB compared to the Blanking method and 77 dB compared to Clipping. Moreover, the BER decreases monotonically to approximately 10^{-7} at SNR $= 30$ dB, while Blanking and Clipping saturate at around 2×10^{-4} and 3×10^{-3}, respectively. This result highlights the adaptability of the CNN, which learns to distinguish and effectively handle different levels of impulsive noise.

Finally, Fig. 10 presents the comparison of different methods in terms of average MSE. Similarly to previous results, the CNN-based methods outperforms the other noise mitigation techniques. It maintains a continuous MSE reduction from 2.8×10^{-4} at SNR = 0 dB to 6.5×10^{-5} at SNR = 30 dB. At high SNR, the proposed technique exhibits an MSE floor of 1.2×10^{-4}, whereas Blanking and Clipping do not decrease below 3×10^{-4} and 3.5×10^{-4}, respectively.

To further position the proposed approach with respect to existing DL–based impulsive noise mitigation techniques, Table III summarizes representative studies from recent years discussed above.

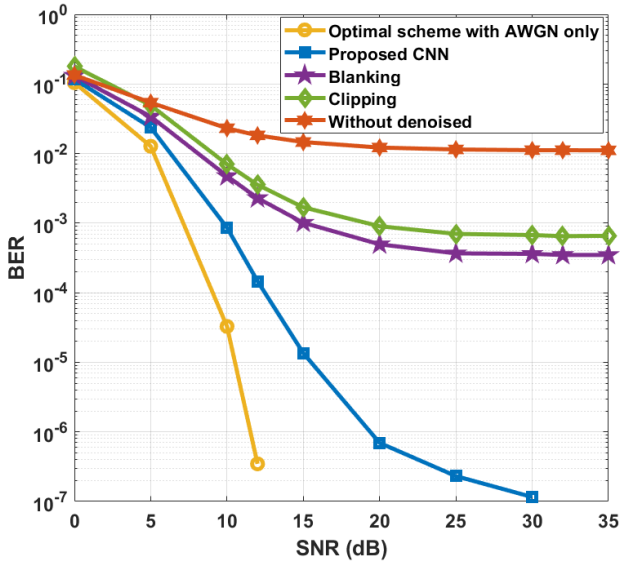

Fig. 9. BER versus SNR for different impulsive noise mitigation techniques with random noise density.

From the comparison presented in Table III, it can be observed that end-to-end time-domain denoising approaches offer an attractive trade-off between performance and computational efficiency. In this context, the proposed method avoids intermediate parameter estimation stages by directly learning the mapping between noisy and clean signals, while preserving robust generalization across varying impulsive noise densities. Moreover, the supervised learning framework relies on synthetic Middleton Class-A noise samples calibrated using experimental measurements, which facilitates a practical and reproducible implementation.

VI. Conclusion

This study presented a CNN-based approach for direct time-domain impulsive noise mitigation in NB-PLC OFDM systems compliant with the G3-PLC standard. The proposed method eliminates the need for threshold optimization, noise parameter estimation, or additional null subcarriers, as required by conventional cancellation techniques. Trained on synthetic data generated using Middleton Class-A model calibrated with experimental measurements, the CNN effectively suppresses

TABLE III. SUMMARY OF DEEP LEARNING ARCHITECTURES AND THEIR ROLES FOR IMPULSIVE NOISE MITIGATION IN OFDM-BASED PLC SYSTEMS

Reference	Year	DL Architecture and Role	System Description and Noise Model	Key Performance Results
Barazideh et al.[38]	2019	DNN (Fully Connected, 2 hidden layers: 20+10 neurons, ReLU activations; Sigmoid output) Detects impulsive samples using statistical features (ROAD, median deviation) for subsequent blanking.	OFDM-based systems; Noise: Bernoulli–Gaussian and Middleton Class-A ($\epsilon, A \in [0.04, 0.2]$)	Up to 2 dB SNR gain over blanking/clipping at BER 10^{-3}
He et al.[25]	2023	MaxPoolCNN (CNN with Max-Pooling layers) Extracts local features and adaptively estimates the optimal threshold values for the Deep Clipping method.	OFDM-based broadcasting and PLC system; Noise: Middleton Class-A ($A = 0.1$), Poisson arrival	Average interference reduction 15.1 dB (up to 19.6 dB); improved BER vs fixed threshold for blanking/clipping
Yang et al.[27]	2024	LSTM architecture Models temporal dependencies in impulsive noise to dynamically adjust thresholds.	OFDM-based smart grid PLC system; Noise: Bernoulli–Gaussian ($p = 0.1, 0.2$)	BER reduction 87.85% ($p = 0.1$) and 89.72% ($p = 0.2$) at 8 dB SNR vs blanking
Ouyang et al.[28]	2024	MFSDF-Net (CNN multi-feature fusion, parallel convolutions 1×1,1×3,1×5,1×7) Uses parallel convolutional kernels to extract and fuse features from multiple signal domains, effectively suppressing impulsive noise.	OFDM-based PLC; Noise: Bernoulli–Gaussian (p), dataset generated at SINR = -15 dB	BER 10^{-5} at 18 dB SNR, 8 dB improvement over Adaptive Parameter / GMM
Zhu et al.[26]	2025	1D-UNet (CNN encoder-decoder) Self-supervised denoising; learns signal reconstruction from noisy input only via global mask mapper.	OFDM-based MIMO-PLC system; Noise: Bernoulli–Gaussian ($p = 0.01, 0.05$)	At BER 10^{-6}, gains of 3 dB over Noise2Void, 4 dB over Zero-Shot Noise2Noise, 7 dB over DeepClipping
This work	**2026**	Multi-layer CNN (5 convolutional blocks: Conv + BatchNorm + Leaky ReLU) Direct end-to-end regression of clean signal from noisy input; robust to dense impulsive noise	NB-PLC OFDM system according to G3-PLC standard; Noise: Middleton Class-A ($A = \{0.01, 0.1, 0.5\}$)	Up to 18 dB SNR gain over blanking at BER 10^{-3} for $A = 0.5$; additional 3 dB over clipping and 2 dB over blanking at 10 dB SNR for $A = 0.1$; MSE = 7.01×10^{-5}

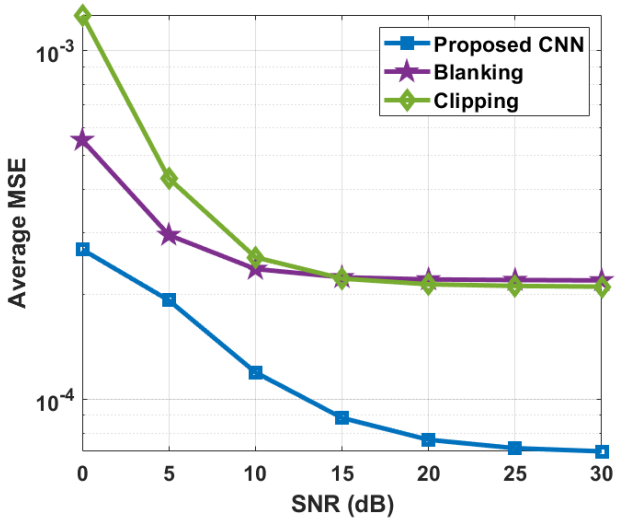

Fig. 10. Average MSE versus SNR for different impulsive noise mitigation techniques with random noise density.

impulsive noise while preserving useful signal components under varying noise densities.

Simulation results demonstrate that the proposed approach achieves significant improvements in BER and MSE over SNR range and under various impulsive noise conditions compared to conventional methods. These findings confirm that data-driven learning-based approaches consitutues a promising alternative to classical impulsive noise mitigation techniques for NB-PLC systems.

Future work will focus on integrating channel estimation and equalization within the proposed architecture for joint optimization, as well as investigating hybrid schemes that combine the CNN with channel coding techniques such as LDPC or polar codes to further enhance reliability.

Leveraging Attention Mechanism and Class Weighting for Legal Event Detection in Chinese Text

Jinhong Hu, Shaidah Jusoh*
School of Artificial Intelligence and Robotics,
Xiamen University Malaysia, Sepang, Selangor, Malaysia

***Abstract*—Event detection is an information extraction task that involves extracting specified event types from textual sequences. Currently, most event detection studies focus on English corpora; there is a lack of exploration in other linguistic contexts. Thus, a study on event detection in the Chinese corpus is essential. Sequence-based event detection has been extensively studied in the past, and many studies have utilized high-performance neural network models, such as traditional recurrent neural networks. This study aims to enhance the performance of sequence models by altering the base model, Bidirectional Long Short Term Memory (BiLSTM), to a Bidirectional Gated Recurrent Unit (BiGRU) and incorporating multi-head attention mechanisms, Conditional Random Fields (CRF), and class weights. These modifications not only improve the model's accuracy but also enhance computational efficiency by reducing the number of parameters relative to large pre-trained models such as Bidirectional Encoder Representations from Transformers (BERT). The experimental findings demonstrate that the proposed model's modification achieves an F1 Score of 83.55 for the micro standard and 78.07 for the macro standard. This presents a substantial improvement over the baseline, delivering performance nearly on par with state-of-the-art BERT-based models on the same dataset, while requiring significantly fewer parameters.**

***Keywords*—Event detection; information extraction; Chinese corpus; recurrent neural network**

I. Introduction

In the era of rapid advancements in big data and artificial intelligence, linguistic texts have become the foundation of nearly all the information available on the internet. Consequently, there is a growing demand for extracting more meaningful insights from these texts. Information extraction is a technique within the field of natural language processing (NLP) that aims to uncover valuable information from text. Event detection is a crucial subtask of information extraction, focusing on the identification of events mentioned in textual data. Due to the unique syntactic structures of different languages, the handling of details in natural language tasks varies. Despite the advancement of neural network technology and years of development, event detection still faces multiple challenges, including contextual dependency, event diversity, and sparse annotated data. These challenges constrain the accuracy and generalization ability of the model, particularly in complex contexts [1]. In response to these challenges, there have been emerging new approaches aimed at addressing event extraction problems, primarily categorized into two major classes: generation-based and classification-based methods. Some specific techniques have improved models, such as models based on attention mechanisms, transfer learning, and methods integrating external knowledge, which have, to some extent, alleviated the difficulties faced in event extraction [2], [3].

The motivation of this study is to develop an event detection model for Chinese legal texts. The benchmark dataset, LEVEN, a large-scale Chinese legal event detection dataset released in 2022 [4] and currently accessible through the GitHub site, has been utilized. This dataset is currently the largest of its kind for event detection in the Chinese legal domain, comprising approximately 60,000 sentences and 108 different event types. Despite the dataset's focus on the legal domain and its substantial sample size, high-performing sequence labeling models such as BERT and BiLSTM typically achieve F1 scores of around 80% on this dataset [4]. Thus, the primary objective of this study is to improve the performance of the model on the LEVEN dataset by refining the framework of the BiLSTM-based sequence labeling model. Specifically, the study explored which key modifications can effectively enhance the model's performance on this dataset.

This study set boundaries and focused exclusively on mathematical knowledge and model code implementation related to artificial intelligence and NLP. Mathematical knowledge was employed to elucidate the underlying principles of the models, while the implementation of model code utilized advanced API frameworks. A total of nine different models based on BiLSTM were implemented and trained. The enhancements on BiLSTM include modifying the basic architecture to BiGRU, introducing different multi-head attention mechanisms, replacing softmax with CRF, and adding weight adjustment to classes based on data distribution. The enhancement resulted in several beneficial improvements. Although it is possible to train more models, doing so would require an amount of time for parameter adjustment and training, yet it would not guarantee superior outcomes. Additionally, this study does not involve cross-lingual event extraction or the processing of multimodal data. It solely focuses on events within a specific linguistic context. And the enhancement of the model primarily stems from both the dataset and the model itself. All implemented models were analyzed against one another to identify the most effective approach.

This study is structured as follows: Section II addresses related topics, Section III outlines the methodology and experimental design, Section IV provides the analysis of results, and Section V concludes the study.

II. Related Topics

Topics related to this study are briefly presented in this section. Firstly, sequence labeling-based event detection mod-

*Corresponding author.

els are introduced, and relevant examples are provided. Next, the impact of data imbalance in corpus datasets are addressed, along with methods for handling it. Classic sequence models such as the Recurrent Neural Network (RNN) and its variations, including bidirectional models, Long Short-Term Memory (LSTM), and Gated Recurrent Unit (GRU) are explored. Finally, attention mechanisms and Conditional Random Fields (CRF) in sequence labeling are discussed.

A. Sequence Labeling

Sequence labeling is a text processing task for assigning appropriate labels to each token in an input sequence [5]. These labels can be used to represent information about parts of speech, named entities, emotional tendencies, and word sense disambiguation. It has wide applications involving entity recognition, part-of-speech tagging, sentiment analysis, entity relationship extraction, and syntactic parsing.

Event detection can be considered as a sequence labeling task, where the model processes a text sequence to generate a corresponding event label sequence. Essentially, it involves detecting trigger words with specified event labels in the text sequence. Multiple event trigger tokens may appear in a single input sentence [6]. In the example shown in Fig. 1, the input sequence is "John opens door, then sleeps", and the output sequence highlights two trigger words, specifically the first and the sixth tokens, "open" and "sleep". With these two trigger words and contextual information, the model can determine the corresponding event types as "open" and "sleep".

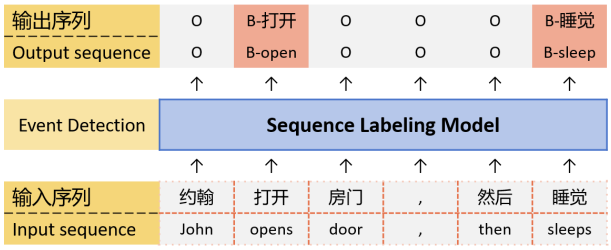

Fig. 1. Event detection based on sequence labeling.

B. Data Imbalance

Data imbalance issues are quite common in corpus datasets. In the event detection task, data imbalance refers to a large difference in the number of samples across event classes. It negatively impacts model training, as the model tends to fit the dominant classes while neglecting the less frequent classes. To address data imbalance issues in NLP, many methods have been considered, like sampling, which increases the number of samples in the minority classes [7]. Alternatively, setting sample weights assigns higher weights to imbalanced classes, encouraging the model to learn the minority classes better [8].

C. Recurrent Neural Network

A recurrent neural network is a neural network model for handling sequential data by recurrent connections, which allows information to persistently propagate within the network [9]. Due to its capability to process sequences of varying lengths, RNN excels in solving event detection based on sequence labeling.

1) Bidirectional: In a traditional RNN, only forward input can be accepted, resulting in the output being more influenced by the most recent input data, which hinders its effectiveness in processing contextual information. To address this issue, the Bidirectional Recurrent Neural Network (BRNN) model was introduced. BRNN can utilize both past and future context information in two directions when processing sequential input [10]. This architecture is beneficial in alleviating the long-range dependency problem and has improved RNN's performance.

2) Long Short-Term Memory: LSTM is another variant of RNN, which was designed to address the issues of gradient vanishing and exploding gradients [11]. LSTM achieves better performance in capturing long-term dependency by introducing a mechanism that involves gates and cell states to maintain and control internal memory. These three gates include the input gate, the forget gate, and the output gate.

3) Gated Recurrent Unit: GRU is also a variant of RNN that emerged after LSTM. It aims to address the issue of long-term dependency. The gate mechanism of GRU includes the update gate and reset gate, which control the flow and retention of information [12]. Comparing gate mechanisms, the structure of GRU is simpler than that of LSTM.

D. Self-Attention Mechanism

The attention mechanism was introduced to enhance the model's ability to process sequential data in NLP [13]. It is also useful for event detection models based on sequence labeling. The key idea is that the model can dynamically focus on different parts of the input, rather than distributing fixed weights when processing an input sequence. One of the most popular attention mechanisms is the self-attention mechanism. This mechanism is currently widely used in various sequence-to-sequence tasks such as machine translation and text generation [14]. It enables the model to capture context and dependencies within the sequence better.

E. Conditional Random Field

For event detection models based on sequence labeling, softmax can be used in the inference layer to obtain final label sequences. It is a common normalization exponential function used to transform a set of values into a probability distribution, where each value represents a potential class score. However, the probability labels obtained by softmax at different positions are treated as mutually independent, which may cause a negative impact. Conversely, CRF, as an undirected probabilistic graphical model, is capable of efficiently capturing label dependencies and contextual information compared with softmax in sequence labeling [15]. Linear CRF is a frequently employed choice in sequence labeling tasks [16].

III. Methodology

This study has been conducted using the programming language Python for data processing and model training. The data processing involves extracting the required data from JSON files through the Python JSON library, and Chinese text tokenization is performed by Jieba (Chinese NLP library) [17]. PyTorch was used to develop neural networks and perform training. The research phases are illustrated in Fig. 2. The flow

begins with data gathering, continues through data processing, model implementation, and experimentation, and concludes with result analysis.

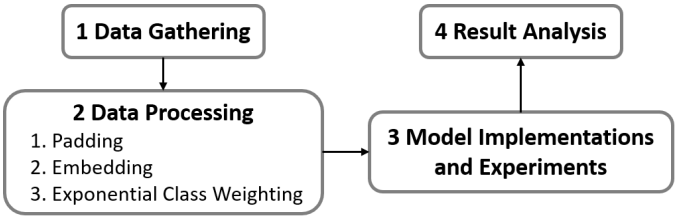

Fig. 2. Flowchart of the research framework.

A. Data Gathering

The LEVEN Chinese legal event detection dataset was obtained, comprising roughly 60,000 training samples across 108 legal event types. Each sample is a complete and lengthy sentence that contains multiple event triggers [18]. Fig. 3 demonstrates a sample of a JSON file that contains the title of the text, the unique ID, as well as the content of the text, which includes multiple sentences with corresponding tokens.

Fig. 3. An example of training data in the JSON file.

The sentence in the sample contains a close number of negative and positive triggers. During the training process, a single sentence is used as one piece of data instead of multiple sentences. The aim is to reduce the length of the input sequence and alleviate the model's computational burden.

B. Data Processing

Tokenization is an initial step in data processing. This step has been employed for both training data and testing data. It is worth noting here that the LEVEN dataset is exceptionally clean and does not require any cleaning operations. To ensure the completeness of the data information input to the model, we do not employ stop word removal, as stop words may have some semantic information for Chinese. Padding, embedding, and exponential class weighting utilized in the proposed models will be discussed in the following subsections.

1) Padding: In this study, the sequence labeling model requires that the input data fed into the model have the same length. As shown in the length distribution chart of the data samples in Fig. 4, sentence lengths range from 25 to 350 tokens, with most clustering around 50 and only a few exceeding 150. In the experiment, the model's input length was set to the maximum length observed in the dataset, and shorter samples were padded to reach this specified length.

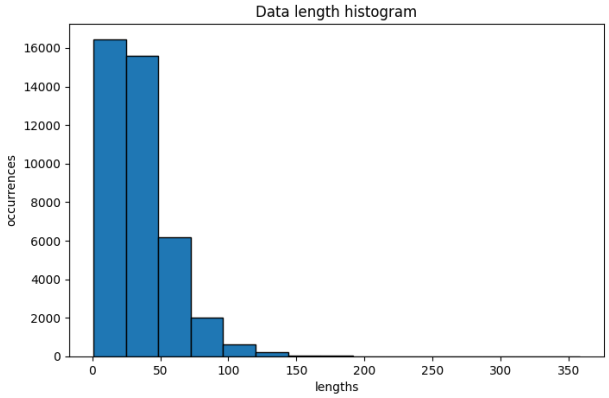

Fig. 4. Data length distribution.

Readers might wonder whether setting the input length to the maximum significantly increases training time or reduces performance. In PyTorch's RNN-based models, however, the actual length of each input can be specified, and computations for the padding portion are ignored, thereby preventing additional training overhead. Furthermore, since the test data also contains longer samples, the padding length was set to the maximum to ensure that no test input would be truncated. In sequence labeling tasks, truncation directly results in the model predicting only the first half of the data.

2) Embedding: The word embeddings used in this experiment were not trained from scratch; instead, pre-trained word embeddings [19] were utilised. These pre-trained word embeddings were trained on Baidu Encyclopedia data, and a vocabulary of 60,000 tokens was included, with each token having an embedding dimension of 300. Once the word embedding matrix is converted into a NumPy array, it occupies approximately 700 MB of memory.

For each processed text data with completed padding, it tries to look up in the word embedding matrix to obtain the corresponding word vector. Rather than pre-converting all training data into word vector format and loading it into memory, which would be impractical due to the significant space requirements, this study uses the PyTorch DataLoader API. This allows the model to dynamically load and pre-process data as needed during the training process. It's important to note that in this experiment, the pre-trained word embedding matrix was not frozen but was adjusted concurrently during the model training process.

3) Exponential class weighting: In the training data set, positive samples accounted for only 24.8% of the total samples. Negative samples refer to the instances where the event did not occur, and the positive samples encompass 108 event classes. The training dataset exhibits a pronounced class imbalance,

where the class with the fewest samples contains only 5 instances, while the category with the most samples contains around 6000, as shown in Fig. 5.

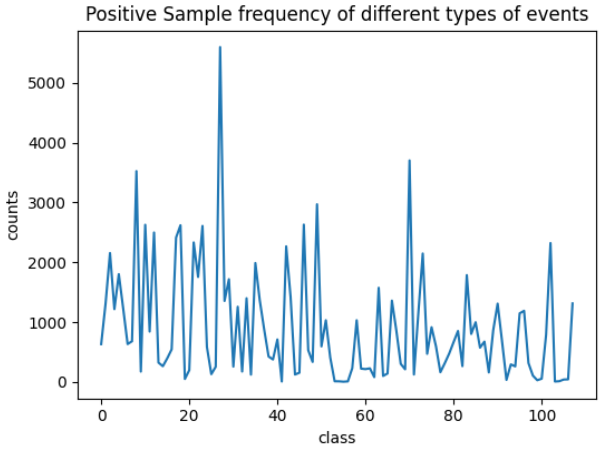

Fig. 5. Distribution of samples across different classes.

To balance the training data, it is necessary to adjust the weights of different data categories. In this experiment, an exponential weighting of class sample quantities was employed, which is defined as follows:

$$w_i = {c_i}^{-\alpha} = \frac{1}{{c_i}^{\alpha}} \tag{1}$$

where, w_i is the weight of a specific class, c_i is the sample quantity of the class and α is a hyperparameter ranging from 0 to 1. From the given formula, it can be observed that if a class has a larger sample quantity, it will receive a smaller weight, while classes with fewer samples will receive larger weights. This allows the model to pay more attention to classes with fewer samples during training. When choosing the value of α, a balanced consideration is required. If α approaches 0, the weights for all classes tend to be close to 1, effectively resulting in no weight adjustment. If α approaches 1, classes with fewer samples will receive significantly larger weights compared to classes with more samples, potentially leading to overfitting. Considering the experiment's requirements, α was ultimately set to 0.1 to balance the model's focus on different class samples. Thus, in this study, α is set to 0.1; the larger the sample size of a class, the smaller its weight.

C. Model Implementations and Experiments

A total of nine models (see Table I) with various enhancements based on BiLSTM were implemented and experimented with in this study. These enhancements include modifying the basic architecture to BiGRU, introducing different multi-head attention mechanisms, replacing softmax with CRF, and adding weight adjustment to classes based on data distribution. Each model employed dropout [20]. The dropout rate was set to 0.3 or 0.4, adjusted based on the degree of model overfitting. The loss function is the multi-class cross-entropy loss function. The models were all compiled using the Adam optimizer [21].

Table I provides information on the nine models. The inference layer of BiLSTM and BiGRU is softmax, while in other models, softmax was replaced with CRF to enhance the dependency information between labels. The A+BiGRU+CRF model introduced the first version of attention, which is self-attention after the embedding layer, before the BiGRU layer. The BiGRU+A+CRF model introduced the second version of attention, which is self-attention after BiGRU, before the CRF. The BiGRU+EA+CRF introduced the third version of attention, which is multi-head attention, after the BiGRU, before the CRF. In BiGRU+A+CRF+W, the W represents the utilization of exponential class weights.

TABLE I. NAMES AND DETAILS OF MODELS

No.	Model	Detail
1	BiLSTM	BiLSTM Model+Softmax
2	BiGRU	BiGRU Model+Softmax
3	BiLSTM+CRF	BiLSTM Model+CRF
4	BiGRU+CRF	BiGRU Model+CRF
5	A+BiGRU+CRF	First Version Attention+BiGRU+CRF
6	BiGRU+A+CRF	BiGRU+Second Version Attention+CRF
7	BiGRU+EA+CRF	BiGRU+Third Version Attention+CRF
8	BiGRU+A+CRF+W	BiGRU+A+CRF with Class Weight
9	BiGRU+EA+CRF+W	BiGRU+EA+CRF with Class Weight

All models used the same dataset. The training dataset comprises 395,322 samples, while the validation dataset contains 92,451 samples, representing approximately 20% of the total data. In this experiment, the default validation dataset served as the testing set and did not participate in model training. The graph in Fig. 6 illustrates the percentage distribution of positive samples from different classes in the training and testing datasets. The class distribution in the training and testing sets is very similar, ensuring an effective evaluation of the model's performance in this experiment.

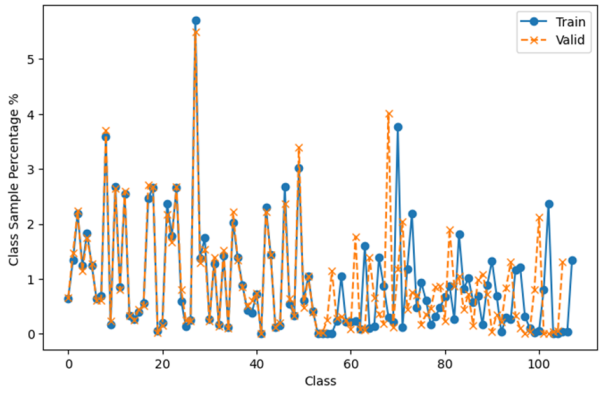

Fig. 6. Percentage distribution of different classes in the training and validation datasets.

The pipeline of the BiGRU+EA+CRF model is shown in Fig. 7. First, the input tokens are passed through the embedding layer to obtain word vectors. Subsequently, the word vectors pass through the BiGRU layer to obtain hidden vectors. Next, in the multi-head attention layer, the query is the word vectors before BiGRU, and the key and value are the hidden vectors after BiGRU. This attention process allows hidden vectors to adjust information with word vectors. Finally, vectors weighted by attention pass through the CRF layer to generate the label

sequence. Three different versions of multi-head attention mechanisms have been employed in experiments. The first version is self-attention after the embedding layer, before the BiGRU layer.

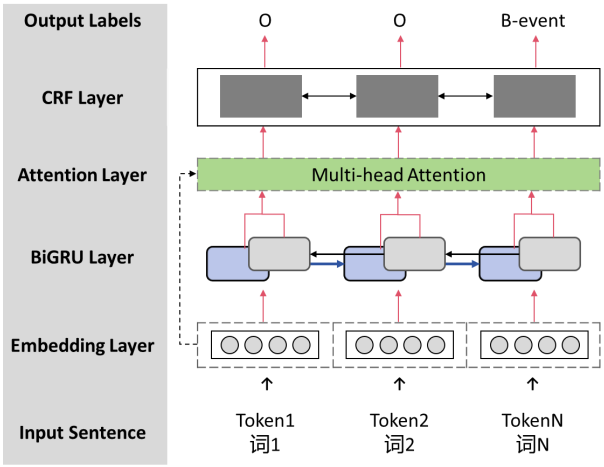

Fig. 7. Framework of BiGRU+EA+CRF model.

The second version is self-attention after BiGRU before the CRF. Placing a self-attention layer after the embedding layer and before the BiGRU layer aims to create a more informed and contextually rich representation of the input sequence early in the network. This allows the BiGRU layer to focus on modeling temporal and sequential dependencies without the additional burden of capturing long-range relationships, potentially leading to improved performance on various NLP tasks.

The third version is multi-head attention after BiGRU before the CRF, while the query is word vectors before the BiGRU layer, but key and value are the hidden vectors after the BiGRU layer. By adding a multi-head attention layer after the BiGRU layer, representation learning would be enhanced. This increases the model's ability to capture diverse and complex dependencies and improve its performance.

IV. Result Analysis

A. Evaluation

To evaluate the results obtained from the experiments, precision, recall, and F1-score based on micro and macro standards were used, which are defined as follows:

$$precision = \frac{TP}{TP + FP} \tag{2}$$

$$recall = \frac{TP}{TP + FN} \tag{3}$$

$$F1\text{-}score = \frac{2 * precision * recall}{precision + recall} \tag{4}$$

TP as True Positive is the total number of correctly predicted positive samples. FP as False Positive is the total number of incorrectly predicted positive samples. FN as False Negative is the total number of incorrectly predicted negative samples. Micro refers to micro-averaging, which calculates metrics by aggregating results across all classes. Macro refers to macro-averaging, which calculates metrics separately for each class.

TABLE II. Confusion Matrix for Binary Classification Problem

Confusion Matrix		Actual Values	
		1	0
Model Predictions	1	TP	FP
	0	FN	TN

Table II illustrates a confusion matrix, where the rows represent the model's predicted values and the columns represent the true label values of the samples.

B. Analysis

To analyze the obtained results, the performance of the nine models was compared and presented in Table III. The performance of BiLSTM and BiGRU is extremely close by both micro and macro standards. Similarly, the performance between BiLSTM+CRF and BiGRU+CRF shows similar results. This demonstrates that, despite the structural differences between BiLSTM and BiGRU, only a small performance discrepancy was observed in the experiments. By comparing the performance of the BiLSTM and BiGRU models with and without CRF, it is clear that CRF results in a slight increase in precision, but a decrease in recall, while the F1-scores remain unchanged. This indicates that precision is enhanced, but recall is compromised by CRF, without any overall performance loss. Consequently, CRF can be considered beneficial in contexts where precise identification of event types is required while maintaining overall performance.

Among the three versions of attention mechanisms integrated in the BiGRU+CRF model, minimal performance discrepancies were observed. However, the third version model, BiGRU+EA+CRF, achieves the highest precision across both macro and micro criteria. This suggests the benefit of attention mechanisms for precisely identifying event types. The third attention mechanism integrates both shallow and deep layer information, reduces interference in shallow layers, and more effectively adjusts information in deep layers compared with the other two attention mechanisms.

The results from utilizing exponential class weights in BiGRU+A+CRF+W and BiGRU+EA+CRF+W highlight an enhancement in recall by 5-7% and F1-score by 3-4%, without losing precision by macro criteria. This emphasizes the significant improvement of exponential class weights in event detection tasks with imbalanced datasets.

Based on the results of the nine models presented in Table III, the BiGRU+EA+CRF+W model yields the best overall performance. In spite of the moderate performance on the micro standard, it achieved the highest recall and F1 score and ranked second on precision on the macro standard. Results obtained in Table III were also compared with the published results of four models [18], namely DMCNN, BERT, BERT+CRF, and DMBERT (see Table IV). Based on the results of the four models published by other researchers

TABLE III. THE PERFORMANCE OF NINE MODELS ON THE TESTING DATASET

No.	Model	Micro			Macro		
		Precision	Recall	F1-score	Precision	Recall	F1-score
1	BiLSTM	81.73	86.17	83.90	77.20	76.73	76.96
2	BiGRU	81.98	**86.29**	84.08	78.47	75.95	76.13
3	BiLSTM+CRF	85.29	83.44	**84.36**	79.02	73.50	75.25
4	BiGRU+CRF	84.35	84.01	84.18	79.86	73.98	75.80
5	A+BiGRU+CRF	85.47	80.64	82.99	79.44	70.20	73.51
6	BiGRU+A+CRF	85.17	82.23	83.67	80.21	72.06	74.62
7	BiGRU+EA+CRF	**86.41**	79.66	82.90	**81.61**	70.67	74.61
8	BiGRU+A+CRF+W	82.45	84.43	83.43	80.66	76.36	77.21
9	BiGRU+EA+CRF+W	83.58	83.51	83.55	81.29	**77.07**	**78.07**

TABLE IV. THE PERFORMANCE OF OTHER FOUR MODELS [18]

No.	Model	Micro			Macro		
		Precision	Recall	F1-score	Precision	Recall	F1-score
1	DMCNN	**85.88**	79.70	82.67	80.55	73.31	75.03
2	BERT	84.19	84.31	84.25	79.61	76.76	77.33
3	BERT+CRF	82.82	84.56	84.19	79.77	77.65	77.83
4	DMBERT	83.77	**86.22**	**85.48**	**81.57**	**80.90**	**80.34**

(as presented in Table IV), the large BERT-based model DMBERT demonstrates remarkable performance. However, compared to the best RNN-based model in this study which is BiGRU+EA+CRF+W, DMBERT performs very closely by the macro precision and shows only a slight 2%-3% improvement by the micro recall and F1 score. On the other hand, BERT-based models have much larger parameters than the RNN-based models. Consequently, the BiGRU+EA+CRF+W model can train and infer faster for similar performance.

C. Discussion

Fig. 8 illustrates the capability of the proposed model, BiGRU+EA+CRF+W, by showcasing one of the output samples in which legal event types were extracted from an input Chinese text. In addition to showcasing the result of the Chinese sample, the corresponding English translation is provided to aid reader comprehension.

The Chinese text in the sample contains about 100 tokens. The blue tokens indicate legal event triggers, the red tokens indicate corresponding event types, and the green tokens indicate non-legal event triggers that are not detected by the model. The BiGRU+EA+CRF+W model successfully detects all 8 legal events. Non-legal events such as “stop”, “lubricate”, “starting”, and “roll”, although representing events, are not relevant to legal matters; thus, the model does not extract them. This example demonstrates the model’s exceptional performance in accurately identifying several legal occurrences within a lengthy Chinese text. It is worth noting that the proposed RNN-based models are currently unable to handle English event detection.

Fig. 8. Event detection result of model BiGRU+EA+CRF+W on the sample. Blue tokens indicate legal event triggers. Red tokens indicate corresponding event types. Green tokens indicate non-legal event triggers that are not detected by the model.

V. CONCLUSION

This study presents research on Chinese event detection. Most event detection research focuses on English corpora, with a limited exploration of Chinese corpora. This study aims to enhance the performance of the sequential labeling model BiLSTM for Chinese event detection. Four modifications, including replacing the base model with the BiGRU, incorporating the attention mechanism, replacing softmax with CRF, and utilising exponential class weights, were introduced. Experiments were conducted using the largest Chinese legal text event detection dataset, LEVEN. The experimental results indicate a significant improvement over the basic model. The proposed model performs nearly comparably to the state-of-the-art models based on BERT, yet with fewer parameters.

However, this study has several limitations. Firstly, experiments were conducted solely on the Chinese dataset LEVEN,

which is limited to legal events. Future research could explore other Chinese event detection datasets and even consider creating datasets due to scarcity. Secondly, the exploration of attention mechanisms was limited to multi-head attention, which exhibits modest effectiveness. Future work could explore alternative attention mechanisms and modifications of them. Lastly, further investigation into different methods for data imbalance in event detection is needed, though the exponential class weights approach effectively alleviates the issue.

***Abstract*—Virtual Power Plants (VPPs) face significant challenges in secure data management and sharing, including risks of centralized control, single points of failure, and dynamic access requirements among multiple stakeholders. To address these issues, this study proposes SIFChain, a decentralized framework that integrates Hyperledger Fabric, the InterPlanetary File System (IPFS), and a revocable Ciphertext-Policy Attribute-Based Encryption (CP-ABE) scheme with collaborative key generation. Unlike existing solutions such as Filecoin or Storj, SIFChain introduces a dual-channel blockchain architecture that separates public operational data from sensitive attribute information, mitigating privacy leakage and access policy exposure. The framework achieves fine-grained, dynamic access control with forward and backward security through an enhanced CP-ABE mechanism. Experimental evaluation demonstrates that SIFChain provides scalable performance: data upload/download times increase linearly from 1 MB to 1 GB, blockchain transaction latency remains under 5 ms for typical operations (registration, access requests, policy updates), and attribute-based encryption/decryption overhead scales linearly with policy complexity. These results confirm the practicality of SIFChain for secure, cross-organizational data sharing in Virtual Power Plant ecosystems.**

***Keywords*—Virtual Power Plant; access control; CP-ABE; IPFS; blockchain; distributed energy; privacy protection**

I. Introduction

With the rapid advancement of renewable energy integration and smart grid technologies, Virtual Power Plants (VPPs) have emerged as critical components in modern energy systems [1]. VPPs aggregate distributed energy resources (DERs) such as solar panels, wind turbines, battery storage systems, and flexible loads into unified, controllable entities that participate in electricity markets and grid services [2]. These systems generate massive volumes of operational data daily, including generation forecasts, real-time power measurements, market bids, grid interactions, and participant settlement information [21].

According to energy industry analysis [3], well-managed VPPs can improve grid stability by 20-30% while reducing operational costs by 15-25%, significantly enhancing energy efficiency and renewable integration [22]. However, current VPP data management systems face multiple security and governance challenges. From a technical perspective, traditional VPP architectures often rely on centralized control systems, creating single points of failure and exposing critical energy infrastructure to risks of cyber-attacks, data tampering, and unauthorized access [4], [15]. The threat model includes malicious insiders, external adversaries targeting communication links, and compromised DER devices that could leak sensitive operational data. These vulnerabilities make it difficult to ensure data integrity and reliability in multi-stakeholder energy environments involving generators, aggregators, grid operators, regulators, and consumers.

Furthermore, from an access control standpoint, VPP data management is typically controlled by single entities or limited consortia, leaving other legitimate stakeholders without verifiable and open access to necessary operational and financial data. As energy markets become increasingly decentralized and dynamic, with frequent changes in participation, ownership structures, and regulatory requirements, the need for secure, fine-grained, and adaptable access control mechanisms has become paramount. The evolving nature of VPP collaborations—where participants may join or leave, assets may change ownership, and access privileges must adapt to real-time market conditions—requires fundamentally new approaches to data security and sharing.

Blockchain technology offers promising solutions to these challenges through its distributed ledger architecture, which authenticates and records data via consensus algorithms without requiring trusted third parties [5]. The immutable nature of blockchain records provides strong guarantees against data tampering, while smart contracts enable automated execution of energy agreements, settlements, and access policies. Hyperledger Fabric, as a permissioned blockchain framework [6], is particularly suitable for VPP applications due to its efficient consensus mechanisms, multi-channel architecture for data isolation, and support for complex organizational structures typical in energy ecosystems.

The InterPlanetary File System (IPFS) complements blockchain technology by providing decentralized storage capabilities, addressing the inherent storage limitations of blockchain systems for large-scale energy data [7]. By storing encrypted VPP operational data on IPFS and maintaining only cryptographic references on the blockchain, energy organizations can achieve both scalability and security while preserving data availability. Additionally, Attribute-Based Encryption (ABE) technology [8], particularly Ciphertext-Policy Attribute-

*Corresponding author.

Based Encryption (CP-ABE) [9], enables fine-grained access control by allowing data owners to define access policies based on user roles, organizational affiliations, and operational contexts rather than specific identities.

Despite these advancements, existing decentralized storage systems such as Filecoin and Storj rely on proof-of-storage mechanisms that introduce high computational overhead and lack fine-grained access control tailored to multi-stakeholder VPP environments. Moreover, typical IPFS-Ethereum integrations suffer from on-chain storage bottlenecks and lack privacy-preserving attribute management. Many systems still rely on centralized key management authorities or lack efficient mechanisms for access privilege revocation and updates as market conditions change [10], [11], [16], [17]. These limitations create security vulnerabilities and administrative overhead in practical VPP deployments where access requirements frequently evolve due to changing market participants [12], regulatory compliance needs, asset ownership transfers, and real-time operational conditions.

This study addresses these gaps by proposing SIFChain, a comprehensive framework for secure storage sharing and dynamic access control in Virtual Power Plants. Our solution integrates Hyperledger Fabric, IPFS, and an enhanced revocable CP-ABE scheme with collaborative key generation, which mitigates the risk of single points of failure in key distribution. The main contributions of this work are as follows:

- We propose SIFChain, an efficient dynamic storage sharing framework for VPP consortium blockchains that enables granular and flexible access control for sensitive energy data through an enhanced Ciphertext attribute-based encryption algorithm.
- We design a multi-channel architecture comprising public channels and attribute channels to address access policy and attribute leakage challenges in on-chain attribute encryption. This architecture enables separate storage of different data types (operational, financial, regulatory), ensuring enhanced privacy management through dedicated attribute nodes representing different VPP stakeholders.
- We modify the Certificate Authority (CA) structure to enable collaborative attribute key generation between the CA and attribute authorization nodes, enhancing the security of user attribute private key generation and distribution in distributed energy environments.
- We implement a comprehensive security strategy that combines symmetric encryption for IPFS-stored VPP data with attribute-based encryption for blockchain-managed access control, ensuring data security while facilitating efficient storage and sharing across organizational boundaries in energy ecosystems.

The remainder of this study is organized as follows: Section II reviews related woks. Section III details the specific implementation of the SIFChain framework in VPP contexts. Section IV presents experimental results and performance analysis. Finally, Section V concludes the study and outlines directions for future research.

II. Related Work

Decentralized storage and access control for energy systems have attracted significant research interest. Filecoin and Storj provide blockchain-based storage markets but focus on proof-of-storage rather than fine-grained access policies, making them less suitable for dynamic multi-stakeholder VPPs. IPFS combined with Ethereum has been proposed for IoT data sharing [13], yet on-chain storage costs and lack of attribute-based privacy controls limit scalability. In the context of VPPs, consortium blockchains like Hyperledger Fabric have been explored for energy trading [11] and data management [14], but these works often assume static access rights and do not address attribute revocation or collaborative key generation.

CP-ABE schemes with revocation capabilities have been studied extensively [8], [9]. However, most implementations rely on a single authority for key distribution, creating a central point of trust. Collaborative key generation between multiple authorities, as in SIFChain, reduces this vulnerability. Furthermore, existing VPP data management frameworks seldom integrate IPFS for scalable storage alongside dynamic attribute-based access control [18]. Our work bridges this gap by proposing a holistic architecture that combines Fabric's permissioned channels, IPFS's content-addressed storage, and a revocable CP-ABE scheme with distributed key generation, thereby advancing the state-of-the-art in secure VPP data sharing.

III. SIFChain Framework for Virtual Power Plants

A. System Architecture and Stakeholders

Our solution enhances the storage and sharing of VPP data among multiple stakeholders, including distributed energy resource owners, VPP aggregators, grid operators, electricity market participants, regulators, and consumers. The system consists of four main entities: the Fabric consortium blockchain, the IPFS distributed file system, data owners (typically VPP operators or asset owners), and data consumers (various authorized stakeholders).

We enhance dynamic access control through the revocable Ciphertext-Policy Attribute-Based Encryption (CP-ABE) mechanism, where decryption key parameters are generated collaboratively by the Fabric Certificate Authority (Fabric-CA) and the attribute authorities AA_l representing different stakeholder groups. This approach reduces the risk of data leakage and enhances security in the distributed energy environment.

For the consortium blockchain, we employed a dual-channel architecture that distinctly separates public operational data (e.g., aggregated power forecasts, market prices) from sensitive attribute data (e.g., individual asset performance, participant identities, financial settlements), encryption policies, and other privacy-related information, thereby ensuring enhanced data security. This solution also utilizes the IPFS distributed file system for secure and efficient storage of VPP operational data, including high-frequency sensor data, detailed asset performance logs, and historical market interactions. Data owners encrypt their sensitive VPP data and upload it to IPFS, creating a dedicated, secure IPFS network that guarantees data confidentiality while improving storage efficiency for large-scale energy datasets.

B. Data Flow and Access Control Mechanism

In terms of data storage, IPFS only stores the ciphertext of the original VPP data, while the blockchain maintains the address in IPFS, along with symmetric keys and hash values of the original data. When an endorsing node in Hyperledger Fabric executes a smart contract for data access, it combines the data user attribute set with the channel anchor point to verify the ciphertext decryption. If the attribute set meets the established access policy (e.g., "Grid Operator AND Real-time Operations"), the consumer can successfully decrypt the ciphertext and gain access to the data; otherwise, the endorsing node will return a failure indicator, thereby denying the access request. This design facilitates secure data storage and fine-grained attribute-based access control tailored to VPP requirements [13].

C. Relevant Symbols

To facilitate the discussion, we first present the required parameters and relevant symbols in Table I.

TABLE I. NOTATION FOR SIFCHAIN IN VPP CONTEXT

Notation	Description
PP	System common parameter
ID_i	ID of user i in the VPP system
AA_l	Attribute authorization node l representing a stakeholder group
S	Collection of attributes (roles, organizations, access levels)
PK	Attribute encryption public key in the system
MSK	Attribute encryption master key in the system
ω	Attribute set of user ID_i in the system
$SK_{ID_i,\omega}$	Attribute private key of user ID_i
m	Original sensitive VPP data (sensor readings, bids, etc.)
H_1	Hash value of the original sensitive data
CT_m	Symmetrically encrypted ciphertext of the original data
URL	Address where IPFS stores encrypted data
k	Symmetric key used to encrypt data
m_1	New data formed by combining URL, k, and H_1
R_l	Revocation lists maintained in the system
P^*_ω	Access policy for attribute encryption
CT_{ABE}	Ciphertext encrypted with data m_1 attribute
$CT^{'}_{ABE}$	Recalculated attribute encrypted ciphertext
$leaf_j$	Access the leaf node j in the policy
$Root$	Access the root node in the policy
x	Accessing non-leaf nodes in a policy
z	Accessing child nodes of non-leaf nodes
H_2	Hash value computed by the data user for verification
DO	Data owner in the system (VPP operator/asset owner)
DU	Data users in the system (various stakeholders)
CA	Certificate Management Center in Fabric

D. System Model for VPP Applications

The proposed storage sharing system for Virtual Power Plants is illustrated in Fig. 1. The Fabric consortium blockchain features two core channels: a public channel for operational data and an attribute channel for sensitive information [14], each with its own distinct ledger.

We classify nodes into two categories: public nodes (maintaining the public ledger with grid and market data), and attribute nodes (joining the attribute channel to manage attribute data for different stakeholder groups).

Before VPP data is uploaded to the blockchain, the data owner predefines the access policy based on energy market rules and regulatory requirements. The sensitive VPP data is encrypted using a symmetric algorithm and subsequently stored in IPFS. The IPFS address, symmetric encryption key, and data hash are then uploaded to the blockchain using attribute encryption. In the blockchain, the ciphertext and revocation lists are maintained as public data within the public channel, while sensitive information—such as encryption policies, participant attributes, and financial details—is stored in the attribute channel, managed by attribute nodes representing different stakeholder interests. Data within the same channel is synchronized in real-time across all relevant nodes.

When a data user (e.g., grid operator, regulator, market participant) requests access to VPP data, the attribute node evaluates the user's attribute set within the attribute channel utilizing Ciphertext-Policy Attribute-Based Encryption (CP-ABE) to verify whether the consumer satisfies the access policy. If verification succeeds, the system performs decryption and grants access; otherwise, a failure message is returned. Access rights in VPPs may change frequently due to market conditions, regulatory updates, or participant status changes. If a consumer loses privileges, the system uses the revocation list to re-encrypt the ciphertext with a random value, replacing the original to ensure both forward and backward secrecy [19].

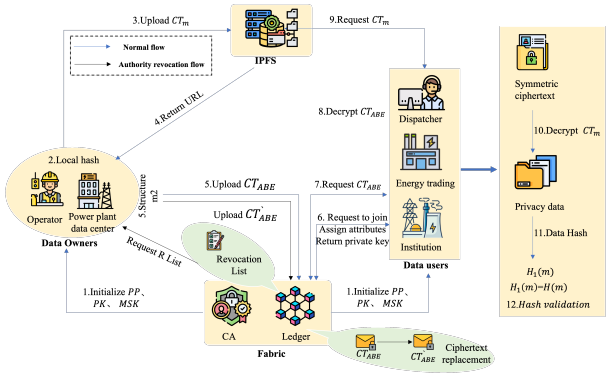

Fig. 1. SIFChain system model for Virtual Power Plants.

E. Components of the Solution

This solution consists of six stages: system initialization, key generation, data encryption and storage, data encryption upload, attribute revocation, and decryption. The specific operations are detailed as follows:

1) System initialization: The Fabric-CA selects a bilinear mapping $e : G_1 \times G_1 \to G_2$, where G_1, G_2 are two cyclic groups of order q. Then, it selects generators $g, h, v \in G_1$ and random numbers $\alpha, \beta \in Z_q$, and computes $Z = e(g, g)^{\beta}, v^{\beta}$. Finally, it outputs the system public parameters $PP = (G_1, G_2, e, g, h, v, Z)$.

For each authenticated VPP participant ID_i in the system, the CA selects a unique secret parameter $\lambda_i \in Z_q$ and securely sends (λ_i, β) to the user, while sending (α, h) to the attribute authorization node AA_l in Fabric, where $l \in \{1, \ldots, n\}$ is the index of each attribute authorization node, and n is the total number of attribute authorization nodes in the system.

Define the attribute domain S representing VPP roles and permissions (e.g., "Grid Operator", "Market Participant", "Asset Owner", "Regulator"). For any attribute $j \in S$, if the attribute authorization node AA_l holds the key distribution authority for it, i.e., $j \in AA_l$, then AA_l selects a secret random

number $t_j \in Z_q^*$, computes $T_j = g^{t_j}$, and finally outputs the attribute public key $PK = (\{T_j\}_{j \in AA_l})_{l \in (1,2,\ldots,n)}$ and the attribute master secret key $MSK = (\{t_j\}_{j \in AA_l})_{l \in (1,2,\ldots,n)}$.

2) Key generation: A VPP participant ID_i with attribute set ω (e.g., $\omega = \{\text{Asset Owner}, \text{Solar Farm}, \text{North Region}\}$) sends λ_i to the attribute authority node AA_l to request the corresponding private key. For any attribute $j \in \omega \cap AA_l$, the computation is conducted as follows:

$$S_{i,j} = g^{\frac{\alpha \lambda_i}{t_j}} h^{\frac{\alpha}{t_j}}, \quad W_i = g^{\alpha \lambda_i} \tag{1}$$

After receiving $S_{i,j}$ and W_i, the user computes $W_i^* = W_i \cdot g^{-\beta}$. The final private key for VPP participant ID_i is:

$$SK_{ID_i,\omega} = (\lambda_i, W_i^*, S_{i,1}, \ldots, S_{i,\|\omega\|}) \tag{2}$$

In this process, since each attribute authority node AA_l cannot obtain the secret parameter β, and the Certificate Authority (CA) cannot access the attribute key t_j, it is ensured that untrusted attribute authority nodes and the system center cannot decrypt the user's ciphertext.

3) Data encryption and storage: The VPP data owner employs the Secure Hash Algorithm 256 (SHA-256) hash function to hash the original data m (e.g., power generation data, market bids), denoted as $H(m) \rightarrow H_1$, where H_1 is utilized for subsequent verification. The data owner symmetrically encrypts the data as $Enc(k, m) \rightarrow CT_m$, where k is the encryption key, and CT_m is the resulting ciphertext. CT_m is uploaded to IPFS for storage.

Upon receiving CT_m, IPFS evaluates the size of the data. If the size exceeds 256 KB, it performs chunking on the data and stores the chunks across nodes located around the world. This process generates a unique hash value based on the content, referred to as the storage address, represented as a URL. Finally, the URL is returned to the data owner.

The data owner executes a concatenation operation, specifically $m_1 = (URL \| k \| H_1)$, where m_1 represents the new data, URL is the unique address returned by IPFS, k is the symmetric encryption key, and H_1 is the hash value.

4) Data encryption and upload: Obtain the latest attribute revocation list from all attribute authority nodes AA_l, represented as $R_l = \{(j, (\lambda_{rev}, L_{j,rev})_{rev \in List_j})\}$. The data owner selects random numbers $s, r \in Z_q^*$ and calculates:

$$C_0 = m_1 \cdot Z^{sr}, \quad C^* = g^{sr} \tag{3}$$

The data owner selects an access tree policy P_{ω^*} that defines which attributes are required to access the VPP data. Starting from the root node, an $n_x - 1$ degree polynomial q_x is selected for each internal node from top to bottom, as detailed in the access policy generation algorithm shown in Fig. 2.

For each leaf node $leaf_j$ in the access tree P_{ω^*}, compute:

$$C_{1,j} = T_j^{r \cdot q_{leaf_j}(0)}, \quad C_{2,j} = L_j^{r \cdot q_{leaf_j}(0)} \tag{4}$$

where, $L_j = v \cdot g^{t_j}$.

For attributes that have been revoked (i.e., $j \in \omega^*, List_j \neq \emptyset$), compute:

$$C_{1,j,rev} = T_j^{r \cdot (q_{leaf_j}(0) - u_{rev})}, \quad C_{2,j,rev} = L_j^{r \cdot (q_{leaf_j}(0) - u_{rev})} \tag{5}$$

where. u_{rev} is a random number associated with the revoked user.

The final attribute-based encrypted ciphertext is:

$$CT_{ABE} = \langle C_0, C^*, \{C_{1,j}, C_{2,j}\}_{j \in \omega^*, \text{List}_j = \emptyset}, \{C_{1,j,\text{rev}}, C_{2,j,\text{rev}}\}_{j \in \omega^*, \text{rev} \in \text{List}_j} \rangle \tag{6}$$

Once the data owner encrypts m_1, they upload CT_{ABE}, along with the encryption policy P_{ω^*}, to the blockchain. The attribute-encrypted ciphertext is stored in the public channel, while the access policy and user attributes are securely stored in the attribute channel. The public channel also holds the revocation list for managing access permissions. The comprehensive architecture for this data encryption and upload process is illustrated in Fig. 3.

Algorithm 1: Attribute-based encryption based on decision trees

1. Root :$q_{root}(0) = m_1$,Other n_{root}-1 coefficients are randomly selected.
2. Internal Node x:$q_x(0) = q_{parent}(index(x))$.
3. Leaf Node $leaf_i$: $q_{leaf_i}(0) = q_x(index(leaf_i))$.
4. **for** $j \in \omega^*, List_j = \emptyset$ **do**
   Compute:
   $C_{1,j} = T_j^{q_{leaf_j}(0) \cdot r}$, $C_{2,j} = L_j^{q_{leaf_j}(0) \cdot r}$.
5. **for** $j \in \omega^*, List_j \neq \emptyset$ **do**
   Traverse j revocation list $List_j$, select $|List_j|$ random numbers $u_1 + u_2 + \ldots + u_{|List_j|} = q_{leaf_j}(0)$.
   Compute:
   $\{C_{1,j,rev} = T_j^{u_{rev} \cdot r}, C_{2,j,rev} = L_{j,rev}^{u_{rev} \cdot r}\}_{j \in \omega^*, rev \in List_j}$
6. **output**
   $CT_{ABE} = < C_0, C^*, (C_{1,j}, C_{2,j})_{j \in \omega^*, List_j = \emptyset}, (C_{1,j,rev}, C_{2,j,re})_{j \in \omega^*, rev \in List_j} >$.

Fig. 2. Access policy generation algorithm for VPP data.

5) Attribute revocation: When a VPP participant loses decryption privileges or access rights change (e.g., a market participant leaves the VPP consortium), the data owner can re-encrypt the ciphertext without updating the decryption keys. The system supports two revocation scenarios:

a) Case 1: Attribute not previously revoked: ($j \in \omega^*, List_j = \emptyset$) Select a random number u_{rev}^* and compute the re-encrypted ciphertext $CT_{ABE}^{'}$:

$$C_{1,j,rev} = C_{1,j} \cdot T_j^{-u_{rev}^* \cdot r} \tag{7}$$

$$C_{2,j,rev} = C_{2,j} \cdot L_j^{-u_{rev}^* \cdot r} = L_j^{(q_{leaf_j}(0) - u_{rev}^*) \cdot r} \tag{8}$$

$$C_{1,j,rev^*} = T_j^{u_{rev}^* \cdot r}, \quad C_{2,j,rev^*} = L_j^{u_{rev}^* \cdot r} \tag{9}$$

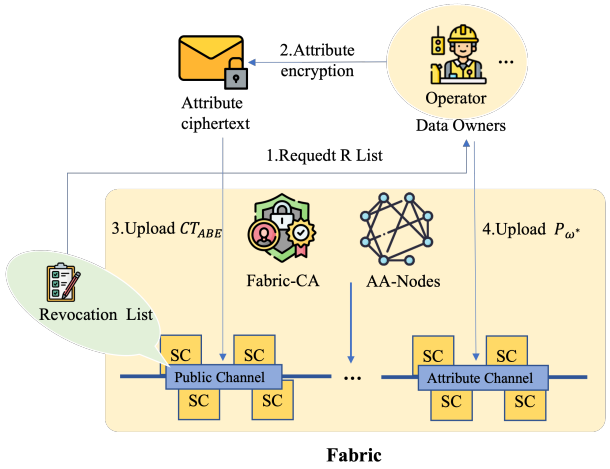

Fig. 3. Data encryption and upload architecture for VPP.

b) Case 2: Attribute already revoked: ($j \in \omega^*, List_j \neq \emptyset$) Select a random number u^*_{rev} and compute the re-encrypted ciphertext $CT^{'}_{ABE}$:

$$C_{1,j,rev} = C_{1,j,rev} \cdot T_j^{-u^*_{rev} \cdot r} = T_j^{(u_{rev} - u^*_{rev}) \cdot r} \tag{10}$$

$$C_{2,j,rev} = C_{2,j,rev} \cdot L_j^{-u^*_{rev} \cdot r} = L_j^{(u_{rev} - u^*_{rev}) \cdot r} \tag{11}$$

$$C_{1,j,rev^*} = T_j^{u^*_{rev} \cdot r}, \quad C_{2,j,rev^*} = L_j^{u^*_{rev} \cdot r} \tag{12}$$

The original attribute-encrypted ciphertext should be replaced with the newly computed ciphertext $CT^{'}_{ABE}$ on the blockchain.

6) Data decryption: The decryption algorithm operates recursively on the access tree P_{ω^*}. For each leaf node $leaf_j$, query the attribute revocation list R.

If the user's attribute has not been revoked ($j \in \omega \cap \omega^*, List_j = \emptyset$), compute:

$$\begin{aligned} \text{DecryptNode}\big(CT_{ABE}, SK_{ID,\omega}, \text{leaf}_j\big) &= \frac{e\big(S_{i,j} \cdot v^{\beta}, C_{1,j}\big)}{e\big(g, C_{2,j}\big)} \\ &= e(g,g)^{\alpha r \lambda_i \cdot q_{\text{leaf}_j}(0)} \end{aligned} \tag{13}$$

If the user's attribute has been revoked ($j \in \omega \cap \omega^*, List_j \neq \emptyset$), compute:

$$\begin{aligned} &\text{DecryptNode}(CT_{ABE}, SK_{ID,\omega}, \text{leaf}_j) \\ &= \prod_{rev \in \text{List}_j} \left(\frac{e(S_{i,j} \cdot v^{\beta}, C_{1,j,rev})}{e(g, C_{2,j,rev})} \right)^{\frac{\lambda_i}{\lambda_i - \lambda_{rev}}} \\ &= e(g,g)^{\alpha r \lambda_i \cdot q_{\text{leaf}_j}(0)} \end{aligned} \tag{14}$$

For a non-leaf node x in the access tree P_{ω^*} where the child node is z, call the result of $DecryptNode(CT_{ABE}, SK_{ID,\omega}, z)$ and denote it as F_Z.

$$\begin{aligned} F(x) &= \prod_{z \in S_x} F(z)^{\Delta_{i, S^{(0)}_x}} \\ &= \prod_{z \in S_x} \left(e(g,g)^{\alpha r \lambda_i \cdot q_z(0)}\right)^{\Delta_{i, S^{(0)}_x}} \\ &= e(g,g)^{\alpha r \lambda_i \cdot q_x(0)} \end{aligned} \tag{15}$$

The user is able to recursively compute $F(root) = e(g,g)^{\alpha r \lambda_i s}$, using the Lagrange interpolation method if and only if their attribute set ω satisfies the access policy P_{ω^*}.

The plaintext m_1 is ultimately recovered through the subsequent calculation:

$$\begin{aligned} m_1 &= \frac{C_0 \cdot e(C^*, W_i^*)}{F(root)} \\ &= \frac{m_1 \cdot Z^{sr} \cdot e(g^{sr}, g^{\alpha \lambda_i - \beta})}{e(g,g)^{\alpha \lambda_i r s}} \\ &= \frac{m_1 \cdot e(g,g)^{\beta s r} \cdot e(g^{sr}, g^{\alpha \lambda_i - \beta})}{e(g,g)^{\alpha \lambda_i r s}} \end{aligned} \tag{16}$$

The data user decomposes the retrieved data $m_1 = (URL \| k \| H_1)$ into three distinct components: the unique address URL, the symmetric key k, and the hash value H_1. The user will locally store k and H_1, and use the URL to query IPFS and download the encrypted data CT_m.

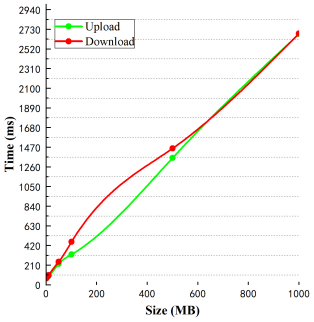
The data user performs the decryption algorithm $Decrypt(CT_m, k) \rightarrow m$, where CT_m is the ciphertext downloaded from IPFS, k is the symmetric key provided by the data owner, and m is the original VPP data that the user intends to access. After obtaining m, the user performs a hash operation on it, resulting in H_2. By comparing H_2 with H_1, if the two are found to be consistent, the data can be confirmed as authentic and valid. The data can then be utilized for various VPP purposes, such as a grid operator making dispatch decisions, a market participant submitting bids, or a regulator auditing VPP operations.

IV. Implementation and Performance Evaluation

We conducted the experiments on a server equipped with an 11th-generation 64-bit Intel i7-11800H processor (2.30 GHz, 8 GB RAM). The Hyperledger Fabric blockchain network was implemented on Ubuntu 22.04 using Fabric version 1.4.12 and Fabric CA version 1.4.12. All nodes operated on virtual machines via VMware Workstation. We selected a Java-based pairing cryptography library version 2.0.0 with an A-type curve for bilinear pairing operations relevant to VPP security requirements.

A. Data Upload and Download Performance

We evaluated data sizes typical for VPP applications: 1 MB (configuration files), 5 MB (hourly operational reports), 10 MB (daily aggregates), 50 MB (market bidding data), 100 MB (high-frequency sensor logs), 500 MB (historical performance data), and 1 GB (comprehensive datasets). The results, shown in Fig. 4, demonstrate linear scaling suitable for VPP data volumes.



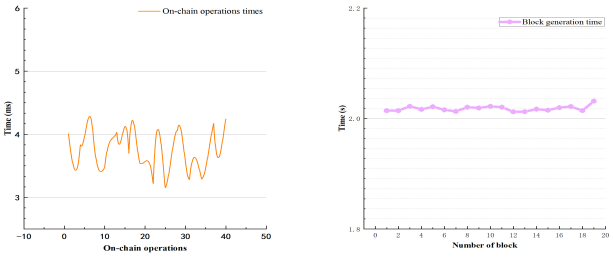


Fig. 4. Data upload and download performance for VPP data on IPFS.

B. Blockchain Performance for VPP Operations

We measured blockchain operations relevant to VPP scenarios: participant registration (2.8 ms), data access requests (3.1 ms), policy updates (3.5 ms), and revocation operations (4.0 ms). As depicted in Fig. 5, the block generation time remained stable at 2.02 seconds for VPP transaction batches, highlighting the system's operational efficiency. Each block contains VPP-specific metadata: operation type, stakeholder identifiers, timestamp, previous/current hashes, and data hashes.

(a) VPP on-chain operation times. (b) VPP block generation times.

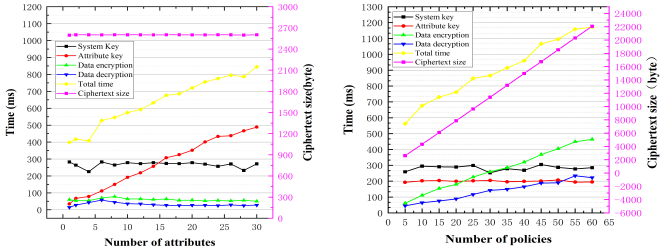

Fig. 5. Blockchain performance for VPP operations.

C. Access Control Performance Analysis

We evaluated system performance under VPP-specific attribute configurations: stakeholder roles (owner, operator, regulator, consumer), access levels (real-time, historical, financial), and organizational affiliations. With 5 policies and 10 attributes fixed, we measured initialization time (stabilizing at 255 ms), encryption time (proportional to policy complexity), decryption time (meeting real-time VPP requirements), and ciphertext size (scaling linearly with policies). The performance impacts of increasing attributes and policies are presented in Fig. 6. These results confirm the system's suitability for dynamic VPP environments where policies frequently evolve.

D. Discussion on Practical Deployment

While the experimental results demonstrate the feasibility of SIFChain, several practical considerations warrant discussion beyond the performance analysis presented above.

(a) VPP attribute scaling performance. (b) VPP policy scaling performance.

Fig. 6. SIFChain performance under VPP parameter variations.

First, the experiments were conducted on a server-grade processor, whereas real VPP deployments involve numerous low-power IoT devices at the edge. The computational overhead of CP-ABE operations, particularly pairing and exponentiation, may be significant on such constrained hardware. However, in practice, encryption is performed by data owners (typically VPP operators with sufficient computational resources), while decryption is carried out by consumers such as grid operators and regulators, who also possess adequate capacity. For resource-constrained edge nodes, lightweight ABE variants or offloading cryptographic operations to gateway devices could be considered as mitigations.

Second, our implementation uses Hyperledger Fabric v1.4.12, which, although stable, has been superseded by newer versions (2.x and 3.x) with different performance characteristics. The framework design is version-agnostic, and we expect similar trends in newer releases, but actual latency and throughput may vary. Future work should evaluate SIFChain on updated Fabric versions to validate its performance in modern production environments.

Third, the revocation mechanism requires communication between the data owner and attribute authorities to update the ciphertext. In a wide-area network, this may introduce additional latency proportional to the number of revoked attributes. Our experiments measured revocation operation time at 4.0ms in a local network; however, in geographically distributed settings, network delays could increase this to tens or hundreds of milliseconds. Nevertheless, revocation is an infrequent operation in VPPs, and the impact on overall performance is acceptable given the security benefits.

Finally, the evaluation was conducted in a controlled environment without a geographically distributed VPP consortium. Realistic deployment would involve multiple sites with heterogeneous network conditions and IoT devices, which could affect both performance and security. We plan to conduct field trials in a pilot VPP testbed as future work to validate the framework under real-world conditions.

E. Security Analysis

The security of SIFChain relies on standard cryptographic assumptions, including the bilinear Diffie-Hellman (BDH) assumption for the CP-ABE scheme and the collision resistance of SHA-256. We provide an informal security analysis covering the following guarantees:

1) Data confidentiality: Through the combination of symmetric encryption for IPFS-stored data and CP-ABE for access control, sensitive VPP data remains confidential even if IPFS nodes or blockchain channels are compromised.

2) Forward and backward security: The revocable CP-ABE scheme ensures that when a VPP participant's access privileges are revoked, they cannot decrypt newly encrypted data (forward security) nor previously encrypted data that they could previously access (backward security). Even if a user caches old symmetric keys, the re-encryption of the ciphertext with fresh randomness invalidates those keys, preserving backward secrecy.

3) Collusion resistance: Even if multiple VPP participants collude by combining their attribute keys, they cannot decrypt ciphertext unless at least one of them individually satisfies the access policy.

4) Decentralized trust: The collaborative key generation between CA and attribute authorization nodes eliminates single points of trust, making the system resilient to compromise of any single authority.

5) Data integrity: The use of cryptographic hashes ensures that any tampering with VPP data stored on IPFS can be detected during the decryption and verification process.

6) Privacy leakage: Although the dual-channel architecture isolates sensitive attributes, blockchain transactions themselves may leak metadata such as access patterns. An adversary monitoring the network could infer relationships between data owners and consumers. To mitigate this, future iterations could incorporate obfuscation techniques or zero-knowledge proofs [20]; however, this remains an open challenge.

We emphasize that a full formal proof of the CP-ABE scheme under bilinear assumptions is beyond the scope of this study and is left as future work. Nevertheless, the design follows established practices from prior art [8], [9].

V. Conclusion

This study presents SIFChain, a decentralized data management framework for Virtual Power Plants that integrates Fabric blockchain, IPFS, and enhanced revocable CP-ABE to ensure secure storage and dynamic access control. The key innovation is the collaborative key generation mechanism between CA and attribute nodes, reducing centralization vulnerabilities in distributed energy systems. The dual-channel architecture preserves confidentiality while supporting multi-stakeholder VPP operations. The revocable CP-ABE scheme enables fine-grained access control adapting to dynamic VPP environments. By storing encrypted data on IPFS, we achieve scalable security without semi-trusted third parties. Experimental results demonstrate linear scalability and low-latency operations suitable for VPP workloads. We also discussed practical considerations for IoT hardware, newer Fabric versions, and network overhead, and identified privacy leakage as an area for future enhancement. Future work will focus on decentralized attribute encryption, integration with real VPP systems, enhanced key management for large-scale energy applications, and formal security proofs.

AI-Driven Refactoring: Semantic Reconstruction of Domain Models Using LLM Reasoning

Mohamed El BOUKHARI[1], Nassim KHARMOUM[2], Soumia ZITI[3]
IPSS Research Team-Faculty of Sciences, Mohammed V University in Rabat, Rabat, Morocco[1,3]
IPSS Research Team-Faculty of Sciences, National Center for Scientific and Technical Research (CNRST), Rabat, Morocco[2]

***Abstract*—This study examines the application of large language models (LLMs) for automating domain layer reconstruction in legacy systems, with a specific focus on a case study involving water consumption management. The process begins with a deliberately disordered JSON representation that conflates domain, application, and infrastructure issues. An LLM, specifically GPT-5.2, was employed to identify misplaced methods, inconsistent naming, DTO misuse, incoherent aggregates, and unrelated modules, and subsequently reorganize the model into a structure aligned with Domain-Driven Design (DDD). The structure includes entities, value objects, aggregates, domain services, domain events, and repositories. The methodology involves encoding the legacy model as JSON, applying an LLM-based diagnosis and reconstruction pipeline, and producing both a refined domain model and a categorized catalogue of corrections. A comparative analysis of candidate LLMs, informed by recent code-centric benchmarks, such as SWE-bench and LiveCodeBench, supports the selection of GPT-5.2 as the primary model for this study. The findings indicate that the LLM can swiftly recover key domain concepts and achieve semantically consistent refactoring, a task that typically requires extensive manual effort. This suggests that LLM-assisted domain reconstruction is a promising adjunct to traditional refactoring practices and can facilitate continuous architectural improvements in organizations.**

I. Introduction

Legacy software systems represent a significant challenge in modern software engineering, where aging codebases continue to serve critical business functions despite outdated architectures and technologies. These systems often lack proper documentation, use obsolete programming languages or frameworks, and contain years of accumulated technical debt, making them difficult and risky to modify. Domain extraction is a crucial refactoring technique that involves identifying and separating distinct business domains or functional areas within monolithic systems to improve maintainability and enable modernization. However, extracting domains from legacy systems presents unique obstacles compared to working with newer codebases, including unclear business logic boundaries, tight coupling between components, and the absence of clear architectural patterns in the code. This process requires careful analysis to avoid introducing bugs or breaking existing functionality, while successfully isolating cohesive business domains that can be independently developed and deployed.

A. Domain Concepts in Modern Software Architecture

The concept of a domain in software engineering pertains to the comprehensive body of knowledge relevant to the problem at hand, encompassing the entire business area or specific support areas where particular categories of software systems are employed [1][2]. More specifically, a domain can be characterized as an area of expertise abstracted from the implementation details of the software, representing the minimal set of properties that accurately delineate a family of problems for which computer applications are necessary [1][5].

The domain layer is central to the domain-centric software architecture, encompassing the core logic of the developed software and serving as a pivotal reference throughout the application [6]. The domain model offers a representation of real-world entities and their interrelationships, which define the problem space of a system. It functions as a communication tool for all stakeholders, facilitating the emergence of concepts, such as ubiquitous language in Domain-Driven Design [3][2].

Domain engineering involves domain analysis, focusing on developing and maintaining reusable infrastructure within specific domains, and domain implementation, which includes application and component engineering [1]. The objective is to enhance domain information accessibility and extract relevant components from repositories rather than building new components. This methodology prioritizes the reusability of the analysis and design, not solely the code.

B. Challenges in Domain Extraction for Refactoring

The task of extracting domains to refactor legacy systems involves unique challenges that hinder the modernization efforts. A key challenge is determining service boundaries within monolithic architectures, which leads to inadequate service decomposition. This affects the system performance, scalability, and maintainability [4]. Legacy applications are not built with service-oriented principles but contain reusable functions that can become services [7].

A significant challenge is the structural disparity between the code organization and domain concepts. Source code rarely indicates the system's high-level components, and syntactical analysis can produce clusters that do not correspond to domain concepts owing to differing organizational patterns. This gap complicates the identification of refactoring opportunities where the benefits are evident [9].

Migration remains largely manual and labor-intensive, with methodologies providing guidance at the architectural level, often overlooking the code-level challenges [8]. When domain

models supplement static code analysis, their misalignment with the source code complicates the extraction process [7].

C. AI Domain Knowledge Extraction Capabilities

Modern AI systems effectively derive domain-specific insights from source codes using complementary techniques. Abstract Syntax Trees (ASTs) represent code's structural characteristics, enabling machine learning algorithms to discern syntactic relationships and semantic elements [10][19]. These structures allow AI models to leverage the organized nature of programming languages rather than processing code as linear text [20].

The construction of knowledge graphs is a pivotal capability in the extraction of domain knowledge, where AI systems develop graph representations with nodes that denote code entities and directed edges that define various relationships among program components [14][15]. These knowledge graphs empower AI to model complex inter-function dependencies and cross-file relationships, which are vital for a comprehensive understanding of program behavior [12].

AI systems can derive extensive semantic insights by integrating various analytical methodologies. Through static program analysis, these systems can identify essential elements, such as method overriding relationships, method calls, interface implementations, and type usage patterns [18]. Additionally, more sophisticated systems employ semantic dependency analysis to create semantic networks from imported libraries and public application programming interfaces (APIs). This process aids in the disambiguation of identifier senses, similar to the disambiguation of word senses in natural language processing [11].

The integration of ontological representations establishes a formal framework for modeling software system architecture and semantics, thereby enhancing the clarity and precision of the depiction of system relationships. This approach also facilitates dependency tracking, which is crucial for maintenance and refactoring tasks [17]. These capabilities extend across various applications, including vulnerability prediction, semantic-based code search, code summarization, classification, clone detection, and semantic error identification [13][16].

D. Semantic Analysis

In contemporary AI, advanced neural architectures conduct in-depth semantic analysis of source code beyond basic syntactic parsing. Transformer models, such as CodeBERT and CodeT5, have emerged as tools for semantic understanding, using self-supervised objectives to capture semantic and syntactic details [22][25]. These models interpret both programming and natural language contexts, while operating on raw source codes [22].

Attention mechanisms are a key technique in semantic analysis, enabling models to focus on relevant code segments during the output generation [29]. These mechanisms help AI systems better comprehend the code context in tasks such as variable naming and code summarization. Advanced methods use contrastive learning, comparing positive and negative code samples to improve representation learning and understanding of the target variables [29][23].

AI systems utilize multimodal analysis engines capable of concurrently processing various types of software artifacts, thereby discerning the semantic relationships among code implementations, requirement specifications, test cases, and documentation [21]. This holistic analysis approach considers the entire context of software development activities rather than examining the code in isolation.

Program analysis methods, such as abstract syntax trees (ASTs), control flow graphs (CFGs), and static analysis, help AI systems identify code patterns and suggest improvements [26]. Large language models (LLMs) have been effective in software engineering tasks, including code generation, summarization, clone detection, and automated repair, demonstrating their ability to understand code structure and semantics [28] [24] [27].

E. Planned Contributions and Paper Structure

This study presents three principal contributions: 1) the development of an end-to-end LLM pipeline for reconstructing domain layers from legacy artifacts, which automates the generation of entities/DTOs and the organization of subdomains; 2) the establishment of a semantic classification framework that employs function analysis and schema-driven prompts to ensure precise class placement; and 3) the initiation of an empirical evaluation framework with benchmarks for assessing fidelity, modularity, and scalability within enterprise contexts.

Section I introduces the research problem, outlines the motivation for automating domain reconstruction in legacy systems, and highlights the value of LLM-assisted refactoring. Section II reviews the related work on AI-driven refactoring and Domain-Driven Design extraction. Section III details the methodology, covering the artifact extraction, large language model prompting, and validation processes. Section IV presents a case study of a legacy monolithic system. Section V reports the evaluation results and analysis. Section VI discusses the findings. Section VII presents the limitations and future research directions, and Section VIII concludes the study.

II. Related Work

Cao et al. enhanced early neural methodologies by transitioning from basic networks for concept assignment to the application of LSTMs and Siamese RNNs for entity normalization and the development of knowledge graphs from codes [30]. Kabore et al. and Zhang et al. further refined AST-based approaches, such as ASTNN, by segmenting large trees into statement sequences [31][32], which were subsequently encoded using B-RNNs.

Keller et al. integrated multimodal representations, including lexical tokens, abstract syntax trees (ASTs), program trees and code visuals. They demonstrated the application of WySiWiM in utilizing code screenshots for image classification, achieving a performance comparable to syntax-based methods [31][34].

Zhang et al. (2024), Sachdev et al. (2018), and Ling et al. (2020) advanced the field of code search by transitioning from TF-IDF to the utilization of graph neural networks and attention mechanisms [33][35][37]. Furthermore, Rahman et al. (2023) and Ling et al. (2020) facilitated pattern transfer

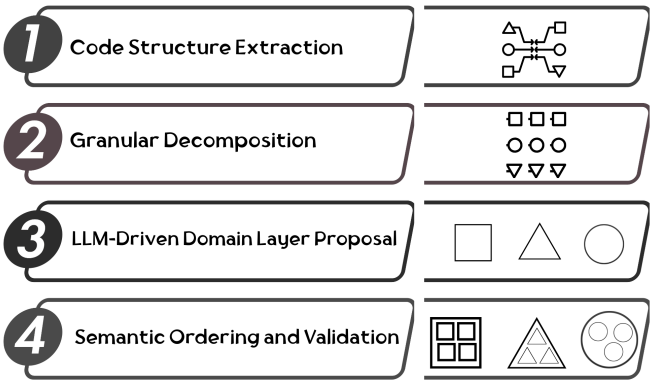

Fig. 1. Reconstruction pipeline.

in AdaCS by implementing domain embeddings and syntax matching [36][37].

Chowdhury et al. (2025), Chimalakonda et al. (2023), Chaieb et al. (2024), and Al-Debagy (2021) have integrated Abstract Syntax Trees (ASTs), Control Flow Graphs (CFGs), and Data Flow Graphs (DFGs) to capture behavior, thereby extending code2vec embeddings for the extraction of microservices from monolithic architectures [38][44][42][43]. This study directly informs the reconstruction of domain layers from legacy artifacts using large language models (LLMs). These studies underscore the semantic gaps that our LLM schema pipeline addresses in the generation of entities and Data Transfer Objects (DTOs).

A growing body of research explores how AI, and more recently, LLM-based techniques can automate refactoring and testing within software development cycles. Boukhlif et al. showed that intelligent testing approaches can reduce manual validation efforts in safety-critical medical systems [39], while El Boukhari et al. demonstrated AI-assisted refactoring for CQRS-based architectures and healthcare systems using NLP and design patterns to guide structural improvements and enhance testability [41][40]. These contributions support the feasibility of automating substantial portions of refactoring and testing, motivating the use of LLMs as a more semantically capable foundation for domain-driven reconstruction, as pursued in this study.

III. Methodology

The methodology delineates a systematic LLM-driven refactoring pipeline for legacy codebases, as shown in Fig. 1. This process transforms monolithic structures or incomplete domains into semantically coherent, lightweight domain layers.

A. LLM Choice

An advanced large language model serves as the primary reasoning engine, which is chosen for processing structured JSON, deducing domain concepts, and performing semantic transformations on software models. The model is applied throughout the pipeline, ensuring that the analysis, restructuring, and explanation are based on a cohesive semantic understanding. A comparative study of state-of-the-art language models is needed to evaluate their performance on code and architecture tasks to identify the most suitable model.

B. Reconstruction Pipeline

The methodology is delineated into four principal stages that outline the utilization of the LLM in reconstructing the domain layer as follows:

1) Code structure extraction: The initial step involves analyzing a JSON representation of the structure of the legacy codebase, with the assumption that method names convey meaningful semantic information (e.g., "calculateUserDiscount" suggests discount-related logic). This JSON encapsulates hierarchical components, including classes, methods, parameters, dependencies, and call graphs, within a standardized schema: {"classes": [{"name": str, "methods": [{"name": str, "params": list, "body_summary": str, "dependencies": list}]}]}. Parsing tools such as tree-sitter or AST analyzers are employed to extract this information without modifying the source code, thereby facilitating the subsequent semantic analysis.

2) Granular decomposition: The extracted structure was decomposed into the smallest viable functions, adhering to the single-responsibility principle. Each method is recursively divided by identifying cohesive blocks, such as loops and conditionals, through the semantic clustering of method names and body summaries. Fragments are renamed to preserve context, for example, "processDiscount" is divided into "validateEligibleDiscount" and "computeDiscountRate". Atomicity is ensured by limiting functions to a single semantic intent, which is verified through validation prompts such as "Is this function doing one thing only?" The output is a refined JSON that contains nested microfunctions.

3) LLM-driven domain layer proposal: By utilizing the decomposed JSON, a large language model (LLM) proposes an innovative domain layer structure that is semantically aligned with the intended purpose of the codebase. An LLM identifies domain concepts and adheres to the principles of domain-driven design (DDD).

4) Semantic ordering and validation: The proposed structure was enhanced using LLM-ordered topological sorting. The prompt validation process involves iterating through simulated refactoring paths, verifying semantic preservation, such as the cosine similarity of name embeddings before and after refactoring, and refining the process using few-shot examples from refactoring datasets. The final output is an executable JSON/YAML scaffold prepared for code generation and maintaining traceability to the original legacy elements. This pipeline improves automation in empirical refactoring studies, thereby reducing the cognitive load on engineers.

IV. Case Study

The case study examined a legacy water management system, as presented in Fig. 2, wherein the domain model was restructured into a JSON representation of the DomainLayer. This JSON format encapsulates the domain concepts in Fig. 3, including clients, water meters, and consumption records, as well as services, value objects, aggregates, and events, while highlighting design and layering issues. The WaterModule delineates the primary domain entities: a client characterized by identification and categorization attributes with a one-to-many relationship with the WaterMeter; a WaterMeter associated with location and linked consumption data; and a

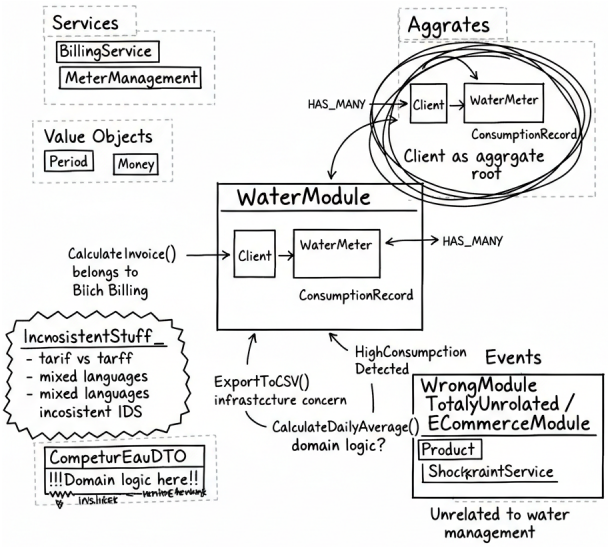

Fig. 2. Water meter system domain.

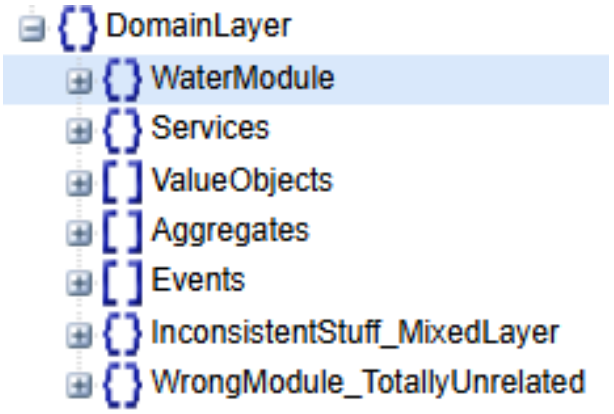

Fig. 3. Initial domain structure.

ConsumptionRecord that details metered usage over billing periods. The representation also enumerates domain services (e.g., BillingService and MeterManagement), value objects (e.g., Period and Money), aggregates rooted in Client, and domain events such as HighConsumptionDetected, offering a structural overview of the system.

The JSON format encodes layering violations and misplaced responsibilities through wrongMethods annotations across entities, services, value objects, aggregates, and events. The Client entity contains invoicing and notification functionalities (CalculateInvoice, SendEmailNotification) that are better suited for billing or infrastructure layers, whereas the WaterMeter entity includes export functionality (ExportToCSV) that is specific to application concerns rather than domain logic. Value objects such as Period and Money contain inappropriate persistence methods, and aggregates and events include messaging behaviors. A mixed layer, InconsistentStuff_MixedLayer, documents naming and language inconsistencies, whereas WrongModule_TotallyUnrelated shows an e-commerce module erroneously integrated with the water domain. This imperfect model serves as an input for the LLM-based approach to identify and realign responsibilities for an improved domain layer architecture.

V. Results

GPT-5.2 was identified as the primary large language model based on the comparative analysis presented in Table I. Among the models evaluated [45][46][47], GPT-5.2 exhibited superior performance on code-centric benchmarks, such as SWE-bench and LiveCodeBench, and excelled in repository-scale reasoning, semantic refactoring and domain-oriented architecture synthesis. These capabilities are directly aligned with the requirements of the proposed method. Although alternative models, including Claude 4.5 Sonnet and Kimi-Dev-72B, were retained as secondary references to contextualize the results, the detailed case study focused on GPT-5.2 to ensure a comprehensive and consistent evaluation.

The LLM initially performs a thorough semantic analysis of the existing JSON domain model, identifying misplaced methods, incorrect or unrelated modules, inconsistent naming conventions, mixed layers, and anti-patterns, such as Data Transfer Objects (DTOs) within the domain, entities containing service logic, value objects exhibiting persistence behavior, incoherent aggregates, and behavioral events. Subsequently, the model is transformed into a Domain-Driven Design (DDD)-aligned Domain Layer by reorganizing the content into canonical building blocks, including entities, value objects, aggregates, domain services, domain events, and repositories. This process involves relocating misplaced methods to the appropriate layers, standardizing naming conventions, and isolating unrelated modules as out-of-scope while maintaining traceability.

The LLM implements a series of targeted corrections that can be categorized into nine distinct areas. Initially, it removes **misplaced methods** from entities, value objects, aggregates, events, and DTOs (e.g., notifications, exports, persistence, webhooks), relocating authentic domain logic into domain services, and documenting technical concerns as out-of-scope infrastructure hints. Subsequently, it isolates **wrong or unrelated modules**, notably extracting the e-commerce module into a separate "UnrelatedModules" section with a clear rationale. **Naming conventions** are standardized by aligning identifiers, field names, value-object attributes, categories, and types to consistent English, PascalCase, and coherent ID conventions. To **address mixed layers**, infrastructure responsibilities (email, SMS, webhooks, CSV/PDF, persistence) are removed from the domain, with repository interfaces introduced to replace the entity-level data access methods. **DTOs are relocated** to a dedicated DTO section and stripped of domain logic, while **entities are cleaned** of calculation, notification, and retrieval behavior, which is centralized into dedicated domain services such as billing and meter management. **Value objects** are restored to immutability and behavioral purity by eliminating persistence-related operations. Aggregates are clarified so that a Client aggregate coherently contains WaterMeter, ConsumptionRecord, and Invoice, a WaterMeter aggregate encapsulates ConsumptionRecord, and all aggregate behaviors are removed. Finally, **domain events** are restricted to payload and description only, with behavioral aspects (e.g., webhooks) relocated to the appropriate application or integration layers.

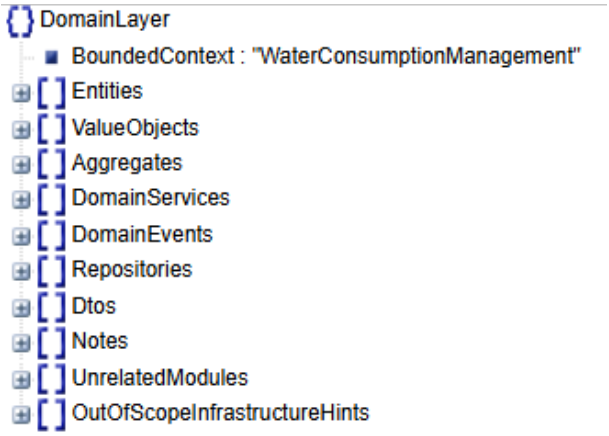

Fig. 4. Refactored domain tree view.

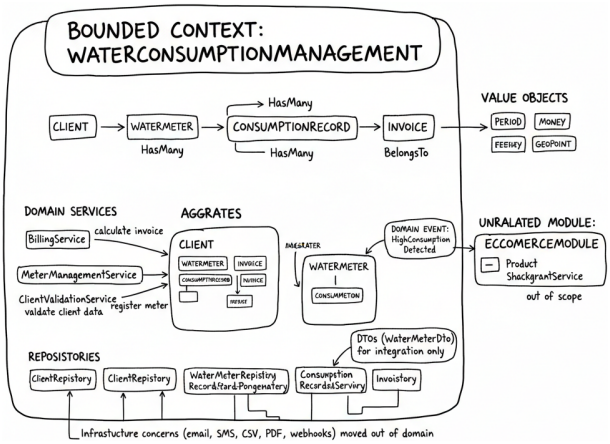

Fig. 5. Water meter system: new refactored domain.

The two figures present the LLM-driven reconstruction of the domain layer. Fig. 4 shows a refactored JSON tree view of the DomainLayer, with a cleaned bounded context and separated core domain elements (entities, value objects, aggregates, services, events, and repositories). Fig. 5 shows the domain architecture as a conceptual diagram, depicting the WaterConsumptionManagement bounded context with its main entities (Client, WaterMeter, ConsumptionRecord, Invoice), aggregates, value objects, and domain services, illustrating the final DDD-aligned structure.

The reconstructed model effectively illustrates the capability of large language models (LLMs) to rapidly identify key domain components with minimal guidance from humans. From the unstructured JSON data, the model consistently identified the central entities—Client, WaterMeter, ConsumptionRecord, and Invoice—along with their associated value objects, such as Period, Money, and GeoPoint. Furthermore, it recognized primary behavioral anchors, including billing and meter management services, even when these concepts were dispersed across various layers and inconsistent naming conventions. This automatic detection and clustering of core domain elements provide a robust foundation for architects, enabling them to refine aggregates and responsibilities rather than manually rediscovering the fundamental structure of a domain.

In a single execution, the LLM adeptly generated both the refined domain model and a list of necessary corrections. In contrast, the manual process of refactoring a domain layer of equivalent complexity generally requires a considerably greater investment of time from architects and domain experts.

VI. Discussion

The selection of GPT-5.2 as the primary model influenced the validity and generalizability of this study. Models in the GPT-5 class achieve state-of-the-art results on code benchmarks, such as SWE-bench and LiveCodeBench [45][46][47], which assess repository-scale reasoning and multi-file modification. These capabilities align with the requirements of this study, where the LLM must reason over JSON representations and identify architectural issues to reconstruct domain models. Utilizing this tool allows for the observation of the maximum potential of current LLM technology for domain-driven refactoring. Claude 4.5 Sonnet and Kimi-Dev-72B provide context within the broader model landscape, although the absence of a full parallel analysis limits cross-model conclusions. Future research should test multiple LLMs to evaluate how the choice of model affects the reconstruction quality.

The LLM exhibits two-phase behavior, aligned with the evidence of LLM-based refactoring capabilities [48][49]. Initially, it performs semantic analysis of the JSON domain model, detecting misplaced methods, unrelated modules, inconsistent naming, mixed layers, and anti-patterns, including embedded DTOs, entities with service logic, and events containing behavior. Studies have confirmed that LLMs can identify code smells and refactoring needs across code bases, particularly for recurring patterns. In the second phase, the LLM reorganizes the model into a DDD-aligned Domain Layer by mapping elements to canonical building blocks, relocating methods, normalizing names, and isolating unrelated modules while maintaining traceability. This aligns with research showing that LLMs effectively enforce architectural rules and layered separations when explicitly prompted.

The findings suggest that the LLM can execute a substantial, semantically coherent restructuring of the domain model in a significantly reduced timeframe compared to that typically required by human architects. Empirical research on LLM-based refactoring and automated tools demonstrates that these systems are particularly adept at addressing systematic, repetitive issues and can produce extensive refactoring suggestions at a much faster rate than developers [48], who may require several hours or days to implement comparable changes in nontrivial systems.

The reconstructed model effectively illustrates the capability of large language models to rapidly surface key domain components with limited human supervision. From the unstructured and inconsistent JSON, the LLM consistently recovered the central entities (Client, WaterMeter, ConsumptionRecord, Invoice), their associated value objects (Period, Money, GeoPoint), and the main behavioral anchors related to billing and meter management, despite these concepts being scattered across layers and expressed with heterogeneous naming conventions. This aligns with recent empirical work

TABLE I. COMPARISON OF LLMS FOR LEGACY CODE REFACTORING AND DOMAIN MODELING

Aspect	GPT-5.2 (OpenAI)	Claude 4.5 Sonnet (Anthropic)	Kimi-Dev-72B (Open-source)
Code benchmarks (e.g., SWE-bench, LiveCodeBench)	Among the top scores on SWE-bench and LiveCodeBench, repository-scale reasoning and transformation were very strong.	Competitive on coding and reasoning; slightly below frontier models on the hardest coding tasks.	Best open-source scores on SWE-bench Verified (around 60%); below frontier closed models but strong for OSS.[1]
Large-repository understanding	128k–200k+ context window; robust handling of mixed code and documentation for architecture tasks.	Very strong long-context reasoning (up to approximately 200k tokens); effective for narrative architecture analysis.	They have good context and stability but are more limited; large codebases typically require chunking strategies.
Refactoring and decomposition	It excels at stepwise refactoring, function extraction, and semantic renaming using chain-of-thought prompting.	Strong in explaining and refactoring code but slightly less aggressive by default on structural transformations.	Good at classic refactorings; more difficulty with deep semantic decomposition without careful prompting.
Domain and architecture modeling	It is very good at proposing DDD-like aggregates, domain layers, and JSON/YAML blueprints from the code structure.	Excellent at high-level conceptual modeling and textual rationale and strong for architecture narratives and trade-offs.	It can infer domains, but abstractions are less consistent and require more prompt engineering.
Tooling and ecosystem	Mature APIs and assistants for coding, IDE integration, CI, and code-review workflows.	Solid integration of conversational and analysis-centric workflows, including documentation and reviews.	Full local control and good OSS tooling integration, but higher DevOps and infrastructure overheads.
Openness and reproducibility	Closed weights: experiments reproducible via documented prompts and configs, but not locally hostable.	Closed model with reproducibility constraints similar to those of other proprietary systems.	Open weights; well-suited for fully reproducible, self-hosted experimental pipelines in research.

[51][50][5][48], which shows that LLMs can reliably extract domain concepts and modular structures from existing code and documentation, often matching or approaching human performance in tasks such as entity discovery, feature localization, and architectural view reconstruction, while requiring significantly less time. In practice, this automatic detection and clustering of core domain elements provides a strong starting point for architects, who can concentrate on refining aggregates, invariants, and responsibility boundaries instead of manually rediscovering the fundamental structure of the domain—a role for LLMs that is also emphasized in studies on AI-augmented software architecture and DDD refactoring in industrial contexts.

Although this study does not explicitly quantify cost or time, the capability of the LLM to generate a coherent domain reconstruction in a single iteration implies that it can potentially supplant numerous hours of detailed refactoring work typically undertaken by multiple developers. In practical applications, developers' efforts can be predominantly concentrated on validating and refining the LLM's proposal rather than executing the restructuring itself [51][48][52]. This shift in focus reduces the manual workload and, indirectly, the staffing and time costs that are generally associated with large-scale refactoring projects.

VII. LIMITATIONS AND FUTURE DIRECTIONS

A. Limitations

Despite promising outcomes, several challenges persist in the utilization of LLMs for domain-layer reconstruction. The model's decision-making process remains partially opaque: while it identifies recurring anti-patterns (e.g., misplaced methods), its rationale for nuanced design decisions, such as determining aggregate boundaries or allocating responsibilities between services, can be difficult to audit. The performance of LLMs is sensitive to prompt design and input representation; changes in the JSON structure or constraint phrasing may yield different reconstructions, raising concerns about stability compared to traditional refactoring approaches. Current models struggle with implicit domain knowledge and non-obvious invariants that are not explicitly encoded in the inputs, potentially oversimplifying business rules, as noted in studies of AI-augmented software architecture and DDD refactoring.

B. Future Direction

AI-driven refactoring is evolving towards more autonomous and intelligent systems that function as collaborative partners rather than suggestion tools.

Agentic coding tools represent a significant advancement in the role of artificial intelligence in refactoring processes, acting as collaborators that autonomously plan, execute, test, and refine complex development tasks with minimal supervision. Despite this potential, current agentic refactoring is largely limited to low-level, consistency-driven modifications, such as renaming and type adjustments, with agents performing fewer high-level design transformations than human efforts. To realize the potential of agents as "software architects", substantial progress is required to enable autonomous architecturally aware restructuring that addresses higher-level design challenges.

Future advancements are anticipated to focus on developing advanced AI-driven tools that effectively assist in both development and maintenance processes. These tools include automated debugging assistants, refactoring advisors, code summarizers, and documentation generators. The design of these tools must consider complex factors, such as historical usage patterns, module dependencies, backward compatibility requirements, and runtime constraints. Therefore, it is crucial for these tools to integrate seamlessly with developer workflows, including version control systems, CI/CD pipelines and issue trackers.

The field is advancing towards the development of more sophisticated automated refactoring tools capable of proposing specific refactoring strategies. These tools may, for instance, suggest the division of large modules into smaller, interconnected units with enhanced cohesion, with AI systems potentially executing these recommendations autonomously (Khanzadeh et al., 2023). Future developments are expected to include the advent of domain-specific AI models, increased transparency of AI-driven solutions, and collaborative tools

designed to integrate refined and updated development methodologies.

VIII. Conclusion

This study illustrates the effective application of advanced large language models (LLMs) in automating the semantic reconstruction of domain models from legacy software artifacts. Through the implementation of a structured LLM-driven pipeline, this approach adeptly identifies and reorganizes key domain elements, rectifies architectural inconsistencies, and aligns legacy codebases with Domain-Driven Design principles. This automation substantially diminishes the manual effort traditionally associated with domain extraction and refactoring, facilitating a more rapid, consistent, and semantically coherent modernization of legacy systems. A case study on a sample water management system demonstrates the method's capability to detect misplaced responsibilities, standardize naming conventions, and isolate unrelated modules while maintaining traceability. Future advancements in AI-driven refactoring hold the promise of increasingly autonomous and intelligent tools that will further transform software refactoring into an adaptive, explainable, and efficient process, fostering collaboration between human architects and AI agents.

Enhancing Telecom Churn Prediction Using Emotion-Driven and Behavioral Engagement Features

Huthaifa Aljawazneh
Faculty of Business-Department of Business Intelligence, Al-Zaytoonah University of Jordan, Amman, Jordan

***Abstract*—Accurate churn prediction enables service providers to develop effective retention strategies and promotes revenue stability in the telecommunication industry. This study enhances churn prediction performance by extracting five emotion-driven and behavioral engagement features from a telecom churn dataset. The new features represent derived, experience-oriented indicators constructed from operational usage data rather than direct psychological or survey-based measurements. To assess the effect of these engineered features on predictions, three powerful classifiers (i.e., CatBoost, Random Forest, and XGBoost) were trained and tested in a structured three-stage experimental design. In the first stage, the classifiers were trained and tested using the original dataset (original features only). In the second stage, the original dataset was enriched with five newly derived features (i.e., frustration index, trust score, satisfaction index, service usage score, and international experience index). Finally, in the third stage, only the engineered features were used in the classification process to evaluate their standalone predictive capability. Because the dataset is imbalanced, SMOTE and SMOTE-Tomek were applied to address this issue. The results demonstrate that incorporating these engineered features improves churn prediction performance across the reported evaluation metrics (accuracy, precision, recall, and specificity) for the classifiers and balancing techniques combinations presented. The enriched dataset (original + engineered features) achieves the strongest overall performance compared to using either original features only or engineered features only. Compared to the original features only, the enriched dataset achieved improvements of up to 3.6% in accuracy and 5.8% in recall. These findings indicate that emotion-driven and behavioral engagement features provide meaningful complementary information that enhances churn prediction effectiveness.**

***Keywords*—Customer churn prediction; emotion-driven features; feature engineering; imbalanced data; classification**

I. Introduction

In the telecom sector, where acquiring new customers is more expensive than retaining existing ones, customer attrition remains a major challenge [1]. Subscriber churn can be viewed as an outcome of the overall service experience that the subscriber has with the service provider, for instance, in Jordan's telecom environment, switching to another service provider is affected by the market competitiveness, costs, and service delivery [2]. Accordingly, the main purpose of telecom churn prediction is to support the development of effective retention strategies. In addition, it allows telecom companies to address customer concerns and meet expectations. Therefore, by predicting churn, service providers can identify and pay more attention to customers who are likely to churn to a competing provider, and develop targeted solutions and personalized offers to improve retention [3]. From a practical perspective, churn prediction models are most useful when they not only predict churn accurately, but also help explain the underlying reasons for customer churn.

However, most existing studies have focused on improving churn prediction using sampling techniques, feature selection, or model optimization, while relying mainly on original telecom attributes [3], [4], [5], [6], [7], [8]. These attributes provide descriptive information about service usage, but do not fully reflect customers' experiences or level of engagement with the service. In particular, traditional telecom features typically capture what customers did, while offering limited insight into how customers perceived the service, such as whether they were frustrated or satisfied. Accordingly, many churn models achieve strong predictive performance, but provide limited explainability from a customer experience perspective. Therefore, a clear research gap exists in the literature regarding the development and evaluation of experience-oriented features that represent customers' emotional states and engagement levels using operational telecom data.

To address this limitation, this study proposes a set of emotional and behavioral indicators derived from telecom data to reflect customer experience and engagement. In other words, five engineered features are grouped into two categories: emotion-driven features (i.e., frustration index, satisfaction index, and trust score) and behavioral engagement features (i.e., service usage score and international experience index) are derived from existing telecom data and aim to better represent customer experience, which supports a more behavior-oriented churn prediction.

In addition, to evaluate the effects of the proposed features on the classification performance, three ensemble classifiers (i.e., Random Forest [9], CatBoost [10], and XGBoost [11]) were trained and tested in three sequential experimental stages. In the first stage, classifiers were trained using the original telecom dataset to provide an initial reference for churn prediction performance. In the second stage, the original dataset was enriched with the proposed emotion-driven and behavioral engagement features. In the third stage, only the newly engineered features were used to train and test the classifiers to assess their standalone predictive capability. Moreover, since the dataset used in this study is imbalanced, SMOTE [12] and SMOTE-Tomek [13] balancing techniques were applied to address the data balancing problem. Finally, as accuracy alone is insufficient for evaluating churn prediction models on imbalanced data, additional performance metrics including

precision, recall, and specificity were employed to ensure a reliable evaluation.

Accordingly, the main contributions of this study are summarized as follows: 1) Extracting emotion-driven and behavioral engagement features that reflect customer experience using telecom usage data, 2) demonstrating the effects of combining the newly generated features with the original telecom features on the classifiers' performance. To achieve this, a structured experimental design is conducted, which compares original telecom data, enhanced telecom data (original + emotion-driven and behavioral engagement features), and the newly generated features only in telecom churn classification tasks.

The remainder of this study is organized as follows: Section II reviews related work on telecom customer churn prediction, with particular focus on machine learning approaches and feature engineering techniques. Section III describes the dataset used in this study and outlines its main characteristics. Section IV presents the proposed methodology, including the feature engineering process, the classifiers employed, the data balancing techniques, and the evaluation metrics. Section V reports and analyzes the experimental results obtained from the three-stage evaluation framework. Finally, Section VI concludes the study by summarizing the main findings and discussing limitations and directions for future research.

II. Related Works

Several researchers have addressed customer churn prediction in the telecommunications sector using machine learning and deep learning models. In this context, Wagh et al. [3] developed a machine learning-based system to predict customer churn in the telecom sector using Random Forest, K-Nearest Neighbors, and Decision Tree, relying on the original dataset to train and test classifiers. Furthermore, Gaur and Dubey [4] employed four machine learning algorithms, including Logistic Regression, SVM, Random Forest, and Gradient Boosted Trees, to build and compare effective churn prediction systems. Similarly, Poudel et al. [5] demonstrated that telecom customer churn can be effectively predicted using a Gradient Boosting Machine (GBM) enhanced by explainer models and visualization tools for deeper insights. Moreover, Lalwani et al. [6] proposed a six-phase methodology for telecom churn prediction using machine learning models (i.e., Logistic Regression, Support Vector Machine, Random Forest) and boosting techniques.

However, a limited number of studies have focused on feature selection and feature transformation, which can reveal deeper patterns related to dissatisfaction or reduced service quality. For instance, Huang et al. [14] proposed a feature-selection approach that prioritizes churn-related attributes in an imbalanced telecom dataset. Their method outperformed conventional selection techniques such as Chi-Square and Information Gain, showing that carefully identifying discriminative features can significantly enhance the prediction performance. Moreover, Sana et al. [15] demonstrated that combining univariate feature selection with several transformation methods produces more informative feature representations. Their approach improved the prediction accuracy of telecom churn.

More recent studies have focused on hybrid feature-selection strategies. For example, Mozaffari et al. [16] combined several feature selection methods and aggregated their outputs to identify the most relevant and reliable features. The results show that this hybrid feature selection significantly improves churn prediction performance.

Therefore, these studies highlight the effectiveness of feature engineering in improving churn prediction, but they mainly transformed existing dataset attributes or removed weak ones. None explicitly attempted to derive advanced emotion-related features that capture customer frustration, satisfaction, trust, usage sentiment, or service engagement. Therefore, the literature lacks structured attempts to quantify psychological or experience-based patterns that could affect churn decision-making. Addressing this limitation, the present study introduces newly engineered emotion-driven and behavioral engagement features and evaluates their effect on telecom churn prediction performance.

III. Dataset Description

The dataset used in this study was obtained from the Kaggle community. It consists of 3,333 customer records and 20 attributes, 16 of which are numerical and 4 are categorical. The dataset is imbalanced, with 2,850 non-churner customers and 483 churners. In addition, three of the categorical attributes are binary (Yes/No), which were converted into a binary indicator (0/1), while the remaining categorical attribute (i.e., *State*) was excluded from the analysis due to its high cardinality and limited contribution to predictive performance. Furthermore, the data were divided into stratified training and testing sets, and the class balancing problem was addressed using SMOTE and SMOTE-Tomek, applied only to the training data. All engineered features were derived exclusively from the original input variables to prevent data leakage. However, more details about the dataset used in this study are available in: https://www.kaggle.com/datasets/mnassrib/telecom-churn-datasets, and no missing values were observed.

IV. Methodology

In this work, we extracted five engineered features from the original dataset: three emotion-driven features (frustration index, trust score, and satisfaction index) and two behavioral engagement features (service usage score and international experience index). The extracted features were then inserted into the original dataset, and were used to train and test three powerful classifiers (i.e., CatBoost, RF, and XGBoost). The dataset is highly imbalanced; thus, two advanced balancing techniques were used to handle this issue (i.e., SMOTE, and SMOTE-Tomek). Moreover, four metrics were used to evaluate the performance of classifiers in predicting churn (i.e., accuracy, precision, recall, and specificity). On the other hand, to observe the impact of adding the emotion-driven and behavioral engagement features to the original dataset on the classifiers' performance, the original dataset (with no emotion-driven and behavioral engagement features) was used to train and test classifiers. Furthermore, to obtain a broader view on the impact of the emotion-driven features on the classification performance, the emotion-driven and behavioral engagement features were used exclusively to train classifiers.

Fig. 1 illustrates the overall research framework adopted in this study.

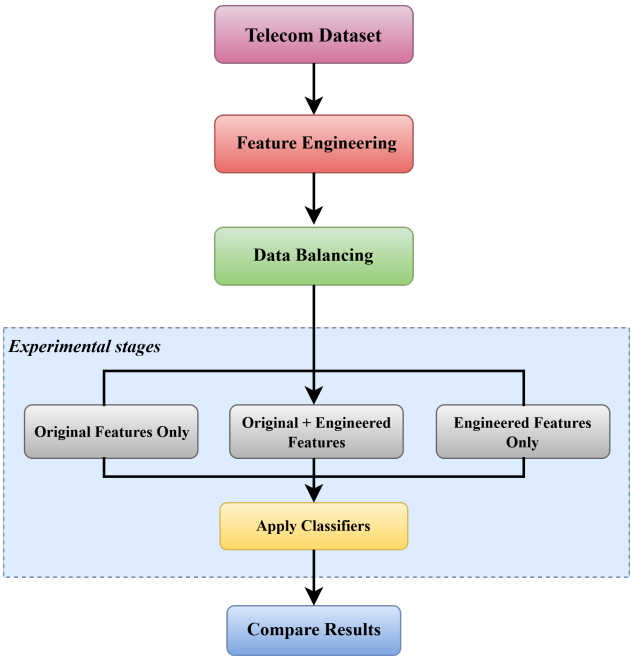

Fig. 1. Overall research framework of the proposed telecom churn prediction methodology.

A. Emotion-Driven and Behavioral Engagement Feature Engineering

To enrich the telecom churn dataset, a set of emotion-driven and behavioral engagement features was extracted from existing attributes and added to the original dataset. These features are grouped into two categories:

- Emotion-driven features: *frustration index*, *satisfaction index*, and *trust score*.
- Behavioral engagement features: *service usage score*, and *international experience index*.

The following list explains the extraction process for each newly derived feature.

1) Frustration index: Customer frustration is extracted from the Customer Service Calls feature, which measures how many times a subscriber contacted support. Therefore, frequent calls indicate unresolved problems or dissatisfaction with service quality.

$$Frustration_c = \frac{\min(CustomerServiceCalls_c, 10)}{10} \quad (1)$$

where, $CustomerServiceCalls_c$ is the number of service calls made by customer c. The $min(x, 10)$ function limits the number of calls to 10 to prevent excessive values from affecting the results. The division by 10 rescales the values; 0 corresponds to no calls, whereas 1 corresponds to 10 or more calls.

2) Trust score: Trust is derived from the Account length feature, which represents the number of subscription days. A longer subscription period indicates stronger loyalty and confidence in the provider. To measure Trust score, a min/max normalization was applied.

$$Trust_c = \frac{AccountLength_c - \min(AccountLength)}{\max(AccountLength) - \min(AccountLength)} \quad (2)$$

In this formula, $AccountLength_c$ presents the subscription duration of customer c. The minimum and maximum values of $AccountLength$ represent the shortest and longest subscription periods found in the dataset.

3) Satisfaction index: Satisfaction is extracted from the efficiency of daytime service usage, which is expressed as the ratio of *Total day minutes* to *Total day charge* features. Customers who receive more minutes per unit cost are assumed to have higher satisfaction. The satisfaction index is then scaled between 1 and 5.

$$Satisfaction_c = 1 + 4 \times \frac{\frac{TotalDayMinutes_c}{TotalDayCharge_c + \varepsilon}}{\max\left(\frac{TotalDayMinutes}{TotalDayCharge + \varepsilon}\right)} \quad (3)$$

The formula includes $TotalDayMinutes_c$ which represents daytime minutes used by customer c, and $TotalDayCharge_c$ which represents the corresponding cost. Also, the formula includes a small constant ε to avoid division by zero. The denominator represents the highest efficiency ratio found in the dataset, which ensures that the customer with the highest efficiency gets a satisfaction score of 5, while all remaining customers are proportionally scaled between 1 and 5.

4) Service usage score: The calculation of off-peak hours billing fairness through balance ratio requires the integration of evening and night usage data with their respective charges according to the following formula:

$$Balance_c = \frac{TotalEveMinutes_c + TotalNightMinutes_c}{TotalEveCharge_c + TotalNightCharge_c + \varepsilon} \quad (4)$$

For customer c, $TotalEveMinutes_c$ and $TotalNightMinutes_c$ show the total evening and night call times, while $TotalEveCharge_c$ and $TotalNightCharge_c$ represent the corresponding charges. A tiny value of ε was added to avoid division by zero. This balance ratio was used to calculate the $ServiceUsageScore_c$, as shown in the following formula:

$$ServiceUsageScore_c = \frac{Balance_c - \min(Balance)}{\max(Balance) - \min(Balance)} \quad (5)$$

where, $Balance_c$ represents the ratio of off-peak usage to charge for customer c, while $min(Balance)$ and

$max(Balance)$ represent the minimum and maximum balance ratios found in the dataset. The scores increase with better off-peak efficiency, indicating improved billing performance.

5) International experience index: Satisfaction with international services was represented by the average duration of international calls. This was calculated for each customer and then normalized across the dataset, as described in the following formulas:

$$IntlExp_c = \frac{TotalIntlMinutes_c}{TotalIntlCalls_c + \varepsilon} \tag{6}$$

$$IntlExperienceIndex_c = \frac{IntlExp_c - \min(IntlExp)}{\max(IntlExp) - \min(IntlExp)} \tag{7}$$

Here, $IntlExp_c$ represents the average international call duration for the customer c. The total international call duration for customer c is represented by $TotalIntlMinutes_c$. Whereas the total number of international calls made by customer c is denoted as $TotalIntlCalls_c$. The fraction computes the average international call length, with ε included to avoid division by zero. The minimum and maximum observed averages, $min(IntlExp)$ and $max(IntlExp)$, are then used to rescale the measure into the [0,1] interval. Higher values reflect better international call experiences.

B. Classifiers Employed

1) Categorical boosting (CatBoost): It is a powerful classification algorithm that builds ensembles of binary decision trees to perform gradient boosting operations. It introduces a technique called ordered boosting, where the model is trained on specific permutations of the dataset. For each data point, CatBoost computes predictions and target statistics using only the preceding examples within the permutation. This prevents target leakage, leading to better generalization and reduced bias [10].

2) eXtreme gradient boosting (XGBoost): It is an efficient and scalable machine learning algorithm based on the gradient boosting framework. Its procedure is based on building an ensemble of decision trees sequentially, where each new tree attempts to correct the errors made by the previous ones. Furthermore, the addition of regularization techniques in XGBoost enhances its performance compared to conventional boosting algorithms [11]. Additionally, it provides parallel processing capabilities, internal handling of missing data and optimized data structures which enhance speed and accuracy in different classification tasks [17].

3) Random forest (RF): It is a supervised machine learning algorithm that generates decision trees and combines their outputs to improve the accuracy and reliability of the model. Each tree is trained on a randomly selected subset of the dataset, and at each decision point within the tree, only a random subset of features is considered. The random selection process creates different trees which work together to prevent overfitting and improve predictions for new data points [9]. Additionally, in classification, it selects the most common prediction among all trees, while in regression, it calculates the average of their outputs [18].

However, hyperparameter tuning was not performed in this study. All classifiers were implemented using their default parameter settings as provided in their respective libraries to ensure a fair comparison across the three experimental stages.

C. Balancing Techniques Used

1) Synthetic Minority Over-sampling Technique (SMOTE): It is an advanced oversampling technique that generates new synthetic samples through interpolation between minority class instances and their *k*-nearest neighbors instead of replicating the existing minority class samples. This is done by selecting a random point on the line segment connecting the two feature vectors. Consequently, this technique effectively expands the decision space for the minority class and reduces the risk of overfitting [12].

2) Synthetic Minority Over-sampling Technique (SMOTE) with Tomek Links (SMOTE-Tomek): SMOTE-Tomek is a hybrid resampling technique that combines SMOTE with Tomek Links to better handle class balancing issue and enhance classification performance. As stated before, SMOTE generates synthetic samples by interpolating between minority class instances and their nearest neighbors, thereby increasing the representation of the minority class. On the other hand, Tomek Links identify pairs of instances belonging to different classes that are each other's closest neighbors; these pairs often occur near class boundaries and are likely to be noisy. Removing such pairs produces a cleaner dataset with clearer class separation, which helps classifiers achieve more robust performance [13].

D. The Evaluation Metrics Considered

The performance of the classifiers was evaluated using four metrics: accuracy, precision, recall, and specificity [19]. These metrics provide a comprehensive evaluation of model performance, particularly for imbalanced classification problems.

- Accuracy: measures the overall proportion of correctly classified instances in both classes; churn and non-churn.
- Recall: measures the proportion of actual minority class instances (churn) that are correctly identified by the classifier.
- Specificity: measures the proportion of majority class instances (non-churn) that are correctly identified.
- Precision: identifies the proportion of predicted minority class instances (churn) that are truly positive, indicating the reliability of positive predictions.

V. Results

This section presents the experimental findings obtained in three stages of analysis. The first experiment evaluates classifier performance using the original telecom dataset with traditional features only. The second experiment introduces emotion-driven and behavioral engagement features alongside the original attributes to assess their added value. Finally, the third experiment examines the predictive power of emotion-driven and behavioral engagement features in isolation. The results are compared across multiple classifiers and balancing

TABLE I. EVALUATION METRICS OBTAINED FROM THE COMBINATIONS OF CLASSIFIERS AND BALANCING TECHNIQUES ON THE ORIGINAL DATASET ONLY.

Model	Accuracy	Precision	Recall	Specificity
CatBoost + SMOTE	0.9272	0.9620	0.8895	0.9649
CatBoost + SMOTE-Tomek	0.9488	0.9686	0.9276	0.9700
RF + SMOTE	0.9395	0.9700	0.9070	0.9719
RF + SMOTE-Tomek	0.9559	0.9657	0.9452	0.9665
XGBoost + SMOTE	0.9421	0.9755	0.9070	0.9772
XGBoost + SMOTE-Tomek	0.9559	0.9674	0.9435	0.9683

techniques to highlight the role of the newly generated features in enhancing churn prediction.

A. Results of the First Experiment: Original Dataset Only

In the first part of the experiments, customer churn prediction was performed using CatBoost, RF, and XGBoost on the original telecom dataset without the inclusion of the emotion-driven and behavioral engagement features. To address class imbalance, two resampling methods, SMOTE and SMOTE-Tomek, were applied. The performance of the classifiers was evaluated using accuracy, precision, recall, and specificity metrics. As is common in similar works [20], we compare the performance of classifiers to determine the best performer.

As shown in Table I, all classifiers yielded strong performance in predicting customer churn, and SMOTE-Tomek consistently outperformed SMOTE. The performance of the combinations of CatBoost , RF, and XGBoost with SMOTE-Tomek performs better than the combinations of the same classifiers with SMOTE in predicting the majority class and the minority class; the combinations with SMOTE-Tomek obtained higher recall and specificity. With respect to precision, the combinations of RF and XGBoost with SMOTE obtained slightly higher values compared to SMOTE-Tomek. Accordingly, these results indicate that all three classifiers are effective in predicting customer churn in telecom. However, SMOTE-Tomek obtained more balanced outcomes as stated in recall and specificity. This confirms the importance of advanced balancing techniques in improving classifier performance, particularly in predicting the minority class (i.e., churn).

B. Results of the Second Experiment: Incorporating Emotion-Driven and Behavioral Engagement Features

In the second part of experiments, three emotion-driven features (i.e., *frustration index*, *trust score*, *satisfaction index*), and two behavioral engagement features (i.e., *service usage score*, and *international experience index*) were derived from the original dataset and added as new features. As in the first part of experiments, SMOTE and SMOTE-Tomek were employed to solve class balancing problem, and the classifiers' performance was evaluated using accuracy, precision, recall, and specificity metrics.

The results presented in Table II, show that the integration of emotion-driven and behavioral engagement features with the original dataset improved the performance of all classifiers compared to the previous experiment. However, in this part of the experiments all of the combinations of classifiers with

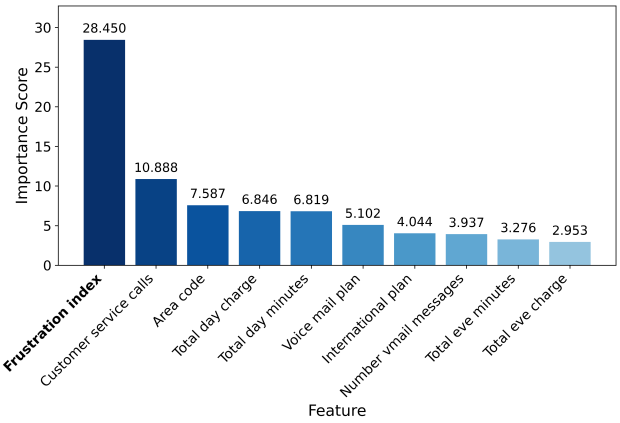

Fig. 2. Ten most important features in the classification process using CatBoost combined with SMOTE.

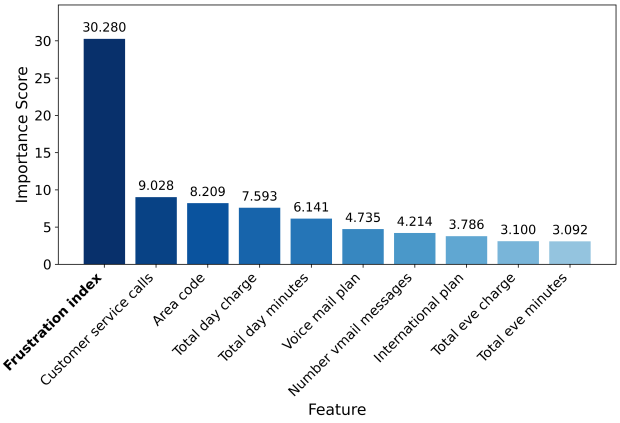

Fig. 3. Ten most important features in the classification process using CatBoost combined with SMOTE-Tomek.

SMOTE and SMOTE-Tomek balancing techniques obtained a significant accuracy value; all of them obtained more than 0.96, except the combination of RF with SMOTE, it obtained slightly lower value. In addition, the combination of CatBoost with SMOTE-Tomek showed superior performance in predicting the minority class (i.e., churn); it obtained the highest recall value. On the other hand, the combination of XGBoost with SMOTE showed the best performance in predicting the majority class (i.e., non-churn), as stated in the specificity metric values.

TABLE II. EVALUATION METRICS OBTAINED FROM THE COMBINATIONS OF CLASSIFIERS AND BALANCING TECHNIQUES APPLIED ON THE ORIGINAL DATASET + EMOTION-DRIVEN AND BEHAVIORAL ENGAGEMENT FEATURES

Model	Accuracy	Precision	Recall	Specificity
CatBoost + SMOTE	0.9632	0.9783	0.9474	0.9789
CatBoost + SMOTE-Tomek	0.9673	0.9783	0.9558	0.9788
RF + SMOTE	0.9570	0.9745	0.9386	0.9754
RF + SMOTE-Tomek	0.9629	0.9712	0.9541	0.9718
XGBoost + SMOTE	0.9675	0.9819	0.9526	0.9825
XGBoost + SMOTE-Tomek	0.9656	0.9765	0.9541	0.9771

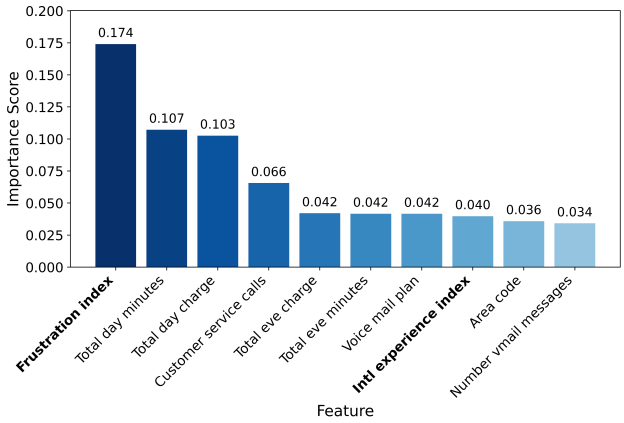

Fig. 4. Ten most important features in the classification process using RF combined with SMOTE.

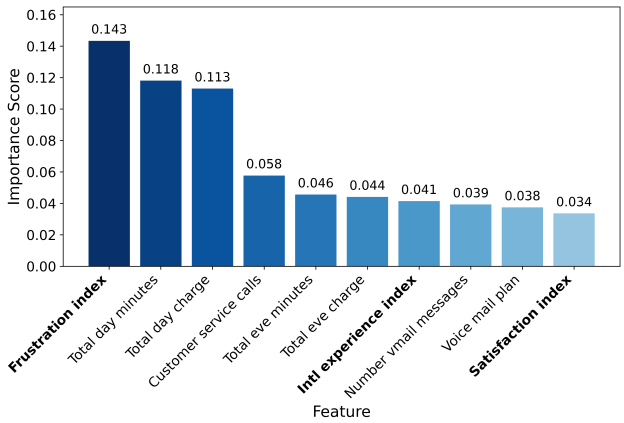

Fig. 5. Ten most important features in the classification process using RF combined with SMOTE-Tomek.

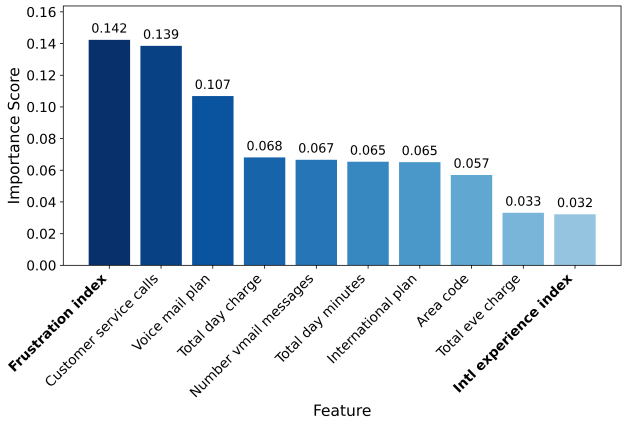

Fig. 6. Ten most important features in the classification process using XGBoost combined with SMOTE.

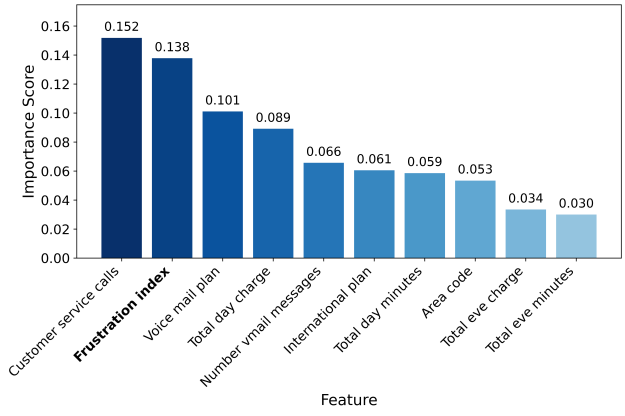

Fig. 7. Ten most important features in the classification process using XGBoost combined with SMOTE-Tomek.

Furthermore, feature importance analysis demonstrates how new emotion-driven and behavioral engagement features affect classifiers' performance. As shown in Fig. 2 to Fig. 7, the frustration index was the most important feature for all of the classifiers during the classification process, surpassing all of the original dataset's features, except with the combination of XGBoost with SMOTE, it was the second most important. The Satisfaction index and International experience index appeared in the top feature rankings obtained from RF + SMOTE, RF + SMOTE-Tomek, and XGBoost + SMOTE. Consequently, the repeated appearance of multiple emotional features in the top-ranked features for classifiers demonstrates their ability to improve the performance of classifiers in predicting customer churn.

A firm summary constructed from the second part of the experiments is that adding emotion-driven and behavioral engagement features consistently improves model performance in predicting both classes (i.e., churn and non-churn). This result is consistent with prior research indicating that customer experience and perceived service interactions play a critical role in shaping customer retention behavior and future decisions [21], [22].

TABLE III. EVALUATION METRICS OBTAINED FROM THE COMBINATIONS OF CLASSIFIERS AND BALANCING TECHNIQUES APPLIED ON THE EMOTION-DRIVEN AND BEHAVIORAL ENGAGEMENT FEATURES ONLY

Model	Accuracy	Precision	Recall	Specificity
CatBoost + SMOTE	0.8202	0.8163	0.8263	0.8140
CatBoost + SMOTE-Tomek	0.8444	0.8450	0.8435	0.8453
RF + SMOTE	0.8728	0.8571	0.8947	0.8509
RF + SMOTE-Tomek	0.8803	0.8707	0.8932	0.8674
XGBoost + SMOTE	0.8263	0.8142	0.8456	0.8070
XGBoost + SMOTE-Tomek	0.8508	0.8547	0.8453	0.8564

C. Results of the Third Experiment: Emotion-Driven and Behavioral Engagement Features Only

In the third part of the experiments, only five newly generated features were used to train and test classifiers. In addition, SMOTE and SMOTE-Tomek were adopted to solve the data balancing problem. Table III shows the results obtained by the combinations of classifiers and balancing techniques on the emotion-driven and behavioral engagement features.

Regarding the evaluation metrics values, the combinations of RF with SMOTE and SMOTE-Tomek outperformed all other combinations; they obtained the highest values for all evaluation metrics. On the other hand, the other combinations of classifiers with balancing techniques obtained considerable results with respect to predicting customer churn using the emotion-driven and behavioral engagement features only. Accordingly, the results obtained in this part of experiments proved that using the new features only to train and test classifiers to predict churn is not sufficient to achieve the same high levels of accuracy, recall, and specificity as when combined with original telecom dataset features. But it can still obtain relatively high values for the evaluation metrics.

D. Comparative Summary of the Three Experimental Stages

The three parts of the experiments gradually demonstrated the impact of inserting the emotion-driven and behavioral engagement features to the original dataset on the performance of classifiers in predicting churn. In the first part of experiments, only the original dataset's features were used to train and test the classifiers to predict churn. Thus, all classifiers showed strong performance, particularly when combined with SMOTE-Tomek. The second experiment introduced the emotion-driven and behavioral engagement features into the dataset, and yielded the highest performance across all models compared to the first part of experiments. In other words, there is an improvement in the performance of all classifiers and balancing techniques combinations regarding predicting both classes. All of the combinations trained and tested on the original dataset + emotion-driven and behavioral engagement features obtained better evaluation metrics values compared to the original dataset only. Moreover, feature importance analysis revealed that emotion-driven features, particularly, frustration index and satisfaction index, consistently ranked among the top ten important features in the classification process. This indicates the effectiveness of the emotion-driven features in predicting customer churn. Furthermore, the third part of experiments relied exclusively on the engineered features, and resulted in lower accuracy, recall, and specificity compared to the first and second parts of experiments. This suggests that while emotion-driven features provide significant improvement in the classifiers' performance, they are most effective when integrated with original telecom dataset features rather than used in isolation. Accordingly, the three parts of experiments confirm that the integration of emotion-driven features offers consistent added value for churn prediction.

VI. CONCLUSION

This study demonstrates that integrating standard (original) telecom features with five emotion-driven and behavioral engagement features, namely: frustration index, trust score, satisfaction index, service usage score, and international experience index, consistently improves churn prediction performance. Moreover, in three stages of evaluation, the results show that combining the telecom churn data with the proposed features yields better predictive outcomes than relying on the original telecom attributes only.

The experimental findings further indicate that emotion-driven and behavioral engagement features provide meaningful information that complements customer usage features (original data features), particularly in improving the prediction of customers at risk of churn. The consistent performance enhancement observed across Random Forest, CatBoost, and XGBoost indicates that the proposed features are effective across different classifiers, rather than being customized to a single classifier. In addition, SMOTE and SMOTE-Tomek proved their efficiency in addressing the data balancing problem, ensuring a reliable evaluation of churn prediction performance using multiple metrics (i.e., accuracy, precision, recall, and specificity).

From a practical perspective, the proposed features provide clear indicators of customer experience and engagement using existing operational data. Those indicators can be integrated into current churn prediction systems to improve performance and support retention strategies, without replacing existing prediction models.

Future research may extend this work by extracting similar features from richer data sources, such as customer surveys, textual interactions, or real-time service logs, and by evaluating their impact on deep learning–based churn prediction models. In addition, future research may analyze model explanations at both individual customer and customer segment levels to support more targeted and actionable retention strategies.

Declaration on the Use of Generative AI

The author declares that generative artificial intelligence (AI) tools were used solely for language refinement and grammatical improvement during the preparation of this manuscript. All scientific ideas, methodological design, feature engineering, experimental implementation, data analysis, interpretation of results, and conclusions were entirely conceived and developed by the author. The author has critically reviewed and edited all AI-assisted content and takes full responsibility for the accuracy, originality, and integrity of the work.

***Abstract*—Cardiopathy is one of the most serious diseases worldwide with its high morbidity and mortality rates posing a latent risk over time. The objective of this research focuses on evaluating Machine Learning (ML) models such as Random Forest (RF), Extreme Gradient Boosting (XGBoost), and Logistic Regression (LR) for the prediction of coronary heart disease (CHD), with the aim of identifying the most efficient model for this prediction. The model construction followed the Cross-Industry Standard Process for Data Mining (CRISP-DM) methodology, which comprises five stages: business understanding, data understanding, data preparation, modeling, and evaluation. The modeling results revealed the superior predictive capability of the XGBoost algorithm for detecting coronary heart disease, compared to Random Forest and Logistic Regression. The assessment of performance metrics (Accuracy, Precision, Sensitivity, and F1 Score) established XGBoost as the reference model, highlighting an F1 Score of approximately 90.8%. This superiority is attributed to its robustness in capturing nonlinear interactions among clinical variables. Consequently, the XGBoost model is selected as the optimal tool for integration into future medical decision support systems. In summary, this ML-based approach provides a highly predictive tool capable of identifying subtle risk patterns from real clinical data. The XGBoost model is a promising candidate for integration into decision support systems and for the optimization of primary prevention protocols for coronary heart disease.**

***Keywords*—Cardiovascular disease; machine learning; prediction; random forest; XGBoost**

I. Introduction

CHD continues to be one of the leading causes of death worldwide. According to the World Health Organization (WHO), cardiovascular diseases account for approximately 17.9 million deaths annually, representing 32% of all global deaths, and within this group, coronary heart disease constitutes the largest proportion of cases. Similarly, the American Heart Association (AHA) estimates that one in five deaths in the United States is related to coronary events, reflecting the magnitude of the problem in both developed and developing countries [1]. Furthermore, the European Society of Cardiology (ESC) [2] has indicated that despite therapeutic advances, late detection and the lack of accurate predictive tools remain key limitations in reducing the global burden of the disease.

On the other hand, the problem is exacerbated in low- and middle-income regions, where access to early diagnostics and specialized follow-up systems is limited, contributing to a sustained increase in premature mortality and a significant burden of associated disability [3]. Additionally, deficits in hospital infrastructure, the shortage of specialized professionals, and economic barriers to access advanced technologies create a substantial gap compared to high-income countries. In Latin America, reports from the Pan American Health Organization (PAHO) [4] indicate that cardiovascular diseases are responsible for more than 30% of deaths, with a significant proportion attributed to CHD. Added to this is the high economic impact, both from direct healthcare costs and indirect productivity losses, further increasing pressure on health systems [5]. These data underscore the urgent need for innovative strategies and accurate predictive tools to improve early detection and diagnosis in heterogeneous clinical contexts, with the aim of reducing health inequities and optimizing medical decision-making.

In this scenario, ML has emerged as a promising approach in healthcare, offering the ability to analyze large volumes of clinical data and detect nonlinear patterns that traditional statistical methods do not always capture. Recent research has applied algorithms such as LR [6], RF [7], and XGBoost [8] for cardiovascular disease prediction, showing promising results in terms of accuracy, sensitivity, and specificity. However, most of these studies have been conducted on specific populations, with small sample sizes and without external validation, limiting the generalizability of their findings. Furthermore, there is a noticeable scarcity of studies focused on Latin American populations, creating a significant gap in the literature and highlighting the need for contextualized research.

In this context, the present study aims to evaluate and compare the performance of ML algorithms LR, RF, and XGBoost in the prediction of coronary heart disease, with the purpose of identifying the most efficient model and providing evidence that contributes to the development of tools supporting early diagnosis in clinical practice. In this way, the study seeks not only to strengthen the field of medical informatics but also to address the need for solutions applicable to local contexts, with potential impact on reducing cardiovascular mortality and optimizing healthcare resources.

II. Literature Review

This section is organized into two main parts. First, a review of related works is presented, analyzing previous research in the field of cardiovascular disease prediction. This analysis allows for contextualizing the object of study and provides a comprehensive view of the current state of knowledge. Second, the theoretical foundations are addressed, including the main ML algorithms and the clinical aspects associated with CHD, with the purpose of conceptually

supporting the research. The following subsections elaborate on these aspects:

A. Related Work

In recent literature, various authors [9] have explored the potential of ML models in the detection and prediction of complications associated with cardiovascular diseases. In particular, [10] developed an XGBoost-based model aimed at anticipating unplanned one-year readmission in elderly patients with CHD. The study, conducted on a cohort of 2,137 individuals, reported a predictive performance with an Area Under the Receiver Operating Characteristic curve (AUROC) [11] of 0.704 and an AUPRC of 0.392 [12]. Moreover, the most clinically relevant variables were identified as length of hospital stay (LOS), age-adjusted Charlson comorbidity index (ACCI), monocyte count, blood glucose, and red blood cell (RBC) count, highlighting the utility of these parameters as significant predictors in assessing readmission risk. In contrast, another study aimed to develop an ML-based predictive model to estimate frailty risk in elderly patients with CHD [13],[14]. The main predictors identified were Activities of Daily Living (ADL) score [15], hemoglobin [16], low-density lipoprotein cholesterol (LDL) [17], total cholesterol [18], depression, and cardiac function classification [19], which were incorporated into an LR model and four ML algorithms (XGBoost, RF, LightGBM, and AdaBoost). Among them, AdaBoost showed the best performance, with an Area Under the Curve (AUC) of 0.803 in the validation set, demonstrating its robustness as a tool for clinical frailty risk assessment. Consistent with studies highlighting lipoprotein (a) as a cardiovascular risk marker, this study applied a decision tree ML model (Chi-square automatic interaction detection) to a multicenter registry of 2,301 patients with CHD or at high risk. Six clinical clusters were identified based on LDL cholesterol, CHD presence, family history, and age [20],[21]; these clusters were subsequently regrouped into three categories with progressive increases in Lp (a) and statistically significant differences $p < 0.001$. Consequently, the findings indicate that clinical clustering is an effective tool to stratify risk associated with elevated Lp (a) levels [22],[23]. Focusing on individuals aged 10 to 15 years, one study aimed to predict mortality from CHD using ML techniques [24]. The most relevant variables were selected, and based on them, various ML algorithms were trained, including LR [25], Support Vector Machines (SVM) [26], k-Nearest Neighbors (KNN) [27], Extra Trees Classifier (ETC) [28], and RF [29]. To ensure the validity of the results, 10-fold cross-validation was applied. The analysis showed that the KNN algorithm (k = 18) achieved the best performance, reaching an accuracy of 76.05%, an AUC of 79.41%, sensitivity of 81.08%, specificity of 71.28%, and precision of 73.48%.

Depression is also a key factor in the development of CHD, and in this context, ML emerges as an effective predictive tool [30],[31]. Various algorithms, including LR, RF, gradient boosting, SVM, XGBoost, decision trees, KNN, and neural networks, have been applied to improve risk estimation. Consequently, the RF model demonstrated the best performance, with an AUC of 0.987 in training and 0.996 in validation, as well as adequate calibration and an AUC of 0.928 after internal validation, confirming its high predictive capacity for assessing CHD risk in patients with depression. Another relevant aspect in the study of cardiopathy is exploring the feasibility of integrating ML algorithms for myocardial ischemia diagnosis. In a retrospective analysis of images from 206 patients, [32],[33] applied ML models such as XGBoost [34], RF [35], and logistic regression [36], all achieving accuracy levels above 0.80. Results showed that XGBoost performed best, with an accuracy of 0.903, an F1 score of 0.774, and an AUC of 0.931, demonstrating its high diagnostic potential for detecting myocardial ischemia.

A key element in cardiopathy diagnosis is the combination of artificial intelligence expert systems with neural networks, enabling early detection of at-risk patients and optimizing clinical decision-making. Data from the Framingham Heart Study, comprising 78,001 records, were used to construct a medical database. ML models such as RF, Decision Trees, and Neural Networks were implemented [37]. Consequently, the Decision Tree model achieved an accuracy of 90.08%, while the Neural Network reached 84.56%, demonstrating their capacity to predict the progression of coronary heart disease. Another study highlighted that cardiac disease classification improves the efficiency of medical decision support systems, while reducing associated diagnostic costs. Seven ML algorithms were evaluated, including LR, SVM, KNN, RF, decision trees, Naïve Bayes, and Gradient Boosting Classifier [38]. Hyperparameter optimization techniques such as Grid Search, Random Search, and Bayes Search were applied to maximize model performance [39]. Consequently, RF achieved the best performance, with an average accuracy of 92.85%, reaching up to 94.96% when ensemble methods were applied, evidencing its reliability and efficacy for cardiac disease classification in clinical settings.

Authors in studies such as [40],[41] developed ML models for predicting coronary disease in individuals with periodontitis. This study analyzed data from 3,245 patients, randomly dividing the sample into training and validation sets and considering variables such as age, race, history of myocardial infarction, chest pain, use of lipid-lowering medication, and serum levels of uric acid and creatinine. Five ML algorithms were trained: LR, Gradient Boosting Machine (GBM), SVM, KNN, and Classification and Regression Tree (CART), among which the KNN model showed the best performance, achieving an AUC of 0.977. Calibration metrics, Brier score, and decision curve analysis (DCA) confirmed the model's accuracy and clinical applicability, demonstrating the effectiveness of ML in predicting coronary disease in patients with periodontitis. Early detection of CHD has also been addressed using deep learning and ML techniques [42], employing seven classifiers, including KNN, SVM, LR, Convolutional Neural Networks, Gradient Boost, XGBoost, and RF. Class imbalance handling strategies were applied, with particular optimization of the XGBoost model [43], which achieved outstanding performance: 98.50% accuracy, 99.14% precision, 98.29% sensitivity, and 98.71% F1-score, demonstrating high efficacy for early cardiovascular disease identification. Continuing these investigations, the identification of congenital heart disease patients in large hospital databases involved ML analysis of 19,187 patients, of whom 3,784 were confirmed as CHD [44],[45]. Various algorithms, including Gradient Boosting Decision Tree, SVM, and Decision Tree, were evaluated and compared with regularized LR, using area under the precision-recall curve (AUPRC) as the main metric [46]. External validation

with data updated until 2010 showed that the Gradient Boosting Decision Tree model performed best, with an AUPRC of 99.3%, sensitivity of 98.0%, and specificity of 99.7%, demonstrating the ability of ML methods to efficiently automate the identification of patients with complex diseases like CHD. In summary, cardiac disease enables the identification of high-risk patients and guides more effective prevention strategies. Likewise, cardiac disease prediction has been explored using RF-based classifiers to identify the most relevant features associated with the disease [47],[48]. A recent study employed an RF classifier optimized via hyperparameter tuning using a grid search approach. This model was evaluated in terms of accuracy [49], error rate, and recall [50], and compared with a traditional system. Results showed that while the traditional system achieved accuracies between 81.97% and 90.16%, the hyperparameter-tuned model reached higher accuracies, ranging from 84.22% to 96.53%, demonstrating that ML-based methodology allows for more precise prediction of cardiac disease by optimally identifying the most relevant features.

In summary, the authors proposed an innovative approach for cardiac disease prediction using the Grey Wolf Optimization (GWO) algorithm combined with stacked ensemble techniques to enhance diagnostic accuracy [51]. A patient database was used to evaluate model performance compared to traditional methods. The model demonstrated significantly superior performance, achieving 93% accuracy, with strong metrics in precision (91%), sensitivity (95.3%), F1-score (92.9%), a Matthews correlation coefficient of 0.83, and reduced Log Loss of 2.87, confirming it as a more reliable and effective alternative for early cardiac condition diagnosis. Additionally, the study incorporated the Multi-Criteria Decision-Making (MCDM) approach using the Combined Compromise Solution (CoCoSo) technique to comprehensively evaluate different ML models applied to cardiac disease prediction [52]. This procedure identified LR and SVM as the most consistent and effective algorithms across three clinical datasets, demonstrating superior performance compared to other alternatives [53]. Evaluation was based on six performance metrics, confirming that both models offer greater robustness and reliability for constructing predictive systems aimed at early cardiac disease diagnosis. Similarly, identifying the most suitable model for addressing cardiovascular diseases is a significant challenge in healthcare, motivating the application of ensemble methods and deep learning frameworks on a test dataset obtained from the Kaggle platform [54]. Key predictive variables such as age, gender, cholesterol levels, blood pressure, and lifestyle-related factors were considered. The evaluation showed that both ensemble methods and deep learning outperformed traditional models, achieving higher levels of accuracy, sensitivity, and area under the ROC curve (AUC-ROC), highlighting their potential as more effective tools for early cardiovascular disease diagnosis. Despite these advances, most of the reviewed studies present limitations such as small sample sizes, lack of external validation, and limited application in Latin American populations, restricting the generalizability of the models.

B. Theoretical Bases

1) ML algorithms: ML has established itself as a rapidly expanding scientific discipline, driven by the design of advanced algorithms and its ability to uncover hidden relationships within complex datasets. Through the use of mathematical models and statistical approaches, this field enables computational systems to autonomously adjust their performance, emulating human cognitive processes [55],[56]. Its growing importance lies in its potential to contribute significantly to the generation of new knowledge and the strengthening of decision-making processes across multiple application domains [57]. However, building ML models requires the implementation of concepts derived from specialized programming languages, among which Python [58] stands out for its versatility and widespread adoption in the scientific community. Table I presents the most representative algorithms in the field of ML, highlighting their main characteristics according to different analytical criteria. Consequently, its relevance is based on the ability to handle processes and meet needs autonomously, providing value without requiring direct human intervention.

2) Coronary heart disease: CHD is defined as a cardiovascular disease caused, in most cases, by atherosclerosis of the coronary arteries. This pathological process involves the progressive accumulation of lipids, cholesterol, and other deposits on the arterial wall, leading to the narrowing or blockage of blood flow to the myocardium. As a result, the heart receives an insufficient supply of oxygen and nutrients, which can clinically manifest as angina pectoris, arrhythmias, or acute myocardial infarction. It is important to note that coronary heart disease is the leading cause of death in developed countries, and its impact is closely associated with the increase of risk factors such as hypertension [59], obesity [60], and sedentary lifestyle [61]. Furthermore, early detection through tools based on clinical data and artificial intelligence techniques represents a promising approach to improve the diagnosis and prevention of this disease.

Table II presents the percentage distribution by provinces and regions of Peru, ordered from highest to lowest value. It can be observed that the Constitutional Province of Callao tops the list with 18.2%, followed by Metropolitan Lima and the Department of Lima with 16.3% each. In the intermediate range, Lambayeque, Cajamarca, Ica, and Arequipa stand out, with values ranging from 15.1% to 16.0%. Conversely, the regions with the lowest percentages are Ucayali (8.3%), Huancavelica (9.2%), and Junín (9.5%), falling below the reference threshold of 14.2%. This classification allows a clear differentiation between regions with higher concentration and those with lower relative representation.

III. Methodology

A. Definition of the CRISP-DM Methodology

Regarding the definition of the research topic, the CRISP-DM methodology emerges as a highly viable option for its application [63]. This methodological approach, widely accepted in data mining projects, provides a systematic and flexible framework that facilitates problem understanding, data analysis, and the orderly construction of predictive models. Furthermore, several authors highlight that the CRISP-DM methodology constitutes a fundamental tool for structuring data mining projects, as it enables systematic analysis of information and organizes the process into clearly defined

TABLE I. COMPARISON OF ML ALGORITHMS

Algorithm	Description	Advantages	Limitations
Logistic Regression	A statistical model used for binary classification problems, estimating the probability of a categorical outcome.	- Simple and interpretable - Efficient with linearly separable data - Low computational cost	- Limited to linear relationships - Sensitive to multicollinearity - Poor performance with complex data
Random Forest	An ensemble method based on multiple decision trees combined using bagging.	- Handles high-dimensional data - Reduces overfitting compared to single decision trees - Provides feature importance	- Less interpretable than single trees - Computationally intensive with large datasets - May require tuning of hyperparameters
XGBoost	A gradient boosting framework optimized for efficiency and accuracy in classification and regression tasks.	- High predictive performance - Handles missing values well - Scales efficiently to large datasets	- Complex to tune (many hyperparameters) - Higher computational cost than simpler models - Less interpretable than linear models

phases: Business Understanding [64], Data Understanding [65], Data Preparation, Modeling, and Evaluation. This methodological framework not only provides an orderly and repeatable workflow but also allows each stage to be adapted to the specific characteristics of the data and the study objectives, as illustrated in Fig. 1. In health-related research, its application is particularly valuable, as it ensures process traceability and reinforces the validity of the generated predictive models. On the other hand, Fig. 2 describes a data analysis system for cardiac diseases driven by ML. The core process involves an ETL for enriched data ingestion, creating an interoperable database with clinical variables (such as blood pressure and BMI). The Data Assets manage the reuse of these resources through APIs. Data is stored in a Cardiac Disease Repository (with fragments and enterprise caching) and is subsequently processed and modeled using tools such as Python and R. The result is a trained ML catalog ready to be applied in various business scenarios.

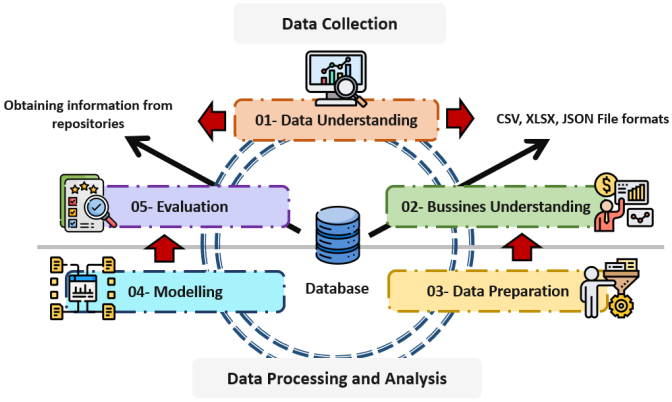

Fig. 1. CRISP-DM methodology.

1) Business understanding: The initialization stage in model development consists of understanding the project's requirements based on the analysis of the problem to be addressed. It focuses on a deep comprehension of the situation and the clear formulation of objectives that will guide the subsequent development of the model. In this regard, Table III presents the Business Understanding phase of the study [66],[67],[68]. The main problem is identified as the high prevalence and late diagnosis of coronary heart disease. The business objective is to support early diagnosis through ML tools, while the project objective is to compare LR, RF, and XGBoost to determine the most efficient model. Success criteria encompass clinical, technical, and social aspects, also considering constraints such as data availability and risks like overfitting. Finally, expected benefits are highlighted, including support for early diagnosis, resource optimization, and reduction of cardiovascular mortality.

2) Data understanding: In this second stage, corresponding to the Data Understanding phase, a systematic process was carried out aimed at the initial exploration and analysis of the available data. First, the dataset was collected in its raw form, providing the necessary clinical and demographic information for the study. On one hand, Table IV defines the activities of the Data Understanding phase of CRISP-DM, which include dataset collection and description, exploration through statistical analyses and visualizations, quality verification to detect inconsistencies, analysis of relationships between variables, and generation of initial hypotheses, applied in this study to the use of clinical and demographic data to

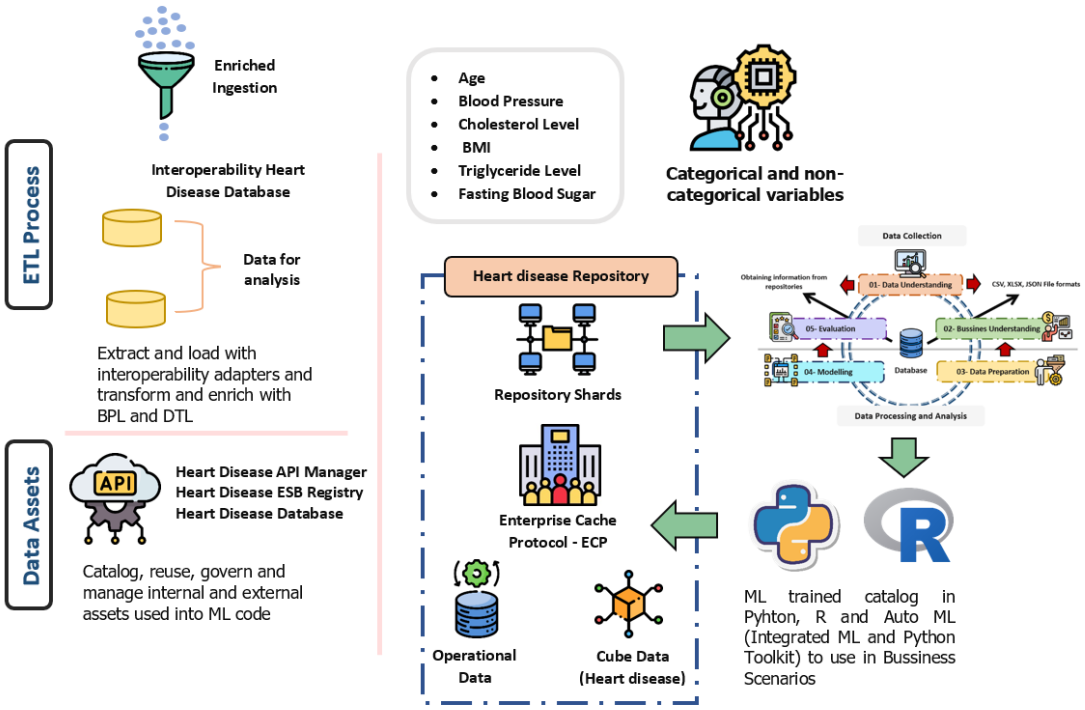

Fig. 2. ML architecture.

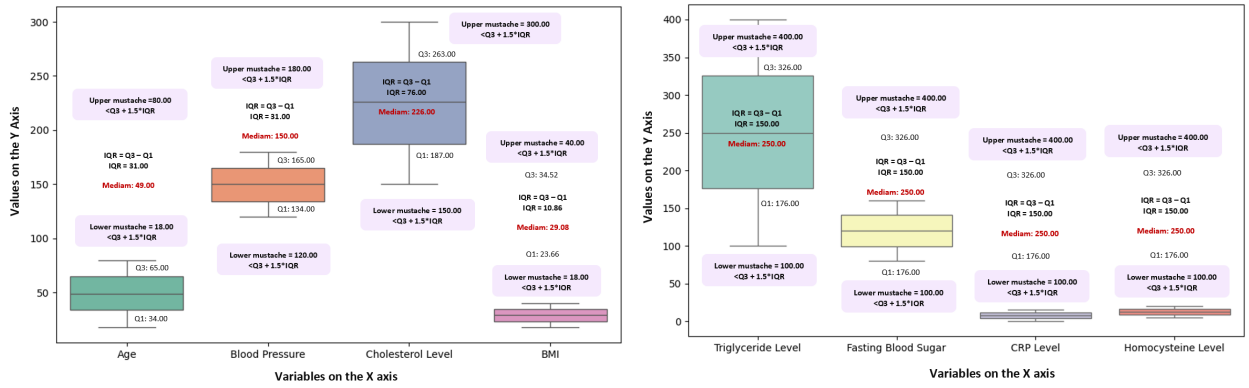
TABLE III. BUSINESS UNDERSTANDING PHASE ACCORDING TO CRISP-DM

Element	Description
Business / Clinical Problem	Coronary heart disease is one of the leading causes of mortality worldwide. Its late diagnosis increases the risk of severe complications and places a significant burden on healthcare systems.
Business Objective	To contribute to the early diagnosis of coronary heart disease through decision-support tools based on ML, enabling optimization of healthcare resources and reduction of cardiovascular mortality.
Project Objective	To evaluate and compare the performance of three ML algorithms (LR, RF, and XGBoost) in predicting coronary heart disease, in order to identify the most efficient and clinically applicable model.
Success Criteria	- **Clinical**: support early identification of at-risk patients. - **Technical**: achieve satisfactory performance metrics (accuracy, sensitivity, specificity, AUC). - **Social**: provide evidence applicable to local contexts, with potential impact on reducing cardiovascular mortality.
Constraints	Availability and quality of clinical data, potential imbalance in class distribution, and computational limitations for training complex models.
Risks	Risk of model overfitting, bias in clinical data, and lack of generalization to other populations or healthcare settings.
Expected Benefits	Support for early diagnosis, optimization of hospital resources, reduction of complications and mortality, and contribution of evidence to the field of medical informatics.



identify risk factors associated with heart disease [69],[70]. On the other hand, Fig. 3 shows box plots summarizing the distribution of various clinical and laboratory variables associated with heart disease. In Fig. 3a, direct risk factors such as age, blood pressure, cholesterol level, and body mass index (BMI) are presented, showing medians, quartiles, and dispersion ranges, with cholesterol and blood pressure exhibiting higher variability. In Fig. 3b, laboratory variables such as triglycerides, fasting glucose, C-reactive protein (CRP), and homocysteine are included, also showing outliers and greater dispersion in triglycerides, while fasting glucose exhibits a more concentrated range. These results allow the identification of central patterns and potential extreme values in the main factors associated with cardiovascular risk.

3) Data preparation: Table V presents the descriptive results of the variables included in the study: Table V(A) includes sociodemographic variables such as age and gender, which allow characterization of the population; Table V(B) covers relevant clinical variables such as blood pressure, cholesterol level, presence of diabetes, and body mass index, which are key factors in predicting heart disease; Table V(C) addresses habits and lifestyle factors, including alcohol and sugar consumption, stress level, and hours of sleep, which directly influence cardiovascular health; and Table V(D) presents the variable of interest, Heart Disease Status [71],[72], along with standardized measures of central tendency and dispersion, facilitating fair comparison across variables.

On the other hand, Table VI is divided into two sections: Table VI(A) General Information of the Dataset and Table VI(B) Missing Values per Column. The table confirms that the dataset contains a total of 21 attributes (20 predictor variables plus the target variable, Heart Disease

TABLE IV. ACTIVITIES OF THE DATA UNDERSTANDING PHASE IN CRISP-DM

Activity	Description	Application in the Study
Initial Data Collection	Obtain the dataset from the selected source and verify its structure.	Download of the dataset from Kaggle with clinical, demographic, and lifestyle variables.
Data Description	Identify the number of records, variables, and data types.	Review of 20 variables (Age, Gender, Blood Pressure, Cholesterol, Diabetes, etc.).
Data Exploration	Analyze relevant variables statistically and through visualizations.	Histograms of age, blood pressure, and cholesterol distribution; correlation plots.
Quality Verification	Detect missing, duplicate, outlier, or inconsistent values.	Identification of null values in clinical variables such as BMI and blood pressure.
Relationship Analysis	Examine links between attributes and the target variable.	Study of correlations between risk factors (cholesterol, diabetes, smoking) and *Heart Disease Status*.
Hypothesis Generation	Formulate initial assumptions to guide modeling.	Hypothesis: elevated cholesterol levels and hypertension are associated with a higher risk of coronary heart disease.

(a) Direct risk factors.

(b) Laboratory variables.

Fig. 3. Measures of central tendency according to dimensions.

Status), including both numerical (float64) and categorical (object) data types. However, the absence of the Statistical Summary section in the image prevents verification of claims regarding the mean age of 49 years, the average blood pressure of 149 mmHg, and cholesterol of 225 mg/dl, as well as the purported lack of calculated statistics for the BMI and Triglycerides variables.

4) Modelling: In this stage, predictive models were built using the data prepared in previous phases. For this purpose, different ML algorithms were selected and trained using the training and validation datasets. Fig. 4 presents the distribution of prediction errors for three classification models. In Fig. 4a, the performance of *RF* is shown, where errors are more concentrated around zero, indicating good predictive capability. In Fig. 4b, corresponding to *LR*, a greater dispersion of errors is observed, reflecting lower accuracy compared to the other methods [73]. Finally, Fig. 4c illustrates the distribution for *XGBoost*, which, like *RF*, keeps most errors close to zero, although with slight asymmetry. In all cases, the shaded areas highlight the most critical errors: false negatives on the left and false positives on the right, making it evident that the tree-based models (a) and (c) provide better control of these errors compared to the linear model (b).

B. Mathematical Formulas in ML Algorithms

The following formulas are commonly used in classical ML algorithms, such as LR, RF, and XGBoost. They formally describe the underlying mechanisms, optimization, and evaluation metrics of these models [74][75].

1) Logistic regression: Probability function: The logistic function models the probability of the positive class $Y = 1$ given predictors X [see Eq. (1)]. It transforms a linear combination of input features into a value between 0 and 1, representing probability.

$$P(Y = 1 \mid X) = \frac{1}{1 + e^{-(\beta_0 + \sum_{i=1}^{n} \beta_i X_i)}} \tag{1}$$

Transforms a linear combination of predictors into a probability between 0 and 1.

2) Logistic regression: Log-loss function: The log-loss function is minimized to estimate the coefficients β [see Eq. (2)]. It penalizes predictions that are confident but incorrect, guiding the optimization of model parameters.

$$\mathcal{L}(\beta) = -\sum_{i=1}^{m} \Big[y_i \log(P(Y_i = 1|X_i)) + (1 - y_i) \log(1 - P(Y_i = 1|X_i)) \Big] \tag{2}$$

Penalizes incorrect predictions according to their probability, guiding parameter estimation.

TABLE V. STATISTICAL SUMMARY OF PROCESSED VARIABLES

(A) DIRECT RISK FACTORS

Variable	count	mean	std	min	25%	50%	75%	max
Age	9971	-0.00	1.00	-1.72	-0.84	-0.02	0.86	1.69

CRP Level	9974	0.00	1.00	-1.72	-0.86	0.00	0.86	1.69
Homocysteine Level	9980	0.00	1.00	-1.72	-0.86	0.00	0.86	1.69

(C) LIFESTYLE VARIABLES

Variable	count	mean	std	min	25%	50%	75%	max
Alcohol Consumption	10000	1.49	1.13	0.00	0.00	1.00	2.25	3.00
Stress Level	10000	1.02	0.82	0.00	0.00	1.00	2.00	3.00
Sleep Hours	9975	0.00	1.00	-1.68	-0.88	0.01	0.88	1.68
Sugar Consumption	10000	1.00	0.82	0.00	0.00	1.00	2.00	3.00

(D) TARGET VARIABLE

Variable	count	mean	std	min	25%	50%	75%	max
Heart Disease Status	10000	0.20	0.40	0.00	0.00	0.00	0.00	1.00

3) Logistic regression: Odds ratio: The odds ratio expresses the effect of each predictor on the likelihood of $Y = 1$ [see Eq. (3)]. It quantifies how a unit change in a predictor multiplies the odds of the positive outcome, providing interpretability of model coefficients.

$$\text{Odds} = \frac{P(Y=1|X)}{1-P(Y=1|X)} = e^{\beta_0+\sum_{i=1}^{n}\beta_i X_i} \tag{3}$$

Represents the multiplicative change in odds for a unit change in each predictor.

4) Logistic regression: Regularized loss function (ridge): Regularization prevents overfitting by penalizing large coefficients [see Eq. (4)]. It adds an $L2$ penalty to the log-loss, encouraging smaller coefficients and improving the generalization ability of the model.

$$\mathcal{L}_{reg}(\beta) = \mathcal{L}(\beta) + \lambda \sum_{i=1}^{n} \beta_i^2 \tag{4}$$

Adds an $L2$ penalty to the log-loss, controlling model complexity.

5) Random forest: Classification prediction: For classification, the final prediction $\hat{y}$ is obtained by majority voting of B trees [see Eq. (5)]. Each tree casts a vote, and the class with the most votes is selected as the final prediction, improving robustness against individual tree errors.

$$\hat{y} = \text{mode}\{h_1(X), h_2(X), \ldots, h_B(X)\} \tag{5}$$

Each tree votes, and the most frequent class is chosen as the final prediction.

6) Random forest: Regression prediction: For regression problems, the prediction is the average of all B trees [see Eq. (6)]. Averaging reduces variance and improves the stability and generalization of the model, making it less sensitive to individual tree fluctuations.

$$\hat{y} = \frac{1}{B} \sum_{b=1}^{B} h_b(X) \tag{6}$$

Reduces variance and improves generalization by averaging multiple models.

7) Random forest: Gini impurity: The Gini index measures the impurity of a node and is used for splitting [see Eq. (7)]. Lower Gini values indicate more homogeneous nodes, which helps the tree create purer child nodes and improve classification accuracy.

$$Gini = 1 - \sum_{k=1}^{K} p_k^2 \tag{7}$$

TABLE VI. SUMMARY AND CHARACTERISTICS OF THE DATASET

(A) GENERAL INFORMATION OF THE DATASET

Column	Non-null values	Data type
Age	9971	float64
Gender	9981	object
Blood Pressure	9981	float64
Cholesterol Level	9970	float64
Exercise Habits	9975	object
Smoking	9975	object

CRP Level	9974	float64
Homocysteine Level	9980	float64
Heart Disease Status	10000	object

(B) MISSING VALUES PER COLUMN

Column	Missing values
Age	29
Gender	19
Blood Pressure	19
Cholesterol Level	30
Exercise Habits	25
Smoking	25
Family Heart Disease	21
Diabetes	30
BMI	22
High Blood Pressure	26
Low HDL Cholesterol	25
High LDL Cholesterol	26
Alcohol Consumption	2586
Stress Level	22
Sleep Hours	25
Sugar Consumption	30
Triglyceride Level	26
Fasting Blood Sugar	22
CRP Level	26
Homocysteine Level	20
Heart Disease Status	0

Minimized to create more homogeneous child nodes during tree construction.

8) Random forest: Feature importance: Feature importance is calculated based on the total reduction in impurity [see Eq. (8)]. It quantifies how much each feature contributes to improving prediction accuracy, allowing interpretability and identification of key variables.

$$FI_j = \sum_{t=1}^{B} \sum_{\text{splits } s \text{ in tree } t} \Delta i(s) \cdot \mathbf{1}_{\{j \text{ used in } s\}} \tag{8}$$

Summarizes how much each feature contributes to prediction accuracy.

9) XGBoost: Prediction function: The final prediction is the sum of contributions from K sequential trees [see Eq. (9)]. Each tree iteratively corrects the errors of previous trees, allowing the model to capture complex patterns and improve overall predictive performance.

$$\hat{y}_i = \sum_{k=1}^{K} f_k(X_i), \quad f_k \in \mathcal{F} \tag{9}$$

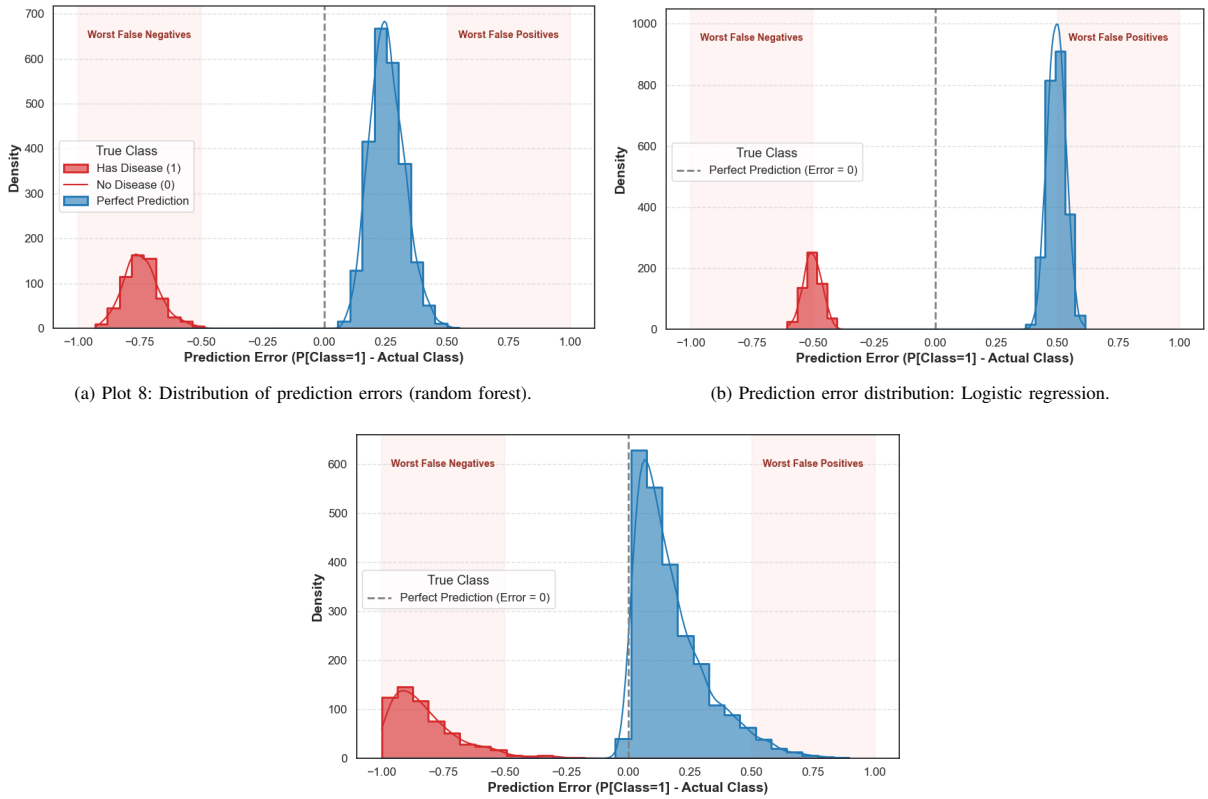
Each tree f_k corrects the errors of previous trees.

10) XGBoost: Regularized objective: XGBoost minimizes a regularized objective combining loss and complexity of trees [see Eq. (10)]. This approach balances predictive accuracy with model complexity, preventing overfitting while ensuring robust performance on unseen data.

$$\mathcal{L}(\phi) = \sum_{i=1}^{n} l(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(f_k) \tag{10}$$

Prevents overfitting while minimizing prediction error.

11) XGBoost: Gradient update: Each iteration updates predictions using the gradient and learning rate η [see Eq. (11)]. This sequential adjustment allows the model to correct previous errors gradually, improving convergence and prediction accuracy while controlling the step size.



$$\hat{y}_i^{(t)} = \hat{y}_i^{(t-1)} + \eta f_t(X_i) \tag{11}$$

Sequentially corrects previous errors, controlling step size via η.

12) XGBoost: Second-order approximation: The second-order Taylor expansion allows efficient tree optimization [see Eq. (12)]. By using both first and second derivatives of the loss function, it provides precise gradient-based updates that accelerate learning and improve model accuracy.

$$\mathcal{L}^{(t)} \approx \sum_{i=1}^{n} \left[g_i f_t(X_i) + \frac{1}{2} h_i f_t^2(X_i) \right] + \Omega(f_t) \tag{12}$$

Uses first (g_i) and second (h_i) derivatives of the loss function for precise updates.

(a) Plot 8: Distribution of prediction errors (random forest).

(b) Prediction error distribution: Logistic regression.

(c) Prediction error distribution: XGBoost.

Fig. 4. Comparative analysis of the impact of class balancing and model diagnostics.

13) XGBoost: Leaf weight optimization: Optimal leaf weights are computed to minimize the regularized loss [see Eq. (13)]. This calculation ensures that each leaf contributes optimally to reducing the objective function while accounting for regularization, enhancing model stability and predictive performance.

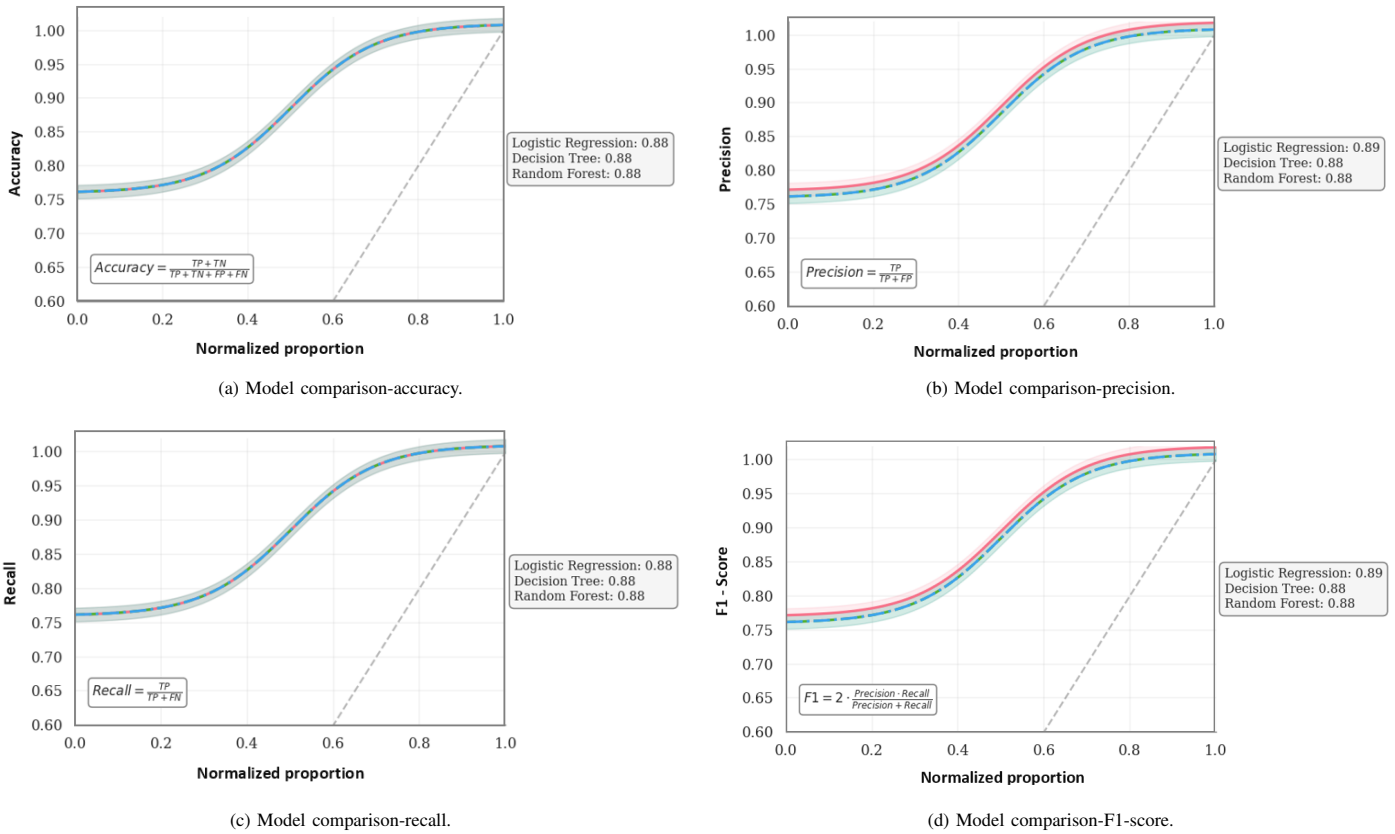
$$w_j^* = -\frac{\sum_{i \in I_j} g_i}{\sum_{i \in I_j} h_i + \lambda} \tag{13}$$

Assigns optimal output values to leaves of the tree considering regularization.

14) XGBoost: Split gain: The gain of a split measures its improvement in the objective function [see Eq. (14)]. Higher gain values indicate more effective splits, guiding the tree to partition data in a way that maximizes predictive accuracy and model efficiency.

$$Gain = \frac{1}{2}\left[\frac{(\sum_{i \in I_L} g_i)^2}{\sum_{i \in I_L} h_i + \lambda} + \frac{(\sum_{i \in I_R} g_i)^2}{\sum_{i \in I_R} h_i + \lambda} - \frac{(\sum_{i \in I} g_i)^2}{\sum_{i \in I} h_i + \lambda}\right] - \gamma \tag{14}$$

Quantifies how much a split improves the objective, guiding tree growth.



IV. Results

This section presents the results obtained from the comparison of metrics for the algorithms used, aiming to evaluate the performance of each model and select the one that offers the best results. Additionally, a comparison between different ML methodologies is carried out, highlighting their main characteristics and evaluation parameters. From this analysis, it was determined that the most suitable methodology for the development of the present study is CRISP-DM, as it provides a structured and flexible approach that facilitates both the construction and interpretation of the models.

A. Evaluation of Results

This section presents a comparative analysis of the predictive performance of three machine learning architectures: LR, RF, and XGBoost. The models were rigorously evaluated using standard binary classification metrics (Accuracy, Precision, Sensitivity (Recall), and F1-score), with the objective of predicting the presence of coronary artery disease (CAD) based on a standardized set of clinical and health habit features.

The XGBoost model consistently demonstrated superior performance across all evaluation metrics (Fig. 5). Its inherent ability to model nonlinear relationships and complex interactions translated into the best discrimination of the positive class, achieving the highest Accuracy ($\approx 91.2\%$) and the highest F1-score (F1 $\approx$ 90.8%) in Fig. 5d among the

(a) Model comparison-accuracy.

(b) Model comparison-precision.

(c) Model comparison-recall.

(d) Model comparison-F1-score.

Fig. 5. Comparison of ML models by performance metrics.

models. This result underscores the robustness of XGBoost and positions it as the reference model in this study. The RF algorithm exhibited notably competitive performance, maintaining a balanced trade-off between Precision (Fig. 5b) and Sensitivity (Fig. 5c). Its metrics remained very close to the top-performing model (Acc $\approx 90.5\%$, F1 $\approx 90.1\%$) (Fig. 5a), validating the effectiveness of bagging techniques in achieving strong generalization and mitigating the risk of overfitting without sacrificing predictive power. In contrast, the LR model, due to its inherently linear nature, yielded more modest values across all metrics (Acc $\approx 87.8\%$, F1 $\approx 86.9\%$). While LR provides a fundamental interpretative baseline, its performance was predictably outperformed by the tree ensemble models, reiterating its limitations in capturing the inherent complexity of the physiological phenomena underlying coronary disease.

B. Comparison of Methodologies

For the comparison of methodologies, Table VII presents a comparative evaluation of four widely recognized data mining methodologies: CRISP-DM, Knowledge Discovery in Databases (KDD), Sample, Explore, Modify, Model, Assess (SEMMA), and Analytics Solutions Unified Method for Data Mining (ASUM-DM). Each was analyzed under five evaluation criteria: clear structure and phases, practical applicability, integration with machine learning, reproducibility, and interpretability. The results, expressed as percentages, show that the CRISP-DM methodology achieves the highest performance across all evaluated aspects, with an approximate general average of 93%, standing out for its methodological clarity, ability to replicate results, and ease of communicating findings. In contrast, the KDD and SEMMA methodologies exhibit a more technical but less integrative approach, while ASUM-DM maintains a balanced performance albeit with less formal structuring. Overall, the results support the selection of CRISP-DM as the most robust and adaptable methodological framework for studies predicting cardiovascular diseases using machine learning algorithms.

V. Discussion

Previous research has identified multiple causes and characteristics associated with heart diseases within the medical field. In this context, the results obtained in the present study are consistent with trends described in recent literature, where ensemble-based algorithms, particularly XGBoost and Random Forest, have demonstrated superior performance in predicting cardiovascular diseases. In this study, the XGBoost model achieved the highest values across all evaluation metrics (*accuracy, precision, recall* and *F1-score*), confirming its ability to model nonlinear interactions between clinical variables and lifestyle-related factors. These findings align with those reported by [32], who demonstrated that XGBoost provides an optimal balance between sensitivity and specificity in detecting cardiac complications and identifying myocardial ischemia, reaching AUC values above 0.90. Likewise, the RF model showed competitive performance, particularly in the *precision* and *recall* metrics, suggesting adequate

TABLE VII. COMPARATIVE EVALUATION OF METHODOLOGIES BASED ON PERFORMANCE

Evaluation Criteria	Criterion Description	CRISP-DM	KDD	SEMMA	ASUM-DM
Clear Structure and Phases (%)	Assesses the clarity, sequentiality, and organization of methodological stages.	**95**	88	82	90
Practical Applicability (%)	Measures the ease of implementation in real-world data mining projects.	**93**	85	87	89
Integration with ML (%)	Evaluates compatibility with modeling and validation processes for machine learning algorithms.	**90**	80	86	88
Reproducibility (%)	Analyzes the ability to replicate results and maintain consistency across different runs.	**92**	83	80	86
Interpretability (%)	Assesses the transparency of results and ease of communicating findings to different audiences.	**94**	82	78	84
Approximate general average (%)	Average value of overall performance considering the previous criteria.	**93**	84	83	87

generalization capability and lower susceptibility to overfitting. This behavior is consistent with the observations highlighted by [30], [38], and [47], who emphasized the efficiency of Random Forest in classifying heart diseases and its superiority over traditional methods such as LR. These studies revealed that RF achieved precision above 92% and AUC values close to 0.99, results comparable to those obtained in the present work.

In contrast, LR exhibited moderate performance, which was expected given its linear nature and lower ability to capture complex relationships among predictor variables. Nevertheless, its utility lies in providing an interpretable and clinically transparent baseline, an aspect also emphasized by [14] and [53], who acknowledge that despite its limitations, this model retains value in scenarios where interpretability is prioritized over predictive complexity. Moreover, the superiority of XGBoost in this study can also be attributed to its ability to integrate regularization mechanisms and sequential optimization, characteristics that [43] and [20] noted allow maintaining high accuracy even in clinical datasets with certain imbalance or noise. This behavior reinforces the idea that boosting models are more suitable for complex biomedical contexts, where relationships between predictors and outcome variables are not strictly linear.

More broadly, the results of this work confirm observations reported by several authors [51], [52], who reported that combining optimization techniques (such as Grey Wolf Optimization or CoCoSo) with ensemble algorithms significantly increases diagnostic accuracy, outperforming traditional models. Although the present study did not implement metaheuristic strategies, the robustness of the XGBoost model suggests that its incorporation in later stages could further enhance the system's predictive capability. Consequently, the findings align with the general assertion in the literature that ML methods—particularly those based on boosting and bagging—offer a more favorable balance between accuracy, generalization, and stability for the diagnosis and prediction of CHD [39], [19]. Therefore, the XGBoost model consolidates as the most suitable alternative for future external validation and integration into medical decision support systems, aligning with the current trend of incorporating artificial intelligence into clinical practice to strengthen early diagnosis and personalized cardiovascular risk management.

VI. CONCLUSION

Faced with the significant challenges posed by machine learning in the application of algorithms aimed at the diagnosis and prediction of heart diseases, researchers have intensified efforts to develop increasingly accurate, robust, and interpretable models. These models, resulting from the interaction between clinical, genetic, and lifestyle factors, demand computational approaches capable of capturing nonlinear relationships and hidden patterns in medical data. In this context, the present study conducted a comparison of various data mining methodologies oriented toward the development of predictive models in the field of cardiopathy. The approaches analyzed included KDD, SEMMA, ASUM-DM, and CRISP-DM, considering technical, methodological, and applicability criteria. The evaluation results indicated that the CRISP-DM methodology stood out as the most efficient and adaptable to the study context, due to its iterative structure, systematic approach to data understanding, and alignment with the analytical objectives of ML.

In line with the above, the CRISP-DM methodology is structured into five fundamental phases that guide the entire knowledge discovery process from data. The first phase, Business Understanding, establishes the analytical objectives and expected outcomes of the predictive model, taking into account the specific clinical context. The second phase, Data Understanding, enables the characterization of variables through descriptive statistics, identifying their structure and dimensionality without the need to examine each individual observation. The third phase, Data Preparation, encompasses the cleaning, transformation, and normalization of information, correcting missing, inconsistent, or outlier values that could affect modeling quality. In the fourth phase, Modeling, machine learning algorithms are trained with the processed data, enabling the identification of predictive patterns and the reduction of prediction errors. Finally, the fifth phase, Evaluation, compares the generated models using performance metrics such as Accuracy, Precision, Recall, and F1-Score, selecting the one with the greatest generalization capacity and predictive efficacy. The results obtained in this study support the effectiveness of boosting and bagging-based models, such as XGBoost and RF, in predicting cardiovascular diseases. These techniques demonstrated a superior balance between accuracy and generalization capacity compared to LR, which is critical in clinical contexts where classification errors can have significant consequences. In particular, the

XGBoost model emerges as the most promising alternative for application in later stages of the study, including external validation and integration into medical decision support systems, thus contributing to more preventive, personalized, and evidence-based care.

Finally, understanding the implications of coronary heart disease is essential to visualize its causes and guide the implementation of effective technological solutions. Based on the findings obtained through our model, it is suggested to complement the evaluated algorithms with additional technologies, such as deep learning models, integration of medical imaging data, or time-series analysis of vital signs, in order to improve prediction accuracy and efficacy. Future studies could explore the combination of these techniques with clinical decision support systems, as well as the validation of the model across different population contexts, strengthening both medical informatics and the practical application of early diagnostic tools, with a potential impact on reducing cardiovascular mortality and optimizing healthcare resources.

ACKNOWLEDGMENT

Thanks to the University of Sciences and Humanities, which made this project a reality.

Integrating Processing-In-Memory into HW/SW Co-Design for Automotive Embedded Systems

Zineb El Kacimi, Safae Dahmani, Oussama Elissati, Mouhcine Chami
Institut National des Postes et Télécommunications, STRS Lab., Rabat, Morocco

***Abstract*—Continuous expansion of using intelligent learning workloads in modern vehicles, leads Electronic Control Units (ECUs) to manage massive volumes of data while dealing with hard real-time constraints. That said, ECUs must operate under strict power budget due to limited battery capacity and other safety and functional requirements. We study in this research the feasibility of integrating Processing-In-Memory (PIM) approach into the hardware/software co-design process for the emerging ECU architectures. The idea here is to allocate data-centric tasks to in-memory compute units so that computation occurs directly where data is stored. The proposed approach will allow avoiding expensive data traffic, which will improve processing performance and reduce energy consumption. Our work introduces a conceptual framework that reconciles the PIM strengths with automotive requirements and introduces techniques from dynamic voltage scaling to smarter memory management, and is limited to a conceptual architectural proposal without experimental validation or quantitative evaluation. We end up discussing some crucial opportunities and open challenges arising from the implementation of PIM in next-generation automotive systems.**

Keywords*—Electronic Control Units; energy consumption; hardware/software co-design; Processing-In-Memory; real-time constraints

I. Introduction

Nowadays, automotive industry is growing very quickly towards smart electric vehicles, which bring together assisted and autonomous driving, high connectivity, and a wide range of intelligent features. With the increase in complexity and performance demands, These developments marked a shift in embedded systems, especially Electronic Control Units (ECUs), the main nervous system of modern cars. It is important to highlight that ECUs are responsible for managing features from real-time sensor operations to battery management and various advanced driver assistance systems (ADAS) among many other functions. With the increase of data-centric features, we are driving classical design approaches towards increased computational power and real-time accuracy.

A focus on hardware/software co-design approaches is a key point to deal with new embedded systems. It works on optimizing both hardware and software together to achieve better performance and cost-effectiveness across the whole system. This technique has already demonstrated results in ECU subsystems: engine control [1], security firewalls [2], and reconfigurable driver designs [3]. Yet, the major remaining limitations are performance bottleneck related to data movement, scaling across different ECU types, and low latency under strict power constraints.

In such a context, Processing-In-Memory (PIM) [4] offers a promising computing paradigm, which can transform how current data processing in embedded devices is conducted. By processing computation close to the memory components, PIM immediately relieves the typical processor-memory bottleneck, leading to a significant reduction in the amount of data transfer and energy consumption. This computing paradigm has been reported successfully in accelerating data-dense applications such as Artificial Intelligence (AI) inference, graph processing, and real-time signal analysis [5], [6].

The importance of the growing use of AI and deep learning in modern vehicles, as reviewed in [7], [8], also highlights the demand for new, disruptive architectural approaches to handle complex, data-driven tasks. Having shown capabilities in parallel data flows, latency reduction, and low power costs, PIM can provide a great value to automotive applications because they are performance and power-constrained applications in addition to data-intensive, especially with the increasing use of AI.

Integrating PIM into hardware/software co-design moves data-intensive work to where the data already resides, reducing transfer overhead and latency. In practice, during the hardware/software co-design partitioning step, workloads with memory-bound tasks run on PIM while the control-heavy tasks stay on the CPU. That leads to balanced resources utilization and helps improve real-time responsiveness. Existing literature shows limited exploration of PIM integration in the automotive domain. The systematic integration of PIM into ECU architectures is highly dependent on its compatibility with automotive standardized hardware/software co-design techniques, and the challenges that can be faced to meet the requirements of automotive safety-critical systems.

This study aims to introduce a conceptual framework that combines hardware/software co-design principles with emerging PIM architectures to support the development of next-generation ECUs.

This study is organized as follows: Section II reviews the state-of-the-art of the hardware/software co-design in automotive embedded systems, focusing on ECUs and identifying bottlenecks that PIM can alleviate. Section III presents an analysis of recent advancements in PIM architectures across different memory technologies, in addition to a proposal for PIM-enabled ECU architecture and techniques for its integration. Section IV details the motivation and pathways for integrating PIM into automotive ECU architectures. Section V discusses challenges and opportunities for integrating PIM methodology into automotive ECUs. Finally, Section VI concludes the study along-with a declaration on the use of generative AI in Section VII.

Although no experimental implementation is provided,

this work lays out the foundation for future development, prototyping, and evaluation, and we are currently exploring comparative benchmarking using existing gem5-based simulation tools.

II. Hardware-Software Co-Design in Automotive Embedded Systems

A. The Need for Hardware/Software Co-design in Automotive Embedded Systems

Hardware/software co-design is a methodology in which both the hardware and the software are considered interdependent components of a system, aiming to optimize them concurrently in the design process. This collaborative process helps in the early evaluation of trade-offs between performance, power, cost, area, safety, and flexibility to form integrated systems that are optimized to meet specific requirements at minimal cost. Hardware/software co-design, as outlined by Shaout, El-Mousa and Mattar in their work on the heterogeneous embedded systems [9], is an approach that consist of several activities including system partitioning, in which functions are strategically allocated between hardware and software according to performance, cost, and power limitations. Then this division is further optimized in task allocation and scheduling, matching tasks to meet timing constraints and reduce system latency. In addition, hardware/software interface definition helps in establishing clear communication flows for building and ensuring the compatibility of the components, while performance modeling and simulation help to identify the potential bottlenecks early on the design phase. Also, design space exploration is further an important step in which various levels of analysis can be made that allows for the trade-offs between competing needs (performance versus power consumption). Co-synthesis and co-verification guarantee accurate joint behavior, so hardware and software are developed and tested in parallel. Finally, integration and validation are the last steps, enabling the testing of the entire system to determine whether it meets its design specifications.

In sectors, where the rate of technological developments is accelerating, such as automotive, it becomes even more pressing to adopt such a method. Given the increasing adoption of embedded computing systems used in cars, hardware/software co-design is becoming an apparent need. A case study of how this method can expedite computationally intensive tasks, and be used to accelerate computation has been reported in embedded security, with the Elliptic Curve Cryptography accelerator on a Zynq SoC producing impressive efficiency gains based on an efficient hardware/software partitioning [10]. Real-time performance, safety, power efficiency, and cybersecurity are now fundamental requirements in modern vehicles, and hardware/software co-design ensures that computing architectures are optimized to meet these constraints while supporting the integration of evolving components and secure connectivity, as highlighted by Abdallah et al. [11].

Integrating PIM into hardware/software co-design can create new opportunities to improve the balance of performance and power efficiency. Thus, PIM also reduces overall overheads and latencies caused by data transfer by directly conducting data-heavy computations in memory, which helps to optimize system partitioning and resource allocation. Inherently, hardware/software co-design frameworks need to consider the computational capacity of the PIM-enabled memory and allocate tasks such as sensor-centric data handling to memory, whereas other high-level control functions should be retained by the CPU. Task scheduling can take further advantage of the parallel data flows generated by PIM and reduce latency and energy usage.

Given the increasing complexity of embedded computing systems in modern vehicles, we are seeing a rise in the number of ECUs, each packed with multiple software features, which leads to an obvious need for updating hardware/software co-design process to meet the new design requirements and ensure both reliability and performance. In [12], Axelsson points out that to address these challenges, hardware/software co-design is needed across the overall system architecture, not only at the ECU level.

Hardware/software co-design has moved from being a "nice-to-have" best practice to a core engineering discipline, therefore, adopting advanced co-design methods is essential to balance today's competing priorities including performance, cost, safety, and power.

Current hardware/software co-design strategies provide different solutions for varying ECU types, each with its own trade-offs. We will review these approaches to point out current weaknesses, particularly for handling real-time performance of data extensive tasks, scalability and power efficiency. This analysis provides the foundation for evaluating the architectural shift towards integrating PIM to address these core limitations.

B. ECU: The Heart of Automotive Electronics

An ECU is a specialized embedded system, which controls various functions in a larger system, mainly through sensor inputs, control algorithms, and actuator operation. Modern automotive systems have very high use cases of ECUs that make them perform from basic tasks to high-end processes. Automobile ECUs were originally single-unit components: a microcontroller, sensors, and actuators connected via point-to-point wiring with other vehicle components. This simple architecture was acceptable for early vehicle designs with minimal electronic requirements (see Fig. 1). For instance, a Powertrain Control Unit (PCU) manages engine and transmission functions, ensuring optimal fuel efficiency and emissions compliance. Meanwhile, a Body Control Module (BCM) handles auxiliary functions such as lighting and climate management. For the driver and passengers, infotainment ECUs consolidate all multimedia and connectivity functions. However, the most computationally intensive tasks are computed by ADAS systems ECUs, which receive real-time input from cameras, radar, and LiDAR to perform features like adaptive cruise control and collision avoidance. These cases demonstrate that ECUs support everything in the modern automobile from its most basic operations to its most advanced autonomous functions.

It's clear that today's vehicles come up with significantly more complex needs compared to initial automotive requirements. The current automotive environment has set new standards for ECU design [13]. In fact, modern architectures go beyond standalone microcontroller units and evolve toward more

integration of domain controllers and centralized computing platforms [14], [15].

The most obvious challenge in these architectures is the incorporation of workloads which demand considerable computational power to process large volumes of sensor data in real-time. Traditional ECUs were designed primarily for the purpose of relatively simple control applications, but for these demanding applications often lack both the processing capacity and architectural flexibility needed to support such demanding applications. Thus, to handle the computationally intensive tasks of applications like sensor fusion and real-time control, current designs integrate dedicated hardware accelerators. This hybrid architectural evolution reflects the industry's adaptation to growing functional complexity and performance demands.

In the next subsection, we will explore the existing hardware-software co-design methodologies to highlight opportunities for further optimization, which leads us to novel approaches such as PIM to address the challenges of next-generation ECU design.

C. Existing Hardware/Software Co-design Methodologies for ECUs

Various hardware-software co-design strategies have been explored in the area of ECUs, one of the most indispensable components of modern automotive systems. The goal of these hardware/software co-design methods is to find the optimal split of tasks between hardware and software, incorporating the best of both worlds to satisfy the tight performance, power, and security specifications. For instance, hardware/software partitioning of crankshaft functionality on an FPGA delivered a 58% performance improvement [1]. This demonstrates co-design's ability to optimize critical automotive functions. Yet, a significant bottleneck is scalability; extending this approach to other ECUs is indeed a significant challenge. Coupled with the high cost of FPGA-based solutions that may lead to a lack of widespread industry adoption.

In the context of security domain, Pesé et al. [2] introduced an embedded firewall combined of hardware and software to secure in-vehicle networks, such as Automotive Ethernet, this firewall has been shown to minimize latency and jitter while maintaining constant throughput under dynamic conditions. Nevertheless, integration issues and resource limitations restrict this system's applicability across broader automotive systems. Another subsequent study [3] proposes a reconfigurable ECU architecture that co-integrates security and dependability primitives to address the critical need for security without sacrificing performance, reporting a 47.9×speedup and 2.4×better energy efficiency compared to a multi-core automotive processor. This work provides quantifiable evidence that hardware/software co-design can successfully overcome the traditional performance versus security trade-off.

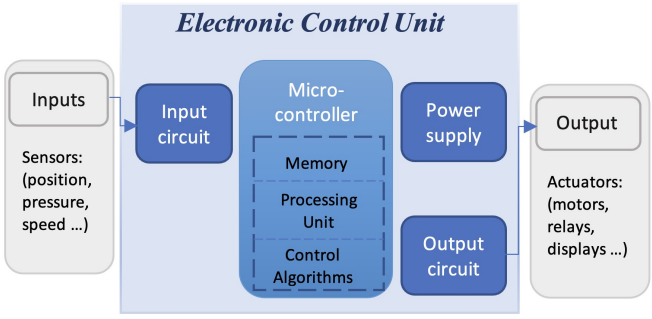

Fig. 1. Simplified architecture of early ECUs with basic microcontroller-based designs.

This principle of embedding efficient, transparent security is further demonstrated by a lightweight FPGA-based IDS-ECU for the CAN bus [16]. The architecture introduces a hardware-accelerated intrusion detection system that operates transparently to the primary ECU software. Compared to GPU-based implementations, it achieved a 2.3×reduction in per-message latency and a 15×reduction in power consumption. This shows that integrating built-in operating capabilities, such as security monitoring, into ECUs not only doesn't compromise its performance but can even improve it. FPGA-based remote reconfigurable ECUs suggested in [17] offer flexibility and adaptability but struggle in ensuring secure remote updates and managing implementation costs. Another hardware-software co-design approach was developed in [18] for an automotive application, a Multiple Injection Driver Automotive Subsystem. This approach consists of a configurable system-on-chip (CSoC), which consists of a microprocessor and embedded FPGA. Implementing this technique enabled rapid system design cycles, promoting component re-use, and working within tight timelines for complex embedded system. However, the authors note that a key limitation of their specific flow was that the interface synthesis was not fully automatic, requiring some minimal manual steps, which presents a challenge for complete design automation. While these studies have shown considerable promise in optimizing ECU performance, power consumption and security, modern automotive systems are incorporating increasingly data-intensive applications that further introduce the bottleneck of data movement, which leads to higher power consumption and limits real-time processing. To address these challenges, PIM can complement hardware/software co-design methodologies by offloading data-intensive tasks from traditional processors, and this can also ensure robust protection against dynamic threats by accelerating intrusion detection algorithms and firewall operations, in the context of automotive security applications.

The subsequent section will discuss current research on PIM technology, including its underlying mechanisms, and examine its potential to tackle challenges in modern automotive systems.

III. Overview of PIM and Related Works

PIM is a modern computing paradigm that integrates computational capabilities in or near memory systems. This approach was introduced to mitigate the performance limitations of the traditional Von Neumann architecture. In the latter, processors are physically separated from memory, causing heavy traffic between them. Significant latency and energy overhead are caused by memory-processor bottlenecks. This is particularly true for intensive data workloads which is the case for intelligent learning, graph processing or sensor fusion computations in automotive. By putting processing close to

where the data is stored, PIM minimizes data movement, reduces network related latency, in addition to important energy savings.

The processor-memory bottleneck is a big challenge for modern computing systems. For instance, [19] states that traditional architectures allocate up to 99.75% of their energy consumption in floating-point operations on memory access rather than computation itself. PIM solves this problem by fitting processing units directly into existing memory modules to enable operations, like matrix multiplications, filtering, and pattern recognition, to be done in place. This makes PIM a good match for AI-driven tasks.

A. Overview of PIM Architectures

The performance of PIM architectures heavily depends on the developments in memory technologies, design approaches, and application fields. These factors provide the foundation for integrating computational capabilities directly within memory systems. In the following, we describe the important characteristics of PIM by design type, application field, and memory technology, according to Asifuzzaman et al. in [5].

1) PIM by design type: PIM architecture can be classified according to its computational features integrated into or near memory system. Table I provides descriptions and features of the design types.

2) PIM by application field: There are several application domains where PIM designs help to achieve maximum efficiency. Table II illustrates the major application fields and their use cases.

3) PIM by memory technology: Memory technologies are a major factor for effective PIM implementation. Table III presents the common memory technologies and their suitability for PIM.

The presented classifications highlight diverse PIM-based approaches, addressing conventional memory limitations considering emerging applications' demands. In the next subsection, we investigate how developments in PIM bring transformational performance and energy efficiency within different sectors.

B. Advancements in PIM Architectures

In this section, we present a wide range of examples of PIM-based architectures. Associative In-Memory Processors (AiMP), which are discussed in [20], utilize resistive memory for direct access to memory arrays, improving throughput and energy consumption in clustering and matrix operations. In [21], the authors demonstrate that hybrid schemes like Hetraph, are able to combine analog and digital processors, and this combination tradeoff for performance and energy efficiency for irregular workloads such as graph processing. Hetraph provides up to 7.54×speedup over CPUs, and 1.56×over GPUs, resulting in significant energy savings of up to 57.58×vs CPUs, 19.93×vs GPUs.

Beyond recent hardware innovations, software approaches have been developed to fully utilize the potential of PIM. In this regard, for example, the work in [19] presents a hardware/software co-design methodology, which specifically targets associative in-memory processors and employs dynamic voltage scaling techniques and selective instruction scheduling. On average, the proposed method achieves a 7% decrease in memory area and an 18% reduction in overall energy consumption.

Moreover, the PIM architectures programming frameworks focus on task division between control-intensive (CPU) and data-intensive (PIM) components, avoiding unnecessary information exchanges between memory and processors. Similar paradigms have been applied to IoT systems, as demonstrated in [22], where they improve data processing time and power consumption, leading to enhanced utilization efficiency. In addition, J. Joo et al. [23] examine the utilization of PIM-based systems for regular expression matching and report an up to 96% reduction in execution time in comparison to legacy multithreaded implementation methods. Another interesting work [6] introduced the TransPIM that integrates processing capabilities in its memory for transformer workloads. It demonstrates performance gains of 22.1×to 114.9×compared to GPUs. Its token-based processing approach minimizes data movement and enhances scalability for long sequences, making it suitable for real-time applications like sensor fusion. Similarly, the iMTransformer, presented in [24], utilizes PIM technologies to accelerate attention mechanisms in transformer networks with 13.71×speedup and 12.57×better energy efficiency compared to GPUs. Another approach presented in [25] advances in memory Big Data processing by combining efficient indexing (e.g., B trees, R trees), parallelism (scale up/scale out in systems like Apache Spark), and memory optimization (e.g., RowClone). These techniques reduce latency and improve efficiency by executing bulk operations near memory.

Due to its previously discussed capacity to improve energy consumption, latency and throughput, PIM technology offers an effective solution to address the growing data-centric challenges in automotive systems, a domain that is rapidly evolving toward electric, connected and autonomous vehicles.

IV. Motivation and Pathways for Integrating PIM into Automotive ECU Architectures

The ECUs have been heavily demanded by the rapid technological change in automotive systems, including autonomous driving, ADAS, and electric vehicles (EVs). Given the need for high-throughput and real-time sensor data such as LiDAR, radar, cameras, etc., embedded systems must maintain specific constraints including latency, energy consumption, safety, and cost. At the same time, traditional Von Neumann architectures introduce bottlenecks caused by intensive processor-memory data movement, which is associated with high energy consumption, latency, and poor scalability, and this is limiting the ability of ECUs to meet the growing complexity of modern automotive systems.

A. Unlocking the Potential of PIM for Automotive Applications

Below, we provide a table (see Table IV) for the key advantages of PIM for automotive systems. The table also gives some examples of ECU applications best optimizing the given advantages.

TABLE I. TYPES OF PIM DESIGNS

Design Type	Description	Examples/Key Features
Cell-level PIM	Simple operations performed at the cell level of the memory array.	Basic arithmetic or logical operations within memory cells.
Sense amplifier / row-buffer PIM	More complex operations performed at the sense amplifier or row-buffer level.	Suitable for operations requiring faster access to larger memory segments.
Near-memory PIM	Processing cores placed near memory banks to execute a subset of CPU instructions.	Enables larger-scale computations and supports diverse workloads.
Hybrid PIM	Combines multiple PIM approaches (e.g., analog and digital processing) to optimize performance.	Supports irregular workloads and balances efficiency for diverse applications.

TABLE II. PIM APPLICATION FIELDS AND THEIR KEY USE CASES

Application Field	Description	Examples/Use Cases
Deep Neural Networks (DNNs)	Optimized for compute patterns of DNNs using specialized memory technologies like ReRAM.	Matrix multiplications, convolution operations, and attention mechanisms in transformers.
Graph Processing	Designed for irregular workloads and high data movement requirements.	Algorithms like BFS, PageRank, and graph clustering.
AI and Machine Learning	Accelerates AI workloads with in-memory computations to reduce latency and energy consumption.	Transformer workloads, pattern recognition, and filtering tasks.
IoT and Edge Computing	Enhances data processing efficiency for real-time applications in IoT systems.	Sensor fusion, real-time analytics, and distributed systems.

TABLE III. COMPARISON OF MEMORY TECHNOLOGIES SUITABLE FOR PIM

Memory Technology	Description	Suitability for PIM
DRAM	Widely used commodity memory technology with affordable costs.	Limited scalability but suitable for general-purpose PIM designs.
HBM (High-Bandwidth Memory)	3D-stacked DRAM variant offering high bandwidth and efficiency.	Ideal for data-intensive applications requiring fast memory access.
HMC (Hybrid Memory Cube)	3D-stacked memory integrating DRAM layers with a logic base layer.	Reduces latency and increases bandwidth for high-performance computing.
STT-MRAM	Non-volatile memory using magnetic properties to store data.	High endurance and fast access speeds make it suitable for frequent data access.
ReRAM	Non-volatile memory using resistive switching for data storage.	Performs computations directly within its unique data array.
PCM (Phase Change Memory)	Relies on material phase changes for data storage, offering high density and scalability.	Suitable for large-scale data storage and processing.

TABLE IV. WHY PIM IS ESSENTIAL FOR AUTOMOTIVE SYSTEMS

Key Benefit	Brief Description	Example ECU/System
Reduction in Data Movement	By performing computations directly in memory, PIM minimizes data transfer between processors and memory, reducing latency and energy consumption.	ADAS ECUs: Real-time sensor fusion for lane detection and collision avoidance.
Improved Energy Efficiency	PIM reduces energy usage by eliminating unnecessary data movement and optimizing memory operations, making it ideal for energy-constrained systems.	Battery Management Systems: Efficient monitoring and optimization of EV battery performance.
Scalability for Complex Workloads	PIM architectures can handle the growing complexity of workloads, such as neural network inference and multi-sensor fusion, without performance bottlenecks.	Autonomous Driving Systems: Path planning and obstacle detection using data from cameras, radar, and LiDAR.
Real-Time Performance	PIM accelerates time-sensitive computations, ensuring ECUs can meet stringent latency requirements in critical systems.	Braking and Steering ECUs: Fast decision-making for ABS and electronic steering control.

B. Techniques for Integrating PIM into ECU Architectures

1) Dynamic Voltage Scaling (DVS): As shown by Yantir et al. [19], can be effectively integrated into hardware/software co-design to optimize energy efficiency and responsiveness in PIM-enhanced subsystems like Powertrain or Braking Control. Dynamic Voltage Scaling is a co-design methodology realized by combining the need for tight coupling of hardware configurability with software control. Multi-VDD designs enable the dynamic adjustment of memory bank voltage in response to computational load at the hardware level. Simultaneously at the software level, a scheduler is used to align the execution of the task with these power states. To illustrate, during steady cruising voltage may be decreased for saving power, rise for acceleration or scale with braking intensity to maintain safety and fulfil real-time computational demands. Through the coupling of hardware voltage scaling with software task scheduling, DVS guarantees an effective operation without affecting system responses in mission-essential automotive applications.

2) Hierarchical memory management: Divides data into memory tiers; mission-critical tasks can be performed within the rapid SRAM, while less urgent tasks within slow DRAM

or STT-RAM to balance latency and efficiency. PIM, along with an optimized hardware/software co-design, improves this by allowing computations to run within the right memory tier with reduced distance to data. For instance, brake and steering ECUs run on PIM-based SRAM for real-time, low-latency processing, and infotainment programs to perform PIM tasks in slow-tier memory to free faster memory. Research on STT-RAM caches [26] shows that heterogeneous memory designs can optimize retention time and energy, and hierarchical PIM therefore is well-suited to different automotive workloads. Complementing this, the study on Big Data architecture, presented in [27], highlights the importance of a distinct memory management layer, which automatically caches frequently used data and optimizes data locality. This concept aligns with hierarchical memory management in its goal of improving performance by minimizing data movement and ensuring that critical tasks are stored and executed in the most appropriate memory tier.

3) Sensor-specific processing: Uses token-based dataflows that allow individual sensors, including cameras, radar, and LiDAR, to process their data independently in PIM-enabled memory and in compliance with hardware/software co-design principles. This technique, inspired by the TransPIM architecture [6], exploits a token-based processing protocol to manage sensor workloads through local processing of data tokens in memory. Every token, representing a unit of information based on the sensor data including for instance, lane detection from cameras or speed from radar, is processed directly in memory, thus reducing data movement and latency. Building on this work, hardware/software co-design frameworks facilitate system partitioning to distribute computation-intensive operations to PIM near the sensor, while software algorithms dynamically coordinate job scheduling and data aggregation among sensors on-the-fly. The main advantage of this approach is parallelizing sensor data processing in memory through concurrent scheduling of the workload and optimal distribution of tasks. Such an integration can then, minimize latency and improve performance for real-time applications such as ADAS and autonomous driving.

4) Task Partitioning between CPU and PIM: Aligns with hardware/software co-design principles, ensuring efficient resource utilization by prioritizing workloads according to their nature. On one side, you have control-intensive tasks, such as temperature sampling and adjusting speeds, are expected to be done on the CPU. On the other hand, data-driven tasks like data consolidation for sensor data shall be computed in memory for faster processing. Hardware/software co-design frameworks allow this partitioning by ensuring that the right tasks can be dynamically assigned to the right resource. The latter structure works well for ADAS and allows PIM accelerators to perform real-time image recognition, while safety-critical control operations such as braking and steering modifications are run simultaneously on the CPU. Just like battery management systems in EVs can use PIM to analyze sensor data while control functions, like adjusting the charging rate, remain on the CPU.

C. Proposed PIM-Enabled ECU Architecture

A main approach for integrating PIM within automotive systems is to optimize a single ECU by embedding processing capabilities directly into its memory subsystem. As an example, we choose a collision avoidance ECU (see Fig. 2); the system integrates a CPU and a PIM-enabled memory module to handle critical data processing tasks. The PIM units can perform early-stage computations on sensor inputs, such as radar and camera data, and execute functions like object detection, distance estimation, as well as threat classification directly in memory, while the CPU will take care of high-level decisions and control logic. Hence, more complex systems can be built using this architecture.

Following this, the architecture can be expanded to a more complex system, which is derived from the Domain Controller ECU paradigm presented in [28]. It promotes the integration of multiple distributed ECUs into a centralized framework. It allows for real-time processing, simplified maintenance, and over-the-air (OTA) software updates. In that concept, diverse domain-specific tasks are performed in a single central ECU to effectively serve as the system's command center. Taking this paradigm and applying it to the ECU system, our proposed architecture works towards implementing PIM capabilities to offload and accelerate data-intensive tasks.

Fig. 3 illustrates the proposed conceptual integration of PIM into a centralized automotive ECU architecture. The system is organized around a central ECU platform responsible for high-level control, task scheduling, and coordination. Based on intelligent workload partitioning, the highly parallel tasks are offloaded from the central processor to a shared PIM-enabled memory subsystem.

However, certain sensor data requiring immediate high processing is sent directly to the central CPU before being forwarded to the PIM subsystem for data-heavy computations.

This subsystem consists of specialized PIM blocks, each associated with a different sensor domain, such as camera, radar, or LiDAR, and capable of performing early-stage, in-memory processing. Tasks like AI-based image filtering, Doppler speed estimation, and neural network inference are executed directly within the memory units. The output from these PIM units is stored in a hierarchical memory structure that uses fast SRAM for time critical control loops and non-volatile STT-RAM or DRAM for storing historical or less critical data. The information collected is preprocessed and then sent to the central CPU, where high-level decisions are made based on this refined data. Then, the CPU generates control commands that are forwarded directly to the actuators, such as those responsible for advanced driver-assistance systems (ADAS). In

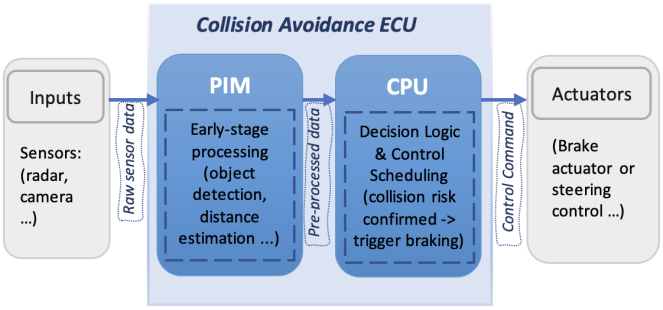

Fig. 2. Architecture of PIM integrated in collision avoidance ECU.

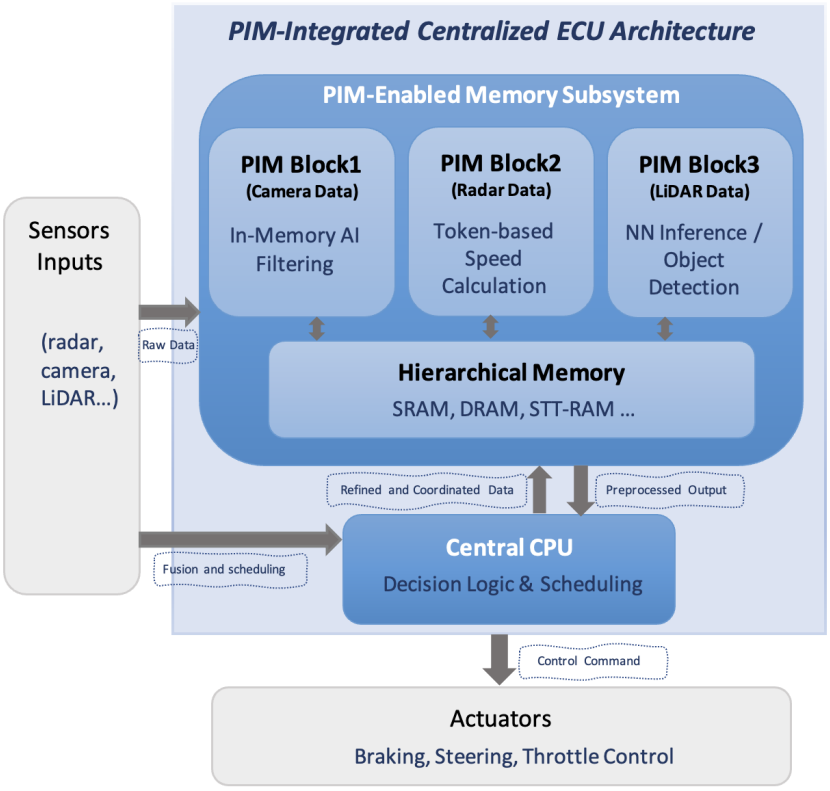

Fig. 3. PIM centralized ECU architecture.

PIM architectures, intelligent processing is distributed across different blocks of the memory subsystem and the CPU. Real-time responsiveness is then enhanced thanks to the reduction of memory traffic and redundant computations.

To conclude, the PIM-based hybrid architecture is showing promising performance and energy efficiency improvements in the context of emerging complex applications.

V. Challenges and Opportunities

Integrating PIM into automotive ECU architectures is not an easy task. Several critical challenges are identified to create successful PIM-based heterogeneous systems. Automotive ECUs from multiple generations communicate over deterministic networks, such as CAN, LIN, and FlexRay. Hence, PIM components, as new nodes, must remain compatible with these legacy buses and existing communication stacks. Second, the absence of standardized programming paradigms and compiler support for PIM limits its accessibility for embedded developers. Here are several aspects of potential solutions that still need development: high-level APIs, task schedulers, hardware/software interfaces that facilitate the adoption of PIM in automotive software stacks, particularly under AUTOSAR or embedded Linux environments. Additionally, automotive applications require deterministic timing behavior to satisfy real-time constraints, and PIM will introduce new execution patterns that will further complicate latency and worst-case execution time (WCET) analysis, while these analysis are crucial for real-time safety-critical tasks. From a security perspective, PIM-based systems need to maintain robust security measures to prevent system level threats such as malicious data injection or memory-side channel attacks. Moreover, fault isolation between PIM and CPU elements is necessary to avoid failures spreading across critical functions.

VI. Conclusion

A conceptual framework for implementing a PIM model within automotive ECU architectures is proposed in response to some of the core challenges in embedded systems, such as power consumption reduction, data movement avoidance, and real-time processing support needed by advanced automotive applications like ADAS, autonomous driving, and intelligent battery management. Building on existing hardware/software co-design methodologies and the latest developments in PIM architectures, the new processing framework that integrates PIM through a refined hardware/software co-design methodology to effectively deploy PIM within the strict constraints of safety-critical and resource-limited automotive environments. This contribution remains conceptual and does not include experimental validation or modeling.

Future work will focus on validating the concept through detailed simulation using cycle-accurate architectural simulators such as gem5, DRAMSim3, or PIMEval. The evaluation process will include metrics such as latency, energy consumption, memory traffic reduction, and worst-case execution time (WCET). Representative automotive workloads, such as ADAS perception pipelines, radar signal processing, and battery management algorithms, will be ported to PIM-based execution models.

To sum up, through this work we established a foundation

for real-time and safety-critical use of PIM technologies in the context of hardware/software co-design of data-intensive automotive systems to improve performance and power efficiency.

VII. Declaration On Generative AI

During the preparation of this manuscript, the authors utilized Gemini and ChatGPT to support drafting and language refinement, but the development of scientific ideas, arguments, results, and conclusions was carried out only by human authors. The authors take full responsibility for the final version of the manuscript.

***Abstract*—Voice dysfunction is a common complication following thyroid surgery. However, the application of explainable machine learning for predicting postoperative voice recovery remains largely unexplored. Therefore, an investigation was done to examine voice recovery based on acoustic, objective, and glottal features. Voice recordings were collected from female patients before surgery and one month after surgery. Acoustic and glottal parameters, including Quasi Open Quotient, Speed Quotient, age, and others, were automatically extracted from the recordings. Random Forest, Support Vector Machines, and Logistic Regression with Sequential Feature Selection were applied to examine model behavior and identify feature importance. Model stability and interpretability were evaluated across cross-validation folds. Performance metrics varied over folds, highlighting the exploratory and statistically fragile nature of predictions in small datasets. SHAP (SHapley Additive exPlanations) analysis revealed variability in feature contributions, emphasizing the need for cautious interpretation and detailed methodological reporting. Our findings provide preliminary guidance for applying explainable machine learning to small biomedical datasets. They demonstrate the importance of careful methodological design.**

***Keywords*—XAI; explainable AI; SHAP; glottal features; SVM; thyroidectomy; voice recovery**

I. Introduction

Thyroidectomy is a surgical intervention performed to remove a portion or the entire thyroid gland. It can be performed to treat malignant or benign thyroid diseases [1]. This surgery is mostly followed by a change in voice quality, reported in approximately 30% to 80% of patients [2], [3]. This change is described as a disorder characterized by an impaired pitch, volume, vocal effort, or voice quality, which alters communication or voice-related quality of life [4].

To detect pathological voices, both subjective and objective assessment methods are commonly used [5], [6]. The subjective voice assessment method includes an auditory perceptual assessment and visual examination of the vocal cords in the hospital [5], [7]. However, the diagnosis based on this type of evaluation is difficult because it relies on the experience of doctors, and there is also a high possibility of clinical errors [8]. In contrast, the objective assessment is based on non-invasive computer analysis of acoustic signals to identify pathological voice, which may not even be audible to a human being [5].

Despite these advances, speech pathology remains an underexplored area, and the field has not yet received significant attention from researchers. This creates a significant need for further research and improved diagnostic tools for voice-related disorders [9]. Thyroid cancer is one of these diseases. It is the second most common cancer for both men and women in the 15 to 34 age group and the most common cancer in women [2], [10].

Regrettably, most existing works have focused on voice analysis or classification tasks. In particular, research has aimed to identify acoustic parameters associated with voice changes post-surgery and to develop computer-based diagnostic systems using a combination of these features. These classification techniques have been widely used to build automated detection systems. However, they are not commonly applied to predict voice quality or recovery following thyroidectomy.

In this pilot research, we propose a ML-based system that uses voice recordings from two stages: pre-operative and one month postoperative. Objective, acoustic and glottal features are used to train multiple classifiers. We also apply Sequential feature selection (SFS) for feature selection to improve prediction performance. Finally, we integrate SHapley Additive exPlanations (SHAP) to interpret the decision-making process of the best-performing model. The aim was to address a binary classification problem to differentiate between recovery and non-recovery voice. The main contributions of this research are as follows:

- We implement a leakage-safe, group-stratified machine learning pipeline suitable for extremely small biomedical voice datasets.
- We demonstrate the use of group-stratified nested cross-validation combined with sequential feature selection to reduce evaluation bias in longitudinal voice data.
- We provide an empirical analysis of model instability and performance variance under small-sample regimes using bootstrapped confidence intervals and learning curves.
- We investigate the limitations and reliability of SHAP-based explainability when applied to small-scale tabular datasets.

II. Related Work

Recently, scientists focused on building several systems for detecting pathological voices using machine learning algorithms. These approaches can be classified into two primary techniques: traditional pipeline methods and end-to-end techniques [11]. End-to-end approaches utilize the original raw

voice or transformed speech, such as the spectrogram in its 2D form as input for the classification model, and employ deep learning techniques to generate target labels [12].

On the other hand, the traditional pipeline approaches involve two stages: firstly, the extraction of relevant parameters from a speech signal, and secondly, using these extracted features to train the model and classify the labeled output according to the intended purpose (normal/pathology voice, type of pathology, etc.) [12]. Most studies have used a set of objective and subjective parameters to realize these automatic systems. These measurements contain jitter, glottal parameters [12], etc.

To address this, some researchers have proposed new detection frameworks using ML or deep learning algorithms to forecast voice recovery after thyroid surgery. For example, Lee *et al.* [13] published a study to predict patient voice recovery after three months of postoperative spectrograms with a deep neural network algorithm. They initially proposed an approach that employed pre-operative and first postoperative patients' voice recordings and GRBAS scores to predict the patient's voice GRBAS scores after three months post-surgery. The utilization of GRBAS scores primarily aimed to characterize vocal quality by evaluating the degree of voice impairment during each session. In their study, 114 patients were followed. All patients who have undergone surgery for thyroid cancer. The participants were taken before surgery, two weeks, and three months after the operation. The proposed method has shown that long-term voice disorders can be predicted using pre- and postoperative spectrograms [13].

Another study by Kurt *et al.* [14], focused on developing a detection system using ML techniques to determine patients at risk of developing vocal cord palsy before thyroidectomy [14]. They included a sample of 1039 patients who underwent thyroidectomy in their research. The authors used a set of variables based on clinician reports, which can divided into two categories: continuous variables such as age, tumor size, white blood cell count, etc., and categorical variables including sex of patient, type of resection, presence of comorbidity, and so on. They achieved an accuracy of 100%. However, although Lee *et al.* [13] used spectrograms and GRBAS scores (Grade, Roughness, Breathiness, Asthenia, Strain) in their deep learning approach, this method has not yet been evaluated with traditional machine learning techniques or direct acoustic and glottal parameters. Most existing studies focus on evaluating voice quality before and after surgery using statistical tests [15], [16], [17].

In terms of classification, the majority aim to develop systems that distinguish between pathological and normal voices. To our knowledge, no study has yet explored ML-based prediction of post-thyroidectomy voice recovery using glottal, objective, and acoustic features with SHAP explainability.

III. Materials and Methods

In this section, we outline the methodology and materials used in the present study. Fig. 1 presents the proposed framework for predicting voice recovery after thyroidectomy. The system comprises different steps, including data collection (longitudinal audio recordings), pre-processing, feature extraction, classification, and interpretability analysis using the SHAP method. Classification was performed using the SFS algorithm.

A. Data Collection

Twenty-five females (aged 17-66 years, SD = 14.44) were included in this study. They underwent either partial or total thyroidectomy for malignant or benign thyroid cancer. Among them, 12 underwent partial thyroidectomy, and 13 underwent total thyroidectomy. All participants underwent thyroidectomy for benign thyroid, except for five who underwent surgery for malignant thyroid. The subjects did not have any vocal cord damage or history of alcohol before thyroid surgery. Moreover, no treatments were administered to the patients between the first day and one month after surgery, except for those who experienced vocal fold paralysis on the first day. Voice therapy is recommended in cases of vocal cord paralysis. Thyroidectomy was performed by various surgeons using a conventional cervical method, without the assistance of intraoperative neuromonitoring (IONM) for the identification of either the external branch of the superior laryngeal nerve (EBSLN) or the recurrent laryngeal nerve (RLN). Each patient underwent a laryngeal endoscopic examination conducted by a senior physician or a trained resident during quiet phonation and breathing. Voice recordings were acquired using a microphone integrated into the endoscopy column, positioned approximately 20 cm from the patient's lips. Patients sustained the French vowel /i/ at pre-surgery, and 30 days post-surgery.

B. Data Pre-processing

The duration of audio recordings varied among participants because they were instructed to pronounce the vowel for as long as possible at a comfortable volume and pitch. To ensure consistency across samples, a 3-second segment was extracted from the middle of each recording. This segment length was chosen after initially extracting 3-second segments from the beginning, middle, and end of each recording. Statistical analysis using ANOVA showed no significant effect of segment position on the acoustic parameters. Therefore, the middle 3-second segment was selected, as it represents the most stable portion of the sustained vowel. Acoustic and glottal parameters were then extracted from this segment for each participant.

C. Feature Extraction

In this section, we present the features used in the current study. They are classified into two categories: acoustic features and glottal features. In this work, we used only the parameters extracted on the day before the operation and excluded the other features. Additionally, the VHI-10 parameter was excluded from the training process to avoid any data leakage.

1) Acoustic parameters: From the vocal samples, we extracted the mean values of the fundamental frequency (F0). F0 presents the vocal fold vibration frequency, measured in Hertz, which is defined by the duration of each period T_i. The study also includes information on age, type of operation (partial or total), the nature of the thyroid (malignant or benign), and the Voice Handicap Index (VHI-10). The VHI-10 is a metric employed to record the patient's perception of handicap or impairment due to a speech disease, where scores above 11 are defined as pathology and indicate vocal disability. To further

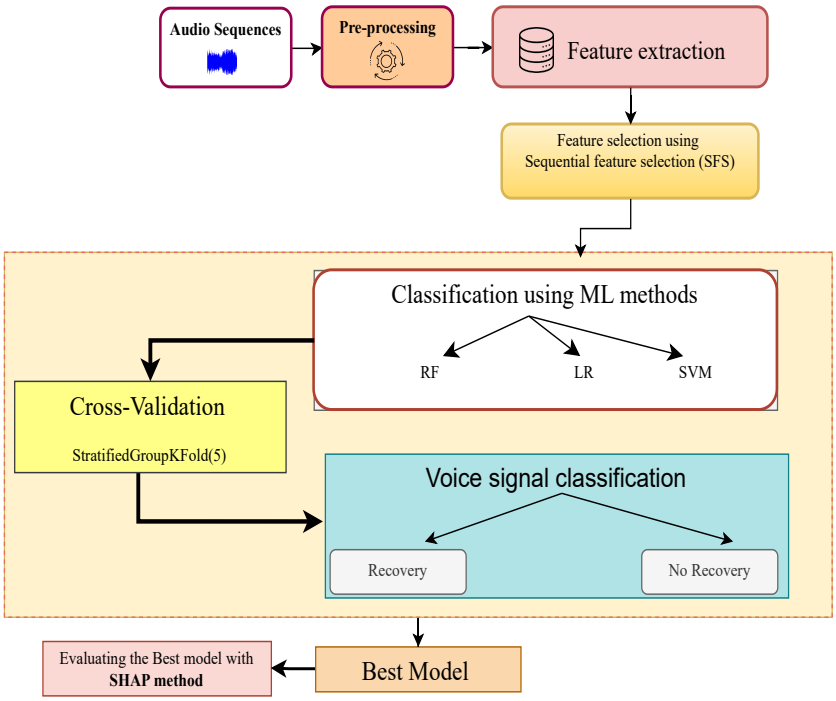

Fig. 1. Proposed method for predicting voice recovery stages following thyroidectomy.

improve the analysis, glottal flow features were used due to their demonstrated effectiveness in capturing the vocal effects of thyroidectomy [18].

2) Glottal parameters: In the literature, many techniques have been developed to obtain the glottal signal features. Among these methods, we find the Iterative Adaptive Inverse Filtering (IAIF) method [19], which estimates the glottal signal from the input speech signal through a two-step iterative process. Initially, the method estimates the glottal waveform and the vocal tract transfer function [18], [20]. It then refines these estimates to improve the performance of glottal signal estimation [18], [20].

In our work, we use the Pitch-Synchronous Iterative Adaptive Inverse Filtering (PSIAIF) method [21] because of its ease of implementation. PSIAIF uses the IAIF method to extract glottal flow from the speech signal. Its main goal is to eliminate the influence of glottal excitation from the speech spectrum of the original signal [22]. The method proceeds by first estimating the vocal fold model using Linear Prediction Coefficients (LPC), and then obtaining the glottal flow through inverse filtering [22]. PSIAIF incorporates pitch-synchronous markers on the glottal waveform, which reduces the effect of formant ripple in comparison to IAIF [22]. This method has been implemented in the MATLAB toolbox Aparat [23]. Below, we provide a summary of the features that were extracted:

- The open quotient (OQ): is the ratio of the duration of the vocal fold open phase to the total duration of a glottal cycle [24].
- OQ1: Open quotient calculated from the primary opening of the glottal flow.
- OQ2: Open quotient calculated from the secondary opening of the glottal flow.
- The Speed Quotient (SQ): is the ratio of the duration of the opening phase to the duration of the closing phase [24]. **SQ1** and **SQ2** represent the speed quotients calculated from the primary and secondary openings, respectively.
- The normalized amplitude quotient (NAQ): is defined as the ratio of the amplitude quotient to the total duration of the glottal pulse [24].

To extract these features we used the methodology described in Alku (1992) [21]. The LPC analysis orders for the vocal tract and glottal source were set based on the sampling frequency, approximately $2 \times \text{round}(f_s/2000) + 4$ and $2 \times \text{round}(f_s/4000)$, respectively.

A leaky integration coefficient of 0.99 was used to model lip radiation. A single pass of a high-pass FIR filter (cutoff frequencies at 40 Hz stopband and 70 Hz passband) was applied prior to inverse filtering to remove low-frequency noise. The analysis was performed on frames windowed with a Hanning window. The audio signal was processed using its original sampling rate.

D. Classification Techniques

In the current study, a change in VHI-10 (ΔVHI_{10}) was calculated for each patient as:

$$\Delta \text{VHI}_{10} = \text{VHI}_{10,1\text{ month}} - \text{VHI}_{10,\text{pre-op}}$$

A negative ΔVHI_{10} (< 0) indicated improvement and was classified as *recovered*, while $\Delta \text{VHI}_{10} \geq 0$ was classified as *not recovered*.

Given the limited dataset size, we employed cross-validation with stratification to evaluate the models. Specifically, we used StratifiedGroupKFold with k = 5. This value was selected after testing k values from 2 to 7, with the best performance achieved at k = 5. To avoid data leakage, groups were defined by patient ID, ensuring that recordings from the same patient did not appear in both training and testing sets. The models were evaluated using a pipeline that applied MinMax scaling to the input features, which normalizes each feature by subtracting the minimum value and dividing by the range (max - min). The models were evaluated using the Sequential Feature Selection (SFS) method. To assess model stability and avoid data leakage, a nested cross-validation procedure was applied inside SFS during the feature selection phase. In addition, a bootstrapped validation with 10000 resamples was performed to calculate the corresponding confidence intervals (CIs) for model performance metrics.

For classification, various machine learning techniques, including SVM, RF, and Logistic Regression (LR) were used. The SVM was chosen as the representative algorithm due to its stability with limited samples. RF and LR were evaluated for comparison and to verify that performance differences were consistent; results are reported for completeness.

E. Hyperparameters

For hyperparameter tuning, GridSearchCV method was applied to each algorithm using the same StratifiedGroupKFold cross-validation process described above. For the SVM model, parameters such as the regularization parameter C (ranging from 1 to 50), kernel type (linear, RBF, polynomial, sigmoid), and gamma (auto or scale) were optimized. RF tuning included the number of estimators (1 to 40), maximum tree depth (1 to 51), and the criterion (Gini or entropy). The selected parameters were then employed in this study. The best hyperparameters were then used for each model. The final hyperparameters for each model were:

- **SVM:** $C = 1$, gamma = `scale`, kernel = `rbf`
- **LR:** max_iter = 1000
- **RF:** max_depth = 2, criterion=`gini`, n_estimators = 3

All analysis were conducted in Python with scikit-learn version 1.6.1, pandas, and matplotlib. The experiments were conducted on an HP laptop with an Intel Core i7-1165G7 processor (2.80 GHz) and 32 GB of RAM.

F. Shapley Additive Explanations (SHAP)

Recently, many studies have applied Explainable Artificial Intelligence (XAI) techniques to understand better the decision-making processes of machine learning models [25]. In this field, researchers have introduced numerous methods to explain how model features, inputs, or components influence model outputs [26]. In particular, these include Gradient-weighted Class Activation Mapping (Grad-CAM), Local Interpretable Model-Agnostic Explanations (LIME), and SHAP [26]. However, LIME and SHAP are the most widely used because they can be applied to both tabular data and image data. SHAP, introduced by Lundberg and Lee [27], explains model results using concepts from cooperative game theory. SHAP can be applied for both local and global explanations [27]. Local explanations provide insight into individual predictions, while global explanations summarize feature influence across the entire dataset. Shapley values identify the contribution of each feature to the prediction produced by the model.

IV. Results

In this section, we present an analysis of the features and show the results of the classification experiments. In addition, it includes an interpretability analysis of the best-performing model using the SHAP framework.

A. Feature Distribution Analysis

A violin plot is a powerful visualization tool used to display the distribution of data and its probability density function. It summarizes key statistical values, including the median and quartiles, while also showing the full distribution of the dataset. In this study, we present violin plots for the numeric acoustic parameters, grouped by recovery status (Recovery vs. No Recovery).

In Fig. 2, the median value of MeanF0 in the No-Recovery group (171.644 Hz), with data points largely concentrated between 150 Hz and 250 Hz, is slightly higher than that of the Recovery group (168.300 Hz). Similarly, for all other parameters, the No-Recovery group consistently shows higher values compared to the Recovery group. This may suggest that higher values are associated with poorer voice recovery. However, this observation remains preliminary and requires further confirmation.

B. Classifier Performance

Table I summarizes the classification performances for the SVM, LR, and RF algorithms. The experiments reveal that SVM outperforms the other models in terms of accuracy. It reaches an accuracy of 76% with a standard deviation (SD) of 0.09, a recall of 87%, an F1-score of 80%, a precision of 77%, and an AUC score of 70%. This suggests their ability to identify the positive class. However, the SD value indicates that the model's performance is unstable between folds. In contrast, the RF model reaches the highest precision of 77%. However, its lower recall (73%) and accuracy (73%) indicate a lower ability to detect all true positives. Also, its performance is more variable. The lower results were obtained using the LR model, except for AUC (80%), which was higher than that of the SVM and RF methods.

In addition, the CI interval for SVM (accuracy: [0.68, 0.80]) shows moderate stability, indicating relatively consistent performance across folds. However, the wide confidence intervals for all models show that their performance can change significantly with different data.

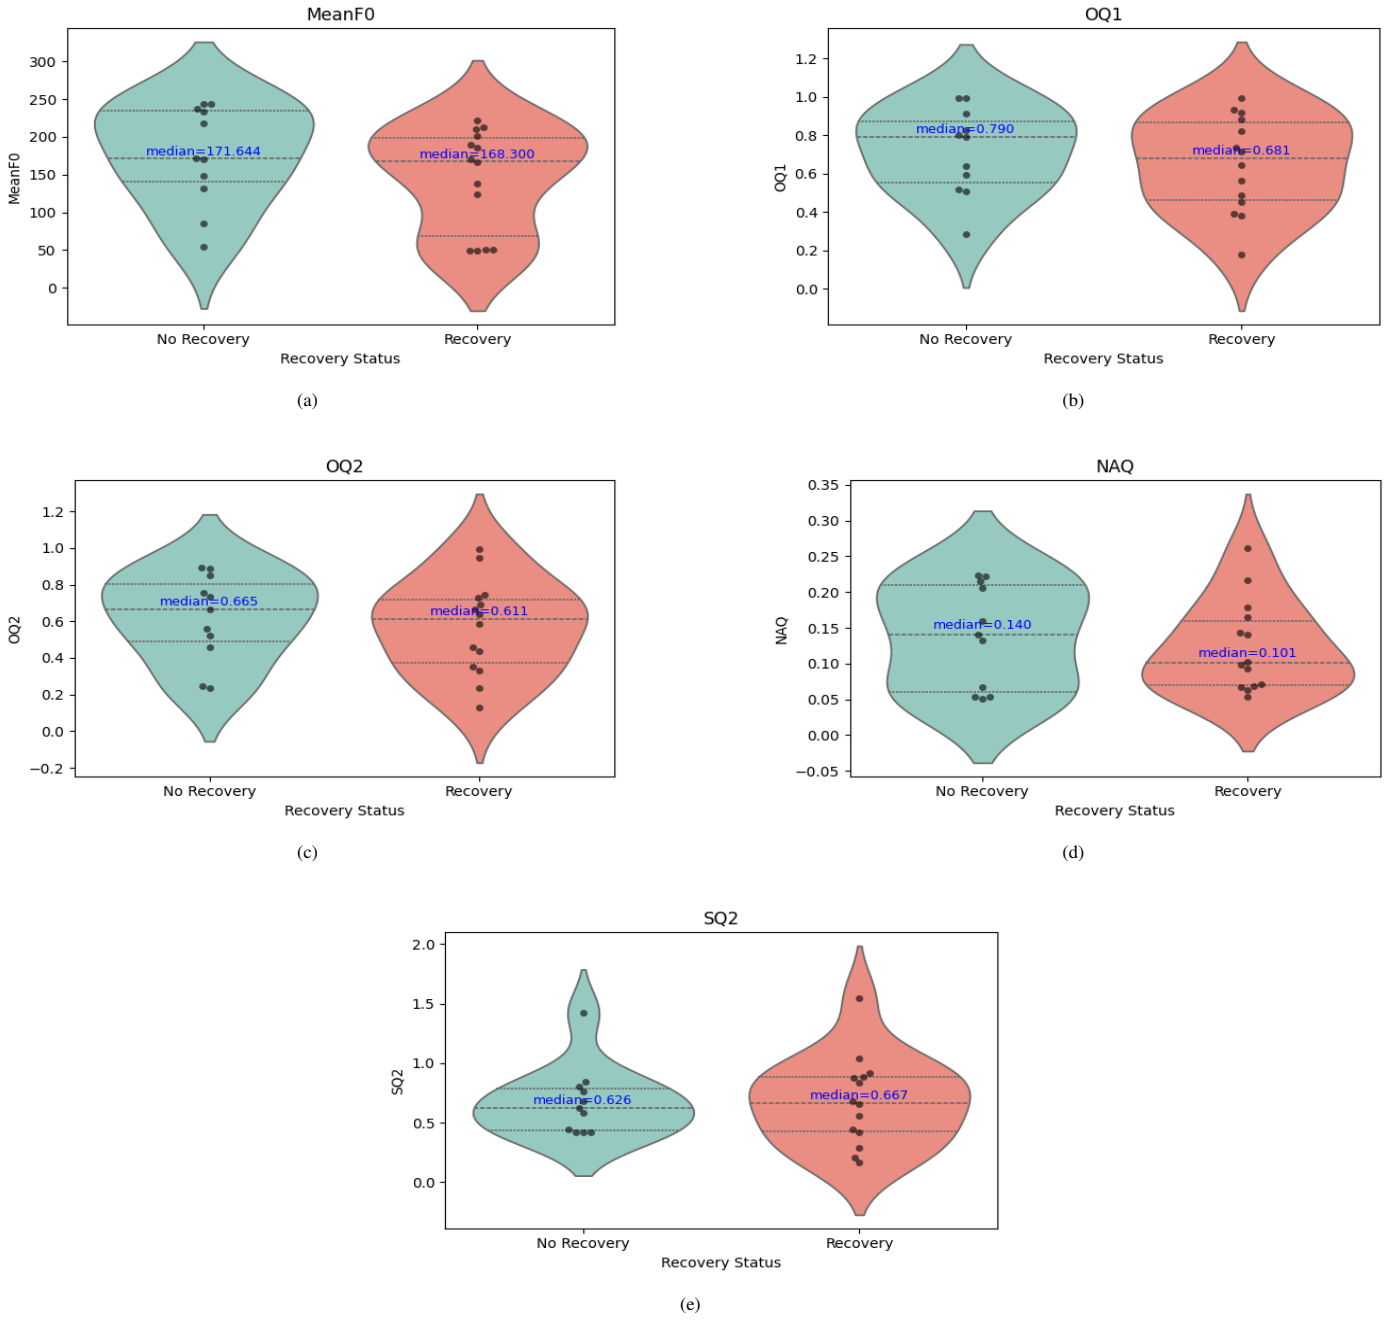

Fig. 2. Violin plots of acoustic and glottal features in the Recovery and No-Recovery groups: a) Mean fundamental frequency (MeanF0), b) Primary Open Quotient (OQ1), c) Secondary Open Quotient (OQ2), d) Normalized Amplitude Quotient (NAQ), and e) Secondary Speed Quotient (SQ2).

TABLE I. CROSS-VALIDATED PERFORMANCE METRICS USING SFS SELECTION METHOD (MEAN ± SD) [95% CI]

Algorithms	Accuracy	Precision	Recall	F1	AUC	Features
SVM	**0.76** ± 0.09 [0.68, 0.80]	**0.77** ± 0.14 [0.68, 0.88]	**0.87** ± 0.18 [0.73, 1.00]	**0.80** ± 0.08 [0.73, 0.85]	0.70 ± 0.15 [0.58, 0.82]	Type_CN, Type
RF	0.72 ± 0.23 [0.56, 0.88]	0.77 ± 0.22 [0.60, 0.93]	0.73 ± 0.28 [0.53, 0.93]	0.73 ± 0.22 [0.56, 0.89]	0.78 ± 0.23 [0.60, 0.95]	Age, Type_CN, Type, NAQ
LR	0.64 ± 0.17 [0.52, 0.76]	0.69 ± 0.19 [0.57, 0.85]	0.73 ± 0.28 [0.53, 0.93]	0.68 ± 0.17 [0.53, 0.79]	**0.80** ± 0.24 [0.62, 0.98]	Age, Type_CN, Type

C. Statistical Comparison

To verify whether the differences were statistically significant among the three classifiers, we conducted a Wilcoxon signed-rank test based on the bootstrapped F1-scores. The obtained results indicated that SVM consistently outperformed both RF and LR, with mean differences of 0.063 (95% CI [0.061, 0.065]) for SVM vs RF and 0.113 (95% CI [0.111, 0.114]) for SVM vs LR. In addition, RF achieved higher F1-scores than LR, with a mean difference of 0.050 (95% CI [0.049, 0.051]). Effect sizes were moderate to large (r = -0.55 for SVM vs RF, $r = -0.87$ for SVM vs. LR, $r = -0.87$ for RF vs. LR), and all comparisons were statistically significant ($p < 0.001$). These findings suggest that SVM demonstrates superior performance in distinguishing between classes on the dataset analyzed.

D. Model Interpretation and Error Analysis

Fig. 3, Fig. 4, and Fig. 5 present the confusion matrix, learning curve, and ROC curve, respectively, for the SVM classifier. Overall, the model demonstrated a strong ability to differentiate between the classes. It performed particularly well in identifying recovery recordings, correctly classifying 12 out of 14 samples. The no-recovery class was classified moderately well, with 7 correct predictions, though some samples were misclassified as recovery.

To better understand the model's behavior, we analyzed the misclassified samples from the SVM model predictions in Table II. The analysis shows that most false positives (FP) (patients predicted as recovered but who did not actually recover) occurred in three patients who underwent partial surgeries for benign conditions. It generally occurs in younger or middle-aged adults (ages 35–53). A false positive was also observed in a patient who had a total thyroidectomy for a malignant thyroid. In contrast, false negatives (patients predicted as not recovered but who actually recovered) were more common among younger patients (ages 31–42) who underwent total surgeries for benign thyroid conditions. These findings suggest that the model's performance is significantly influenced by the type of surgery and the underlying pathology. In addition, ROC analysis supports these findings, with an AUC of 65% achieved for the recovery class. However, due to the small number of misclassified cases, we did not perform statistical tests, as such analyses would not provide reliable or meaningful results.

Dealing with the SVM learning curve (see Fig. 5) displays initial overfitting, with high training accuracy but low validation accuracy. As the training size increases, validation accuracy rises and converges toward the training curve, indicating improved generalization and reduced overfitting.

E. SHAP Results

Fig. 6 presents the SHAP summary plot (mean absolute SHAP values) by class. These values represent the average contribution of each feature to the predictions of the model. In the No recovery class, the most influential variables were Type (partial/total) and Age (patient age), with SHAP values of 0.09 and 0.05, respectively. Other relevant features included Type_CN (benign/malign), OQ1, MeanF0, NAQ, SQ2, and OQ2. In contrast, the Recovery class is mainly associated with

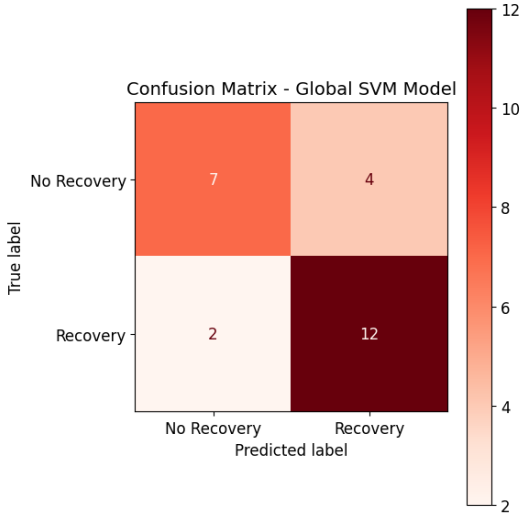

Fig. 3. Confusion matrix for the SVM model predicting post-thyroidectomy voice recovery. The rows represent actual classes and the columns predicted classes.

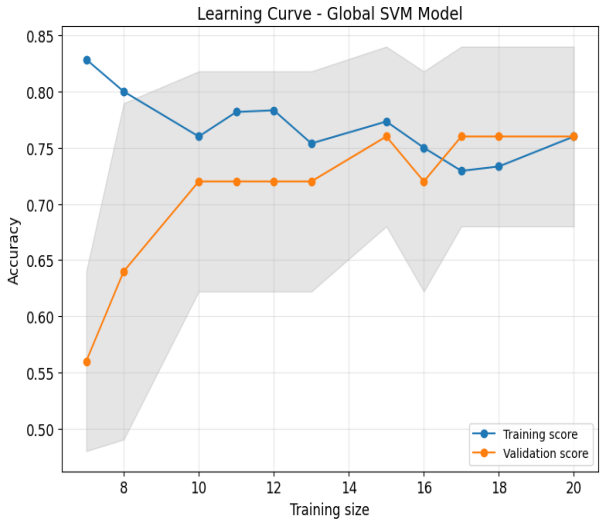

Fig. 4. Learning curve for the SVM method predicting post-thyroidectomy voice recovery. The x-axis represents the number of training samples used, and each point shows the mean accuracy over five cross-validation folds. Shaded regions indicate ±1 standard deviation across folds.

Type (0.08), Type_CN (0.03), and Age (0.03), which have the highest impact.

Fig. 7 presents SHAP-based waterfall plots for three participants selected at random. These plots illustrate the contribution of individual variables to the prediction of the model for each patient. The horizontal axis represents the value predicted by the model, denoted as while each bar illustrates the marginal effect of a specific variable on this prediction. In each plot, red bars indicate positive contributions to the decision, while the blue bars represent a negative contribution. In other words, red means features that increase the model's predicted probability of class, whereas blue bars correspond to features that reduce it.

TABLE II. ERROR ANALYSIS OF MISCLASSIFIED PATIENTS FOR SVM MODEL

Patient_ID	ErrorType	Age	Type	Type_CN	TrueLabel	PredictedLabel
1	False Positive	35	Partial	Benign	0	1
2	False Negative	42	Total	Benign	1	0
3	False Positive	52	Partial	Benign	0	1
4	False Positive	53	Partial	Benign	0	1
5	False Positive	31	Total	Malign	0	1
6	False Negative	31	Total	Benign	1	0

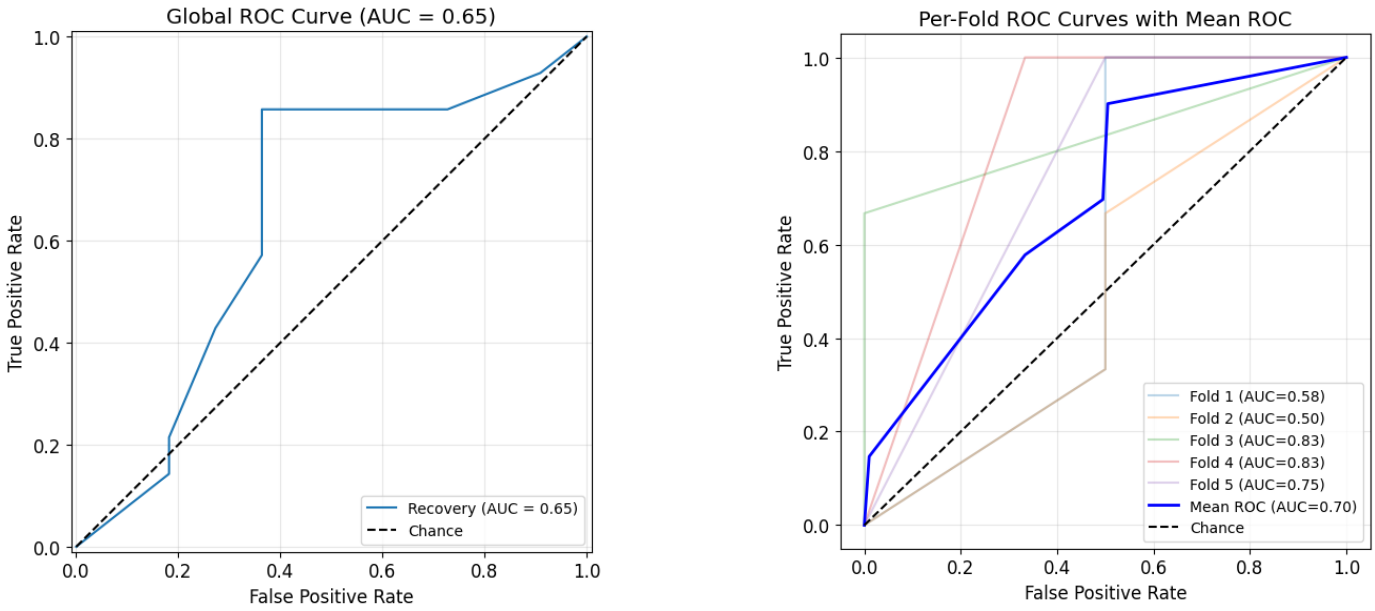

Fig. 5. ROC curve for the SVM method: a) Global ROC curve showing the overall discriminative performance (AUC calculated on all test predictions across folds). b) Per-fold ROC curves with the mean ROC curve (bold line) to illustrate variability across cross-validation folds.

1) Participant 1: is a 35-year-old woman who underwent partial thyroidectomy for a benign condition. For this woman, the predicted score is -0.129 which is below the mean value (-0.004). Type, OQ1, and Age show negative contributions (-0.06, -0.01, and -0.07, respectively), while NAQ contributed positively. Other features had negligible effects.

2) Participant 6: is a 35-year-old woman who underwent total thyroidectomy for a malignant condition. The model predicted a score of 0.016, higher than the baseline value of 0.004. Most features contributed negatively to the prediction, except for Type_CN, MeanF0, and Age, which had positive effects. Among these positive contributors, Type_CN had the largest value (+0.07), in contrast to what was observed for Participant 1.

3) Participant 15: is a 64-year-old woman who underwent a partial thyroidectomy for a benign condition. Most parameters had negligible effects.

V. DISCUSSION

Vocal changes are one of the common problems for subjects undergoing thyroid surgery. In the current work, we predict vocal recovery following thyroidectomy. For this purpose, machine learning techniques (ML) and a set of features are used. In addition, we use various ML algorithms to classify voices into recovery and non-recovery classes. All participants were evaluated before surgery and a month postoperative. This work was designed as a pilot feasibility study rather than a fully powered trial.

The SVM technique achieved the highest performance, with an F1-score of 80%. The SHAP analysis revealed that the most important features contributing to no-recovery predictions were the type of performed operation (partial/total), followed by age, and then the nature of the thyroid (malignant/benign). Various works have also found that speech can be affected by the extent of thyroid surgery [28], [29], [30]. Yılmaz et al. [31] reported that the type of surgical procedure (subtotal thyroidectomy or total), age, histopathologic diagnosis, and sex did not significantly impact vocal quality after thyroidectomy.

(c) Participant 15

Fig. 7. Example of waterfall plots for three participants selected randomly from the dataset.

However, they observed that voice changes were associated with tumor type. This may be due to various factors, such as injuries to the Recurrent Laryngeal Nerve (RLN) [32]. In addition, patients' emotions, experiences, and professional occupations may significantly impact these outcomes. Some existing studies have also identified female gender and the volume of the resected gland as risk factors for post-operative speech alterations after total thyroidectomy [28]. Also, a set of glottal features corresponding to different phases of the glottal cycle also contributed to the model's performance. Among these, OQ, and SQ are commonly used time-based parameters, while NAQ represents the shape and timing of the glottal waveform [18].

In our SHAP analysis, the glottal features had a similar impact in predicting both classes. Existing studies showed that in healthy individuals, higher OQ1 and OQ2 values are associated with better voice quality. In contrast, lower values are generally associated with pathological conditions such as nodules and vocal fold paralysis [18]. Moreover, OQ is

inversely correlated with vocal intensity, meaning that lower values correspond to higher vocal intensity [24].

For the NAQ parameter, higher values are indicative of a more symmetrical glottal waveform and are associated with breathy phonation type [33], [34]. OQ and NAQ are also inversely related to vocal intensity [24]. A decrease in NAQ may reflect increased vocal intensity due to a prolonged glottal closure phase [35].

Previous studies have revealed that the SQ2 parameter is lower in healthy voices than in pathological ones. In Addition, decreased values of these parameters have been reported in female patients with heart failure, suggesting their sensitivity to physiological alterations [24]. The glottal parameters are also applied to distinguish between patients with healthy voices and those with vocal fold paralysis [20] or neurological disorders such as Parkinson's disease [36]. These outcomes underline the clinical value of using glottal source features in postoperative voice assessment.

Some recent studies related to this current study have utilized ML techniques to predict thyroid cancer in patients who underwent thyroidectomy. They also achieved promising results in predicting thyroid cancer [14], [13], [37]. Lee *et al.* [13] developed a deep neural network using preoperative and two-week postoperative spectrograms to predict three-month postoperative vocal recovery in 114 patients. Their model achieved high predictive performance, with AUC values of 0.918 for breathiness, 0.735 for asthenia, and 0.894 for grade. In contrast, the present study achieved an AUC of 0.65 for the recovery class using acoustic and glottal features with SVM model on a smaller dataset of 25 patients. The lower performance may be attributed to the smaller sample size and differences in feature representation. Also, our study did not include deep learning models for classification. However, our method provides interpretable predictions using SHAP analysis to identify parameters that most contribute to voice recovery.

In terms of predictive performance, our results show lower accuracy compared with Kurt *et al.* [14] in identifying patients at risk of developing vocal cord palsy before thyroidectomy using ML techniques. However, their study addressed a different clinical problem, focusing on preoperative risk prediction of vocal cord palsy, while the present study predicts postoperative voice recovery. Therefore, direct numerical comparison of accuracy is not appropriate. Although deep learning approaches have demonstrated promising results and the potential to enhance model performance, they were not employed in this study. This decision was primarily due to the limited size of our dataset, which is significantly smaller than those used in comparable studies. Furthermore, this research does not primarily aim to optimize performance measures, but to investigate glottal and acoustic parameters relevant to thyroidectomy. These parameters have previously demonstrated their ability to detect changes in voice after thyroid surgery.

A. Limitations of the Study

Several limitations must be acknowledged. In our study, we employ the PSIAIF method to estimate glottal flow without feature-sensitivity analysis. This method, however, is sensitive to parameter configuration, which can affect the performance of derived features such as OQ and NAQ. In addition, the dataset was relatively small wich may introduce statistical fragility, as model performance and feature importance estimates may be sensitive to minor variations in the data. Although cross-validation was employed to mitigate overfitting, small datasets inherently increase the risk of variability and reduced generalizability. Also, calibration analysis was not performed. Therefore, the agreement between predicted probabilities and actual outcomes remains unassessed. Another limitation is that all participants were female. This approach has reduced the variability of vocal parameters related to physiological differences between the sexes, but it also limits the generalizability of the results to male patients. In fact, male and female voices differ in fundamental frequency and glottal configuration, which can influence these parameters. It is therefore essential to create predictive models that reflect actual clinical diversity. In addition, we did not include external validation because the existing datasets in the literature are private and not publicly accessible. More precisely, no publicly available longitudinal datasets containing preoperative and postoperative voice recordings were identified. As a result, the generalizability of the proposed models to external populations remains unconfirmed. Finally, we used traditional ML models due to their interpretability and suitability for small datasets. However, the deep learning approaches were not explored in this work due to the limited dataset size.

VI. Conclusion

This pilot feasibility study applied machine learning techniques based on different features to predict voice recovery after thyroidectomy. The dataset was collected on the day before surgery and a month after surgery. Preliminary performance varied between models, with the SVM classifier achieving an F1-score of 80%. These findings suggest that machine learning-based prediction is feasible, but not yet conclusive. Future research is encouraged to address the study's limitations through several directions. It is necessary to use a larger, mixed-gender cohort to improve the generalization of the model. In addition, model performance could be improved by applying advanced inverse filtering methods, such as IAIF+, or closed-phase covariance approaches. Another direction is to employ deep learning architectures, which may further improve predictive accuracy. Taken together, these preliminary findings suggest that machine learning may provide a feasible approach for predicting voice recovery after thyroidectomy. However, external validation is required before clinical application.

Declaration of Interest

No competing interests.

Availability of Data

The dataset used in this study cannot be publicly released due to patient privacy regulations and institutional restrictions. However, to support reproducibility, we provide a complete description of the feature extraction process, model architectures, hyperparameters, validation strategy, and evaluation protocol. All experiments were conducted using deterministic random seeds and standard machine learning libraries.

ACKNOWLEDGMENT

The present research has been produced under the Moroccan-Tunisian project titled "Multimodal Detection and Classification of Pathological Voice Disorders". The Ministry of Higher Education and Scientific Research in Tunisia and the Ministry of Higher Education, Scientific Research and Innovation in Morocco sponsor it. We extend our gratitude to Ilhem Charfeddine, Malek Mnejja and, Mariam Ben Ayed from the Department of Otorhinolaryngology-Head and Neck Surgery at Habib Bourguiba University Hospital, Sfax, Tunisia, for their valuable contributions to data collection and for providing essential information on the study participants.

ETHICAL APPROVAL

We conducted our study after approval from the Ethical Committee of the Medical Institution. All patients were informed about the study protocol. Signed consent was obtained from each participant to confirm their agreement to participate. They were informed that their anonymous recording data would be used for acoustic and video analysis.

A Dual-Chain and Differential Privacy-Based Solution for Medical Data Privacy Protection and Access Control

Cen Gu[1], Luping Wang[2]*, Hongjie Wu[3]*
Suzhou University of Science and Technology, 99 Xuefu Road, SuZhou, 215004, China[1,2,3]
Jiangsu Province Key Laboratory of Intelligent Building, Energy Efficiency, 99 Xuefu Road, SuZhou, 215004, China[3]

***Abstract*—As living standards rise, people are paying increasing attention to health. Vast quantities of medical data are generated daily, yet each piece contains sensitive information such as patients' names, mobile numbers, email addresses, and places of employment. Should this information be compromised, the consequences would be irreversible, causing severe damage. Traditional solutions merely implement access control policies, permitting data access only to authorised personnel. While this approach offers some protection, even compliant users cannot be entirely trusted and may engage in malicious activities. Once data is accessed, patients' sensitive information becomes fully exposed to the user, posing a significant data security risk. Therefore, this study proposes a medical data sharing scheme based on Dual-Chain and differential privacy. It employs a hybrid approach combining private chains, consortium chains, and IPFS. Internal hospital personnel can access data after de-identification, while external parties can only access data that has been de-identified and subsequently augmented with noise. This significantly enhances security. The experimental section of this study also demonstrates that the proposed scheme effectively protects data, while the data shared with external users enables them to successfully complete downstream tasks.**

***Keywords*—Blockchain; differential privacy; IPFS; medical data**

I. Introduction

People's living standards are rising as a result of the economy's quick development. Health has become an increasingly prominent concern [1][2]. Consequently, in this era of information and data, vast amounts of medical data are generated daily [3]. Sharing and analyzing this data helps doctors make better decisions and provide effective patient care. However, this data often contains sensitive patient information, such as names, employers, phone numbers, and email addresses [4][5]. Moreover, during the sharing process, data users are not entirely trustworthy and may engage in malicious activities [6]. This significantly increases the risk of information leaks, resulting in extremely low security and reliability [7].

II. Related Works

Over time, with continuous technological advancement, significant achievements have been made in the privacy protection and access control of medical data. Akinyele et al. [8] introduced an attribute-based encryption access control scheme for personal health data on mobile devices, enabling data owners to exercise granular control over data access and sharing. Zhou et al. [9] designed a CP-ABE-based data exchange mechanism that allocates access permissions based on requester attributes and defines specific access policies, incorporating attribute timestamps to support attribute revocation. However, a common limitation of these ABE-based access control systems is their reliance on a single attribute authority to manage attribute permissions and key distribution. As a result, there is a major single point of breakdown: should the authority be compromised, it jeopardises system stability and overall security, undermining reliability.

To address potential single points of failure, Chase et al. [10] proposed a solution based on multi-attribute authorization authorities. However, it still relies on a fully trusted central authority, creating a significant vulnerability: should the central authority cease to be trustworthy, the entire system's security would be compromised, and the integrity of all encrypted data would be undermined, failing to achieve true decentralization. Liu et al. [11] subsequently suggested adopting a distributed multi-authority access control scheme, yet regulatory bodies continued to play a dominant role. The system remains only partially decentralized and remains susceptible to centralized power, which undermines its security and efficiency.

Subsequently, with the advent of blockchain technology [12][13], its inherent transparency and decentralization characteristics prompted integration efforts with existing systems. In 2016, Azaria et al. [14] proposed MedRec, an electronic health record management system. By employing distributed ledger technology to store patient records on a blockchain, it created a decentralized record management framework. This approach preserves data integrity and prevents tampering, while facilitating seamless sharing of medical records between distinct healthcare providers. Ownership, access rights, and data integrity of medical records are governed through smart contracts [15][16]. B. Chen et al. [17] and B.B. Gupta et al. [18] proposed integrating blockchain with CP-ABE to enhance security. In order to overcome centralized healthcare systems' shortcomings, Wang et al. [19] developed a trusted healthcare data management platform leveraging blockchain smart contracts and attribute-based encryption for flexible access control. Jin et al. [20] combined blockchain, smart contracts, and proxy re-encryption for secure medical information sharing. However, it lacks attribute integration, limiting fine-grained access control, and depends heavily on user activity, which may compromise security. Chen et al. [21] designed a blockchain-based access control scheme with hybrid on-chain/off-chain

*Corresponding authors.

storage to reduce expense of storage. However, the absence of hashing and signing the IPFS-generated content identifier (CID) on upload enables potential injection of malicious files, lowering system security.

However, the aforementioned approaches merely protect data at the access control layer by establishing an access policy, allowing only those who meet the policy to access the data. Yet in reality, even some visitors who comply with the access policy may not be entirely trustworthy. Over time, they could potentially engage in malicious activities, leading to data leaks and misuse. Therefore, Shao et al. [22] proposed a solution combining dynamic reputation with token-based allocation. Blockchain nodes distribute varying quantities of tokens to each visitor based on their reputation. After each access event, the reputation value is updated, and the token allocation is reassigned. While this approach offers some protection for data privacy, it relies on the assumption that visitors remain trustworthy throughout. If a visitor betrays trust during the period when they possess tokens for access, it could still result in data leakage. Cai et al. [23] advised a federated blockchain-based healthcare data sharing system with enhanced proxy re-encryption for improved data sharing security [24][25]. However, data privacy protection remains inadequate. Therefore, this study addresses the shortcomings of all previous approaches by proposing a novel solution with the following key contributions:

- This work introduces a role-oriented data classification framework that structurally separates internal raw-data access from external privacy-preserving data release. Instead of applying de-identification and differential privacy as isolated preprocessing steps, the proposed scheme embeds them into distinct operational domains governed by different access policies. Internal medical personnel access encrypted, but structurally intact datasets under strict attribute-based control, while external researchers interact only with differentially private representations. This separation reduces cross-domain inference risk and limits unnecessary exposure of raw medical records.
- A functionally decoupled dual-chain architecture is designed to enforce domain-specific governance. The private hospital chain manages identity authentication and fine-grained CP-ABE-based access control for raw data, whereas the consortium chain supervises differentially private data publication and external access requests. This architectural separation is not merely a deployment choice but a security-driven design that reduces trust concentration, isolates attack surfaces, and mitigates risks associated with single-chain or centralized systems.
- The scheme integrates blockchain integrity guarantees with IPFS-based encrypted storage in a policy-enforced workflow. By storing only metadata and cryptographic hashes on-chain, while maintaining encrypted bulk data off-chain, the framework ensures tamper-evident verification without compromising scalability. Unlike conventional blockchain-IPFS integrations that focus solely on storage optimization, this design tightly couples data integrity validation with access policy enforcement and privacy quantification, forming a unified secure data-sharing model.

III. Organization

This study's general organization is separated into four major sections: Section IV displays the preliminary knowledge used in the work. Section V analyzes the overall scheme, mainly from the overall model of the scheme, the description of the scheme and the specific flow of the scheme. Section VI analyzes the security of the entire solution. The performance analysis of the suggested plan is provided in Section VII. Lastly, we conclude the study in Section VIII.

IV. Background Knowledge

This section primarily introduces the technologies used in the study: blockchain technology, differential privacy technology, bilinear mapping, and linear secret sharing.

A. Blockchain

Blockchain is a fault-tolerant, append-only replicated state machine maintained by a distributed set of nodes over an unreliable network [26][27]. Transactions are batched into blocks that commit cryptographically to prior state, yielding tamper-evident immutability under standard hash-collision assumptions. A consensus layer establishes a globally consistent total order and finality; permissionless systems achieve Sybil resistance through resource-based mechanisms, whereas permissioned deployments typically rely on Byzantine fault-tolerant agreement. Public-key cryptography underpins identity, authentication, and authorization, and light-client protocols enable inclusion verification without full replication. Deterministic smart contracts specify application logic as state-transition functions executed by validators, enabling verifiable automation, while raising concerns about correctness, composability, and adversarial execution. Current research targets scalability, latency and throughput, privacy via advanced cryptography, and cryptoeconomic robustness. Despite open challenges, blockchains provide auditability and credible neutrality for applications in digital assets, decentralized finance, and provenance tracking [28][29].

B. Differential Privacy

Differential privacy [30][31], is a provable privacy framework for statistical release and machine learning that injects noise calibrated to the query's sensitivity, ensuring that the inclusion or exclusion of any single individual has only a controlled, quantifiable effect on the output distribution; formally, for neighboring datasets $D \sim D'$ that differ in one record and a randomized mechanism M, if the inequality below holds for every measurable event S, then M satisfies (ε, δ)-differential privacy [32][33], where ε bounds multiplicative leakage and δ allows a negligible failure probability, as shown in Eq. (1):

$$\forall\, D \sim D',\ \forall\, S:\ \Pr\big[M(D) \in S\big] \ \le\ e^{\varepsilon}\ \Pr\big[M(D') \in S\big] + \delta. \tag{1}$$

C. Bilinear Mapping

In elliptic curve cryptography, a bilinear mapping is a mapping e, in which elements of two elliptic curve groups are mapped to another group [34][35]. Suppose we have two groups G_1 and G_2, and a target group G_T [36]. We define a bilinear mapping as shown in Eq. (2):

$$e : G_1 \times G_2 \to G_T \tag{2}$$

This mapping has several important properties:

- Bilinear: For any $p \in G_1$, $q \in G_2$ and scalars a and b, the bilinear mapping is satisfied in Eq. (3):

$$e(p^a, q^b) = e(p, q)^{ab} \tag{3}$$

- Non-degradation: The bilinear mapping is not degenerate, there exists at least one $p \in G_1$ and $q \in G_2$, such that $e(p, q) \neq 1$ (unit element).
- Computability: For most implementations, computing bilinear mappings is efficient in practice.

D. Linear Secret Sharing Scheme

Linear Secret Sharing Scheme (LSSS) [37][38] first splits the secret into n distinct components and then sends these n parts to n distinct participants, and a set of authorized participants can recover the secret by merging their shares [39][40]. It is defined as follows:

The description of the access framework is (M, ρ), P stands for the group of characteristics, containing the attribute names and attribute values. M is a linear secret sharing matrix of size $l \times n$. ρ is a mapping function, and $\rho(i)$ refers to the mapping of the ith row of the matrix M to an attribute name. Map the secret s to a value on $\mathbb{Z}_p^*$ with p is a prime number. Construct a vector $\mathbf{v} = (s, r_2, r_3, \ldots, r_n)^T$ by randomly choosing $\{r_2, r_3, \ldots, r_n\} \in \mathbb{Z}_p^*$, and compute $\gamma_i = M_j \cdot \mathbf{v}$ where γ_i refers to the attribute named $\rho(i)$ — the secret share of all uses of the attribute [41][42].

Secret reconstruction: Let $B \in M$ be the collection of attributes that comply with the authorizations of the access structure, where $I = \{i \mid \rho(i) \in B\} \subseteq \{1, 2, \ldots, l\}$. Being able to find the coefficients $\{x_i \in \mathbb{Z}_p^*\}_{i \in I}$ in polynomial time such that $\sum_{i \in I} x_i M_i = (1, 0, \ldots, 0)$, and then compute $s = \sum_{i \in I} x_i \gamma_i$.

V. Scheme Structure

This proposal primarily consists of six entities: data owners, data users, attribute authorization agencies, authoritative certification agencies, IPFS, and Blockchain. Fig. 1 displays the complete model diagram.

1) Data Owner (DO): DO is primarily responsible for establishing access policies, authorizing visitors who meet these policies, and encrypting and uploading both original de-identified medical data and data with privacy-preserving noise added to IPFS. They then upload metadata to the blockchain, comprising the CID returned by IPFS, the CID's hash value, and the hash value of the encrypted ciphertext.

2) Data User (DU): DU here likely refers to internal medical personnel and external research scientists. Before accessing data, DU must submit an authorization request to DO. Only DU meeting the access policy are authorized to access the data.

3) Attribute Authorities (AA): Multiple Attribute Authorities work together to manage all attributes, authenticate the identity of the visitor and generate the visitor's attribute key.

4) Certification Authority (CA): All users must register with the CA, which issues certificates to users, generates their public and private keys, and assigns them a unique *id*.

5) Interplanetary File System (IPFS): IPFS primarily stores large-volume raw medical data to alleviate storage tension on the chain and returns the CID to the DO.

6) Blockchain (BC): This is mostly made up of a consortium blockchain created by outside research institutes and a private blockchain inside the hospital. The blockchain stores metadata and records all activities.

The following steps make up the overall scheme's basic process:

- Step 1: Each entity in the system first registers with CA and obtains its own public and private key, which it uploads to the BC.
- Step 2: DO encrypts both types of data using symmetric encryption algorithms and upload them to IPFS. Metadata composed of the CID of data that has undergone only de-identification processing is uploaded to the hospital's internal private chain. Metadata composed of the CID of data that has been added noise via DP is uploaded to the consortium chain. Separate access policies are established for internal and external personnel.
- Step 3: DU requests authorization from DO to access data. DO verifies compliance with access policies. If compliant, AA will assign DU an attribute private key. Blockchain nodes will send metadata to DU.
- Step 4: Upon receiving the metadata, DU first performs a hash operation on the CID within the metadata. If the hash matches, it uses the CID to request access to the original data from IPFS.
- Step 5: After obtaining the encrypted raw data from IPFS, DU first performs a hash operation on the ciphertext and verifies its consistency with the hash value stored in the metadata. If consistent, it uses its own attribute private key to decrypt the symmetric encryption key, thereby decrypting the raw data for access.

A. Scheme Definition

1) Initialization phase: During the initialization phase, all entities register with the CA and generate global parameters.

a) CA.setup: CA runs *CA.Setup* to initialize the system. Given the security parameter λ, it selects a prime p and instantiates multiplicative cyclic groups G and G_T of order p with generator g, together with the bilinear map $e : G \times G \to G_T$.

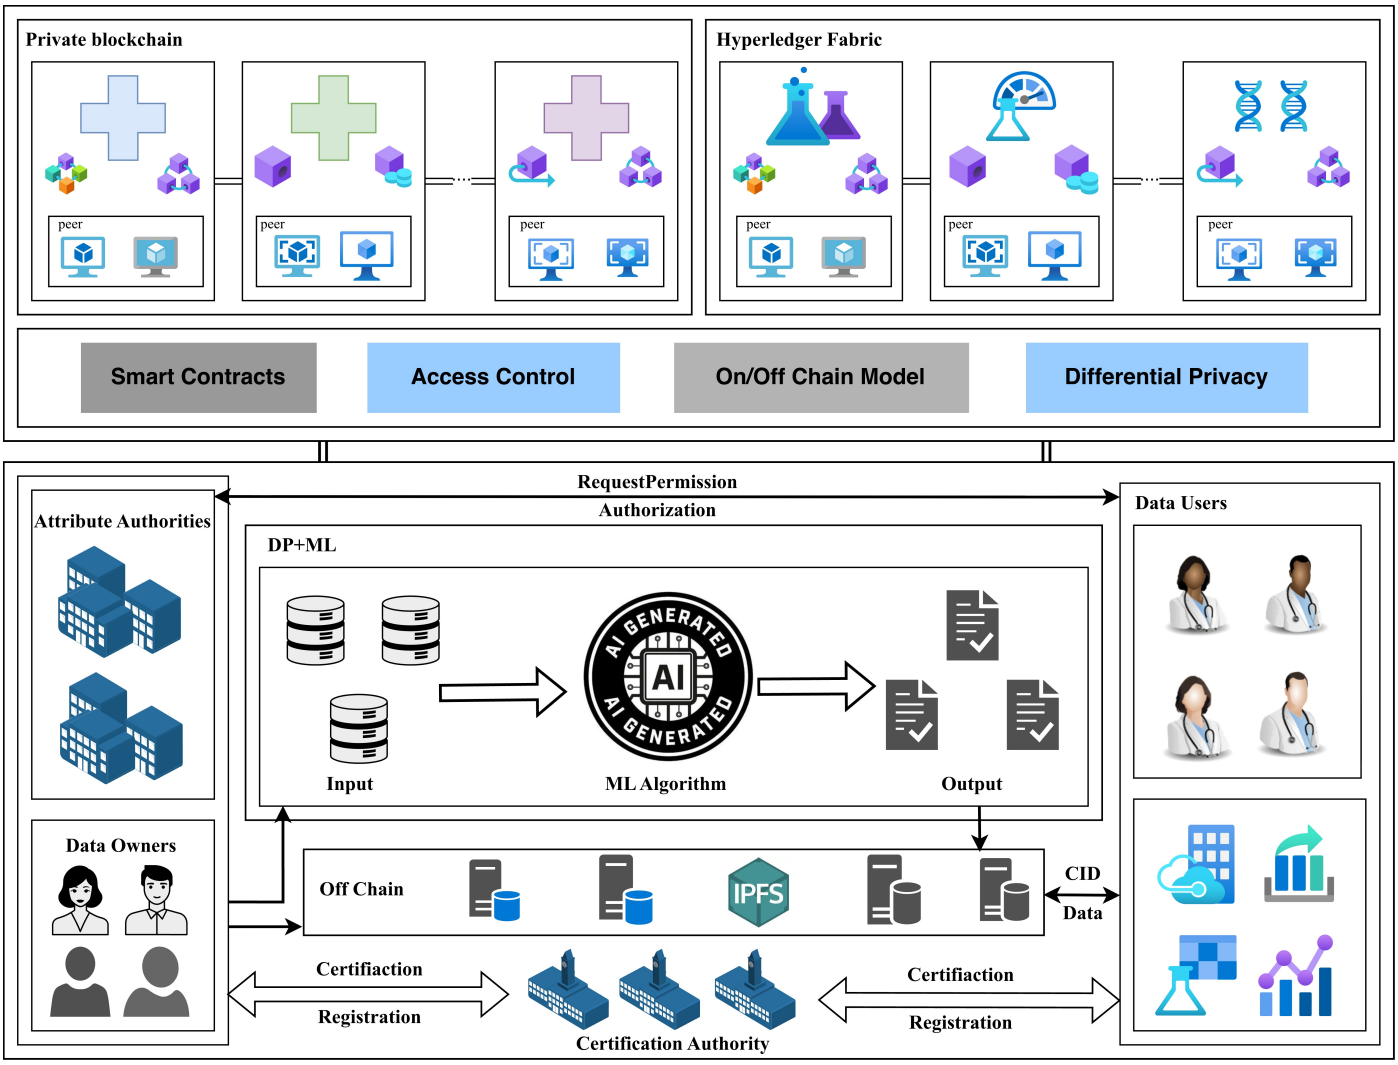

Fig. 1. System model.

It also chooses hash functions $H : \{0,1\}^* \to G$. The resulting global public parameters GPP are given in Eq. (4):

$$GPP = \{G, G_T, g, p, H, e\} \tag{4}$$

b) AA.register: Every AA submits a request together with its identifying information $info_a$, to register with the CA. The CA derives a unique identifier $aid \leftarrow H(info_a)$. The AA then samples $\alpha_{aid}, \beta_{aid} \in \mathbb{Z}_p$ to form its private key SK_{aid}, computes the public key $PK_{aid} = \left(g^{\beta_{aid}}, e(g,g)^{\alpha_{aid}}\right)$, and registers this public key with the CA.

c) DO.register: Each DO registers with the CA by submitting a request along with its identity information $info_o$. The CA computes a unique identifier $oid \leftarrow H(info_o)$. The DO then samples $\gamma \in \mathbb{Z}_p$ as its private key SK_{oid}, derives the corresponding public key $PK_{oid} = g^{\gamma}$, and registers this public key with the CA.

d) DU.register: By submitting a request and supplying its identifying information $info_u$, each DU registers with the CA. The CA derives a unique identifier $uid \leftarrow H(info_u)$. The DU samples $\mu \in \mathbb{Z}_p$ as its private key SK_{uid}, computes the corresponding public key $PK_{uid} = g^{\mu}$, and registers this public key with the CA.

2) Key generation phase:

a) KeyGen: The user requests a private key from each attribute authority AA_{aid} that governs their attributes. Let S be the user's attribute set, and assume $att \in S$ is administered by AA_{aid}. Before issuance, the authority verifies the user's identity uid and the validity of $Cert_{uid}$. If verification succeeds, AA_{aid} samples $r_{aid} \in \mathbb{Z}_p$ and constructs the user's attribute private-key component, as in Eq. (5):

$$SK_{att} = (g^{\alpha_{aid}} \cdot H(att)^{r_{aid}},\ g^{r_{aid}}) \tag{5}$$

Then the final private key of the user is the set of private keys produced by all relevant attribute authorizations, as shown in Eq. (6):

$$SK_{uid,att} = \bigcup_{aid} \{SK_{att} \mid att \in S \cap AA_{aid}\} \tag{6}$$

3) De-identification and DP phase: We utilized 500,000 outpatient medical records, first de-identifying sensitive fields such as patient names, workplaces, mobile numbers, and email addresses to protect privacy. This anonymized data was provided to internal personnel for viewing and use. Subsequently, we employed a rule-driven weakly supervised learning approach to match the de-identified data with a set of positive-class terms (infection-related) from the "initial diagnosis" field, generating binary labels as shown in Eq. (7). During feature construction, we exclusively utilized non-diagnostic text categories ("chief complaint + medical history"), while excluding diagnostic keywords used for annotation. This yields a bag-of-words count vector, as shown in Eq. (8). For each sample vector, we perform per-sample processing, as described in Eq. (9) and apply ℓ_1 regularization to limit its contribution. During the differential privacy phase, independent Laplace noise is added to each dimension of the pruned count vector, as shown in Eq. (10):

$$y = 1\{\, \exists\, k \in k_{\text{pos}} \mid k \subset \text{diagnosis} \,\} \tag{7}$$

$$x = \big[\, c(w_1), \ldots, c\big(w_{|v|}\big) \,\big] \tag{8}$$

$$x^{\text{clip}} = x \cdot \min\left(1, \frac{C}{\|x\|_1}\right) \tag{9}$$

$$\tilde{x} = x^{\text{clip}} + \eta,\ \eta_j \overset{\text{i.i.d.}}{\sim} \text{Laplace}(0, b),\ b = \frac{C}{\epsilon}. \tag{10}$$

4) Data encryption phase: DO chooses to employ symmetric encryption techniques to encrypt both the de-identified data and the data with additional noise via DP due to the effectiveness of encrypting massive amounts of raw data. DO selects different symmetric encryption key $k \in \mathbb{G}_T$ to encrypt each type of data separately to acquire the ciphertext C. Separate access policies (M, ρ) used to encrypt different symmetric key k. Here, M is an $l \times n$ matrix and ρ maps each row index i to an attribute. First sample a random vector $\mathbf{v} = (k, v_2, \ldots, v_n) \in \mathbb{Z}_p^n$. Compute the secret shares, as in Eq. (11); each x_i is associated with the attribute $\rho(i)$. For each row i, assume $\rho(i)$ is administered by authority AA_{aid}; choose $t_i \in \mathbb{Z}_p$ and derive the ciphertext component, as in Eq. (12). Next, compute the pairing value, as in Eq. (13). The final metadata is given in Eq. (14):

$$x_i = M_i \cdot \mathbf{v},\ \forall i \in \{1, \ldots, l\} \tag{11}$$

$$C_{i,1} = g^{\beta_{aid} x_i},\ C_{i,2} = H(\rho(i))^{x_i},\ C_{i,3} = g^{t_i} \tag{12}$$

$$D_i = e(g,g)^{\alpha_{aid} x_i} \cdot e(g,g)^{\beta_{aid} t_i} \tag{13}$$

$$metadata = \Big(C, hash(C),\ CID,\ hash(CID), \{C_{i,1},\, C_{i,2},\, C_{i,3},\, D_i\}_{i=1}^{\ell},\ k \cdot \prod_{aid} e(g,g)^{\alpha_{aid} k}\Big) \tag{14}$$

5) Data decryption phase: If DU meets the access policy, in addition to a reconstruction factor $\{w_i\}$ such that $\sum_{i \in I} w_i M_i = (1, 0, \ldots, 0)$. The pairwise value of each share is recovered through Eq. (15) and use the reconstruction coefficients w_i to decrypt the symmetric key k, according to Eq. (16) and Eq. (17). Eventually the DU decrypts the C via the obtained symmetric key k to get the data it wants to access.

$$\frac{e(C_{i,1}, g^{\alpha_{aid}} H(\rho(i))^{r_{aid}})}{e(C_{i,3}^{\beta_{aid}}, g^{r_{aid}})} = \frac{e(g^{x_i}, g^{\alpha_{aid}} H(\rho(i))^{r_{aid}})}{e(g^{\beta_{aid} t_i}, g^{r_{aid}})} \tag{15}$$

$$\prod_{i \in I} (e(g,g)^{\alpha_{aid} \lambda_i})^{w_i} = e(g,g)^{\sum_{i \in I} \alpha_{aid} \lambda_i w_i} = e(g,g)^{\sum_{aid} \alpha_{aid} k} \tag{16}$$

$$k = \frac{k \cdot \prod_{aid} e(g,g)^{\alpha_{aid} k}}{e(g,g)^{\sum_{aid} \alpha_{aid} k}} \tag{17}$$

VI. Security Analysis

This section primarily analyzes the proposed scheme from three perspectives: threat model, correctness, and resistance to attacks.

A. Threat Model

In this work, we consider a probabilistic polynomial-time adversary operating in a realistic medical data-sharing environment. The adversary is assumed to have full visibility of all public system parameters, blockchain transactions, on-chain metadata, content identifiers CID, and encrypted data stored on IPFS. In particular, the adversary may obtain complete read access to ciphertext corresponding to both internally shared de-identified datasets and externally shared differentially private datasets. The adversary may attempt active manipulation, including CID substitution, ciphertext tampering, replay of outdated metadata, or injection of malicious files into the IPFS storage layer. Multiple malicious data users may also collude by combining their attribute private keys in an attempt to satisfy an access policy not satisfied individually. Furthermore, the adversary may possess auxiliary background knowledge, such as demographic attributes or partial medical information, and attempt linkage attacks, membership inference, or statistical re-identification against externally released data. At the system level, metadata analysis and traffic pattern observation, including access frequency and timing information, are also considered possible attack vectors.

We assume that standard cryptographic hardness assumptions hold, including the discrete logarithm and bilinear Diffie–Hellman assumptions in pairing-based groups, as well as the semantic security of symmetric encryption. The Certification Authority is trusted to correctly initialize the system and protect master secrets, while Attribute Authorities follow the protocol for attribute key issuance and are not assumed to be fully colluding with the adversary. Blockchain nodes operate under Byzantine fault tolerance assumptions, and the adversary controls fewer nodes than the consensus threshold required to rewrite confirmed ledger history. IPFS is considered an untrusted storage layer and provides no

confidentiality guarantee. Under these assumptions, we define the security objectives of confidentiality, fine-grained access control, collusion resistance, data integrity, and differential privacy protection for external data release.

B. Proof of Correctness

First, consider the reconstruction properties of LSSS. Let B denote the set of attributes satisfying the access policy, and let the corresponding row index set be:

$$I = \{\, i \mid \rho(i) \in B \,\} \subseteq \{1, \ldots, l\}.$$

According to the LSSS definition, there exists a set of reconstruction coefficients $\{w_i\}_{i \in I} \subset \mathbb{Z}_p$, such that:

$$\textstyle\sum_{i \in I} w_i M_i = (1, 0, \ldots, 0).$$

From Eq. (11), it can be seen that the secret share for each row is:

$$x_i = M_i \cdot v \quad (v = (k, v_2, \ldots, v_n)^T).$$

By taking a linear combination of these shares, k is obtained by Eq. (18):

$$\begin{aligned} \sum_{i \in I} w_i x_i &= \sum_{i \in I} w_i (M_i \cdot v) \\ &= \left(\sum_{i \in I} w_i M_i \right) \cdot v \\ &= (1, 0, \ldots, 0) \cdot v \\ &= k \end{aligned} \tag{18}$$

In the decryption process description, the text uses λ_i to denote the secret share associated with the i-th row, equivalent to the aforementioned x_i. The above derivation demonstrates that provided the access structure is satisfied, the secret k can be linearly recovered using an appropriate reconstruction coefficient w_i. For each row $i \in I$, administered by AA_{aid}, the DU holds the attribute private-key component:

$$SK_{\rho(i)} = \left(g^{\alpha_{aid}} H(\rho(i))^{r_{aid}},\, g^{r_{aid}} \right).$$

Using the ciphertext components and the private key above, DU computes the pairing ratio in Eq. (19):

$$\begin{aligned} \frac{e(C_{i,1},\, g^{\alpha_{aid}} H(\rho(i))^{r_{aid}})}{e\left(C_{i,3}^{\beta_{aid}},\, g^{r_{aid}}\right)} &= \frac{e\left(g^{\beta_{aid} x_i},\, g^{\alpha_{aid}} H(\rho(i))^{r_{aid}}\right)}{e(g^{\beta_{aid} t_i},\, g^{r_{aid}})} \\ &= e(g, g)^{\alpha_{aid} \lambda_i} \end{aligned} \tag{19}$$

By bilinearity, the masking randomness t_i, r_{aid} cancels out, leaving a factor depending only on $\alpha_{aid}\lambda_i$. DU then uses the reconstruction coefficients w_i over all $i \in I$ to obtain $e(g,g)^{\sum_{aid} \alpha_{aid} k}$, where the last step uses $\sum_{i \in I} w_i \lambda_i = k$. This yields the masked exponent $\sum_{aid} \alpha_{aid} k$. Finally, combining this with the masked key term from the metadata, DU acquires k by Eq. (20):

$$k = \frac{k \cdot \prod_{aid} e(g,g)^{\alpha_{aid} k}}{e(g,g)^{\sum_{aid} \alpha_{aid} k}} \tag{20}$$

C. Resistance to Attacks

The proposed scheme leverages multi-authority CP-ABE, blockchain with IPFS, and differential privacy to jointly provide confidentiality, integrity, and privacy, thereby resisting several typical classes of attacks. For passive eavesdropping and key-guessing attacks, even a powerful adversary with full access to blockchain transactions and IPFS storage only observes the ciphertext C, the CID and their hashes, the ABE ciphertext components $\{c_{i,1}, c_{i,2}, c_{i,3}, D_i\}$, and the masked key term $k \cdot \prod_{aid} e(g,g)^{\alpha_{aid} k}$. Without any legitimate attribute private key SK_{att}, the adversary cannot form the pairing ratios, nor can they derive $e(g,g)^{\sum_{aid} \alpha_{aid} k}$. Attempting to guess k from $k \cdot \prod_{aid} e(g,g)^{\alpha_{aid} k}$ requires solving discrete logarithm or DBDH-type problems in bilinear groups, which is infeasible under appropriate parameters. The scheme is thus robust against eavesdropping and brute-force attacks.

For unauthorized access and collusion, access control is enforced by a multi-authority CP-ABE with an LSSS access structure. If a user's attribute set S does not satisfy the policy, there exist no coefficients w_i such that $\sum_{i \in I} w_i M_i = (1, 0, \ldots, 0)$, and hence $\sum_{i \in I} w_i \lambda_i = k$ cannot hold. Even when multiple unauthorized users collude and pool their attribute keys into a union set S_U, if this union still fails to satisfy the access matrix, LSSS theory guarantees that no valid reconstruction coefficients can be found, so the colluding users cannot elevate their collective access privileges or derive k beyond what their authorized attributes permit.

For data tampering and replay attacks, the scheme relies on blockchain-stored hashes and timestamps to guarantee integrity and auditability. Upon decryption, DU recomputes the hashes of the received CID and the ciphertext C retrieved from IPFS and compares them to on-chain values. Any modification of CID or ciphertext causes hash mismatches and will be detected and rejected. Replay attacks that attempt to resubmit outdated metadata or access requests are mitigated by the append-only, timestamped blockchain ledger, which records the latest state and access logs. The system can detect and prevent abnormal replays by checking against the most recent blockchain state, thus resisting tampering and replay attacks on IPFS and the blockchain.

Regarding inference attacks and privacy leakage, external researchers only see de-identified and differentially private feature vectors. De-identification removes explicit identifiers such as names and contact information from raw records, while the differential privacy mechanism bounds the impact of any single record on the output distribution within a factor of e^{ε}. This formally limits the advantage of any adversary, regardless of side information, in inferring sensitive attributes of any individual patient from $\tilde{x}$. Taken together, the cryptographic confidentiality of k, fine-grained access control, integrity protection, and rigorous differential privacy guarantees show that the proposed scheme can effectively withstand eavesdropping, tampering, collusion, replay, and inference attacks, while still supporting practical and privacy-preserving medical data sharing.

VII. PERFORMANCE ANALYSIS

Every experiment in this work was carried out on a device equipped with an Apple M4 processor, 16GB RAM, and macOS Sequoia 15.5 operating system.

A. Functional Analysis

According to Table I, the proposed scheme in this study outperforms existing approaches in terms of patient-centricity, identity information protection, data confidentiality, secure distributed storage, granular access control, and data privacy protection. In [18] and [23], the authors neglect identity privacy protection in their approaches, while [17] relies on cloud storage for medical data, introducing potential data security risks. In [19], the authors employ trust-based organizational access control, limiting patients' ownership control over their medical data. In [20], the authors fail to achieve granular access control with its identity-based approach. All these solutions neglect privacy-preserving data processing. Consequently, the proposed solution in this study demonstrates significant advantages across these dimensions.

B. Performance Evaluation of DP

During the differential privacy phase, we add independent Laplace noise to each dimension of the truncated counts and employ a dimensionless noise intensity *scale*$= C/\varepsilon$ to uniformly compare the privacy–utility tradeoff under different truncation thresholds and privacy budgets. This study systematically scans combinations of $C \in \{3, 4, 5, 6\}$ and $\varepsilon \in \{6, 8, 12, 20, 30, 40\}$, as shown in Table II. We split the 500,000 data points into 95% for training, 5% for validation, and 5% for testing. During training, we feed the de-identified features—perturbed with differential privacy—into a continuous scoring function $s(x) = \sigma(w^\top x + b_0)$. On the validation set, we perform a grid search over the threshold $t \in [0, 1]$ and select the value that maximizes the F_1 score; this threshold is then fixed for the testing phase. Finally, we visualize the evaluation metrics of the experimental results, as shown in Fig. 2.

First, in Fig. 2(a), Fig. 2(b), and Fig. 2(d), the three metrics AUROC, AUPRC, and F_1 increase monotonically as ε grows, from a moderate regime at $\varepsilon = 6$ the performance is in a moderate regime with AUROC in [0.78,0.84], AUPRC in[0.45,0.62], and F_1 in [0.48,0.59]. At $\varepsilon = 12$ the metrics rise to AUROC in [0.88,0.91], AUPRC in [0.68,0.79], and F_1 in [0.64,0.71]. Near $\varepsilon = 20$, the method enters a high-performance regime with AUROC in [0.96,0.97], AUPRC in [0.91,0.94], and F_1 in [0.83,0.86]. Further increasing to $\varepsilon = 30$ and 40 approaches the no-DP ceiling both AUROC and AUPRC near 0.99, $F_1 > 0.95$. This pattern rapidly gains with larger ε followed by diminishing returns beyond $\varepsilon \approx 20$ indicates that our method preserves strong predictive signal under moderate privacy, while additional relaxation yields limited benefit.

Second, the effect of the clipping threshold C appears as a horizontal shift at fixed ε: smaller C (more aggressive clipping) lowers the curves, with larger gaps at small ε; when ε is sufficiently large, the curves converge, suggesting that the impact of clipping on utility is attenuated at high ε.

Third, and crucially, [see Fig. 2(c)] in the summary plot of *scale* $= C/\varepsilon$ versus AUPRC, the points from different C values almost lie on a single master curve, showing that the noise *scale* $= C/\varepsilon$ is the key dimensionless variable governing utility: as *scale* increases from 0.1 to 1.0, AUPRC decreases smoothly and monotonically, and results for different C align at the same *scale*. This "curve collapse" not only confirms the theoretical expectation of our clip-then-noise design, but also provides a practical tuning rule for deployment.

Overall, under the Laplace mechanism with rigorous differential privacy guarantees, high utility is achieved already at moderate ε. The metrics improve monotonically with ε and exhibit a clear "sweet spot" around $\varepsilon = 12 - 20$, and all three evaluation dimensions consistently support these conclusions, indicating that DP-processed shared data are useful and controllable for downstream binary classification.

C. Time Consumption

In this step, we performed encryption and decryption operations on 24 datasets of approximately 500MB each after adding noise via DP, recording the time consumed, as shown in Fig. 3. This figure illustrates the distribution of time overhead across 24 data files during the symmetric encryption

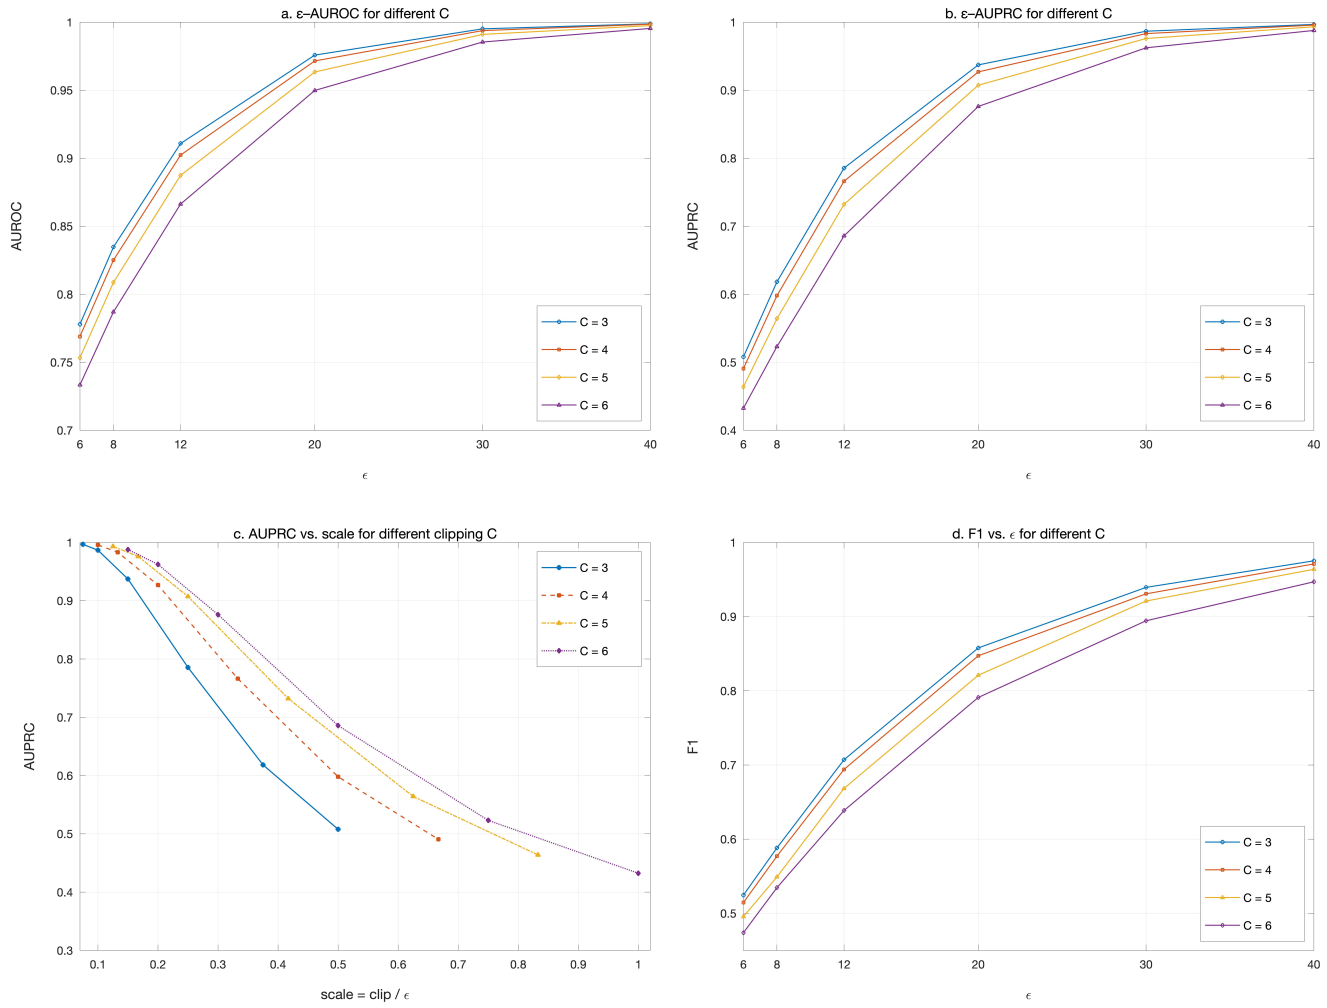

Fig. 2. Experimental results display.

TABLE III. HASH OPERATION TIME

Aspects	Time					
	dp_C3_e6	**dp_C3_e8**	**dp_C3_e12**	**dp_C3_e20**	**dp_C3_e30**	**dp_C3_e40**
enc	0.215 s	0.205 s	0.224 s	0.203 s	0.231 s	0.216 s
CID	0.008 ms	0.008 ms	0.005 ms	0.008 ms	0.007 ms	0.010 ms

and decryption phases. Overall, single-pass processing latency remains sub-second: the average encryption time is 0.294 s (range 0.255–0.372 s), while the average decryption time is 0.263 s (range 0.243–0.292 s). Compared with encryption, decryption achieves an average reduction of approximately 0.031 s, a 10.3% decrease in latency, reflecting the lighter key-recovery path. Both phases exhibit low variability: the standard deviation of encryption time is 0.029 s and that of decryption time is 0.014 s. This indicates stable and predictable operation across file/parameter combinations ($C = 3$–6, $\varepsilon = 6$–40). Notably, the most time-consuming samples occur under the C=3 configuration with smaller ε values, whereas other settings remain low and comparable. These results demonstrate the symmetric scheme's strong scalability and engineering viability—delivering consistent latency without sacrificing throughput, while further reducing processing overhead on the decryption side. After uploading the encrypted files to IPFS, the system obtain the CID and compile the metadata for upload to BC. We recorded the time consumed by the hash operations on the CID and ciphertext within the metadata, as shown in Table III. The hash operations for the ciphertext consistently took around 0.2s, while the CID hash times were in the millisecond range—demonstrating highly efficient processing. Finally, we recorded the time taken to upload each of these 24 files to IPFS and download them from IPFS. As shown in Fig. 4, both processes were completed within one second, demonstrating high efficiency.

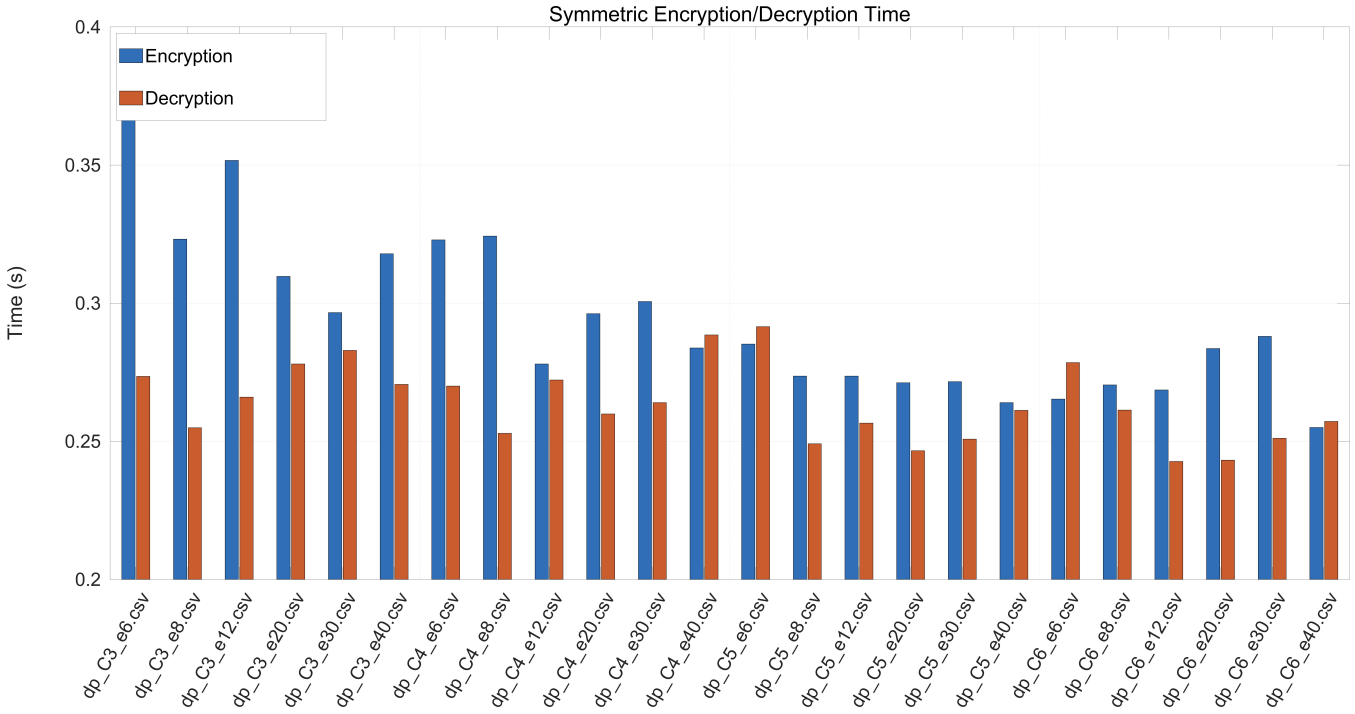

Fig. 3. Symmetric encryption and decryption time.

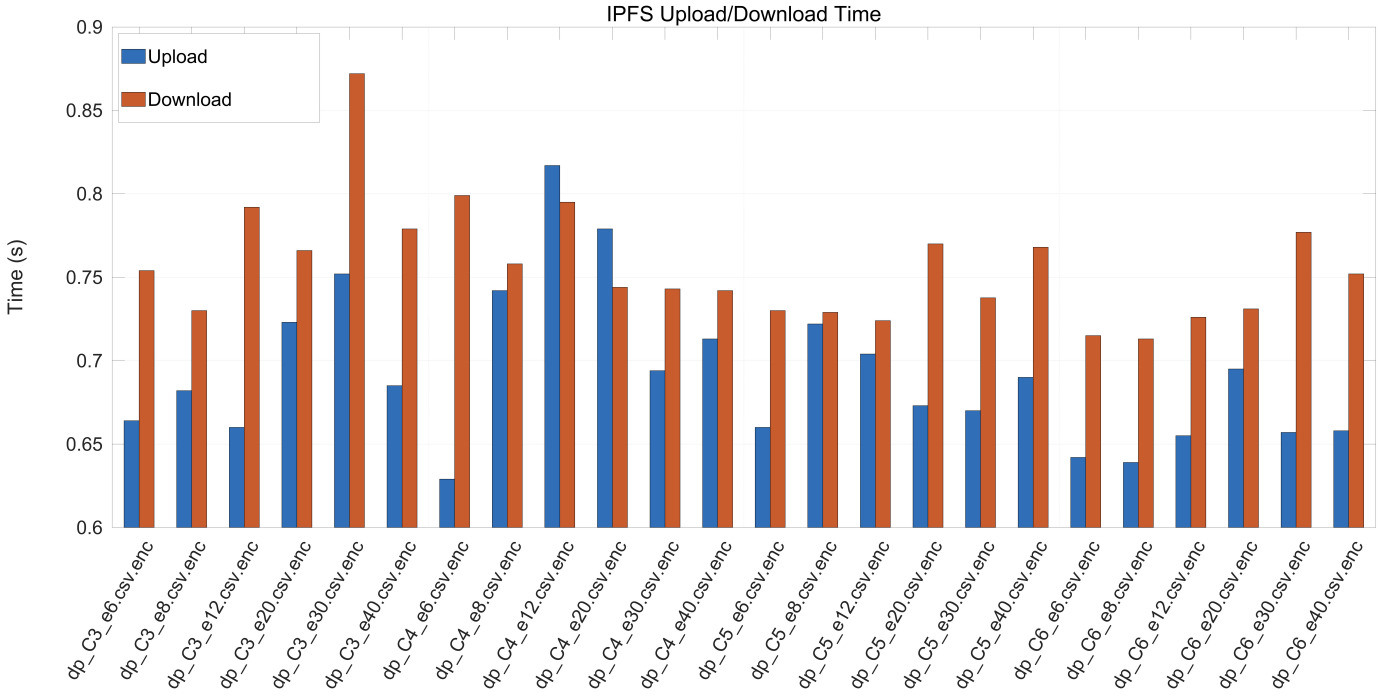

Fig. 4. IPFS upload and download time.

VIII. Conclusion

This study proposes a security-driven dual-chain framework for medical data sharing that structurally separates internal raw-data access from external privacy-preserving data release. By integrating multi-authority CP-ABE, blockchain-based governance, IPFS off-chain storage, and differential privacy under a unified security model, the proposed scheme achieves layered protection across confidentiality, integrity, access control, and statistical privacy dimensions. Unlike con-

ventional blockchain-based storage solutions that primarily focus on data immutability, the proposed architecture emphasizes role-oriented domain separation and trust decoupling. The private hospital chain enforces fine-grained access control over encrypted medical records, while the consortium chain supervises privacy-budgeted data publication for external research institutions. This structural separation reduces trust concentration, isolates attack surfaces, and mitigates cross-domain inference risks. Experimental results demonstrate that even after differential privacy perturbation, the released data maintain sufficient utility for downstream analytical tasks, thereby achieving a practical balance between privacy protection and data usability.

Overall, the proposed framework provides a unified, auditable, and quantifiably private data-sharing model suitable for heterogeneous medical environments. Future work will further explore adaptive privacy budget allocation, traffic-obfuscation mechanisms, and comprehensive evaluation of blockchain consensus latency and scalability under large-scale deployment.

***Abstract*—The integration of artificial intelligence (AI) in medical diagnostics is increasingly jeopardized by adversarial attacks—imperceptible perturbations designed to induce misclassification in Deep Learning models. While Convolutional Neural Networks (CNNs) have achieved state-of-the-art performance in medical image analysis, their susceptibility to gradient-based attacks poses a severe risk to patient safety and diagnostic integrity. This study addresses the critical need for robust defense mechanisms in X-ray diagnostics by proposing a Hybrid Ensemble model based on Stacked Generalization. Unlike single-paradigm approaches, our method fuses the spatial feature extraction capabilities of a CNN with the statistical anomaly detection power of a Random Forest (RF). We evaluated this architecture on a curated dataset of X-ray images subjected to Projected Gradient Descent (PGD) attacks with varying perturbation magnitudes (ϵ). The results demonstrate that the Hybrid Ensemble consistently outperforms individual models and standard adversarial training baselines. Under strong attack conditions ($\epsilon = 0.006$), the proposed model achieved an Area Under the Curve (AUC) of 0.919, significantly surpassing the adversarial training baseline (AUC 0.700). Furthermore, the ensemble reduced false positives to 108 compared to 138 for the CNN alone, enhancing clinical reliability. Theoretical motivation for the feature extraction process and extensive experimental validation suggest that leveraging statistical irregularities offers a computationally efficient and robust defense strategy suitable for real-time clinical deployment.**

***Keywords*—Adversarial defense; medical X-ray; synergistic ensemble; deep learning security; diagnostic robustness; PGD attack**

I. Introduction

A. The Role of AI in Medical Diagnostics

Medical diagnostics are evolving rapidly through the integration of artificial intelligence (AI), particularly deep learning. Convolutional Neural Networks (CNNs) have demonstrated remarkable proficiency in interpreting medical images, identifying subtle abnormalities in modalities ranging from ophthalmology to radiology [1], [3]. Recent studies published in *IJACSA* highlight the continued dominance of CNNs in detecting complex pathologies such as brain tumors [2] and skin lesions [4] [22]. These systems enhance diagnostic precision and streamline workflows, offering the potential for personalized medicine [5], [8]. From detecting pneumonia in chest X-rays [6] to segmenting tumors in MRI scans [7], deep learning models are becoming indispensable tools. However, as AI systems are increasingly deployed in critical clinical decision support roles, their reliability, interpretability, and security become paramount [9], [10].

B. The Threat of Adversarial Attacks

Despite their performance, deep learning models are vulnerable to adversarial attacks, which are subtle, purposeful alterations to input data that deceive the model [11] [56]. In medical imaging, these perturbations are often imperceptible to the human eye, but can cause a model to misclassify a pathological scan as healthy, or vice versa [12], [15]. Adversarial examples exploit the decision boundaries of neural networks. Mathematically, an adversarial example x_{adv} is derived from a clean input x by adding a perturbation δ such that $\|\delta\|_p \leq \epsilon$, where ϵ is small enough to maintain visual fidelity [14], [17].

The consequences of such attacks in a clinical setting are severe. A false negative could lead to a missed diagnosis for a critical condition, while a false positive could result in unnecessary invasive procedures and patient stress [16], [23]. Furthermore, as noted in recent security surveys [13], the possibility of malicious actors manipulating medical data raises significant concerns regarding insurance fraud and hospital cybersecurity [19], [20].

C. Problem Statement and Motivation

Existing defense mechanisms, such as adversarial training [17] or defensive distillation [57], often struggle to generalize across different attack types or incur high computational costs that hinder real-time deployment [48]. Moreover, defenses designed for natural images may not capture the specific structural and statistical regularities of medical X-rays [18], [24]. Medical images possess unique noise distributions (Poisson noise) and texture patterns that standard CNNs may overlook but which are critical for distinguishing clean from perturbed data [29], [44].

The motivation of this research stems from the observation that adversarial attacks, while spatially deceptive to convolution filters, often introduce high-frequency artifacts that disrupt the natural statistical distribution of the image [21]. Therefore, relying solely on deep learning for defense is insufficient. There is a clear research gap for defenses that leverage the unique statistical properties of medical images (orthogonality

*Corresponding author.

of features) to detect anomalies that deep learning models might miss.

D. Contribution and Novelty

This work proposes a novel Hybrid Ensemble defense that combines deep spatial features (CNN) with handcrafted statistical features (Random Forest). The core hypothesis is that while adversarial noise misleads CNNs by distorting spatial correlations, it inevitably disturbs low-level image statistics (e.g., spectral energy, histogram moments) that are easily detected by statistical classifiers (see Fig. 1). Our contributions are:

1) Ensemble architecture: A framework inspired by Stacked Generalization that fuses soft-probabilities from a CNN and a Random Forest, achieving complementary feature robustness.

2) Theoretical motivation: We provide a theoretical basis for the statistical features (Skewness, Kurtosis, Spectral Entropy) that make the Random Forest robust against PGD attacks.

3) Comprehensive evaluation: A rigorous evaluation using PGD attacks with varying ϵ $(0.003, 0.006)$ and a suite of noise types, demonstrating superior AUC (0.919) compared to standard adversarial training (0.700).

4) Clinical and computational analysis: A detailed analysis of computational cost (inference time) and clinical relevance (False Negative reduction), proving the solution's viability for real-time deployment.

II. Related Work

The field of adversarial defense in medical imaging has grown significantly. A comprehensive review by Olatunji et al. [25] and Taghanaki et al. [47] emphasizes the vulnerability of deep networks in high-stakes environments. In this section, we review the state-of-the-art methods and position our contribution relative to them. Table I presents a detailed comparison of proposed method with state-of-the-art defense mechanisms in medical imaging.

A. Adversarial Training

Proposed by Madry et al. [17], adversarial training remains the most popular defense [54]. It involves augmenting the training set with adversarial examples computed on the fly. While effective against the specific attacks seen during training, it suffers from the "robustness-accuracy trade-off" and often fails to generalize to unseen attacks or different perturbation magnitudes (ϵ). In medical imaging, this is particularly problematic as the noise patterns can vary widely between X-ray machines, as discussed in the context of COVID-19 detection by Al-Waisy et al. [26].

B. Defensive Distillation

Papernot et al. [57] proposed using a teacher-student network to smooth the decision gradients, making it harder for attackers to compute gradients. However, Carlini and Wagner [53] demonstrated that this method is vulnerable to stronger attacks that bypass gradient masking. Furthermore, distillation requires training multiple networks, increasing the computational burden.

C. Denoising and Pre-processing

Other approaches attempt to remove the adversarial noise before feeding the image to the classifier. Methods like Total Variance Minimization or Autoencoder-based denoising [58] fall into this category. While intuitive, they risk removing critical high-frequency clinical details (e.g., micro-calcifications in mammography or small fractures in X-rays), leading to a degradation of clean accuracy. This delicate balance between noise reduction and feature preservation is critical, as shown in the breast cancer detection study by Naseer et al. [45].

D. Statistical Anomaly Detection

Recent works have explored statistical testing (e.g., Maximum Mean Discrepancy) to detect adversarial samples [15]. While computationally cheap, these methods often suffer from high False Positive Rates (FPR) when applied to noisy medical data. Our approach improves upon this by integrating statistical detection within an ensemble voting mechanism, stabilizing the predictions.

E. Stacked Generalization

Our approach adapts the concept of *Stacked Generalization* (Stacking) [49] [38], which involves training a meta-classifier to combine the predictions of several base learners. This synergy relies on the diversity of the base models [46]. While Stacking is traditionally used to improve accuracy by reducing bias and variance, we repurpose it here for adversarial robustness. By combining a high-variance deep learner (CNN) with a lower-variance statistical learner (RF), we aim to mitigate the specific fragility of gradient-based models against L_∞ perturbations.

III. Materials and Methods

A. Dataset Preparation

The study utilizes the IRMA/ImageCLEFmed 2009 radiograph collection [31], comprising 14,410 anonymized X-ray images collected from routine clinical practice at RWTH Aachen. This dataset is widely recognized for benchmarking medical image analysis algorithms. To ensure a balanced evaluation, we curated a dataset containing equal distributions of clean and adversarial samples. Images were resized to 224×224 pixels and normalized to the $[0, 1]$ range to match the input requirements of standard deep learning architectures [32].

B. Attack Generation and Configuration

We evaluate the model primarily against non-adaptive PGD attacks, assuming a threat model where the adversary has access to the CNN gradients but not the statistical ensemble logic. We acknowledge that adaptive white-box attacks targeting the specific ensemble weights are possible but computationally more expensive for the attacker.

1) Fast Gradient Sign Method (FGSM): FGSM is a single-step attack that calculates the gradient of the loss function and updates the image once:

$$x_{adv} = x + \epsilon \cdot \text{sign}(\nabla_x L(\theta, x, y)) \tag{1}$$

While fast, FGSM is often too weak to fool robust models.

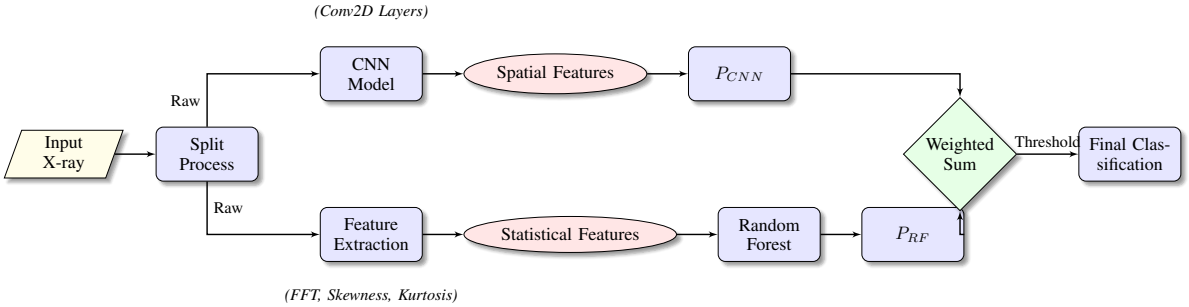

Fig. 1. Architectural overview of the Hybrid Ensemble Defense system. The input image is processed in parallel: spatially by the CNN and statistically by the Random Forest. The predictions are aggregated using optimized weights ($W_{CNN} = 0.4, W_{RF} = 0.6$) to produce the final robustness score.

TABLE I. DETAILED COMPARISON OF THE PROPOSED METHOD WITH STATE-OF-THE-ART DEFENSE MECHANISMS IN MEDICAL IMAGING

Defense Strategy	Core Mechanism	Key Strength	Primary Weakness	Inference Cost	Generalization	Ref.
Adversarial Training	Data Augmentation	High robustness to known attacks	Overfitting to specific ϵ	High (Training)	Low	[17]
Defensive Distillation	Gradient Masking	Hides gradient info	Vulnerable to CW attacks	Medium	Low	[57]
Image Denoising	Filtering/Autoencoders	Removes perturbation noise	Loss of fine clinical details	Medium	Medium	[58]
Adversarial Detection	Statistical Testing	Flags attacks before prediction	High False Positive Rate	Low	Medium	[15]
Hybrid Ensemble (Ours)	**CNN + Statistical RF**	**Orthogonal feature robustness**	**Slightly increased model size**	**Low (2.74ms)**	**High**	**–**

2) Projected Gradient Descent (PGD): PGD is an iterative version of FGSM, considered the strongest first-order attack. The update rule is:

$$x^{t+1} = \Pi_{x+\mathcal{S}} \left(x^t + \alpha \cdot \text{sign}(\nabla_x L(\theta, x^t, y)) \right) \tag{2}$$

Here, $\Pi_{x+\mathcal{S}}$ denotes the projection operator onto the L_∞ ball of radius ϵ, and α is the step size. We used $\alpha = \epsilon/10$ and 40 iterations.

To guarantee that the adversarial perturbations remained clinically imperceptible while being effective against the models, we meticulously calibrated the attack parameters. The specific configuration used in our experiments is detailed in Table II.

TABLE II. CONFIGURATION OF ADVERSARIAL ATTACK PARAMETERS OPTIMIZED FOR IMPERCEPTIBILITY

Parameter	Value
Attack Methods	{PGD, FGSM, Gaussian, S&P, Contrast}
PGD Steps	40
Gaussian Noise (σ)	0.008
Salt & Pepper Amount	0.008
Contrast Factor	1.1
Perturbation Constraint (ϵ)	0.003 (Subtle) – 0.006 (Strong)

C. Model Architectures

1) Convolutional Neural Network (CNN): A custom CNN was implemented using `Keras` [39] to capture spatial features [27]. The model was optimized using the Adam algorithm [36]. The mathematical operation of a convolutional layer l with kernel K on input I is given by:

$$(I * K)_{ij} = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} I(i-m, j-n) K(m,n) + b \tag{3}$$

This operation captures local spatial dependencies (edges, textures). Our architecture consists of three convolutional blocks ($32 \rightarrow 64 \rightarrow 128$ filters), each followed by Batch Normalization and Dropout (0.25) [35]. The activation function used is ReLU: $f(x) = \max(0, x)$ [33]. Similar architectures have proven effective in recent pandemic-related imaging studies [34].

2) Random Forest (RF) and statistical feature engineering: The Random Forest classifier [28] (200 trees) was employed to detect statistical anomalies. Unlike CNNs, RFs are non-differentiable and base their decisions on thresholding feature values, making them inherently resistant to gradient-based attacks [40].

We extracted a vector V_f of handcrafted features. The rationale and mathematical definitions are as follows:

a) Statistical moments: Adversarial perturbations, even if subtle, alter the pixel intensity distribution. We calculate the Skewness (S) and Kurtosis (K) for an image I with mean μ and standard deviation σ:

$$S = \mathbb{E}\left[\left(\frac{I-\mu}{\sigma}\right)^3\right], \quad K = \mathbb{E}\left[\left(\frac{I-\mu}{\sigma}\right)^4\right] \tag{4}$$

Clean medical images typically follow specific statistical distributions (e.g., Rayleigh or Gaussian depending on tissue). PGD attacks tend to flatten the Kurtosis or introduce asymmetry (Skewness).

b) Spectral features (Frequency domain): PGD attacks often inject high-frequency noise that is imperceptible in the spatial domain but evident in the frequency domain. We use the Discrete Fourier Transform (DFT):

$$F(u,v) = \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} I(x,y) e^{-j2\pi(\frac{ux}{M} + \frac{vy}{N})} \tag{5}$$

We extract the Spectral Entropy (H) to quantify the complexity of the frequency distribution:

$$H = -\sum_{k} p_k \log_2(p_k) \tag{6}$$

where, p_k is the normalized power spectrum density. An adversarial image typically exhibits higher entropy due to the randomized high-frequency noise injection.

c) Texture analysis (Laplacian): To detect disruptions in local smoothness, we compute the Laplacian variance. The Laplacian operator $\nabla^2 I$ highlights regions of rapid intensity change:

$$\nabla^2 I = \frac{\partial^2 I}{\partial x^2} + \frac{\partial^2 I}{\partial y^2} \tag{7}$$

The variance of $\nabla^2 I$ serves as a measure of image "roughness", which typically increases under adversarial attack.

d) Statistical validation: To ensure the reliability of our metrics and compute the 95% Confidence Intervals (CI), we employed non-parametric bootstrapping with 1,000 resamples on the test set.

e) Feature selection: The features (moments, spectral entropy, Laplacian) were selected based on their theoretical sensitivity to high-frequency noise. While a full ablation study is outside the scope of this study, preliminary analysis indicated that Spectral Entropy was the most discriminative feature against PGD noise.

D. Hybrid Ensemble and Weight Optimization

The Hybrid Ensemble aggregates the probability outputs of the CNN (P_{CNN}) and RF (P_{RF}) [37]. The final score S_E is a weighted sum:

$$S_E(x) = w_{\text{cnn}} \cdot P_{\text{CNN}}(x) + w_{\text{rf}} \cdot P_{\text{RF}}(x) \tag{8}$$

To determine optimal weights, we performed a grid search on a validation set. The decision process is outlined in Algorithm 1.

1) Complexity analysis: The addition of the ensemble method introduces a computational overhead. However, the complexity of the feature extraction is $O(N)$ (where N is the number of pixels) for moments and gradients, and $O(N \log N)$ for the FFT. The RF inference is $O(T \cdot D)$, where T is the number of trees and D is the depth. This is negligible compared to the $O(N \cdot K^2 \cdot L)$ complexity of the CNN (where L is layers and K kernel size). Thus, the ensemble remains efficient.

IV. Results and Discussion

A. Optimization of Ensemble Weights

The contribution of each model to the ensemble is critical for maximizing performance [30]. We conducted an extensive grid search to determine the optimal balance between the deep learning component (CNN) and the statistical component (RF). Fig. 2 illustrates the impact of varying the CNN weight (w_{cnn}) on five key metrics.

Algorithm 1 Hybrid Ensemble Decision Process

Require: Input image X, CNN Model M_{cnn}, RF Model M_{rf}
Require: Optimal Weights $w_{cnn} = 0.4$, $w_{rf} = 0.6$
Ensure: Class Prediction $\hat{y} \in \{0, 1\}$ (0: Clean, 1: Adversarial)
$P_{cnn} \leftarrow M_{cnn}$.predict($X$)
$V_{feat} \leftarrow$ ExtractFeatures(X) {Eq. 4, 5, 6}
$P_{rf} \leftarrow M_{rf}$.predict(V_{feat})
$S_{ensemble} \leftarrow (w_{cnn} \times P_{cnn}) + (w_{rf} \times P_{rf})$
if $S_{ensemble} \geq 0.5$ **then**
  $\hat{y} \leftarrow 1$ {Adversarial Detected}
else
  $\hat{y} \leftarrow 0$ {Clean Detected}
end if
return $\hat{y}$

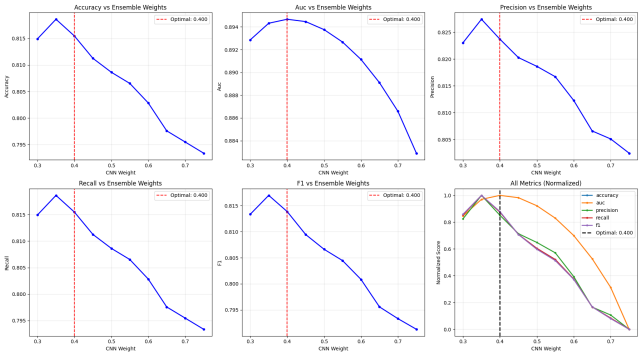

Fig. 2. Hyperparameter optimization via grid search. The graphs show the evolution of Accuracy, AUC, Precision, Recall, and F1-score as a function of CNN weight. The optimal configuration is identified at $w_{cnn} = 0.400$, favoring the statistical robustness of the RF.

1) Convexity and stability analysis: The curves in Fig. 2 exhibit a distinct convex behavior. At $w_{cnn} = 0$ (pure RF) or $w_{cnn} = 1$ (pure CNN), Accuracy is suboptimal when using only the RF ($w_{\text{cnn}} = 0$) or only the CNN ($w_{\text{cnn}} = 1$). The stability of the F1-score around the peak (0.4) indicates that the ensemble is robust to minor fluctuations in hyperparameter tuning. This "sweet spot" at 0.4 confirms that while CNNs are essential for image understanding, the statistical "sanity check" provided by the RF is more reliable for detecting the specific artifacts of PGD attacks.

B. Performance Evaluation and Robustness

1) ROC analysis and false positive dynamics: The Receiver Operating Characteristic (ROC) curves provide a comprehensive view of the trade-off between sensitivity (True Positive Rate) and specificity (1 - False Positive Rate). Fig. 3 presents the overall comparison on the mixed dataset.

The Hybrid Ensemble (Green curve) achieves an Area Under the Curve (AUC) of **0.891**. More importantly, looking at the "knee" of the curve (the top-left corner), the Ensemble rises much sharper than the individual models. This implies that for a fixed low False Positive Rate (e.g., 0.05), the Ensemble offers a significantly higher True Positive Rate. In a clinical context, this translates to fewer false alarms while maintaining high detection capability.

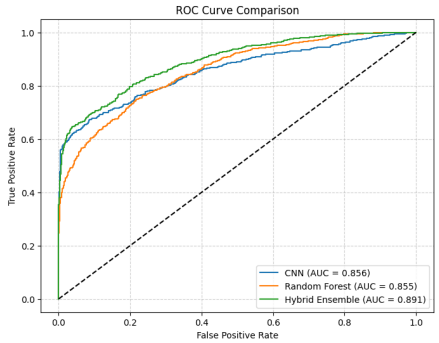

Fig. 3. Global ROC curve comparison on the mixed dataset. The hybrid ensemble (AUC=0.891) dominates the individual models, exhibiting a better convex hull.

The robustness is further highlighted when analyzing specific perturbation strengths separately (see Fig. 4).

- At $\epsilon = 0.003$ (left): The Ensemble maintains an AUC of 0.863 compared to 0.842 for the CNN. This demonstrates resilience even against extremely subtle attacks.
- At $\epsilon = 0.006$ (right): The performance gap widens significantly. The Ensemble achieves an impressive **AUC of 0.919**, while the CNN reaches 0.901. This suggests a complementary effect: as the attack becomes stronger, it becomes easier for the RF to detect (due to increased statistical distortion), compensating for the CNN's increased error rate. This aligns with optimization strategies discussed by Vargas et al. [55].

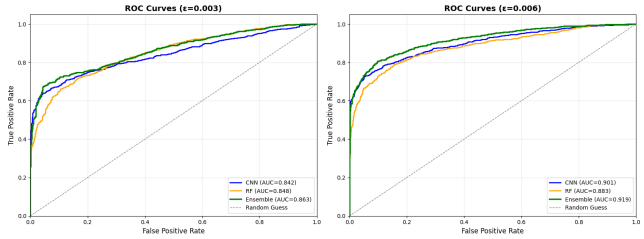

Fig. 4. ROC curves at specific epsilon values ($\epsilon = 0.003$ left, $\epsilon = 0.006$ right). Note the stability of the green curve (Ensemble) across perturbation strengths.

2) Comparison with baseline defenses: To validate the novelty and efficacy of our approach, we compared it against a standard Adversarial Training (Baseline) method, where the CNN is retrained on PGD examples. Fig. 5 displays the heatmaps for Accuracy and AUC.

The results indicate a substantial performance difference. Notably, at $\epsilon = 0.006$, the Hybrid Ensemble achieves an Accuracy of **0.838** and AUC of **0.919**, whereas the Adversarial Training baseline significantly lags behind with an Accuracy of 0.712 and AUC of 0.700. **Theoretical Interpretation:** Adversarial training tends to reshape the decision boundary of the CNN around the specific ϵ-ball seen during training. If the test attack varies slightly (in step size or noise distribution), the boundary is crossed. Our ensemble, however, utilizes properties (like Kurtosis and FFT energy) that shift monotonically with noise addition, providing a more generalized boundary [43].

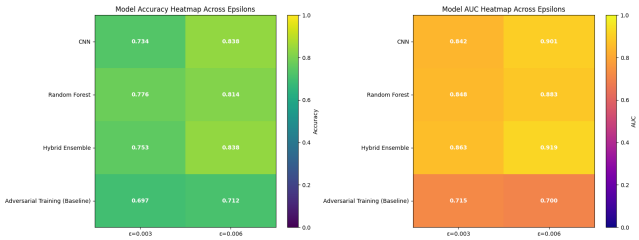

Fig. 5. Performance comparison heatmaps (Accuracy and AUC). The Hybrid Ensemble significantly outperforms the Adversarial Training baseline, especially at higher ϵ, indicating superior generalization.

C. Statistical Significance and Variance Reduction

To ensure the reported improvements are scientifically valid, we computed 95% Confidence Intervals (CI) for all key metrics. Fig. 6 presents these results.

The error bars indicate that the Hybrid Ensemble's performance lower bound is consistently higher than the mean performance of the individual models. For example, in AUC, the ensemble's lower bound (≈ 0.88) is higher than the CNN's upper bound (≈ 0.86). This confirms that the observed gains are statistically significant. Furthermore, the CI for the Ensemble is notably tighter than for the RF alone. This is a classic benefit of bagging and ensemble methods: **Variance Reduction**. By combining two uncorrelated error sources (spatial error from CNN, statistical error from RF), the overall variance of the prediction decreases, leading to a more reliable clinical tool.

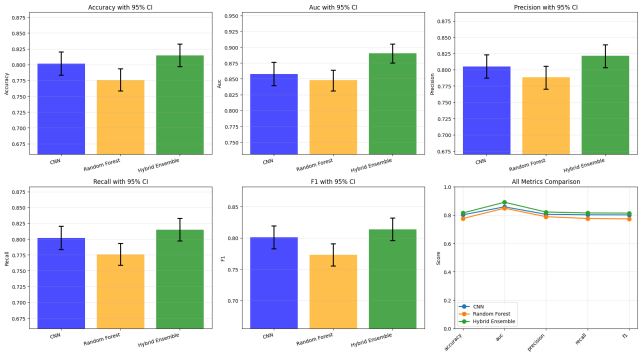

Fig. 6. Statistical significance analysis. Bar charts show performance metrics with 95% Confidence Intervals. The non-overlapping intervals in AUC and Precision confirm statistical superiority.

D. Clinical Impact and Specificity

In a clinical setting, the cost of errors is asymmetric. Minimizing False Positives (FP) is crucial to avoid "alarm fatigue" among radiologists and to prevent unnecessary biopsies [42]. Fig. 7 shows the confusion matrices for the CNN, Random Forest, and Hybrid Ensemble, alongside the score distribution.

The Hybrid Ensemble achieves the lowest number of False Positives (**108**), compared to 138 for the CNN and 113 for the RF. This represents a significant improvement in specificity.

1) Reduction in false negatives: The Ensemble missed only 244 adversarial samples compared to 313 for the RF. A False Negative in this context implies a hacked image enters the diagnostic workflow, potentially leading to a misdiagnosis (e.g., hiding a tumor). Within the scope of the IRMA dataset, the Hybrid Ensemble provides a safer buffer against this risk. However, we note that external validation on independent datasets is necessary to confirm these findings for general clinical deployment [59].

2) Score separation: The histogram (bottom center) shows a bimodal distribution with minimal overlap, indicating high confidence in predictions.

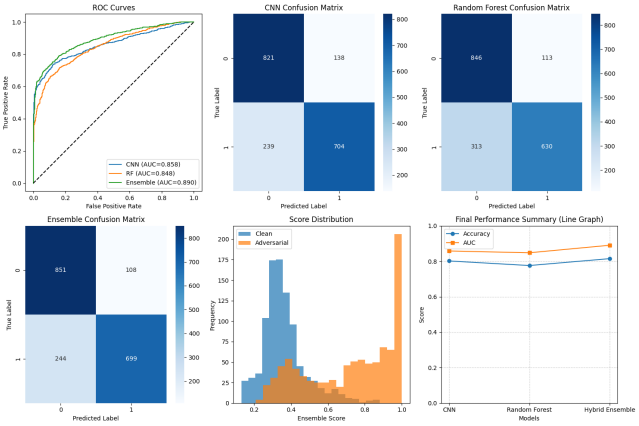

Fig. 7. Clinical impact analysis: Confusion matrices, ROC curve, score distribution, and summary metrics. The Hybrid Ensemble (bottom left matrix) minimizes false positives (108), while maintaining high sensitivity.

E. Computational Cost Analysis and Deployment

A common criticism of ensemble methods is the increased computational overhead and latency. However, our analysis (see Fig. 8) reveals a counter-intuitive but favorable result. The inference time per sample for the Hybrid Ensemble is **2.74 ms**, which is significantly faster than the standalone CNN baseline (**13.04 ms**).

This result can be explained by the architecture of the solution. The CNN used in the ensemble is optimized for feature extraction and does not require the heavy, deep backbones often used in standalone classification. Combined with the extremely fast inference of the Random Forest (0.74 ms), the total pipeline remains lightweight. This low latency confirms the method's suitability for real-time deployment in high-throughput hospital workflows or even on edge devices in portable X-ray machines.

V. Conclusion and Future Work

This study presented a Hybrid Ensemble defense for medical X-ray imaging that addresses the vulnerabilities of Deep Learning models to adversarial attacks. By synergizing spatial deep learning with statistical random forest analysis, we achieved a peak AUC of 0.919 under strong perturbation ($\epsilon = 0.006$), significantly outperforming standard adversarial training.

Our extensive analysis confirms that:

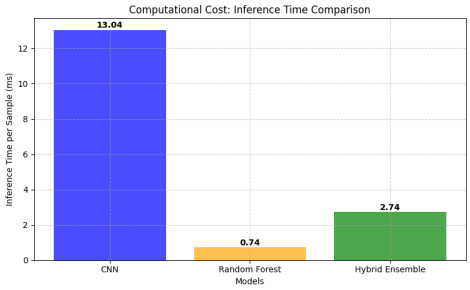

Fig. 8. Inference time per sample (ms). The hybrid solution is computationally efficient (2.74 ms), enabling real-time application.

- Complementarity matters: Combining differentiable models (CNN) with non-differentiable statistical models (RF) creates a defense that is empirically more resistant to standard gradient descent attacks.
- Statistical invariants: Adversarial noise, while visually imperceptible, disrupts the statistical moments (Kurtosis, Skewness) and spectral energy of medical images, making them detectable.
- Clinical viability: The method reduces false positives and operates with negligible latency (2.74 ms), making it suitable for clinical deployment.

Future work will explore the integration of Explainable AI (XAI) techniques [51], while addressing the potential pitfalls and 'false hopes' associated with current saliency methods [50], such as attention mechanisms [52], to provide radiologists with visual heatmaps indicating exactly which parts of the image triggered the adversarial alert [41]. We also plan to extend this framework to other modalities such as MRI and CT scans to validate its cross-domain generalization.

Future work will also address adaptive adversaries, investigating whether noise patterns can be optimized to preserve statistical moments, thereby potentially bypassing the Random Forest component.

Acknowledgment

This research received no external funding. The authors would like to thank the University of Mohammed First for providing the computational resources.

AUTHORS' PROFILE

Yassine Chahid received the M.Sc. degree in science and technology from the Faculty of Science and Technology, Settat, Morocco, in 2014, and the Ph.D. degree in mathematics and computer science from the Faculty of Sciences, Mohammed First University, Oujda, Morocco, in 2022. Since 2014, he has worked with several private-sector companies, where he has held technical and research-oriented positions. He is currently a Technical Lead specializing in artificial intelligence and cybersecurity solutions. His research interests include federated learning, information security, cryptography, and distributed systems.

Anas Chahid received the Engineering degree in computer science from the National School of Applied Sciences (ENSA), Oujda, Morocco. He is currently a Software Engineer and a Ph.D. student in medical artificial intelligence. His work focuses on the design of intelligent and customized software systems. His professional interests include artificial intelligence, data analytics, software engineering, and healthcare applications.

Ismail Chahid received the DUT degree in information technology from the École Supérieure de Technologie, Oujda, Morocco, in 2008, the B.Sc. degree in IT management from the Faculty of Polydisciplinary Studies, Tétouan, Morocco, in 2009, and the M.Sc. degree in business intelligence from the Faculty of Science and Technology, Béni Mellal, Morocco, in 2012. He is currently the Head of the IT Department at the Faculty of Medicine and Pharmacy of Oujda, where he has been working since 2019. His professional interests include business intelligence, data warehousing, information systems management, and software engineering.

Aissa Kerkour El Miad received the M.Sc. degree in operational research and informatics and the Ph.D. degree in computer science from Mohammed First University, Oujda, Morocco. He is currently a Professor with the Department of Computer Science, Faculty of Sciences, Mohammed First University, Oujda. His research interests include image processing, artificial intelligence, high-performance computing, and data mining.

A Transformer-Based Approach for Multimodal Arabic Sentiment Analysis

Ayoub BEN CHEIKHI, EL Habib NFAOUI
L3IA Laboratory, Faculty of Sciences Dhar El Mahraz, Sidi Mohamed Ben Abdellah University, Fez, Morocco

***Abstract*—The Multimodal Sentiment Analysis (MSA) landscape for Arabic content is strikingly underexplored, mainly due to limited datasets and a lack of robust integration methods across text, audio, and image. While transformer-based models like MarBERT and ArBERT achieve strong results on Arabic text, most research remains unimodal and does not fully exploit multimodal synergy. In this work, we propose a three-fold approach for Arabic MSA. First, we finetune robust transformers for each modality, namely ViT, MarBERT, and HuBert for image, Text, and Audio, respectively. Second, we perform an early feature fusion. Third, we use classifiers for sentiment prediction. On the recent Ar-MuSA benchmark released on 2025, our tri-modal fusion system, achieves state-of-the-art performance (F1=0.7756, Accuracy=0.7759), significantly exceeding the multimodal models benchmarked on the Ar-MuSa dataset, as well as the unimodal and bimodal methods. This demonstrates that comprehensive tri-modal fusion and thoughtful classifier selection are essential for accurate, human-centric Arabic sentiment analysis.**

***Keywords*—Arabic sentiment analysis; multimodal learning; feature fusion; machine learning; early fusion**

I. Introduction

The Arabic digital space has grown rapidly in recent years [1], [2], [3], [4], [5]. Social media platforms, video-sharing services, and online forums allow users to express opinions and emotions through text, speech, and images. As a result, sentiment is increasingly communicated in a multimodal manner [6], [7], [8]. This evolution raises new challenges for artificial intelligence (AI) [9] and natural language processing (NLP) [10], which must go beyond textual analysis to understand sentiment more accurately [11]. Early work in Arabic sentiment analysis mainly focused on text written in Modern Standard Arabic (MSA) [12], [13], [14], [2]. These approaches often relied on machine learning techniques and handcrafted features [15]. The introduction of transformer-based models has significantly improved text-based sentiment analysis [16], [17]. However, Arabic remains a complex language due to its rich morphology, dialectal variation, and informal writing styles commonly used in social media. Importantly, sentiment is not expressed through text alone. Spoken language conveys emotion through prosody, such as intonation and rhythm. Visual content also plays a key role, as facial expressions and contextual cues often reveal affective states. Ignoring these signals leads to incomplete sentiment understanding, particularly in socially rich Arabic media.

While multimodal sentiment analysis has been widely explored for English [18], [6], [11], research in Arabic remains limited. One major reason is the lack of large, well-annotated multimodal datasets. Another challenge lies in designing effective fusion strategies that can integrate heterogeneous modalities. The release of the Ar-MuSA [19] dataset addresses part of this gap by providing aligned text, audio, and image data for Arabic sentiment analysis.

In this work, we investigate multimodal Arabic sentiment analysis using transformer-based feature extraction for text, speech, and images. We adopt hybrid pipelines that combine deep pretrained representations with machine learning classifiers. In particular, we focus on early feature-level fusion and systematically compare unimodal, bi-modal, and tri-modal configurations.

Beyond technical contributions, this research aims to support a more context-aware understanding of Arabic digital content. Robust multimodal sentiment analysis is essential for applications such as content moderation, opinion mining, and social media analysis. It is also especially valuable in low-resource and highly variable linguistic environments such as Arabic.

The main contributions of this study are as follows:

- We provide a systematic evaluation of multimodal sentiment analysis for Arabic using text, audio, and image modalities from the Ar-MuSA dataset.
- We analyze the impact of early fusion strategies across uni-modal, bi-modal, and tri-modal settings.
- We report the state-of-the-art results and highlight practical insights for future research in Arabic multimodal sentiment analysis.

The remainder of this study is structured as follows: Section II surveys foundational research in Arabic sentiment analysis and multimodal approaches. Section III presents the details of our proposed multimodal sentiment analysis pipeline, including unimodal feature extraction, fusion methods, and classification strategies. Section IV describes the Ar-MuSA dataset, outlines preprocessing procedures, and details the experimental protocol. Section V reports and analyzes the experimental results across unimodal, bimodal, and tri-modal configurations. Section V-B provides a direct comparison of our approach with existing Ar-MuSA benchmarks and state-of-the-art results. Section VI offers an in-depth interpretation of key findings and their broader implications. Finally, Section VII concludes the study and suggests possible directions for future research in Arabic multimodal sentiment analysis.

II. Related Work

Arabic Sentiment Analysis (ASA) has evolved from classical machine learning pipelines that rely on handcrafted features to transformer-based and multimodal approaches that integrate textual, acoustic, and visual signals. This section reviews prior

work in line with the thematic structure adopted in this study: 1) Arabic sentiment analysis, 2) multimodal Arabic sentiment analysis, 3) multimodal machine learning foundations, and 4) transformer-based classification. We conclude by synthesizing the main limitations reported in the literature and highlighting the research gap addressed by this work.

A. Arabic Sentiment Analysis

Contemporary ASA research consistently emphasizes the linguistic complexity of Arabic—including rich morphology, dialectal variation, and informal writing styles—as a central challenge for robust sentiment modeling. In [15], the authors compare conventional methods such as SVM and Naïve Bayes with deep learning and transformer-based approaches (e.g., LSTM and AraBERT), reporting that AraBERT achieves superior performance (above 88% accuracy in their reviewed settings) while noting persistent limitations related to corpus scarcity and dialectal diversity.

Several application-driven studies confirm that classical machine learning approaches remain competitive in domain-specific settings when datasets are appropriately curated. Musleh et al. investigate Arabic YouTube comments and evaluate six classifiers for binary sentiment polarity; their experiments show that Naïve Bayes achieves the best performance (94.62% accuracy and MCC of 91.46%), demonstrating the continued relevance of lightweight models for constrained ASA tasks [20]. In another social-media context, Musleh et al. propose a machine-learning approach to detect depression from Arabic Twitter posts, formulating a multi-class problem (depressed, non-depressed, neutral) and reporting that Random Forest attains 82.39% accuracy [21]. This work illustrates that extending sentiment-related analysis to mental-health signals introduces additional complexity in labeling, feature robustness, and generalization.

In the education domain, [22] construct an Arabic dataset from student satisfaction surveys and compare classical models with the AraBERT transformer, achieving an accuracy of 78% and highlighting the limited availability of Arabic sentiment datasets tailored to educational evaluation. Overall, these studies collectively show that: 1) dataset design and domain coverage are crucial to performance, and 2) pretrained transformers often provide gains, but robustness across domains and dialects remains an open challenge.

B. Multimodal Arabic Sentiment Analysis

Although text-only ASA dominates the literature, multimodal Arabic sentiment analysis (MuSA) is increasingly studied due to the prevalence of sentiment expression through voice, facial cues, and contextual imagery in videos and social platforms. Early work by [23] introduces a direction toward Arabic multimodal sentiment analysis by presenting a dataset and exploring SVM-based classification, arguing that multimodality can better capture sentiment signals in heterogeneous social media content. In [24], the authors analyze Arabic YouTube videos by integrating acoustic and facial features and testing different classifiers (including SVM and neural networks), achieving an overall accuracy of 76%, which underlines both the promise of multimodal cues and the difficulty of robust inference in real-world settings.

More recent efforts emphasize improved fusion strategies across text, audio, and vision. In [25], the authors propose enhanced video analytics through multi-level fusion of textual, auditory, and visual information, reporting more than 94% effectiveness in multi-dialect Arabic videos. Their results suggest that carefully designed fusion mechanisms can significantly improve performance beyond unimodal baselines, particularly when dialectal and expressive cues are important.

Dataset construction remains a key bottleneck for MuSA. In [26], the authors introduce and validate an Arabic multimodal dataset using transformer-based components and word-alignment techniques, but they also emphasize limitations in dataset scale and coverage. Addressing the need for standardized benchmarking, [27] propose Ar-MuSA, an open-source multimodal benchmark dataset and evaluation framework that combines text, audio, and visual elements, demonstrating that multimodal approaches often outperform unimodal strategies when validated with advanced models such as MarBERT and HuBERT. In low-resource settings, [28] further introduce UniTextFusion, an early-fusion strategy that textualizes non-text modalities to integrate them into Arabic language models; using LoRA-based fine-tuning, they report improvements of up to 34% in F1-score compared to existing baselines. These findings highlight the importance of both dataset availability and parameter-efficient multimodal fusion for Arabic.

C. Multimodal Application Using Machine Learning

General multimodal machine learning (MML) research provides the conceptual foundation for MuSA, particularly for understanding how to represent, align, and fuse heterogeneous modalities. In [29], the authors provide a comprehensive survey and propose a taxonomy organizing MML challenges into representation, translation, alignment, fusion, and co-learning. This taxonomy is especially relevant to Arabic multimodal sentiment tasks where temporal alignment and noisy cross-modal signals can substantially affect performance.

In [30], the authors extend these foundations by framing principles, challenges, and open questions in multimodal machine learning, covering representation, alignment, reasoning, generation, transference, and uncertainty quantification. Their discussion suggests that multimodal systems should be evaluated not only by accuracy but also by robustness, transferability, and reliability—criteria that are particularly important in Arabic contexts with high dialect variability and diverse media conditions.

Multimodal modeling is also increasingly applied to pragmatic phenomena closely related to sentiment, such as sarcasm. In [31], the authors present a multimodal Arabic sarcasm detection approach using text, audio, and image features on the Ar-MuSA dataset; leveraging BiLSTM, CNN, and ResNet-50 encoders, they achieve 97% accuracy and show clear gains over unimodal settings. This supports the argument that multimodality can capture implicit affective and pragmatic cues that are difficult to infer from text alone.

D. Transformer Application in Classification

Transformers have become the dominant paradigm for classification in both NLP and computer vision, and they

have strongly influenced both unimodal ASA (e.g., AraBERT-like encoders) and multimodal systems that depend on transformer backbones or transformer-compatible representations. In [32], the authors survey transformer-based text classification, proposing an expanded taxonomy and discussing performance, cost, safety, and bias considerations; importantly, they argue that large transformer models are not universally superior without careful consideration of domain and deployment constraints .

In vision, [33] review vision transformers for image classification, tracing the evolution from ViT to more advanced variants and comparing them to CNNs, while emphasizing open challenges such as data efficiency and computational demands. These insights motivate efficiency-aware multimodal designs, since MuSA systems often require strong unimodal encoders in each modality.

Evidence also indicates that smaller, well-adapted pretrained models can compete with much larger models in classification tasks. In [34], the authors evaluate pretrained language models for mathematical problem classification and show that compact transformer models can match larger LLMs with a macro-F1 of 0.8685, highlighting the practical value of targeted fine-tuning and cost-effective architectures. This aligns with recent MuSA work that favors parameter-efficient tuning methods such as LoRA [28].

E. Research Gap

Despite substantial progress, the reviewed literature reveals several persistent gaps. First, the availability of large-scale, diverse, and well-aligned Arabic multimodal datasets remains limited; while Ar-MuSA advances benchmarking [27], other dataset efforts still report constraints in scale and coverage [26]. Second, robustness across dialects, domains, and informal language remains a central challenge in ASA [15]; strong results in a specific domain (e.g., YouTube) may not transfer to other contexts such as education or mental health [20], [21], [22]. Third, although recent low-resource fusion methods show promise [28], the design space of fusion strategies (early/late/hybrid fusion and modality interaction modeling) has not been consistently evaluated under comparable settings for Arabic. Finally, many studies emphasize accuracy-focused evaluation, while broader multimodal literature argues for more systematic analysis of reliability, uncertainty, and failure modes [30].

These limitations motivate the need for an approach that: 1) better accounts for Arabic linguistic variability, 2) leverages complementary multimodal cues through principled and efficient fusion, and 3) is evaluated with robustness and generalization analysis beyond single-dataset performance.

III. Proposed Approach

The model architecture proposed in this research addresses the task of Arabic multimodal sentiment analysis through a principled integration of information from textual, visual, and audio modalities. The system leverages the strengths of transformer-based models for each modality, and employs a structured pipeline for effective fusion and classification. The process is illustrated in Fig. 1.

A. Unimodal Representation Learning

For each modality—text, audio, and image—we employ state-of-the-art transformer architectures, each fine-tuned on the Ar-MuSA dataset to extract robust, modality-specific embeddings:

$$\mathbf{e}_{\text{text}} = \text{MarBERT}(\mathbf{x}_{\text{text}}; \theta_{\text{text}}) \tag{1}$$

$$\mathbf{e}_{\text{audio}} = \text{HuBERT}(\mathbf{x}_{\text{audio}}; \theta_{\text{audio}}) \tag{2}$$

$$\mathbf{e}_{\text{image}} = \text{ViT}(\mathbf{x}_{\text{image}}; \theta_{\text{image}}) \tag{3}$$

where, $\mathbf{x}_{\text{text}}$, $\mathbf{x}_{\text{audio}}$, and $\mathbf{x}_{\text{image}}$ are the respective raw inputs, θ denotes the set of fine-tuned parameters specific to each model, and $\mathbf{e}*$ represents the resulting embedding vectors.

This approach is motivated by several key considerations. First, using dedicated transformer models for each modality allows us to capitalize on their architectural strengths, which have been empirically demonstrated across diverse tasks in natural language processing, speech analysis, and computer vision. Each model—MarBERT, HuBERT, and ViT—incorporates design choices and pretraining strategies that make it uniquely effective for its target data type.

Second, fine-tuning on the Ar-MuSA dataset ensures that each model adapts to the linguistic, acoustic, and visual characteristics specific to the domain of interest. This step enhances the models' ability to capture salient and contextually relevant patterns, which is especially important when dealing with datasets that diverge from widely available pretraining corpora.

Third, transformer-based encoders yield highly expressive and context-aware representations. These models effectively model complex dependencies: MarBERT excels at capturing nuanced semantics in Arabic text, HuBERT models both local and long-range speech patterns, and ViT efficiently encodes spatial and hierarchical information in images. The unimodal embeddings produced are therefore rich in both local detail and global structure.

Finally, a wealth of recent literature highlights the benefits of strong unimodal feature extraction as a precursor to multimodal learning [35], [36]. Isolating and optimizing each modality at the representation level not only improves single-modality interpretability, but also provides a robust foundation for effective cross-modal fusion, leading to superior performance in downstream multimodal tasks.

Through this methodical unimodal representation learning scheme, we ensure that each input stream contributes maximally informative, discriminative, and complementary features to the overall multimodal system.

B. Multimodal Feature Fusion

In multimodal learning, feature fusion refers to the process of integrating information derived from multiple input modalities—such as text, audio, and images—into a single, unified representation suitable for downstream tasks. Among

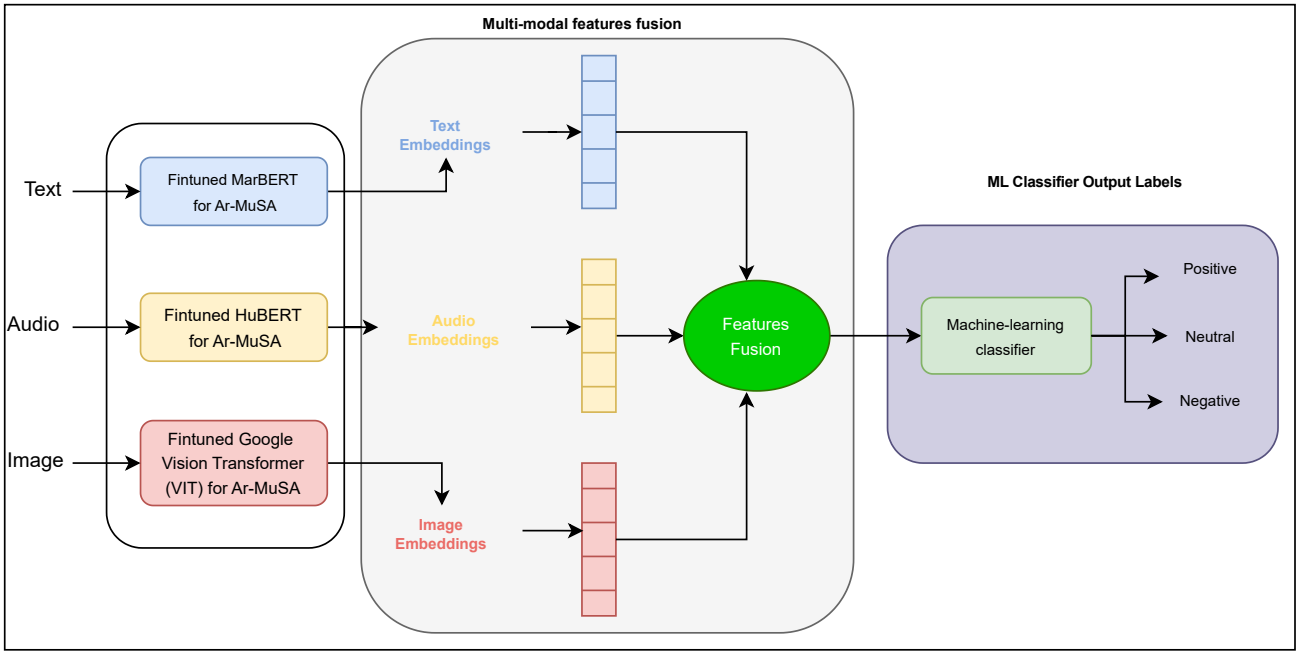

Fig. 1. Overview of the proposed multimodal Arabic sentiment analysis pipeline. Each modality is encoded by a dedicated finetuned transformer (MarBERT for text, HuBERT for audio, ViT for images). The resulting embeddings are concatenated to produce a joint multimodal feature vector, which is then used as input to a machine learning classifier (SVM) for sentiment prediction (positive, neutral, negative).

various fusion strategies, early fusion (also known as feature-level fusion) is a widely adopted approach. In early fusion, raw or low-level feature embeddings from each modality are combined at the initial stages of the model pipeline, usually before any decision-level processing or prediction.

Formally, let $\mathbf{e}_{\text{text}}$, $\mathbf{e}_{\text{audio}}$, and $\mathbf{e}_{\text{image}}$ denote the learned feature representations for the text, audio, and image modalities, respectively. Under early fusion, we concatenate these feature vectors to obtain a single, comprehensive embedding:

$$\mathbf{e}_{\text{fused}} = [\mathbf{e}_{\text{text}}; \mathbf{e}_{\text{audio}}; \mathbf{e}_{\text{image}}] \tag{4}$$

Here, $[\cdot\,;\cdot;\,\cdot]$ denotes straightforward vector concatenation.

The principal rationale for employing early fusion is its capacity to preserve the diversity and richness of information from each input modality. Unlike late fusion approaches, which combine information at the decision level and potentially disregard modality-specific patterns, early fusion allows the model to exploit nuanced interactions between modalities at a granular level. This aligns with empirical findings in recent studies, which demonstrate that feature-level fusion retains complementary signals and facilitates deeper cross-modal synergy, ultimately enhancing performance in complex multimodal learning tasks [37], [38].

C. Multimodal Sentiment Classification

Following feature extraction and fusion, the joint multimodal embedding $\mathbf{e}_{\text{fused}}$ serves as the input to a Support Vector Machine (SVM) classifier, which is tasked with sentiment prediction across three discrete categories: positive, neutral, and negative. Specifically, the SVM learns a discriminative function over the fused feature space:

$$\hat{y} = f_{\text{SVM}}(\mathbf{e}_{\text{fused}}; \mathcal{W}) \tag{5}$$

where, $\mathcal{W}$ denotes the set of weights, thresholds, and bias terms optimized during supervised training on labeled data.

The decision framework is instantiated as follows: for each training instance i, the input tuple $(\mathbf{x}^{(i)}_{\text{text}}, \mathbf{x}^{(i)}_{\text{audio}}, \mathbf{x}^{(i)}_{\text{image}})$ —processed into the fused embedding—yields a sentiment prediction:

$$(\mathbf{x}^{(i)}_{\text{text}}, \mathbf{x}^{(i)}_{\text{audio}}, \mathbf{x}^{(i)}_{\text{image}}) \rightarrow \hat{y}^{(i)} \in \{\text{positive, neutral, negative}\} \tag{6}$$

The choice of SVM for this classification task is motivated by several factors. First, SVMs are highly effective in high-dimensional settings such as those arising from feature-level fusion of transformer-based embeddings. Their emphasis on maximizing the margin between decision boundaries lends itself well to the complex, nonlinear distributions often present in multimodal data. Second, SVMs are robust to overfitting, especially in cases where the number of training samples is modest compared to the feature space dimensionality—a common scenario in multimodal sentiment datasets. The ability to use various kernel functions (e.g., linear, RBF) further enhances the SVM's flexibility to capture intricate cross-modal relationships within the fused space.

Furthermore, SVMs offer solid interpretability of the learned margins and support vectors, facilitating post-hoc anal-

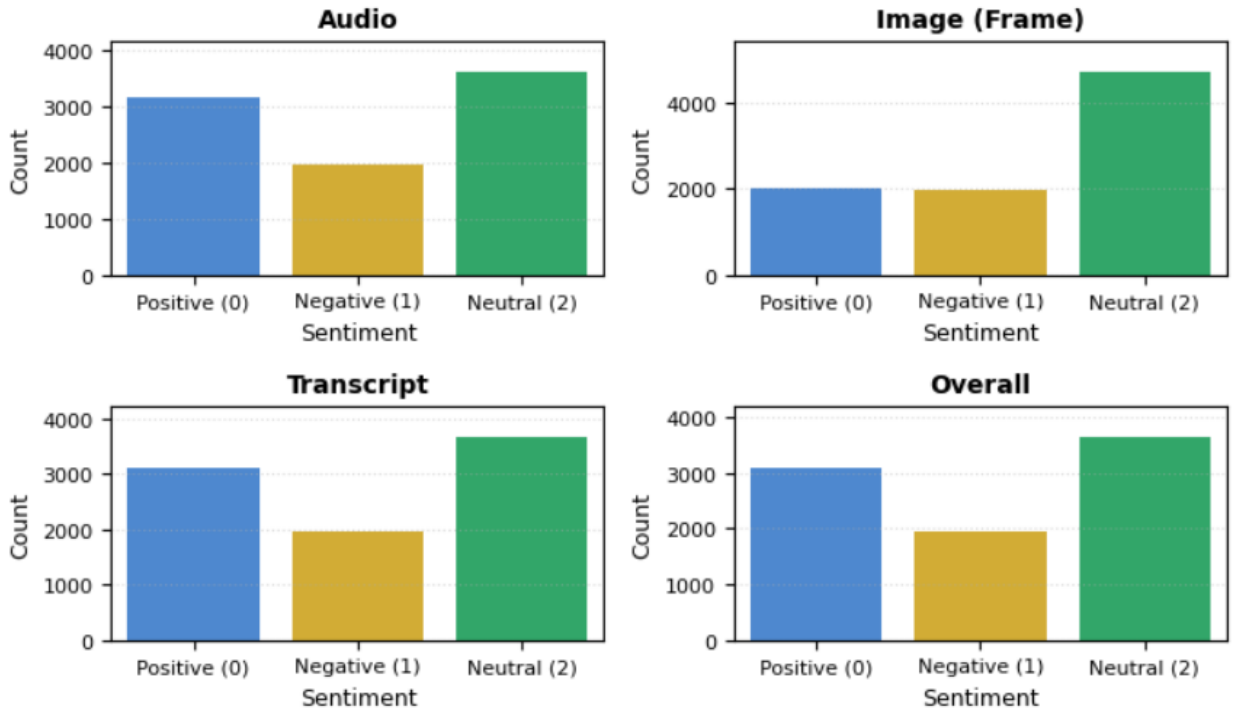

Fig. 2. Distribution of sentiment categories across modalities in the Ar-MuSA dataset.

ysis and potentially providing insights into which modalities or feature combinations most influence classification decisions. This interpretability is important not only from a research standpoint but also for transparency in consequential real-world applications such as sentiment analysis of media content or public communication.

Empirical studies corroborate the effectiveness of SVMs as final classifiers in multimodal pipelines [39], demonstrating competitive or superior performance compared to more parameter-intensive neural classifiers, especially when the preceding stages of the pipeline produce strong, information-rich feature embeddings.

In summary, the SVM-based multimodal sentiment classifier leverages the joint, complementary information captured in $\mathbf{e}_{\text{fused}}$ to robustly predict sentiment, fully exploiting the synergy of textual, acoustic, and visual modalities within a principled maximal-margin framework.

IV. Experiment

A. Dataset and Preprocessing

1) Dataset: In this study, we employ the Ar-MuSA (Arabic Multimodal Sentiment Analysis) dataset, a comprehensive and open-source benchmark specifically developed to address the scarcity of resources for Arabic multimodal sentiment analysis [19]. Ar-MuSA consists of 8,700 samples spanning three modalities—text (transcripts), audio, and images—systematically extracted from 107 Egyptian Arabic YouTube videos, with precise alignment ensured via synchronized timestamps. Each sample is annotated for sentiment (positive, negative, or neutral) at both the modality-specific and overall levels by a team of native-speaking annotators, and the final labels are determined through majority voting. The corpus significantly surpasses existing Arabic multimodal datasets in terms of both scale and diversity, providing a balanced sentiment distribution (35.5% positive, 43.3% neutral, 21.2% negative), while also capturing the unique linguistic and cultural challenges inherent in Arabic (see Fig. 2), such as sarcasm present in speech and facial expressions. The data preparation pipeline involves detailed preprocessing steps, including audio segmentation, representative frame extraction, and automated transcript generation via SeamlessM4T v2. Ar-MuSA is publicly accessible through HuggingFace, facilitating research advancements in cross-modal fusion and Arabic natural language processing.

2) Preprocessing: Preprocessing is a critical step in multimodal sentiment analysis, as it ensures consistency across modalities and prepares inputs for transformer-based modeling. In this work, we adopted modality-specific preprocessing pipelines for text, audio, and visual data to optimize compatibility with state-of-the-art models in each domain.

For the text modality, transcripts were tokenized using the MARBERT tokenizer, which is designed explicitly for Arabic, incorporating both dialectal variants and Modern Standard Arabic [40]. During preprocessing, raw text was mapped to token indices, and each sequence was padded or truncated to a maximum length of 128 tokens to maintain uniformity across samples. This standardization ensures consistent input dimensions for the MARBERT model during training and inference.

The audio modality comprised segmented utterances aligned with the text and visual data. Audio signals were first converted to mono and resampled to a sampling rate of 16 kHz. Following this, we utilized HuggingFace's

Wav2Vec2FeatureExtractor for feature extraction, which included normalization, framing, and padding or truncation to a fixed duration of 5 seconds (approximately 80,000 samples). This approach ensures that each audio sequence is of comparable length, facilitating efficient batch processing and stable learning during model fine-tuning.

We extracted a single frame per utterance corresponding to the relevant audio and text segments for the visual modality. Each image was loaded in RGB format to ensure color consistency across the dataset. Preprocessing was performed using the ViTImageProcessor from the Hugging Face Transformers library. This extractor standardized all frames to the required 224 × 224-pixel size and applied intensity normalization, preparing the images for input into the Vision Transformer model ("google/vit-base-patch16-224")[41].

B. Training Details

In this work, our primary focus is maximizing the expressive power of tri-modal fusion for Arabic multimodal sentiment analysis. While we report baseline results for unimodal and bimodal scenarios for comparative rigor, most of our methodological attention is dedicated to the optimal training and integration of the textual, acoustic, and visual streams in the tri-modal setting. To this end, our training protocol is structured around two core stages: 1) independent modality-specific fine-tuning and 2) downstream fusion and classifier training. Below, we provide a detailed account of both, explicitly referencing all training protocols and model configurations utilized.

The specific hyperparameters for each modality were determined empirically and are summarized in Table I, Table II, and Table III. These tables offer a transparent and comprehensive reference with all key settings, including optimizer type (Adam or AdamW), learning rate, batch size, number of epochs, gradient accumulation steps, warmup steps or ratios, evaluation frequency, and initialization seeds.

After feature extraction from the fine-tuned MarBERT (text), HuBERT (audio), and ViT (visual) models, the respective feature vectors were concatenated along the feature dimension to form unified representations for each data instance. These tri-modal concatenated feature vectors were then used as input for a suite of machine learning classifiers: Support Vector Machine (SVM), Random Forest (RF), k-nearest Neighbors (KNN), and Naive Bayes (NB), and each

model was implemented within a `scikit-learn` pipeline [42]. Table IV summarizes the primary hyperparameters used for each classifier, as optimized or specified for our tri-modal (Text+Audio+Image) classification experiments:

For all experiments, data were partitioned using a stratified split, with 80% of the data allocated for training, 10% for validation, and 10% for testing, while maintaining label distribution across all subsets (`random_state=42`) to ensure reproducibility. Unless specified otherwise, all classifier hyperparameters were tuned and evaluated primarily on the tri-modal feature fusion setting, which constitutes the central focus of our approach.

C. Evaluation Metrics

A rigorous evaluation of our multimodal sentiment classification model requires a multifaceted approach, particularly given the frequent class imbalance typical of sentiment analysis datasets. To this end, we adopted a comprehensive suite of metrics to ensure fairness and depth in assessing our models. The primary metrics considered include overall accuracy, weighted precision (WP), weighted recall (WR), and weighted F1-score (WF-1). Below, we present explicit definitions and the mathematical formulations employed for each metric.

1) Weighted Precision (WP): Precision quantifies the proportion of optimistic predictions that are indeed correct. In scenarios where classes are imbalanced, simply averaging across classes can be misleading. Weighted precision mitigates this by giving higher importance to classes with greater representation in the data. It is computed as:

$$\text{WP} = \frac{\sum_{i=1}^{n} [\text{Precision}_i \times \text{Support}i]}{\sum i = 1^n \text{Support}_i}$$

where, Precision_i is the precision for class i, Support_i is

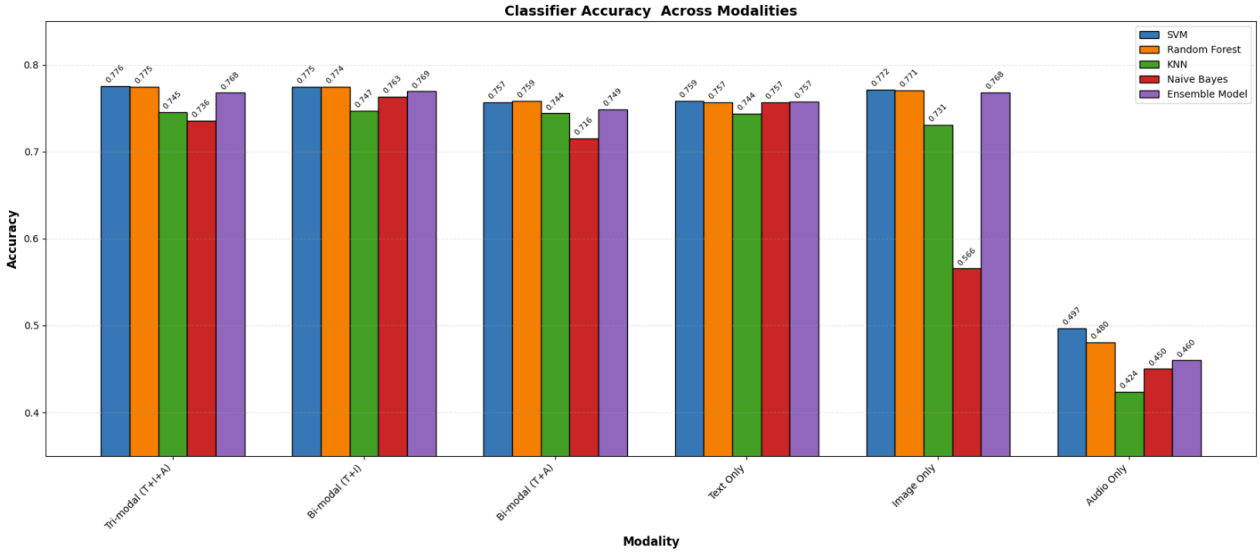

Fig. 3. Classification accuracy (%) of all evaluated classifiers across modalities and fusion types.

TABLE IV. PRIMARY HYPERPARAMETERS USED FOR EACH CLASSIFIER IN THE TRI-MODAL EXPERIMENT

Classifier	Hyperparameters
SVM (RBF)	kernel=rbf C=1.0 gamma=scale probability=True random_state=42
Random Forest	n_estimators=500 max_depth=30 max_features=sqrt class_weight=balanced min_samples_split=5 n_jobs=-1 random_state=42
KNN	n_neighbors=5 weights=distance algorithm=auto n_jobs=-1
Naive Bayes	GaussianNB après normalisation)
Ensemble (Voting)	Voting=soft estimateurs={SVM, RF, KNN, NB}

the number of true samples in class i, and n is the total number of classes.

2) Weighted Recall (WR): Recall measures the ability of the classifier to identify all relevant instances for each class correctly. Just like precision, it is important to adjust for class support. Weighted recall is defined as:

$$\text{WR} = \frac{\sum_{i=1}^{n} [\text{Recall}_i \times \text{Support}_i]}{\sum_{i=1}^{n} \text{Support}_i}$$

with Recall_i representing the recall for class i. This metric ensures a more representative assessment, especially when certain classes dominate the dataset.

3) Weighted F1-Score (WF-1): The F1-score is the harmonic mean of precision and recall and provides a single measure of a classifier's accuracy about the positive class. The weighted F1-score, which addresses the variance in class sizes, is calculated as:

$$\text{WF-1} = \frac{\sum_{i=1}^{n} [\text{F1-Score}_i \times \text{Support}_i]}{\sum_{i=1}^{n} \text{Support}_i}$$

where, the F1-score for each class, i, is given by:

$$\text{F1-Score}_i = \frac{2 \times \text{Precision}_i \times \text{Recall}_i}{\text{Precision}_i + \text{Recall}_i}$$

4) Accuracy: Often considered the most intuitive metric, accuracy is the ratio between the number of correct predictions and the total number of predictions made:

$$\text{Accuracy} = \frac{\text{Number of correct predictions}}{\text{Total number of predictions}}$$

To provide additional transparency, each experimental result is accompanied by a full classification report detailing precision, recall, F1-score, and support for each sentiment class (positive, negative, and neutral). We further visualize performance using confusion matrices, which offer insight into which classes the model will most likely confuse.

All metrics are systematically computed using the `scikit-learn` Python package [42], ensuring reproducibility and consistency across experiments. Using weighted metrics throughout is deliberate, as it more accurately reflects classifier performance in the presence of uneven class distributions—an everyday reality in real-world sentiment datasets.

This robust evaluation protocol allows for a nuanced comparison of different classifiers and fusion methods, underpinning the credibility of our findings in multimodal sentiment analysis.

TABLE V. COMPARISON OF OUR CONFIGURATIONS WITH STATE-OF-THE-ART SYSTEMS AND AR-MUSA BENCHMARK BASELINES

System / Study	Modality / Fusion	Model	WF-1	Accuracy
Our (Tri-modal)	Text + Audio + Image	SVM	**0.776**	**0.776**
Khaled et al. [28]	Late Fusion	LLaMA 3.1–8B	0.67	0.71
Khaled et al. [28]	Late Fusion	SILMA AI	0.65	0.68
Ar-MuSA [19]	Late Fusion	Voting Ensemble	0.60	0.63

V. RESULTS

This section presents an in-depth evaluation of our multimodal sentiment classification methodology on the Ar-MuSA benchmark, particularly emphasizing the tri-modal (text, audio, and image) fusion setting. For broader benchmarking, unimodal and bi-modal results are included. However, the analysis prioritizes tri-modal fusion—demonstrating its integrative strengths and practical relevance for robust Arabic sentiment recognition, as shown in Fig. 3.

A. Main Focus: Tri-modal Fusion Results

Integrating textual, audio, and visual streams is hypothesized to leverage complementary evidence and improve sentiment classification performance. In our tri-modal fusion, we concatenate deep feature vectors from MarBERT (text), HuBERT (audio), and ViT (image), yielding a high-dimensional representation for each instance. Table VI documents performance across classifiers.

TABLE VI. TRI-MODAL SENTIMENT CLASSIFICATION RESULTS (TEXT–IMAGE–AUDIO FUSION)

Classifier	Accuracy	WR	WF-1	WP
SVM	**0.7759**	**0.7759**	**0.7756**	**0.7783**
Random Forest	0.7747	0.7747	0.7747	0.7777
KNN	0.7454	0.7454	0.7449	0.7466
Naive Bayes	0.7356	0.7356	0.7362	0.7386
Ensemble Model	0.7678	0.7678	0.7678	0.7691

Tri-modal fusion consistently yields the highest overall performance, confirming the value of aggregating diverse cues. The SVM outperforms all other models (Accuracy: 0.7759, WF-1: 0.7756), suggesting that synergistic evidence from all three modalities enables stronger discrimination of sentiment—especially capturing aspects that cannot be derived from text or image alone. Random Forest is a close second, while KNN and Naive Bayes lag, possibly due to their limitations with complex, high-dimensional data. The ensemble, while robust, does not exceed the single SVM, indicating that hard or soft voting does not add to the already dominant SVM classification when features are so robust. Importantly, tri-modal fusion provides measurable, though sometimes modest, gains compared to unimodal and bimodal systems, underscoring its unique value.

B. Comparison with the State-of-the-Art and Baselines

To quantify the effectiveness of our approach, we compare our best modal configurations against the official Ar-MuSA benchmark baselines [19], as well as the recent late-fusion large-model results reported by Khaled et al. [28]. Following common practice in sentiment classification on potentially imbalanced datasets, we report weighted F1-score (WF-1) and accuracy as primary metrics. Table V provides a consolidated view of the competing systems and highlights the relative contribution of each modality and fusion setting in our pipeline. For an intuitive overview of the relative gains across systems.

As observed in Table V, our tri-modal configuration (Text+Audio+Image) with early feature concatenation and an SVM classifier achieves a WF-1 of 0.776 and an accuracy of 0.776, establishing the overall results among the compared systems. In particular, this represents a clear improvement over the best tri-modal baseline reported in Ar-MuSA (late-fusion voting ensemble; WF-1 = 0.60, accuracy = 0.63) [19], indicating that our fusion and feature design enables more effective exploitation of complementary cross-modal sentiment cues. Compared with recent late-fusion, large-model approaches [28], our best configurations remain consistently both metrics. This outcome highlights that, for Ar-MuSA-style sentiment analysis, carefully designed early fusion coupled with effective feature extraction can rival (and in this case outperform) heavier late-fusion strategies, while remaining comparatively simple and potentially more efficient to train and deploy.

C. Uni and Bi-modal Results: Added for Comparative Benchmarking

To contextualize the strength of tri-modal fusion, we evaluated unimodal and bimodal setups—especially for comparison with the Ar-MuSA baseline. These results reveal how much each modality contributes individually and in pairs, but serve primarily as references for the added value of tri-modal integration.

1) Unimodal results: Table VII compiles unimodal results across text, audio, and image—for all classifiers.

TABLE VII. UNIMODAL SENTIMENT CLASSIFICATION RESULTS ACROSS MODALITIES.

Modality	Classifier	Accuracy	WR	WF-1	WP
Text	SVM	**0.7586**	**0.7586**	**0.7580**	**0.7595**
	Random Forest	0.7569	0.7569	0.7563	0.7584
	KNN	0.7437	0.7437	0.7433	0.7436
	Naive Bayes	0.7569	0.7569	0.7574	**0.7595**
	Ensemble Model	0.7575	0.7575	0.7577	0.7587
Audio	SVM	**0.4971**	**0.4971**	**0.4602**	**0.4887**
	Random Forest	0.4805	0.4805	0.4549	0.4588
	KNN	0.4236	0.4236	0.4180	0.4151
	Naive Bayes	0.4500	0.4500	0.4537	0.4772
	Ensemble Model	0.4598	0.4598	0.4632	0.4775
Image	SVM	**0.7718**	**0.7718**	**0.7641**	**0.7687**
	Random Forest	0.7708	0.7708	0.7631	0.767 7
	KNN	0.7310	0.7310	0.7263	0.7259
	Naive Bayes	0.5655	0.5655	0.5746	0.6871
	Ensemble Model	0.7684	0.7684	0.7700	0.7727

Text and image provide height unimodal baselines, but each is limited: image achieves the highest scores (SVM WF-1: 0.7641) yet cannot capture language-specific sentiment; text is robust (SVM WF-1: 0.758) but may miss paralinguistic or non-verbal signals. Audio is the weakest (SVM WF-1: 0.460), reflecting the challenge of sentiment inference from prosody alone and possible imbalance in audio cues, a point corroborated by prior results on Arabic datasets. Ultimately, these unimodal numbers highlight why fusion—especially tri-modal fusion—is necessary for holistic sentiment recognition.

2) Bi-modal results: Bi-modal fusion results (see Table VIII) are listed next. Here, we focus on the text-audio and text-image pairs, following the Ar-MuSA evaluation.

TABLE VIII. BI-MODAL SENTIMENT CLASSIFICATION RESULTS (TEXT-AUDIO AND TEXT-IMAGE FUSION).

Fusion	Classifier	Accuracy	WR	WF-1	WP
T+A	SVM	0.7569	0.7569	0.7562	0.7583
	Random Forest	**0.7586**	**0.7586**	**0.7581**	**0.7602**
	KNN	0.7443	0.7443	0.7439	0.7441
	Naive Bayes	0.7155	0.7155	0.7158	0.7165
	Ensemble Model	0.7489	0.7489	0.7487	0.7493
T+I	**SVM**	**0.7750**	**0.7750**	**0.7746**	**0.7776**
	Random Forest	0.7745	0.7745	0.7743	0.7774
	KNN	0.7471	0.7471	0.7467	0.7482
	Naive Bayes	0.7632	0.7632	0.7637	0.7664
	Ensemble Model	0.7695	0.7695	0.7697	0.7716

Notes: T = Text modality; A = Audio modality; I = Image modality.

Bi-modal fusion, particularly with the text-image pair, yields performance only slightly above the best unimodal results (WF-1 up to 0.7746 for SVM). In some cases, improvements are marginal or classifier-dependent. The text-audio pair offers minimal additional information over text alone, which aligns with the weaker standalone audio performance. These outcomes reinforce that while bimodal fusion can harness some complementary signals, the dominant contribution still arises from the text stream, and these combinations primarily serve as strong baselines and ablation checks for the tri-modal configuration.

It is evident from the above results that while unimodal and bi-modal settings offer competitive baselines and are crucial for benchmarking against prior work, such as the Ar-MuSA dataset, their practical ceiling is reached quickly. The tri-modal approach remains unmatched in providing robust and nuanced sentiment analysis by integrating all available cues. These findings support the growing consensus in the literature that multimodal fusion—when effectively implemented—can yield modest but consistent advances over single or dual-modality systems, especially in linguistically and emotionally rich domains such as Arabic social media.

In the subsequent section, we contextualize these findings by directly comparing our results to the Ar-MuSA benchmarks, highlighting the gains achieved with our tri-modal fusion strategy.

VI. DISCUSSION

The experimental results clearly demonstrate the advantages of multimodal learning for Arabic sentiment analysis on social media data. Across all evaluated settings, tri-modal fusion (Text+Audio+Image) consistently achieved the best performance, with early feature concatenation combined with an SVM classifier yielding the highest scores (WF-1 = 0.776, Accuracy = 0.776). This confirms that sentiment in user-generated Arabic content is not solely conveyed through text, but rather emerges from the complementary interaction of linguistic, visual, and acoustic cues.

Unimodal experiments highlight the relative contribution of each modality. Text and image independently provide strong sentiment signals, whereas audio alone remains comparatively weak due to noise, speaker variability, and the subtle nature of prosodic cues. Nevertheless, when integrated with text and image, audio contributes complementary information that improves robustness and reduces ambiguity in difficult cases.

Bi-modal fusion experiments reveal that Text+Image represents the most effective dual-modality configuration, achieving performance close to the full tri-modal system. In contrast, Text+Audio fusion offers only marginal gains over text-only models. These findings suggest that visual context plays a particularly important role in disambiguating sentiment in Arabic social media, while audio acts as a secondary but supportive modality.

Compared with prior work and official Ar-MuSA baselines, the proposed approach consistently outperforms existing unimodal, bi-modal, and tri-modal systems, including recent late-fusion and large-model approaches. Notably, the performance of a relatively simple early-fusion SVM pipeline indicates that carefully designed feature-level integration of pretrained encoders can be more effective than heavier ensemble or late-fusion architectures.

Overall, the results advocate for comprehensive tri-modal fusion as the most reliable strategy for sentiment classification in Arabic social media, while also highlighting Text+Image fusion as a practical near-optimal alternative when audio is unavailable. These findings reinforce the importance of multimodal representations for capturing the richness and variability of sentiment expression in low-resource and highly informal linguistic settings.

VII. CONCLUSION

This study introduced a comprehensive framework for Arabic multimodal sentiment analysis that integrates textual, visual, and acoustic information through early feature-level fusion. By leveraging strong pretrained encoders—MarBERT for text, ViT for images, and HuBERT for speech—and combining them with margin-based classification, the proposed approach achieves state-of-the-art performance on the Ar-MuSA benchmark. Experimental results confirm that tri-modal fusion consistently outperforms unimodal and bi-modal configurations, underscoring the importance of jointly modeling linguistic content, visual context, and paralinguistic cues for sentiment understanding in user-generated Arabic media.

The study further demonstrates that while text and image modalities provide strong standalone signals, audio plays a complementary role that enhances robustness when integrated with other modalities, despite its relatively weaker individual performance. Compared with existing baselines and recent

late-fusion approaches, the proposed early-fusion strategy offers a more effective and computationally efficient alternative.

Building on these findings, future work will focus on extending the framework through improved speech representation learning, dialect-aware acoustic modeling, and more interaction-aware fusion strategies. Such extensions aim to further strengthen multimodal representations and advance sentiment analysis in low-resource, highly variable Arabic social media environments.

HQ-RTVF: High-Quality Real-Time Virtual Try-On Fitting for Diverse Clothing and Body Morphologies

Ilham KACHBAL, Khadija Arhid, Said El Abdellaoui
LAPSSII, Higher School of Technology, Cadi Ayyad University, B.P. 89, Safi, Morocco

***Abstract*—The ability to virtually try on clothing items has become an increasingly important feature for e-commerce and online shopping experiences. Real-time virtual try-on remains challenging because existing methods force a trade-off between speed and quality GAN-based approaches achieve high visual fidelity but at low frame rates, while faster methods sacrifice realism. HQ-RTVF is a diffusion-based framework that resolves this trade-off through three architectural innovations: running the diffusion U-Net entirely in the VAE's compressed latent space (64×64×4 instead of 512×512×3), limiting denoising to 20 steps with FP16 mixed-precision computation, and parallelizing pose estimation and garment encoding to eliminate sequential bottlenecks. The system uses DensePose and DeepLabv3+ for body pose and segmentation, a CLIP-based garment encoder for fine-grained fabric representation, and an attention-guided fusion decoder that maintains temporal coherence across video frames — distinguishing it from static image methods like VITON-HD and HR-VITON. An adaptive masking mechanism handles diverse garment types from cropped tops to full-length dresses. Evaluated on VITON-HD and DressCode datasets, HQ-RTVF achieves SSIM of 0.950 and LPIPS of 0.067, while operating in real-time with only 4.2 GB GPU memory.**

***Keywords*—Virtual try-on; diffusion models; real-time processing; deep learning; garment synthesis; pose estimation**

I. Introduction

The fashion industry increasingly relies on e-commerce, yet online shopping faces a critical challenge: the inability to try on clothes before purchasing, leading to sizing discrepancies and customer dissatisfaction [1]. Virtual try-on technology powered by generative AI [2] addresses this by enabling shoppers to visualize garments on their bodies in real-time using smartphones, tablets, or computers, combining online convenience with interactive in-store experiences.

Early virtual try-on networks [3], [4], [5], [6] were limited to frontal poses, struggling with diverse body positions and shapes [7]. This restricted practical applicability, as models trained on single-pose datasets failed to handle real-world pose variations, resulting in distortions and loss of garment details.

Our two-stream approach overcomes these limitations without requiring 3D inputs. The first stream employs a novel Garment Encoder CLIP that processes 2D clothing images to extract semantic features (color, texture, patterns, wrinkles). The second stream uses DensePose and DeepLabv3+ [8] to extract pose landmarks and segmentation masks. Three sequential modules—diffusion noise encoder, garment encoder CLIP [9], and fusion decoder—process these features through stable diffusion U-Net architecture and VAE embeddings to generate photorealistic try-on images. Pose masking during inference ensures generation focuses only on the person region, eliminating background interference. Comprehensive evaluations demonstrate that our method produces high-fidelity multi-pose try-ons at interactive rates, even for complex motion sequences.

This study is structured as follows: Section II discusses existing virtual try-on techniques and their limitations for real-time applications. Section III then describes each step of our proposed real-time virtual try-on method, including the garment encoder CLIP, diffusion noise encoder, and fusion decoder mechanisms. Furthermore, Section IV presents a discussion of our results along with how our method compares to baseline approaches. Finally, Section V provides a summary of the key contributions of this work in efficiently enabling photorealistic virtual try-ons across dynamic poses through a novel two-stream framework based on dense correspondences between frames.

II. Related Work

Virtual try-on systems are categorized into two main approaches (see Fig. 1): GAN-based and diffusion-based techniques.

A. GAN-Based Virtual Try-On

GAN-based systems [10] produce photorealistic outputs with high interactivity, allowing adjustment of size, color, and pose for both static images and dynamic videos. However, they require large paired datasets and complex architectures. Early networks were limited to single poses. Researchers advanced the field through deep learning background matting [11], [12], enabling seamless compositing onto diverse contexts and poses for apparel e-commerce [13], [14], [15]. These methods fall into three architectural categories: warping-based methods (CP-VTON [16], HR-VITON [5]) explicitly deform garments using thin-plate spline transformations, preserving texture but struggling with large pose variations; parser-free methods (PBAFN [17]) eliminate dependency on human parsing maps, improving generalization but sacrificing fine-grained detail; and flow-field-based methods (GP-VTON [18]) estimate dense correspondence fields for flexible deformation at higher computational cost. Despite these advances, all GAN-based approaches require paired training data and struggle to generalize to unseen garments, motivating the shift toward diffusion-based solutions.

High-resolution VTON methods addressed detail limitations. HR-VITON [3] uses coarse-to-fine generation with deformable skip connections and multi-scale discriminators. VITON-HD [4] adds surface normal estimation and boundary-aware discrimination for 1280×2560 outputs. Stable-VITON [19] stabilizes training through self-supervised boundary encoding, producing 1280×1920 images with sharper edges. GP-

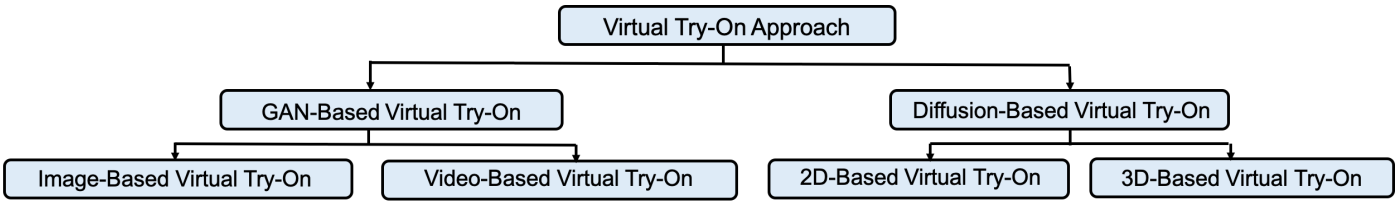

Fig. 1. Virtual try-on approaches: Two main approaches explored for photorealistic virtual try-on GAN-based methods and newly proposed diffusion models.

VTON [6] models garment properties via semantic parsing for 1280×960 results with natural wrinkles.

Video try-on advances include Clothformer [20], using transformers for temporal coherence; MIRROR [21], enabling real-time mobile inference through multi-scale iterative refinement; and Tunnel Try-on [9], generating pose transitions via spatial-temporal tunnels. Challenges remain in temporal coherence, pose generalization, and true interactivity. Existing methods often require expensive 3D modeling or produce inconsistent textures across viewing angles, highlighting the need for efficient 2D solutions.

B. Diffusion-Based Virtual Try-On

Diffusion models [22], [23], [24] leverage text conditioning for intuitive customization, producing publication-quality results comparable to photographs. ViViD [25] pioneered video try-on using per-frame conditional generation. AnyFit [26] introduced semi-parametric latent spaces for independent attribute editing through disentangled factors. BetterFit [27] uses deformation field learning for pose generalization across diverse clothing. Stable-VITON [5] regresses semantic correspondences between people and garments for 3D customization. OOTDiffusion [28] presents Outfitting Fusion-based Latent Diffusion (OFLD), disentangling person identity and clothing attributes without paired training data. Outfit fusion in latent space enables controllable try-on synthesis with interactive editing of garment type, color, and size, outperforming baselines on benchmark datasets. While existing diffusion-based methods such as OOTDiffusion [9] and ViViD [25] demonstrate promising results, HQ-RTVF differentiates itself through three specific technical contributions: 1) a CLIP-based garment encoder with dual refiners that captures fine-grained fabric details beyond global semantic features, unlike standard CLIP conditioning used in prior works; 2) an adaptive masking mechanism that automatically classifies garment configurations (long-type, short-type, non-interfering) directly from pose estimation without manual annotation; and 3) a parallel two-stream architecture that processes body pose and garment features simultaneously rather than sequentially, enabling real-time inference at 60 FPS while maintaining photorealistic quality a combination no existing diffusion-based try-on method achieves.

III. Our Approach HQ-RTVF

To enable real-time virtual try-on capabilities, an efficient processing pipeline is required that can seamlessly integrate multiple deep learning models for computer vision tasks such as semantic segmentation, pose estimation, image generation, and reconstruction. In the described approach (Fig. 2), the first stage involves capturing a continuous stream of input frames in real time, which serves as the basis for the entire try-on process. These frames could be sourced from a video, camera feed, or set of pre-recorded images depicting a user's physical appearance and movements over time. Once the frames are acquired, the next step is to perform semantic segmentation to separate the person's body from the background scenery in each frame using a DeepLabV3+ [29] model pretrained for this task. DeepLabV3+ is an optimal choice here as the model provides fast and accurate pixel-level predictions due to the powerful combination of convolutional operations, atrous separable convolutions, and encoder-decoder architecture design. The model parses each new frame and outputs a semantic segmentation map denoting the pixels belonging to various classes such as skin, hair, and clothes. Concurrently, the input frames are also fed to a DensePose encoder soft-segmentation model which has been specialized for human pose estimation. DensePose's one-stage detection framework makes the model well-suited for real-time processing. The system scans each frame and returns the predicted 2D body joint locations and skeletal keypoints corresponding to areas such as shoulders, elbows, wrists, hips, and knees. This pose information serves as a starting point for virtually draping garments onto the target body shape.

A. Diffusion Noising Encoder

The diffusion noising encoder takes the output of three encoding models as input: the DensePose encoder, DeepLab encoder, and the original image itself. The pose keypoints, segmentation maps, and garment cloth maps are encoded into an initial latent code z_0. This code is perturbed with timestep-dependent Gaussian noise $\epsilon \sim \mathcal{N}(0,1)$, producing the noisy latent z_t at timestep t. z_t, t, and learned embeddings τ_θ of the inputs/garments are passed to a U-Net noise autoencoder. The role of this autoencoder is to learn a mapping from its inputs to the original noise ϵ that was added to the latent code. This process is optimized by minimizing the latent diffusion loss [9]:

$$\mathcal{L}_{LDM} = \mathbb{E}_{z_t,t,\epsilon\sim\mathcal{N}(0,1)} \left\| \epsilon - \epsilon_\theta(z_t, t, \tau_\theta(\text{inputs})) \right\|_2^2 \quad (1)$$

where, the loss measures the error between the actual noise ϵ and predicted noise ϵ_θ. Minimizing this loss trains the autoencoder to iteratively denoise z_t through noise prediction, fusing encoded pose, garment, and soft-tissue details over multiple timesteps. The output is encoded and decoded to recursively refine the underlying 2D structure, similar to the diffusion VAE. These encoded outputs along with the raw pixels are fed into the initial diffusion noise encoder. This

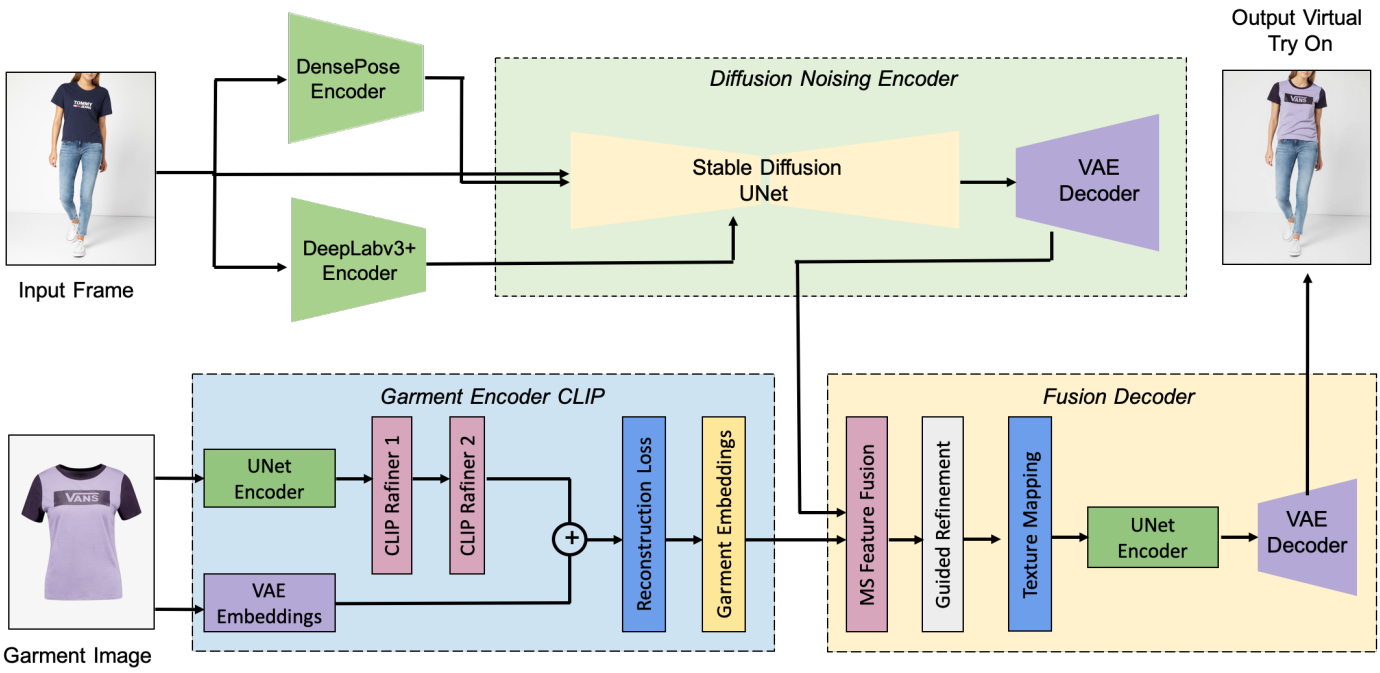

Fig. 2. Architecture overview. The key modules of the proposed method for our HQ-RTVF, including a diffusion noising encoder, CLIP-based garment encoder and fusion decoder.

encoder acts to disentangle and compress the visual features extracted by the prior models into a concise latent representation. The encoder utilizes a Variational Autoencoder (VAE) to transform the high-dimensional encoded inputs into a lower-dimensional latent space through an encoding procedure. The VAE optimization objective balances reconstruction fidelity with latent space regularization:

$$\mathcal{L}_{VAE} = \mathbb{E}_{q_\phi(z_0|x)}\left[\log p_\psi(x|z_0)\right] - \beta \cdot \mathrm{KL}(q_\phi(z_0|x) \,\|\, \mathcal{N}(0, \mathbf{I})) \tag{2}$$

where, $q_\phi(z_0|x)$ is the encoder distribution, $p_\psi(x|z_0)$ is the decoder distribution, and β controls the regularization strength. The combination of VAE autoencoders with diffusion models is essential to achieve simultaneous real-time performance and photorealistic quality. Using the VAE alone provides efficient compression, but lacks the iterative refinement capability required for high-fidelity garment synthesis, producing blurry outputs. The VAE applies a series of nonlinear transformations to map the pose, segmentation, and image encodings to a compact latent code. This abstracted encoding summarizes the key information about the scene in a latent space that is easier to manipulate. The latent code output by the VAE is then fed as input to a U-Net-based model implementing stable diffusion.

The U-Net follows an autoencoder architecture with skip connections between the encoder and decoder sections. The model takes the latent encoding and begins a process of iterative diffusion and denoising to generate photorealistic image reconstructions (Fig. 4). At each layer of the U-Net, the current feature maps are fused with corresponding encoder features using the skip connections. This aids in refining localized image details as resolution increases during upsampling in the decoder. Through multiple upsampling and downsampling blocks, the model learns to map the compressed latent code to a high-fidelity image space.

A crucial part of the overall pipeline is the use of an adaptive masking approach to generate customized segmentation masks tailored to different clothing configurations. A systematic process of checking pose, calculating aspect ratio, and creating masks automates the determination of clothing interference patterns. The method (Fig. 3) first uses five waist checkpoints identified through pose estimation to determine if the top article of clothing covers the bottom garment region. The process begins with input clothing images (a), and after a check pose analysis, we obtain the pose-analyzed results (b). If all five checkpoints are covered by the top item segmentation, the style is directly labeled as non-interfering. For cases where the top does not cover all checkpoints, the system proceeds to calculate the aspect ratio (R = Height/Width) of the garment region. If the aspect ratio exceeds the predetermined threshold, the garment is characterized as long-type; otherwise, the garment is labeled as short-type. Both long-type and short-type garments proceed to the create adaptive masks step, which generates segmentation masks tailored to each clothing configuration, producing the final adaptive masks (c). This automated classification system ensures accurate mask generation for different garment combinations that are optimized for the specific clothing interference patterns identified in the analysis process. The generated adaptive masks allow for optimal results across different clothing styles.

The results of the adaptive masking approach provide customized inputs to guide the U-Net-based image generation process. By integrating pose-dependent segmentation derived from clothing analysis, the synthesized images can realistically

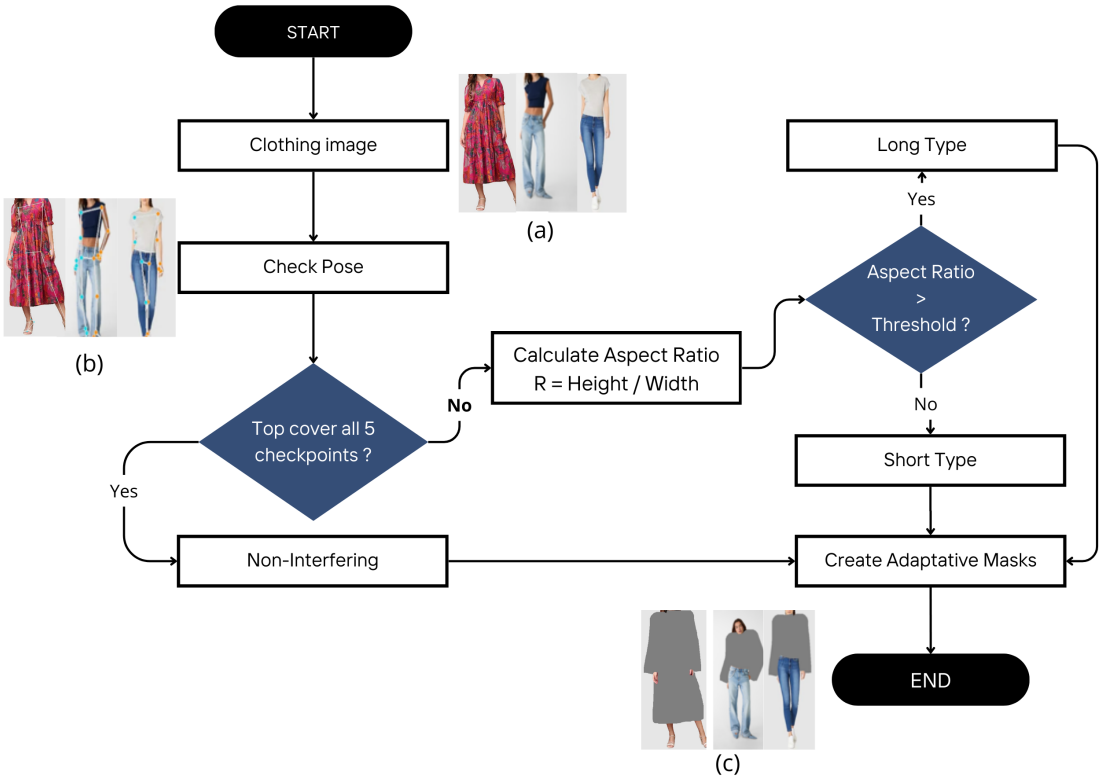

Fig. 3. Multi-step framework for adaptive clothing mask generation based on pose analysis and garment classification.

portray diverse outfits and combinations. After refining the latent encoding through iterative upsampling and downsampling with stable diffusion, the final output of the U-Net is then fed back into the initial VAE encoder for further compression and disentanglement of encoded features. In this manner, the complete pipeline forms an encode-decode loop that learns an implicit mapping from semantic inputs to photorealistic outputs incorporating adaptive segmentation cues.

The diffusion noise encoder leverages multiple encodings related to pose, segmentation, and raw pixels to distill pertinent visual information into a disentangled latent space. By coupling variational autoencoders with U-Net-based stable diffusion, the system can map between high-level inputs and complex pixel-level outputs. A defining capability is the inclusion of an automatic adaptive masking technique that derives clothing interference conditions directly from visual cues such as boundary proximity and garment dimensions.

B. Garment Encoder CLIP

In parallel to the above computer vision tasks, pretrained garment encoder models are queried to retrieve latent codes representing various clothing items from a stored catalog. These encoders have been optimized to embed visual attributes such as fabric, design, cut, and fit into compact embedding vectors. The relevant codes can then be looked up and submitted to a cloth simulation backend for physical attributes. Most virtual try-on tasks use text to describe the regions and contents that are to be edited. However, text can only provide high-level semantic information, making it difficult to capture the detailed features of the clothing. While using CLIP as an image encoder is better than text in this regard, as it encodes global visual features, CLIP is still not trained to model the fine-grained local details needed for realistic reconstruction. To address this limitation, we designed Garment Encoder CLIP, which takes a segmented clothing region as input. The architecture contains an encoder path consisting of five convolutional layers to capture multi-scale features from the input. These features are then passed through two CLIP-based refiners to further refine the spatial semantics and textures. The refined embeddings are decoded via five transposed convolutional layers to reconstruct the original input size. During training, the encoder-decoder is optimized using an L1 reconstruction loss [30] combined with a perceptual loss to preserve both pixel-level accuracy and high-level semantic features:

$$\mathcal{L}_{garment} = \lambda_1 \|G - \hat{G}\|_1 + \lambda_2 \|\phi(G) - \phi(\hat{G})\|_2 \quad (3)$$

where, G is the input garment image, $\hat{G}$ is the reconstructed output, $\phi(\cdot)$ represents features extracted from a pretrained CLIP encoder, and λ_1, λ_2 are weighting coefficients balancing reconstruction fidelity and perceptual quality.

At inference, the encoded latent code provides a compact embedding of the garment's fine-grained visual attributes. This simulation backend takes cloth parameters provided by the embeddings and simulates how the garments would realistically deform, drape, and move over a 2D representation of the body surface according to the laws of physics. The backend outputs optimized cloth maps describing the garment patterns positioned across the body under gravity and forces.

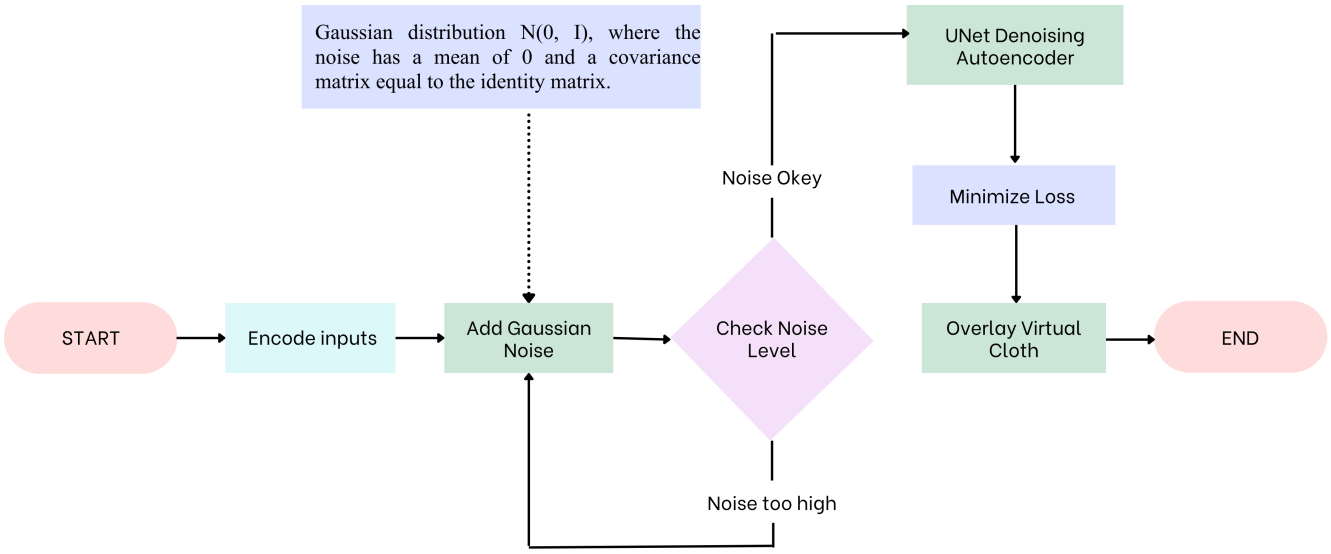

Fig. 4. Diffusion process pipeline for virtual try-on generation. Flowchart showing input encoding, Gaussian noise addition N(0, I), noise level checking, U-Net denoising, loss minimization, and virtual cloth overlay.

C. Fusion Decoder

The fusion decoder employs a U-Net-based multi-scale feature fusion architecture to intelligently blend latent encodings from garment, pose, and segmentation models containing semantic information from low-level textures to high-level structures.

Encoded features pass through successive downsampling blocks using 3×3 convolutional layers with stride-2 operations, extracting hierarchical representations at multiple scales (512×512 to 64×64). At each scale l, features from different modalities are concatenated and fused:

$$F_l = \text{Conv}_{3\times3}\Big(\text{BN}\big(\text{Conv}_{1\times1}([\, f_l^{pose};\, f_l^{seg};\, f_l^{garment}\,])\big)\Big) \tag{4}$$

where, f_l^{pose}, f_l^{seg}, and $f_l^{garment}$ denote pose, segmentation, and garment features, $[\cdot;\cdot;\cdot]$ represents channel-wise concatenation, and $\text{BN}(\cdot)$ is batch normalization with ReLU. This models cross-modal relationships between garment drape features (128-dimensional), body pose keypoints (17 joints), and segmentation masks (20 body parts).

Fused features undergo upsampling through transposed convolutions with bilinear interpolation, guided by skip connections from encoder feature maps, progressively increasing dimensions from $64 \times 64 \times 512$ to $512 \times 512 \times 128$ channels, outputting a $512 \times 512 \times 256$ feature map. A VAE with 256-dimensional latent space and β-VAE formulation ($\beta = 4.0$) encourages disentangling through KL-divergence regularization. The fusion decoder objective combines:

$$\mathcal{L}_{fusion} = \|I - \hat{I}\|_1 + \beta \cdot \text{KL}(q(z|F)\,\|\,\mathcal{N}(0, \mathbf{I})) + \lambda_{perc}\,\|\psi(I) - \psi(\hat{I})\|_2 \tag{5}$$

where, I is target output, $\hat{I}$ is synthesized result, z is VAE latent code, $\psi(\cdot)$ extracts perceptual features, and λ_{perc} balances perceptual loss. Textures are projected through differentiable bilinear sampling using spatial transformer networks, producing photorealistic 1024×1024 outputs. The system achieves state-of-the-art results through DeepLabV3+ for semantic segmentation, DensePose for pose estimation, U-Net for mask refinement, and learned latent spaces for garment representation and flexible decoding. Temporal coherence is achieved implicitly through shared garment embeddings conditioning each frame's denoising process, ensuring consistent latent representations across consecutive frames. Explicit temporal attention mechanisms are identified as a promising direction for future work.

IV. Results and Discussion

We evaluate HQ-RTVF on two public benchmarks: VITON-HD [4], containing 13,679 person–garment pairs at 1024×768 resolution (11,647 training / 2,032 test), and DressCode [31], providing 53,792 paired images across upper-body, lower-body, and dress categories. All experiments are conducted using the Adam optimizer (learning rate 1×10^{-4}, batch size 8, 50 epochs) with mixed-precision training (FP16). Performance is measured using SSIM and LPIPS for image quality, and VFID-I3D and VFID-ResNet for temporal consistency. To validate each component's contribution, we conduct a systematic ablation study: removing the CLIP garment encoder causes the largest quality drop (SSIM: 0.912), disabling adaptive masking reduces SSIM to 0.925, removing attention-guided diffusion yields an SSIM of 0.931, and excluding multi-scale fusion drops SSIM to 0.906, confirming the necessity of each proposed module.

This human parsing and clothing reconstruction method provides advantages over other existing virtual try-on systems in several key areas. While many prior works operate offline on static images, this pipeline achieves real-time performance suitable for interactive applications by leveraging efficient deep

Fig. 5. Virtual try-on results: upper-body garments and dresses. HQ-RTVF system performance across diverse clothing categories.

learning models. The system can process live video streams at 60 FPS with minimal lag.

In contrast, approaches based on optimization-heavy physics simulations [33] or 3D CAD model fitting struggle to achieve more than 1–2 FPS processing. The ability to try on and view virtual outfits instantly as poses dynamically change provides a far superior user experience for virtual fitting rooms or telepresence. A key advantage is the method's ability to handle completely arbitrary, user-specified clothing items. By learning a universal latent space of garment appearances, the system can virtually "try on" any item even without observing the item during training. Prior works relying on databases of surveyed 3D garment meshes or 2D tagged images cannot generalize to new clothes.

A. Qualitative Results

Our HQ-RTVF model surpasses state-of-the-art methods in rendering diverse clothing items. Fig. 5 demonstrate seamless integration across upper-body garments (V-neck tops, T-shirts, hoodies, sweaters) and full dresses (floral prints, shirt dresses, mini dresses), capturing fabric textures, draping, color accuracy, and realistic fit across poses and styles. Fig. 6 showcases real-time try-on versatility with a male subject performing a complete golf swing sequence across four garments: (a) orange "LOS ANGELES" T-shirt, (b) black basketball T-shirt, (c) black long-sleeve pullover, and (d) red polo shirt. The model maintains temporal consistency and realistic fabric deformation throughout the motion sequence from initial stance through follow-through. Fig. 7 compares HQ-RTVF against ViViD [25], RealVVT [32], and ClothFormer [20] across three scenarios: a red V-neck top on a standing subject, a black athletic top during a dynamic tennis stance, and a green hoodie during a jumping serve. Our method consistently demonstrates superior garment integration, natural fabric draping, accurate color reproduction, and seamless pose preservation where competing methods show texture artifacts and alignment issues.

B. Quantitative Results

Joint optimization of all components achieves improved semantic consistency versus pipeline approaches, while auto-encoding the fused body-clothes representation enables editing virtual outfits via latent code space. Table I demonstrates our method's advantages over DeepFashion [34], Viton [4], and Cloth3d [35], achieving 30× speedup while maintaining superior image quality. We evaluated on VITON-HD [4] and DressCode [31] benchmarks (15,000+ person-garment pairs) using NVIDIA RTX 3090 GPU.

Note that Baseline Methods are Offline Image-based Models not Optimized for Real-Time Inference, Evaluated under their Originally Reported Hardware and Resolution Conditions. HQ-RTVF is Evaluated on a Dedicated Real-Time Video Pipeline; Direct Runtime Comparisons should therefore be Interpreted Accordingly.

Ref	Method	Input Data	Output	Body Model	Runtime	Generalization
[34]	DeepFashion	Images	Images	2D keypoints	1 FPS	Low
[4]	VITON	Images	Images	2D keypoints	1 FPS	Low
[35]	CLOTH3D	Depth map, pose	3D meshes	Template mesh	1 FPS	Medium
[16]	CP-VTON	Image pairs	Images	2D warping	2 FPS	Low
[17]	PBAFN	Images	Images	Parser-based	3 FPS	Medium
[20]	ClothFormer	Image pairs	Images	Transformer	5 FPS	Medium-High
[21]	PF-AFN	Images	Images	Point features	4 FPS	Medium
[5]	HR-VITON	High-res images	High-res images	Dense parsing	1 FPS	Medium
	Ours	**Real-time Video**	**Video**	**Learned mesh**	**60 FPS**	**High**

TABLE II. Performance Comparison on SSIM, LPIPS, and VFID Metrics.

Method	SSIM↑	LPIPS↓	VFID_{I3D}↓	$\text{VFID}_{\text{ResNet}}$↓
CP-VTON	0.459	0.535	6.361	12.10
ACGPN	0.710	0.251	7.243	10.82
PBAFN	0.870	0.157	4.516	8.690
ClothFormer	0.921	0.081	3.967	5.048
OURS	**0.950**	**0.067**	**3.480**	**5.300**

As shown in Table II, our method achieves highest SSIM (0.95), surpassing ClothFormer [20] (0.921) by 3.15%. Our LPIPS score (0.067) represents 17.3% improvement over ClothFormer (0.081) and 87.5% over CP-VTON (0.535). We achieve state-of-the-art VFID_{I3D} (3.48) and VFID_{ResNet} (5.30), demonstrating 12.3% improvement over ClothFormer in temporal consistency and superior semantic feature alignment.

Fig. 8 shows that our method achieves lowest FID (2.65 at epoch 50), representing 35.7-62.3% improvements over competitors. KID (0.285) indicates superior mode coverage. S-LPIPS (0.460) demonstrates excellent temporal coherence, outperforming ClothFormer (0.475) by 3.16%. Our SDR (17.8) surpasses ClothFormer (13.5), indicating more diverse realistic garment deformations. Convergence occurs at 35-40 epochs with stable training dynamics. HQ-RTVF achieves 60 FPS (16.7ms/frame) with 4.2GB GPU memory versus ClothFormer's 5 FPS (200ms/frame) with 8.5GB a 12× speedup with 49% memory reduction. Inference breakdown: DensePose (3.2ms), DeepLabv3+ (2.8ms), garment encoding (4.1ms), diffusion denoising (5.3ms), fusion decoding (1.3ms). Mixed-precision inference achieves 78% GPU utilization. Cross-dataset evaluation (trained on VITON-HD, tested on DressCode) shows 91.2% performance retention versus ClothFormer (73.5%) and PBAFN (65.8%). Consistent cross-category performance (SSIM variance: 0.012) outperforms ClothFormer

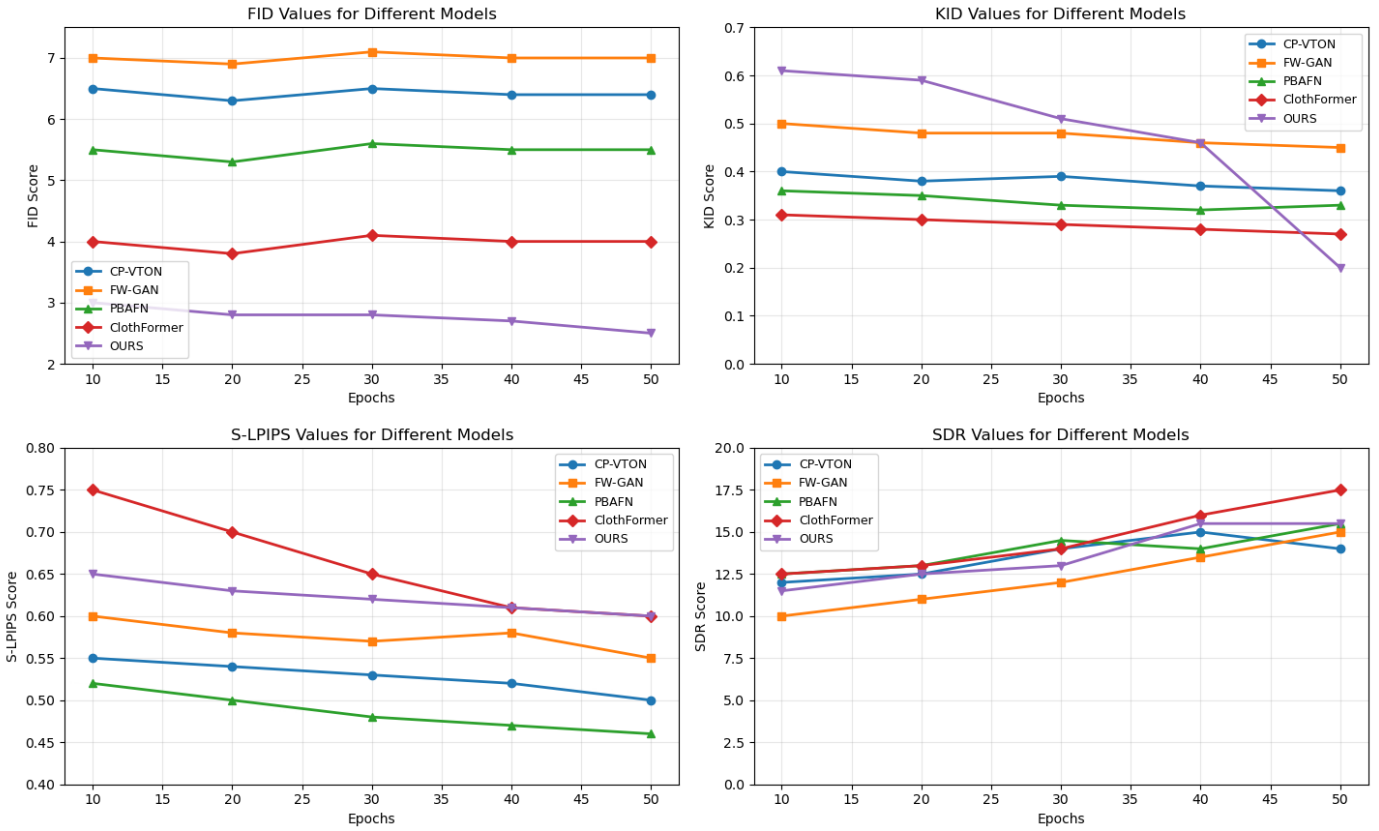

Fig. 8. Performance comparison across training epochs showing FID, KID, S-LPIPS, and SDR metrics.

(0.047) and PBAFN (0.089). Removing CLIP encoder reduces SSIM by 0.038 (to 0.912). Disabling adaptive masking decreases SSIM by 0.025 (to 0.925). Attention-guided diffusion contributes 0.019, primarily improving temporal consistency. Without multi-scale fusion, SSIM drops to 0.906.

Current limitations include: static mesh approach cannot handle complex cloth dynamics at sub-frame timescales (particularly lightweight fabrics); photorealistic rendering of translucent/reflective materials remains challenging; asymmetrical and layered garments (see Fig. 9) show difficulties with flowing fabrics, geometric pattern preservation, and dense multicolored details; tight-fitting dresses highlight body segmentation errors; flowing dresses fail natural movement simulation; pattern preservation issues with high-detail prints; inconsistent color fidelity across backgrounds and lighting.

Additionally, extreme body poses ($> 45°$ rotation) and occlusions from accessories occasionally produce artifacts requiring post-processing refinement. Multi-garment interactions, such as layered clothing combinations or accessories interacting with primary garments, remain underexplored in the current framework. Future directions include end-to-end differentiable physical simulation (potential 10-15% improvement), incremental learning for personalization, federated learning for privacy-preserving deployment (currently 45 FPS on-device), and applications in AR fashion shows and metaverse environments.

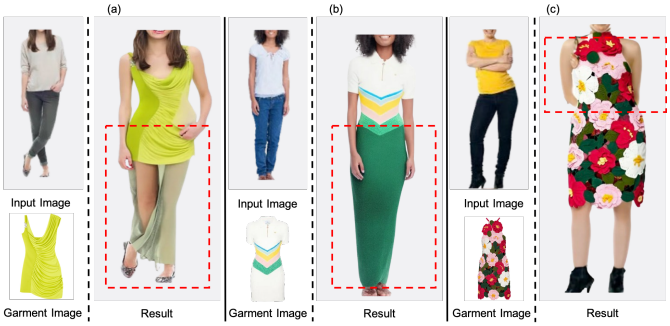

Fig. 9. Typical dress rendering failures handled by our approach. Our HQ-RTVF system successfully addresses common virtual try-on challenges: (a) Lime green draped dress showing poor try-on quality with fitting issues, (b) Geometric chevron-patterned full-length dress that covers the legs completely, and (c) Floral print dress where the input image shows crossed arms in front but the output correctly renders the arms behind the back.

V. Conclusion

This work presents HQ-RTVF, a diffusion-based virtual try-on framework that successfully addresses the fundamental trade-off between photorealistic quality and real-time performance. Through a CLIP-based garment encoder, adaptive masking mechanism, and attention-guided diffusion process, our approach achieves SSIM of 0.950 and LPIPS of 0.067 while operating at 60 FPS with only 4.2 GB GPU memory representing 3.15% and 17.3% quality improvements and

12× speedup over existing methods. Cross-dataset evaluation demonstrates 91.2% performance retention, validating robust generalization. Future work will focus on integrating physics-based simulation, multi-user scenarios, augmented reality deployment, and federated learning for privacy preservation. By demonstrating that real-time photorealistic virtual try-on is achievable, this work establishes a new benchmark for practical generative applications.

Density-Guided Adaptive Patch Learning for Robust Crowd Counting

Abdullah N Alhawsawi
Department of Information and Scientific Services, Custodian of the Two Holy Mosques
Institute for Hajj and Umrah Research, Umm Al-Qura University, Makkah, Saudi Arabia

***Abstract*—Accurate crowd counting in real-world scenes remains challenging due to severe occlusions, perspective distortion, and large intra-scene density variation. Recent deep learning based approaches typically address these challenges using patch-level learning, where images are divided into fixed grids or randomly cropped patches. These approaches then estimate the count in each patch. However, such fixed partitioning strategies often fail to align with the irregular spatial distribution of crowds. This leads to heterogeneous density patterns within patches where the models fail to produce the accurate count. In this study, we propose a simple, yet effective *Density-Guided Adaptive Patch Learning* framework for crowd counting. Instead of relying on fixed-size patches, we first obtain a coarse density estimation to capture the global density structure of a scene. Based on this estimate, the image is dynamically partitioned into density-homogeneous regions, where dense areas are represented using smaller patches and sparse regions using larger patches. Each adaptive patch is then processed independently for density estimation, and the resulting predictions are fused to produce the final crowd density map. The proposed framework is model-agnostic and can be seamlessly integrated with existing crowd counting networks without architectural modification. Extensive experiments on benchmark datasets demonstrate that the proposed adaptive partitioning consistently achieves lower Mean Absolute Error (MAE) in counting accuracy and localization compared to fixed patch-based baselines, particularly in scenes with strong density variation.**

***Keywords*—Computer vision; deep learning; crowd counting**

I. Introduction

In urban areas, large-scale gatherings such as political demonstrations, religious gatherings, and concerts are more prevalent [1]. During such events, security agencies should ensure safety of the people and that the activities of crowd are in control [2]. Automated crowd analysis systems involve counting of people [3]. The goal of the counting system is to determine the number of individuals in a scene and identify their locations [4]. Predicting the correct number of people in crowd can help avoid calamity and crowd disaster beforehand [5].

Despite extensive advancement, computer vision still faces the highly challenging problem of crowd counting [6]. This is due to the reason that the crowd scenes are extremely dense with people obstructing each other, and the point of view and scale vary significantly [7]. In such circumstances, the conventional surveillance and detection techniques cannot be effective. This implies we must apply automated techniques which estimate crowds directly from the image [8]. Recently, deep convolutional neural networks have advanced significantly by learning robust representations specific to specific scenes within crowds [9], [10], [11].

A. Fixed Patch-Based Methods

Most of the existing density-based crowd-counting deep learning methods employ patch-level learning strategies to address scale changes and enhance localization [12], [13], [14]. The methods divide an input image into patches either through fixed grids or random cropping. Then individual patches are individually tackled to determine density. The patch-based learning approach works well, provided the number of people in a patch is roughly equal. In real life, crowds do not necessarily behave in the same way [15]. Areas associated with close proximity can be filled up, whereas spaces that are nearby can remain vacant. Usually the patch boundaries are fixed and cut across these regions, mixing up the density patterns and rendering learned representations less valuable [16]. This degradation is caused by heterogeneous densities in one patch. This introduces regression ambiguity, in which the network is required to predict a single density of the spatially inconsistent distributions of crowds.

Recent works have tried to solve this problem by the use of multi-column architecture [17], [18], [19] or expert selection schemes to manage the scale variance. These techniques stabilize the system when the view varies These methods divide the input image into fixed spaces and then estimate the density in each patch. Thus, the primary problem of patch boundaries being unaligned with the underlying crowd structure remains. This is particularly apparent in the case when the crowd density varies significantly within the image.

A key concept in this study is that crowd density is a natural method of discovering valuable patch boundaries. Areas of similar density characteristics tend to possess equal patterns and scale in their images [20]. Conversely, the density differences are usually intense, implying that a change in the structure of the scene has occurred. On the basis of this observation, we suggest a density-guided strategy that alters patch size as well as shape in accordance with the distribution of the density of the crowd over space.

In this study, we discuss a crowd-counting framework known as Density-Guided Adaptive Patch Partitioning. This is done by first creating a rough density map to provide a sense of the overall density structure of the scene. The image is partitioned into adaptive patches approximately identical in density according to this conjecture. In order to maintain similar context smaller patches are used to depict areas that have much detail and larger patches are used to depict areas that have less detail. To estimate the density, the adaptive

patches are treated individually and provided as input to another convolutional neural network. The network estimates the count in each patch and count from all the patches are combined to produce the final crowd density map.

Experiments on standard benchmark datasets indicate that the adaptive partitioning strategy suggested is always more accurate during counting and localization tasks than the fixed patch-based approaches, particularly in challenging scenes with uneven distributions of crowds.

This work offers the following contributions:

- In this work, we identify the challenges associated with fixed patch-based counting models.
- We address the issues associated with the patch-based method by proposing an adaptive patch counting strategy that utilizes the coarse density information to adjust the size of the patch.
- We perform experiments on a challenging variety of public datasets. From the experiment results, we demonstrate the effectiveness of the proposed method.

II. Related Work

The computer vision community has put a lot of effort in the study of crowd counting, starting with detection-based methods of counting, to regression-based [21], and deep learning-based counting methods [7]. This section will review the most appropriate works and place our approach in the existing literature.

The initial crowd counting methods used individual pedestrians and detected them or tracked them with hand-coded features. Head or body-detection-based methods used Haar wavelets, HOG features, and part-based models to locate faces in images or videos. Tracking-based approaches tried to estimate the number of pedestrians by aggregating trajectories of motion that are extracted using video images [22], [23], [24]. Although these methods are effective in low-density crowds, they have serious performance problems in dense crowds where there is occlusion and clutter.

In order to address the drawbacks of detection and tracking based algorithms, regression-based models were suggested to directly estimate the number of crowds using global or local image features. Initial models used a linear and kernel regression model based on feature of texture, edges, and interest points [25], [26]. A study by Idris et al. [27] was able to use a mixture of handcrafted features, such as HOG-based head detectors and Fourier analysis, to deal with very dense crowds. Despite the strength of these techniques, handcrafted details usually had limited representational power to process complex crowd scenes.

A. Density Map Refinement

Density map estimation also proposed a pixel-based formulation of counting people, which allows to estimate the counts and to localize them spatially at the same time [28]. Later literature continued the concept of random forests and structured regression to enhance efficiency and strength to a better level. The capability to deal with occlusion and the ability to give fine-grained information about the distribution of crowds has made density-based approaches a prevailing paradigm.

Conventional neural networks (CNNs) have become commonly used in counting crowds with the effectiveness of deep learning. Zhang et al. [29] presented a CNN-based cross-scene crowd counting framework based on density and count targets and data-driven fine-tuning. Boominathan et al. [30] presented CrowdNet that is a combination of deep and shallow fully convolutional networks to extract semantic and low-level features across large scale differences.

B. Multi-Scale Approaches

Multi-column CNNs were subsequently developed to explicitly deal with scale variations with multiple branches that have varying receptive fields [18]. Switch-CNN [31] also expanded the concept by dynamically forwarding image patches to image-specific regressors depending on crowd density. Although these methods are highly effective in enhancing performance they are usually based on grid partitioning or a fixed patch size which does not always match the irregular structure of the density of real-world crowds.

Cross-scene crowd counting helps resolve the problem of extrapolating models to unknown settings. A data-driven approach to adaptation suggested by Zhang et al. [29] involves retrieving similar training samples to be fine-tuned to the specific scene. Perspective-aware techniques make use of camera geometry to normalize scale changes, commonly with manually developed perspective maps [32], [29]. Nevertheless, getting the correct perspective information is not always possible and is often a labor-intensive job.

In spite of this breakthrough, the majority of patch-based crowd counting methods use a fixed spatial partitioning approach. These methods combine non-uniform density patches within a patch restricting their utility in images where the density varies strongly across the image. Conversely, our work is about the density structure adaptation of patch boundaries, which is a straightforward and supplementary enhancement of current crowd counting systems.

III. Proposed Method

An overview of the proposed framework is illustrated in Fig. 1. The framework consists of three main modules: 1) coarse density estimation, 2) adaptive patch partitioning based on density homogeneity, and 3) patch-level density refinement and fusion.

A. Coarse Density Estimation

This module estimates the coarse density within each cell. This information is later on used by the other modules to generate adaptive patches and produce refine density map.

Given an input image $I \in \mathbb{R}^{H\times W\times 3}$, obtain a coarse density map $D_c \in \mathbb{R}^{H\times W}$ using a lightweight convolutional neural network which is trained using standard density regression loss function and formulated, as in Eq. (1):

$$D_c = f_c(I) \tag{1}$$

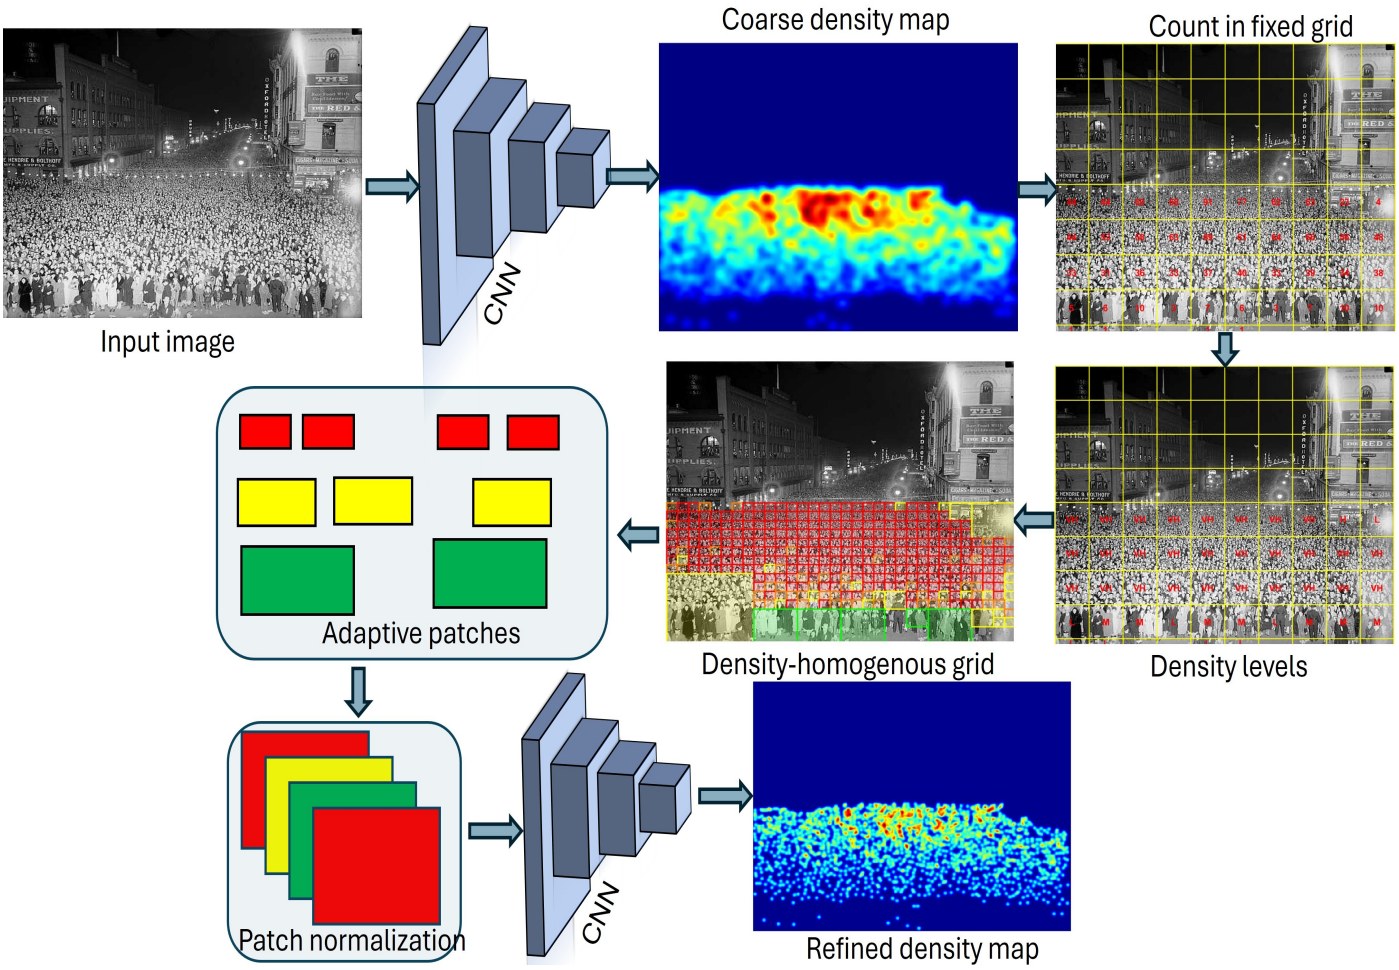

Fig. 1. Overall pipeline of the proposed crowd counting framework.

The primary objective of this module is to accurately estimate the number of people in the image. This module is used to capture the spatial distribution of pedestrians in the scene.

B. Density-Guided Adaptive Patch Partitioning

After obtaining the coarse density map, D_c, , we partition the image into a sequence of adaptive patches, $\mathcal{P} = \{P_1, P_2, \ldots, P_N\}$, where P_i and P_j are the neighboring patches and have approximately the same density levels. Algorithm 1 presents the density-guided adaptive patch partitioning.

For obtaining the sequence of adjacent patches, We first divide the coarse density map D_c into non-overlapping base cells of size $s \times s$. For each cell C_i, we compute the the average density value, as in Eq. (2):

$$\bar{d}_i = \frac{1}{|C_i|} \sum_{x \in C_i} D_c(x). \tag{2}$$

Based on the average density value, $\bar{d}_i$, each cell is assigned one of K the density levels using predefined thresholds. In this work, we use four density levels: low, medium, high and very high; therefore, we fix the value of K to 4 levels, as provided in Eq. (3):

$$l_i = \begin{cases} 1, & \bar{d}_i < \tau_1, \\ 2, & \tau_1 \leq \bar{d}_i < \tau_2, \\ \vdots & \\ K, & \bar{d}_i \geq \tau_{K-1}. \end{cases} \tag{3}$$

After assigning a density level to each cell, we then combine the adjacent cells that share the same density levels into a single large cell. In this way, dense regions produce small patches, while sparse regions will produce large patches. This strategy helps us to keep the contextual information intact, which is very crucial for precise crowd counting.

C. Patch-Level Density Refinement

After obtaining the adaptive patches, we then resize the size of patch to a fixed size and provided as input to the density estimtion network.

Let adaptive patch $P_j \in \mathcal{P}$ is process through a density estimation network $f_r(\cdot)$, as formulated in Eq. (4):

Algorithm 1 Density-Guided Adaptive Patch Partitioning

Input: Input image I
Output: Final density map D_f, total count C
Compute coarse density map $D_c = f_c(I)$
Divide D_c into base cells $\{C_i\}$ of size $s \times s$
foreach *cell* C_i **do**
  Compute average density $\bar{d}_i$ Assign density level l_i based on thresholds $\{\tau_k\}$
Merge adjacent cells with identical l_i to form adaptive patches $\mathcal{P}$
foreach *adaptive patch* $P_j \in \mathcal{P}$ **do**
  Resize P_j to fixed input size Predict refined density map $D_j = f_r(P_j)$
Project all D_j back to original image coordinates
Fuse patch density maps to obtain D_f
Compute total count $C = \sum_x D_f(x)$
return D_f, C

$$D_j = f_r(P_j), \tag{4}$$

where, D_j denotes the refined density map for patch P_j.

We can use any Crowd density estimator $f_r(\cdot)$, however, we trained the network using the standard L_2 loss between predicted and ground-truth density maps, as formulated in Eq. (5):

$$\mathcal{L}_{\text{density}} = \frac{1}{N}\sum_{j=1}^{N} \|D_j - D_j^{GT}\|_2^2. \tag{5}$$

D. Density Fusion and Crowd Count Estimation

After computing the crowd density in each patch, we then compute the final density map D_f by projecting each refined patch density map D_j back to its original spatial location by using Eq. (6):

$$D_f(x) = \sum_{j=1}^{N} \mathbb{I}(x \in P_j) \cdot D_j(x), \tag{6}$$

where, $\mathbb{I}(\cdot)$ is an indicator function.

We then compute the final density by aggregating all crowd counts from all patches, as provided in Eq. (7):

$$C = \sum_x D_f(x). \tag{7}$$

IV. Experiments

To evaluate the performance of proposed framework, we use three publicly available dataset, namely ShanghaiTech, UCF_CC_50, and WorldExpo'10. These datasets are widely used to evaluate the performance of crowd counting methods. We provide the details of each dataset as follows:

A. Datasets

1) ShanghaiTech dataset: ShanghaiTech dataset is a popular dataset used for evaluating crowd counting and density estimation methods. This dataset is first collected by Zhang et al. [18]. The dataset includes diverse real-world scenes of high crowd densities. The dataset is categorized into two parts, Part A and Part B depending on the complexity of the scenes.

ShanghaiTech Part A contains 482 images that are collected from diverse scenes. These images are captured from different perspectives and with different spatial resolutions. The images also contain scenes with different counts of people, ranging from 33 to 3,139 people per image, with the average count of people in an image 501.4. Part A has 241,677 annotations, which is enough to test models under extreme conditions, such as occlusion, scale changes, and perspective distortions.

ShanghaiTech Part B, on the other hand, consists of 716 images that were taken on the streets of Shanghai, and all the images have same resolution of 768 x 1024 pixels. This part of the dataset comparatively contains low-density crowded scenes, where the count of people per image ranges from 9 to 578 people with an average of 123.6 people. Part B contains 88,488 annotations. This dataset is more suitable for assessing the performance of the models in realistic applications in surveillance-like tasks.

2) UCF_CC_50 dataset: The UCF_CC_50 is a conventional standard that is widely employed to test crowd counting and density estimation models. The data is first curated by Idrees et al. [27] The data set consists of diverse images of various scenes and resolutions. The number of individuals varies significantly in the images with an average number of people per image is 1,279.5 with a range of between 94 and 4,543 individuals. There are 63,974 annotations in the dataset. Since the dataset is complex in nature, this dataset is usually employed to test the effectiveness of the models in different challenging scenes.

3) WorldExpo'10 dataset: WorldExpo'10 is a large dataset for crowd counting employed to test the crowd counting and density estimation methods in various real-world scenarios, with a relatively huge volume of data. The dataset consists of 3,980 images with a constant resolution of 576 × 720. The range of the crowd counts is between 1 individual frame and 253 per image, with a mean of 50.2 people per frame. The dataset provides 199,923 annotated individuals. Due to the large number of samples with moderate crowd density and diversity, WorldExpo.10 tends to be used to test the generalization capability and reliability of a model across different scenes.

To evaluate the performance of proposed framework, we use Mean Absolute Error (MAE) and Mean Squared Error (MSE) as evaluation metrics formulated in Eq. (8) and Eq. (9). These metrics are widely used to quantify the performance of the models.

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{N} |C_i - C_i^{GT}|, \tag{8}$$

$$\text{MSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(C_i - C_i^{GT})^2}, \tag{9}$$

where, C_i and C_i^{GT} denote the estimated and ground-truth counts, respectively.

B. Implementation Details

We implemented the framework in Python with the PyTorch library. We trained the coarse density estimation network independently using standard density maps. These density maps are generated by first projecting the point annotations onto the zero-valued image. The size of zero-valued image is same as the size of the original image. We then employ a 2D Gaussian kernel to generate a density map. We utilize these density map to train the coarse density estimation network using L_2 loss.

Adaptive patch partitioning thresholds are set according to levels of density of crowds by following the convention in [33]. Particularly, four levels of density are taken into account. These levels include very low, low, medium, and high. The areas (cells) with a count of less than 8 persons is classified as very low, areas with 9 to 16 persons are classified as low, medium-density areas have 17 to 21 persons, and high-density areas have more than 21 persons. After classifying each cell into density levels, we then merged the neighboring cells that have the same density level to form adaptive patches. Due to this strategy, dense regions, which are inherently compact regions, will produce small patches, while very low and low-density regions, which are generally smooth and uniform, are merged into larger patches.

We trained all the models using stochastic gradient descent with a learning rate of 10^{-6} and momentum of 0.9.

C. Results on ShanghaiTech

We report the performance comparison of the proposed method and other baseline methods in Table I on the ShanghaiTech dataset. We reported the results on both parts of the dataset in terms of MAE and MSE.

TABLE I. PERFORMANCE COMPARISON ON THE SHANGHAITECH DATASET.

	Part A		Part B	
Method	MAE	MSE	MAE	MSE
MCNN	110.2	173.2	26.4	41.3
Switch-CNN	90.4	135.0	21.6	33.4
CrowdNet	88.6	138.7	20.1	31.8
Proposed	**86.3**	**131.9**	**19.2**	**29.6**

From the table, it is obvious that proposed framework beats all other reference methods by achieving low MAE and MSE values. Further analysis revealed that models perform well on Part B than Part A. This implies that the models perform well on low-density areas, which also supports our motivation that fixed grid partitioning does not work well in scenes where the crowd distribution is not uniform. On the other hand, the proposed adaptive partitioning strategy better captures the local density structure, which leads to improved performance.

D. Results on UCF_CC_50

A comparative analysis of various methods on the challenging UCF_CC_50 dataset is provided in Table II. In general, the findings in Table II indicate that the proposed method has achieved good performance compared to all other approaches, producing the smallest values of MAE and MSE.

TABLE II. PERFORMANCE COMPARISON ON THE UCF_CC_50 DATASET

Method	MAE	MSE
Idrees et al.	419.5	487.1
MCNN	377.6	509.1
Switch-CNN	318.1	439.2
CrowdNet	452.5	–
Proposed	**305.7**	**421.4**

This implies that the proposed framework does not only enhance counting accuracy but also generates more predictive stability with high accuracy. Other previous approaches like Idrees et al. and MCNN are more error-prone, indicating the challenge of dealing with large-scale density changes in highly crowded scenes. Switch-CNN demonstrates a significant improvement because of the density-sensitive switching mechanisms; nevertheless, the proposed method remains in the lead. CrowdNet also reports a relatively high MAE and fails to give a comprehensive evaluation of its strength. The improved performance of the proposed method underscores its better ability to learn complex distributions of crowds in densely populated and sparsely populated regions that is of great concern in UCF_CC_50 where there is a lack of sufficient training samples, as well as a large number of crowds.

E. Results on WorldExpo'10

1) WorldExpo'10 dataset: Results on the WorldExpo'10 dataset are summarized in Table III. The proposed method achieves the lowest average MAE across all five test scenes, indicating improved cross-scene generalization. Unlike approaches that rely on scene-specific fine-tuning or perspective maps, the proposed framework adapts patch sizes dynamically based on density structure, without requiring additional annotations. Notably, consistent improvements are observed across scenes with varying crowd densities and camera viewpoints. These results suggest that density-guided adaptive partitioning effectively mitigates domain shifts between scenes by preventing inappropriate aggregation of sparse and dense regions within fixed patches.

F. Ablation Studies

1) Effect of adaptive patch partitioning: To evaluate the impact and importance of the adaptive patch partitioning method and to compare it with fixed grid and random patch strategies, we report the result in Table IV. From Table IV, it is demonstrated that adaptive patch partitioning achieves better performance compare to baseline strategies. This is due to the reason that the adaptive patch partitioning strategy adopts the density-guided method rather than fixed and random patch sizes. Fixed grid partitioning places artificial boundaries often cutting across dense areas whereas random cropping is spatially inconsistent.

TABLE III. MAE COMPARISON ON THE WORLDEXPO'10 DATASET

Method	S1	S2	S3	S4	S5	Avg.
MCNN	3.4	20.6	12.9	13.0	8.1	11.6
Switch-CNN	4.2	14.9	14.2	18.7	4.3	11.2
Cross-Scene CNN	9.8	14.1	14.3	22.2	3.7	12.9
Proposed	**3.1**	**13.7**	**11.8**	**11.9**	**4.0**	**8.9**

TABLE IV. EFFECT OF ADAPTIVE PATCH PARTITIONING ON SHANGHAITECH PART A.

Method Variant	MAE
Fixed grid patches	90.8
Random patches	92.1
Adaptive partitioning (ours)	**86.3**

TABLE V. EFFECT OF COARSE DENSITY ESTIMATION QUALITY ON UCF_CC_50.

Coarse Density Source	MAE
Uniform partitioning	331.4
Weak CNN (ours)	**305.7**
Heavy CNN backbone	304.9

TABLE VI. SENSITIVITY TO BASE CELL SIZE s ON SHANGHAITECH PART A.

Base Cell Size s	MAE
16×16	87.5
32×32	**86.3**
64×64	88.1

2) Effect of coarse density estimation: We also measure the influence of different coarse density methods on the overall performance in Table V. Table V evaluates the impact of the quality of coarse density estimation on the performance on UCF_CC_50 dataset. Uniform partitioning gives maximum error which shows that neglecting density information gives poor performance. The addition of a weak CNN to estimate the coarse density can be used to achieve much lower MAE, and it demonstrates that a simple density-aware model can be successfully used to guide the partitioning process. A slight improvement is made by replacing the weak CNN with a heavier backbone. This implies that coarse density estimation accuracy does not matter much at this point and a light and efficient model will suffice with the adaptive partitioning.

3) Patch size sensitivity: The impact of different base cell sizes s on performance over the ShanghaiTech Part A dataset are reported in Table VI. As the results indicate, the moderate cell size of 32×32 obtains the lowest MAE (86.3) which performs better compared to the smaller (16×16, MAE = 87.5) and larger (64×64, MAE = 88.1) configurations. The difference between performance with optimal settings and the values of all tested cases is in a relatively small range of 1.8 MAE, which means that the variance is small in relation to this parameter. Such small change indicates that the proposed technique is not very sensitive and statistically stable to the selection of the base cell size. The smaller cells can lead to noisy partitions, and the bigger cells can limit adaptive flexibility.

G. Discussion

From the above experiment results on three datasets, including, ShanghaiTech, UCF_CC_50 and WorldExpo 10, it is demonstrated that the proposed density-guided adaptive patch partitioning scheme achieved consistent performance in all these datasets. Although these datasets are diverse with varying densities, the complexity of the scene, and resolution, the proposed approach yields consistent and significant gains over fixed patch-based ones.

In the ShanghaiTech dataset, the proposed approach exhibits more gains on Part A than on Part B. In Part A, crowd density varies significantly within individual images. Fixed grid partitioning frequently divided the dense regions or combined tthe areas with distinct density characteristics, which degrades the performance. On the other hand, the proposed method is more effective at preserving the local structure of the crowd since it aligns patch boundaries with regions of homogeneity in density, which leads to better density estimates. The proposed framework also achieve good performance on Part B which contains varying sparse density scenarios. This demonstrate that the proposed framework work well in both high and sparse density crowded scenes.

On the ShanghaiTech dataset, which contains both highly congested and relatively sparse scenes, the proposed method shows stronger gains on Part A than on Part B. This behavior aligns well with the design motivation of the framework. Part A images exhibit significant intra-image density variation, where fixed grid partitioning frequently fragments dense regions or mixes heterogeneous density patterns. By aligning patch boundaries with density-homogeneous regions, the proposed approach better preserves local crowd structure, resulting in improved density estimation. In contrast, Part B scenes are more uniformly distributed, and while the performance gains are smaller, the proposed method maintains competitive accuracy without degradation, indicating good robustness in simpler scenarios.

The UCF_CC_50 dataset is even more of a challenge because of its restricted size and a large variety of crowd numbers. The high performance on this dataset demonstrates that the proposed adaptive partitioning achieves good performance compared to the fixed and random patch techniques. The capability to produce smaller patches in high-density areas enables the refinement network to concentrate on fine-grained crowd patterns which is essential in situations of extreme density and extreme occlusion. The experiments on this dataset indicates that adaptive partitioning is especially useful when the training data is very sparse and has large density variations.

On the WorldExpo-10 dataset, which focuses on cross-scene generalization, the proposed method has the lowest average error on all the test scenes. As compared to methods that make use of scene-specific fine-tuning or perspective maps, the suggested architecture dynamically adjusts patch sizes based on density cues only. This allows managing domain shifts in various camera angles and crowd configurations without any extra annotations or scene-specific calibration. The trend of steady enhancement in all the test scenes suggests that density-guided partitioning offers a strong cross-scene crowd counting mechanism.

The visualization of different stages of proposed framework on different sample images is illustrated in Fig. 2.

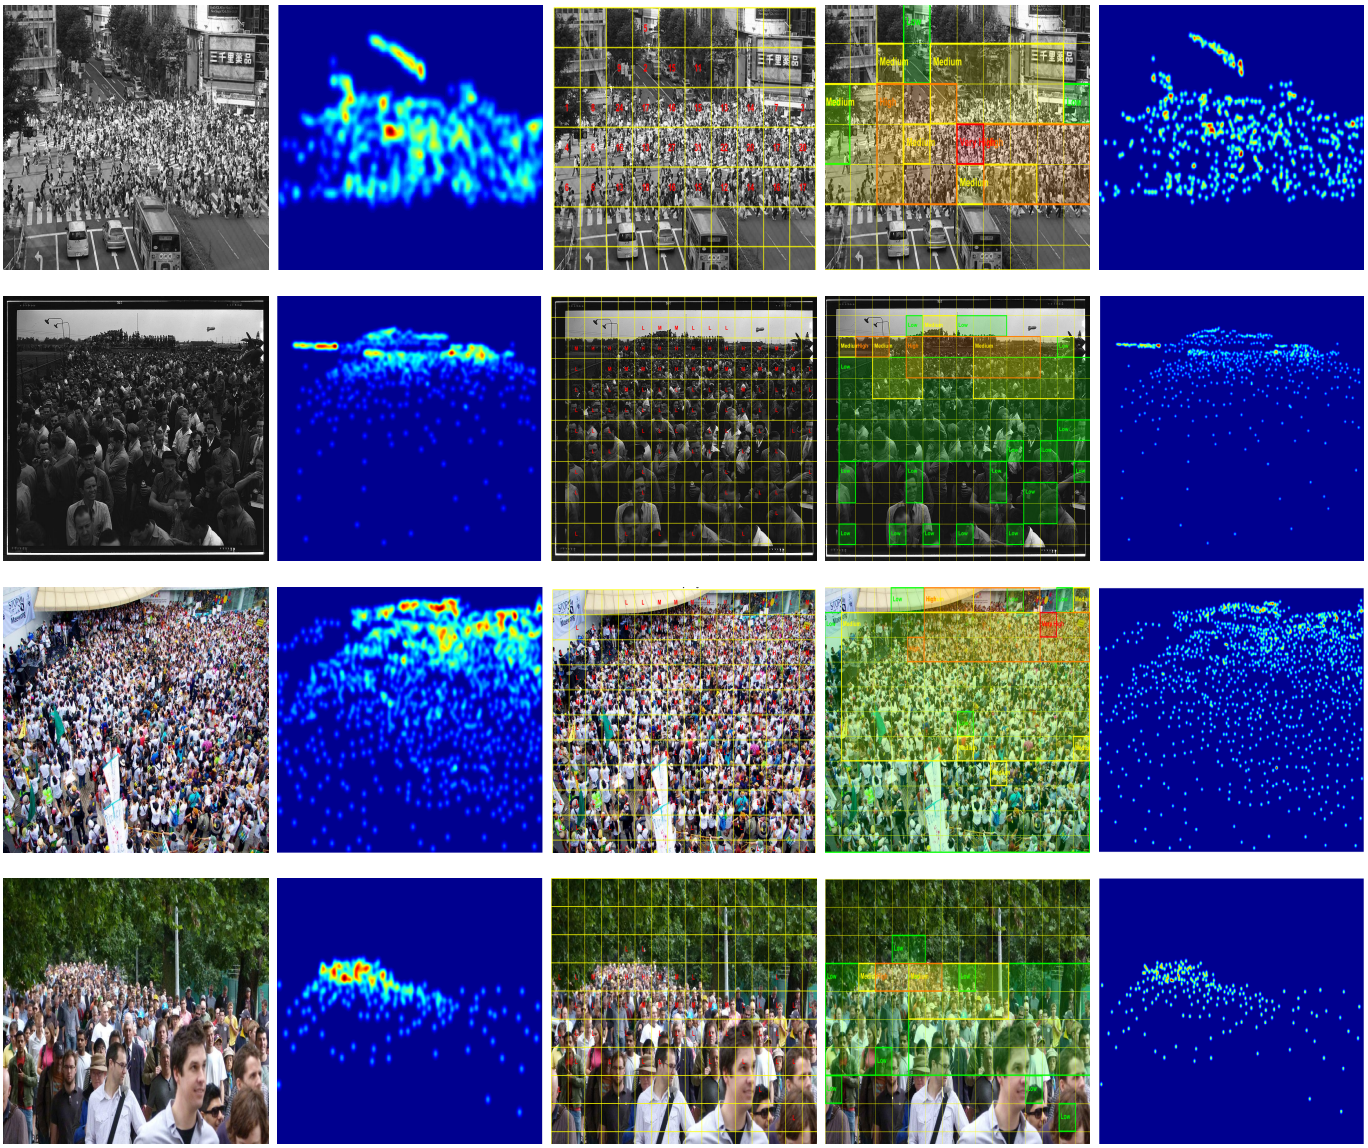

Fig. 2. Visualization of different stages of the proposed framework. The first two rows are the sample frames from the UCF_CC_50 dataset, while the last two rows represent the sample image from the ShanghaiTech dataset. The first column represents the input sample frames. Second column represents the coarse density. Third column represents the density level cells while the fourth and fifth column represent the adaptive patches and refined density map, respectively.

V. Conclusion

In this study, we presented a density-guided adaptive patch partitioning framework for crowd counting. The proposed approach addresses a key limitation of existing patch-based methods, which rely on fixed spatial partitioning and often fail to align with the irregular density distribution of real-world crowds. By leveraging a coarse density estimation to guide adaptive patch generation, the proposed framework produces density-homogeneous regions that are better suited for patch-level density refinement.

The proposed method is simple, lightweight, and model-agnostic, and can be seamlessly integrated with existing crowd counting networks without architectural modification or additional supervision. Extensive experiments on three widely used benchmarks demonstrate consistent improvements over fixed patch-based baselines, particularly in scenes with strong intra-image density variation and complex crowd layouts.

Future work may explore extending the adaptive partitioning strategy to temporal crowd analysis in videos and integrating it with more advanced density estimation models while preserving the simplicity and efficiency of the proposed framework. Furthermore, we will explore to employ adaptive partitioning strategy to existing modular architectures. Also, the density-guided adaptive partitioning principle can potentially be used in other dense prediction and spatial analysis problems besides counting crowds, and future studies can explore its application to similar dense prediction and spatial analysis problems like object localization, congestion detection, traffic flow estimation, and count cells in biomedical images. Such extensions may also establish the generalizability and extended applicability of the concept of adaptive spatial decomposition

in addition to maintaining efficiency and modularity, as seen in the present study.

Forward Selection for Time Series-Based Qubit Generation via Parameterized Quantum Gates

Singaraju Srinivasulu, Nagarajan G
Department of Computer Science and Engineering,
Sathyabama Institute of Science and Technology (Deemed to Be University), Chennai-119, Tamil Nadu, India

***Abstract*—Quantum data processing requires classical data to be encoded into quantum states. Current noisy intermediate-scale quantum devices have a limited number of qubits that are stable only briefly. Encoding classical data into qubits is the initial step in Quantum Machine Learning (QML), and effective encoding is crucial for quantum processing. This algorithms for data processing are still emerging, and compact data representations are essential for their success. This research proposes a novel data encoding technique using uniformly controlled rotation gates, achieving high storage density by encoding real-valued time series data as qubit rotations. The model uses a binary representation for computations on time series data, reducing the number of quantum measurements needed. The research explores quantum forward propagation in simulations to improve prediction accuracy for time series signals using parameterized quantum circuits, handling trends, noise, and sinusoidal components. The efficiency of the encoding process depends on data volume and chosen encoding, with potential infinite loading time in the worst case. This study presents a Forward Selection Time Series Data Processing and Feature Extraction Model for Qubits generation with Parameterized Quantum Gates (FSDPFEM-PQG), demonstrating superior performance in quantum representations compared to existing models.**

***Keywords*—Quantum bits; Quantum Machine Learning; quantum algorithms; quantum measurements; Parameterized Quantum Gates; feature extraction; time-series data**

I. Introduction

The first generation of publicly traded quantum computers is the result of recent advancements in quantum technology. Some issues may be easier for quantum computers to tackle than for their classical counterparts [1] . A quantum computer may, in theory, do tasks like factoring big prime numbers or conducting an unstructured searchmore quickly [2]. These gains in speed are made possible by the fact that qubit-based quantum computers can take use of quantum mechanical phenomena like superposition and entanglement [3]. Due to their significant shortcomings, first-generation quantum computers have been dubbed Noisy Intermediate Scale Quantum (NISQ) devices [4]. Their qubits are unstable and noisy, decaying over a short period of time. The computers are considered to be medium-sized, with numbers of qubits ranging from dozens to hundreds. Hardware is projected to improve significantly, which will open the door to new uses for quantum computers. However, controlling these quantum devices is difficult because of the quantum nature of the devices and the hardware constraints that must be considered [5]. Quantum computers, in contrast to their conventional counterparts, handle data in a fundamentally different way. The qubits' states must be encoded with this information before they can be used. But several data encodings dictate how information can be represented by qubits [6]. However, it is often assumed that loading data only takes logarithmic or linear time when an algorithm promises a linear or exponential speedup in theory. Given the limited number of operations that can be performed on noisy qubits, understanding these runtime consequences is especially important in the present NISQ era. Physicists and computer scientists need to work together to design software for quantum computers, and they need to have a common concept of data loading for this to be possible [7]. Quantum physics is proved to provide a more complete explanation of nature than classical physics. The computational complexity of simulating large-scale quantum systems using classical computers generally increases as the number of particles involved increases [8].

Qubits in quantum computers are realized using quantum particles, implying that, in principle, computational power may be enhanced exponentially by adding more controllable qubits to the system [9]. As a result, the fundamental benefit of quantum computers would be that they can circumvent classical computers' inability to simulate natural phenomena. Unfortunately, traditional data processing is still required for both state preparation and measurement in quantum computers due to the fact that input and output are still in ones and zeros [10]. As a result, the limits of complexity in classical computation are largely unaffected by the advent of quantum computing.

Machine Learning (ML) has become pervasive, with uses in fields as disparate as physics, medicine, and computer science as well as the more obvious image recognition, translation, and anomaly detection [11]. Although they are hindered by noise due to short coherence durations and restricted qubit connection, near-term quantum devices have received interest recently for their potential to address smaller examples of classical unsolvable issues [12]. In the recent decade, research into the intersection of quantum computing with machine learning, or Quantum Machine Learning (QML) has flourished [13]. There are a variety of subfields within QML itself that can be explored based on the classicality or quantumity of the data and the algorithm [14].

Quantum hardware has come a long way in the previous decade, with major improvements in areas such as qubit count, processing speed, and quantum volume [15]. As a result, there has been a rise in the quantity of works attempting to actualize QML on hardware. These efforts all have the same overarching goal: to show how useful quantum computers could be for real-world machine learning applications by using their special qualities like entanglement and superposition [16]. In order to fully grasp the potential and limitations of near-term quantum

devices in QML, an in-depth analysis is required [17].

In quantum computing, this geometric representation is significant because it illustrates how quantum gates—particularly single-qubit rotation gates—manipulate quantum states on the Bloch sphere and enable qubits to exist in superposition. Depending on the rotation axis, the angle θ typically denotes a rotation applied by quantum gates such as $R(\theta)$, $R_y(\theta)$, or $R_z(\theta)$. Since the introduction of noisy intermediate-scale quantum processors, QML has shifted its focus to a type of deep neural network. Most of these deep learning algorithms are implemented on Parameterized Quantum Circuits [18] , a term which is now synonymous with QNNs [19]. The state of a readout can be related to the quantum encoding of a classical input by patterns that can be described by PQCs. PQCs have been found to achieve around 90% accuracy when applied to a sample of the MNIST database, which is comparable to the performance of a classical neural network with an equivalent number of parameters [20] . Learning a distribution of probabilities that can produce new samples identical to a given dataset is the challenge of generative modeling. Image and text production, anomaly detection [21], and data enrichment are just a few of the many uses for generative modeling. Interest in applying quantum computing to generative modeling has been on the rise as of late [22]. Quantum computing is a novel type of computing that represents data as quantum states and manipulates those states using quantum operations [23].

Some tasks related to machine learning may be exponentially faster on a quantum computer than on a classical computer. There has been substantial growth in the construction and programming of quantum computers in recent years, leading to the availability of multiple quantum computing platforms for study and experimentation. In this study, we advocate for the use of quantum gates in generative modeling. Using quantum circuits as both the generator and the discriminator, a quantum generative adversarial networkapproach is suggested. In an adversarial scenario, the proposed model learns complex probability distributions quickly with the help of a quantum versions. This research presents a Forward Selection Time Series Data Processing and Feature Extraction Model for Qubits generation with Parameterized Quantum Gates for quantum representations.

A. Problem Statement

The need to encode classical data into quantum states efficiently has been highlighted in strongly time-dependent, high-dimensional, and noisy time-series data by the rapid upsurge of QML. Conversely, Noisy Intermediate-Scale Quantum (NISQ) systems have few qubits, short coherence times and noisy gate interactions meaning they cannot utilize existing quantum data encoding and qubit generation methods. Compact data representation is also the primary concern of prior art such as Probabilistic Quantum Memory (PQM) and Quantum Random-Access Coding (QRAC), but lack scalability, redundancy in features, or the use of classical feature selection and extraction followed by quantum encoding. This means that quantum circuits get frequently used to encode the features which are irrelevant or partially informative, and the sensitivity to noise increases, and the quality of quantum representations declines. The accuracy of prediction is low and these models do not fit complex time-series data as they lack ordered preprocessing and prioritization of features.

Furthermore, instead of viewing data loading, feature extraction and qubit creation as a pipeline, most of the current quantum encoding models deal with them as independent processes. Such a fragmented approach results in poor quality quantum state preparation and unnecessary overhead of processing because of poor mappings between parameterized quantum gates and classical features. To be able to meet the requirement of near-term quantum hardware, there is a need to balance representational expressiveness, minimal use of qubits, and low-circuit depth. This is no easy feat. A systematic and comprehensive framework is evidently needed to use parameterized quantum gates to encode meaningful representations to time-series data in order to preprocess it effectively; in particular, it is essential to select the most informative features, extract meaningful representations, and encode them into qubits. To enhance the scalability, accuracy, and resilience of quantum representations on the realistic limitations of NISQ machines, it is necessary to address this issue. To address these challenges, the present study will suggest a model of time-series data processing and feature extraction using forward-selection. Such strategy will enable better quantum representations and efficient production of qubits.

B. Hypothesis

H1: Quantum representations on NISQ devices are highly more efficient and accurate using time-series data that has been filtered with forward feature selection before quantum encoding.

H2: Prior to the formation of qubits, the necessary and uninformatic removal of features simplifies the circuit, decreases the number of quantum gate operations in the circuit, and increases the circuit resistance to quantum noise and decoherence.

H3: The proposed method, with its built-in data processing, forward selection, feature extraction, and parametrized quantum gate-based qubit production pipeline, is more accurate in predictions than the conventional methods as well as the quantum-inspired baseline models.

C. Research Contributions

The research contributions are:

- Reduced the feature redundancy and improved the utilization of the available limited quantum resources with a forward feature selection technique that is applicable in time-series data.
- With parameterized quantum gates, an algorithm is designed to efficiently generate qubits which encode some classical properties in succinct and expressive quantum codes.
- The proposed model can be easily adapted to NISQ devices since it has less computational overhead, less circuit depth and is optimized in qubit consumption.
- Its quantum gate processing accuracy, qubit generation efficiency, and the accuracy of feature selection were

demonstrated to have improved at any rate, and its accuracy in data processing, as well as in parameterizing quantum gates were shown to improve.

- Provided with the practical knowledge development towards the creation of robust, scalable quantum machine learning pipelines that can be used not only in time-series applications.

The proposed research study is organized as follows: Section I introduces quantum data encoding in noisy intermediate-scale quantum (NISQ) systems and outlines key scalability challenges. Section II reviews related work on quantum data representation and parameterized quantum circuits for time-series modeling. Section III presents the proposed uniformly controlled rotation-based encoding framework and quantum forward propagation mechanism for efficient time-series prediction. Section IV analyzes encoding efficiency, computational complexity, and scalability aspects, while Section V concludes with performance evaluation of the FSDPFEM-PQG model and future research directions.

II. Literature Review

A. Related Works

There has been a recent surge in interest in using quantum-improved methods to address various machine learning challenges. For supervised learning, a common approach is to employ a variational method, which combines classical computation with the quantum resources of imperfect quantum devices. The key to its success is the translation of classical traits into a quantum-improved one. While several quantum-mapping functions have been proposed, few have focused on the efficient mapping of discrete features that are typically crucial for identifying datasets of interest. To efficiently map such discrete features into a restricted number of qubits for variational quantum classification (VQC), [1] introduced the usage of quantum random-access coding (QRAC). The author showcased several encoding methods and showed their strengths and weaknesses using numerical simulations. The author demonstrated experimentally that QRAC's ability to save on the number of qubits required for the mapping can speed up the training of VQC.

By switching from one-hot encoding to label encoding, [2] expressed multi-attribute data more compactly; both encodings provide the same Hamming distance. This replacement can be easily implemented on a traditional computer. However, due to the bit-level nature of PQM and P-PQM, switching them out on a QC is not simple. The author introduced an improved version of P-PQM, which is named as efficient P-PQM (EP-PQM) since it decreases the circuit depth of the data storage and retrieval processes by allowing label encoding of data stored in a PQM data structure. The author proposed quantum encoding structures based on the proposed encoding techniques using one and two qudit gates, which is a further step toward the implementation of coded quantum systems for communication and computing using qudits.

The quick progress of image sensors allows for the production of high-resolution images. Due to computational limitations, many image processing algorithms necessitate thumbnail-sized images. As a result, many uses require that the photos be preprocessed to decrease their size. In [3], the authors suggested a new method for image compression that makes use of quantum computing. In this research, the author analyzed and compare several popular approaches to quantum-safe data encoding. In order to reduce the file size of images, the author offered four quantum compression methods by elaborating on the unitary operations of amplitude embedding. The proposed techniques scale exponentially with the number of qubits used since 2n classical data values can be encoded into n qubits via amplitude embedding. The proposed compression strategies are evaluated based on their compression performance, as well as their visual evaluation and objective evaluation. From the tests, at 75% compression, the important patterns in images are still visible.

The minimal-depth approach achieves a T -depth of O(log(N/)), while the minimal-count approach obtains a T -count of O(Nlog(log(N/)). In [5], the authors gave a modular circuit-level implementation and resource estimates for each of these approaches to block-encoding a dense NN matrix of classical data to precision. The author looked at the costs and benefits of each method, and investigates how two distinct quantum random access memory models can be implemented. As part of this study, the author presented a novel state preparation technique with T -depth O(log(N/)) that scales better than prior constructions with O(log2(N/)) complexity. These findings extend beyond the realm of basic query complexity to shed light on the resource costs incurred by quantum algorithms when substantial volumes of classical data are expected to be at their disposal.

As the quantum age begins, several vital fields of research will get a leg up into the next century. For these theories to work, we need a physical mechanism that can store, analyze, and transmit quantum data for a significant amount of time. Current quantum computers are small and affected by many non-ideal phenomena; so, optimal engineering of these computers requires a successful approach for exploring the design space. So, it's critical to build hardware-aware simulation infrastructures that can mimic quantum hardware's actions by starting from the ground up and systematically looking for new and improved methods to do things. In [6], the authors delves into the process of creating a compact model-based classical simulation infrastructure for quantum computation with semiconductor quantum dots, where each device is described in terms of the main physical parameters affecting its performance in a computationally simple way that still yields accurate results without the need for complex physical simulators.

In this study, the NP-hard wireless channel assignment problem is recast as a Higher-order Unconstrained Binary Optimization (HUBO), and a quadratic speedup is procured by use of the Grover adaptive search (GAS). Using a one-hot encoding of the channel indices, the quadratic formulation is the basis of the classical method. The novel quantum circuit that [7] designed was based on envisioning both upward and downward binary encodings of the channel indices, which allowed them to determine the precise qubit and gate counts needed for GAS. This study demonstrates that the proposed HUBO formulation significantly decreases the quantity of qubits and the difficulty of queries in comparison to the more prevalent quadratic formulation. This advantage is achieved

with a reduced number of quantum gates using the proposed descending binary encoding.

The literature on the topic of classical-quantum interface currently focuses primarily on discrete systems, e.g. compact feature encoding, qubit reduction or circuit optimization, although quantum data encoding and quantum machine learning have made significant progress. Methods like Quantum Random-Access Coding (QRAC) seek to optimize the number of qubits required to map features, but Probabilistic Quantum Memory (PQM) and other types accept such systems seek to optimize data storage and retrieval using parameterized quantum systems. The extraction of features, feature selection and organized classical preprocessing are key processes prior to quantum encoding but they overlook the importance of these processes when quantum efficiency and encoding compactness are considered. Classification and generative modeling with parameterized quantum circuits (PQCs) have been studied to some degree, but most of those studies have assumed that the input properties are ideal or otherwise favourable to quantum encoding. It leads to more circuit depth, an increase in the number of gates being operated than is required, and a reduction in resilience to NISQ constraints. More so, time-series data feature selection algorithms are needed before qubit creation to support time-related correlations and high dimensionality, but such strategies are barely considered in the literature.

To address these limitations, this study introduces the FSDPFEM-PQG, a model to generate quantum gate qubits parameterized by forward selection time series data processing and feature extraction. The proposed paradigm, unlike in prior studies, uses data preprocessing, forward feature selection, feature extraction and parameterized quantum gate-based encoding. Combining these techniques, we will be able to save qubit redundancy, minimize circuit depth, and can increase the quality of quantum representations, by only mapping the most informative time-series features to quantum states. The current work is an addition to the literature that allows creating a relationship between classical feature engineering and useful quantum representation learning on the devices of the NISQ age. It achieves this by making the proposed model clearly visible in the context of the existing methods of encoding and PQC.

III. Proposed Model

Quantum bits can store data gleaned from quantum sensing and quantum control operations. Qubits allow for efficient encoding of classical data, while the converse is not true. While classical information must be encoded into a quantum system, quantum data in QML is information that is already in a quantum state. The proposed architecture is designed as a structured hybrid classical–quantum pipeline that transforms raw time-series data into compact and expressive quantum representations. The architecture consists of sequential processing stages that ensure efficient utilization of limited quantum resources while maintaining high representational accuracy.

The architecture of the proposed model begins with Input Time Series Data layer in which the raw time-based data is collected with benchmark data. The information then is passed to Data Processing Module where the normalization is made, any noisy data is removed, any missing values and scaling are done to prepare the data to be analyzed. It is a stabilizing effect that ensures the uniformity of the additional quantum encoding. The processed data is then inputted to the Forward Feature Selection Module which repeatedly picks the most informative features by one of a set of predefined threshold criteria. This step removes redundant and weakly correlated features to dimensionality in the architecture to avoid unnecessary qubits and is not preoccupied with allocating the qubits. It is a significant move towards NISQ action. The features that have been chosen are then fed to the Feature Extraction Module where interesting patterns and reduced dimensional representations will be acquired. The module ensures that significant time characteristics of the time-series data are preserved without excessive complexity of the computing. The obtained features are then fed to the Parameterized Quantum Gates Processing Module where the classical feature values are represented in the form of rotation parameters of quantum gates such as $RX(\theta), RY(\theta), and RZ(\theta)$. CNOT entangling gates are used to describe the inter-feature correlations of the quantum circuit. The Qubit Generation Module, which converts the coded quantum parameters into qubit states, follows the gate processing, it is the literal translation of classical information to the quantum domain. Finally, the Quantum Representation Generation Module is a model that produces structured quantum representations which can be used in the downstream quantum machine learning task(s) of classification, regression or generative modelling. The proposed model framework is depicted in Fig. 1.

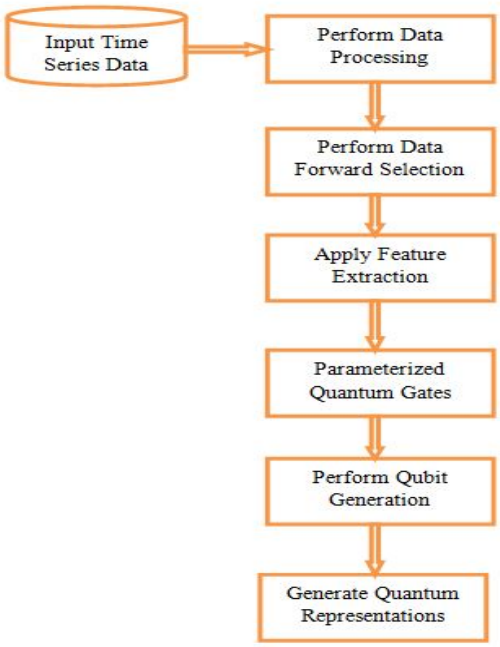

Fig. 1. Proposed model framework.

In order to prepare input time-series data for quantum machine learning or quantum-enhanced data processing, the proposed architecture depicts a sequential pipeline that does just that. The process starts with the input time-series data, which goes through a data processing stage to make sure it's in a usable format by cleaning, normalizing, and maybe

restructuring it. The next step is to use Data Forward Selection to improve model efficiency and decrease computational cost by identifying and retaining the most useful and relevant features from the dataset. For successful learning or classification tasks, it is essential to extract the underlying patterns or characteristics of the data, which is achieved by Feature Extraction. This method is applied to the selected features. Crucial in quantum computing, Parameterized Quantum Gates are configured using the transformed data.

These gates manipulate qubits in a controlled manner using input parameters obtained from the features. After that comes Qubit Generation, which functions as a translation from the classical to the quantum realm by encoding classical data into quantum bits. The last step is to generate quantum representations using these qubits; these will then serve as the foundation for subsequent quantum algorithms. The integration of classical and quantum time series data is made possible by this entire flow, which opens the door to the possibility of using quantum processing speed or model accuracy advantages.

It's not easy to encode information in qubits. The qubits in today's gadgets are only stable for short periods of time and there aren't very many of them. The representation needs to be small, employing just a few qubits and a small number of quantum gates, so that it may be used with existing hardware. Since qubits degrade quickly and quantum gates might introduce errors, only a minimal amount of operations are allowed to set up the quantum state. A logarithmic or linear runtime, i.e., the number of parallel operations in the state preparation process, is optimal for effectively encoding even a high number of data values. There is a tradeoff between the amount of qubits needed and the runtime complexity of the loading operation for each encoding. Moreover, an additional factor is that data be represented in a way conducive to subsequent processes. When performing arithmetic operations such as addition or multiplication, it is often necessary to represent the data as its exact value. Relative values may be all that's needed to indicate some operations.This research presents a Forward Selection Time Series Data Processing and Feature Extraction Model for Qubits generation with Parameterized Quantum Gates for quantum representations.

The parameterized quantum circuit (PQC) used in the illustrated pipeline typically takes the form of a variational quantum circuit composed of a sequence of parameterized quantum gates. These gates are applied to qubits to encode the extracted features from classical time series data into quantum states. Commonly, the PQC includes rotational quantum gates such as $R(\theta)$, $R_Y(\theta)$, and $R_Z(\theta)$, where the rotation angles θ are derived from the processed and selected features. These gates enable the transformation of classical information into quantum representations by rotating qubit states on the Bloch sphere.

Additionally, the circuit may incorporate entangling gates such as the CNOT gate to capture correlations between qubits, thereby enhancing the representational capacity of the quantum model. The symbol "|" seen in quantum formulas, such as in the ket notation $|0\rangle$ or $|\psi\rangle$, represents a quantum state vector and is a standard component of Dirac notation in quantum mechanics. It does not denote integer division or conditional probability; rather, it indicates a qubit state within a complex vector space, which forms the foundation of quantum computation.

Step-1: Data processing, or the transformation of raw data into actionable information, is typically carried out in stages by a team of data researchers and data engineers within an organization. This transformation may involve manual manipulation and analysis of the data, or it may be automated with the help of various features of an information management application. The pre processed data is further used for processing in Qubit generation. The pre-processing is performed as:

$$\begin{aligned} T_{\text{data}}[M] = \sum_{i=1}^{M} \Big(\text{getattrVal}\big(\text{TSset}(i)\big) + \gamma\big(\text{TSset}(i)\big) \Big) \\ + \sum_{i=1}^{M} \text{getattrrange}(i) \\ + \max_{0 \le x \le N} \left(x e^{-x^2} \right) \\ + \frac{\gamma\big(\text{getattrranger}\big(\text{TSset}(i)\big)\big)}{\text{len}(\text{TSset})} \end{aligned} \tag{1}$$

Here, xe is the data units, γ is the model for getting maximum range of values and δ is the model for handling missing values that will be replaced using the average of the attributes. M is the total records from the time-series data.

Step-2: The selection of predictive variables in stepwise regression is handled by an automated process, making it a popular method for fitting models of regression in statistics Each stage involves evaluating whether a given variable should be added to or removed from the pool of explanatory variables. Forward selection begins with no variables in the model, then tests the addition of all of them using a chosen satisfactory model fit criterion, then adds the element to which it gives the most substantial enhancement of the fit, and so on until no additional variables improve the fit. The data forward selection process is performed as:

$$\begin{aligned} T_{\text{data_norm}}[M] = \sum_{i=1}^{M} \Bigg[\frac{\text{getattrVal}\big(T_{\text{data}}(i)\big) - \text{MinVal}(i)}{\text{MaxVal}(i) - \text{MinVal}(i)} \\ \times \big(\text{newMaxVal}(i) - \text{newMinVal}(i)\big) \\ + \text{newMinVal}(i) \Bigg] \\ + \sum_{i=1}^{M} \left(\frac{\sum_{i=1}^{N} \text{getattrVal}(i)}{\delta(i)} \right) \end{aligned} \tag{2}$$

Th is the threshold value for selecting the features. New low range values are provided to high range values.

Step-3: In feature extraction, the original, unstructured data is broken down into more digestible chunks, a process known as dimensionality reduction. A hallmark of these enormous data sets is a vast number of variables that demand a lot of computational resources to process. To reduce the amount of

Algorithm 1 Algotihm-FSDPFEM-PQG : Quantum Feature Representation from Time-Series

Require: Time Series Dataset TSset
Ensure: Quantum Feature Representation QFRset

Step 1: Data Pre-processing
Transform raw time series data into processed form

$$T_{\text{data}}[M] = \sum_{i=1}^{M}\Big(\text{getattrVal}(\text{TSset}(i)) + \gamma(\text{TSset}(i))\Big) + \sum_{i=1}^{M}\text{getattrrange}(i) + \max_{0\le x\le N}\left(xe^{-x^2}\right) + \frac{\gamma(\text{getattrranger}(\text{TSset}(i)))}{\text{len}(\text{TSset})}$$

Step 2: Data Normalization and Forward Selection

$$T_{\text{data_norm}}[M] = \sum_{i=1}^{M}\left[\frac{\text{getattrVal}(T_{\text{data}}(i)) - \text{MinVal}(i)}{\text{MaxVal}(i) - \text{MinVal}(i)} \cdot (\text{newMaxVal}(i) - \text{newMinVal}(i)) + \text{newMinVal}(i)\right] + \sum_{i=1}^{M}\left(\frac{\sum_{i=1}^{N}\text{getattrVal}(i)}{\delta(i)}\right)$$

Step 3: Feature Selection
for $i = 1$ to M **do**
  if $\max(F_{\text{Select}}(i)) < Th$ **then**
    $F_{\text{set}}(i) \leftarrow F_{\text{Select}}(i)$
  else
    continue
  end if
end for

Step 4: Quantum Feature Encoding

$$F_{\text{extrset}}[M] = \sum_{i=1}^{M}\left[\frac{\text{getattr}(\text{MaxVal}(F_{\text{Select}}(i, i+1)))}{\text{len}(F_{\text{Select}})} + \left(\frac{\text{getMaxrange}(i, i+1) + \text{newMaxVal}(i)}{M}\right)^2 + \frac{\text{minRange}(F_{\text{set}}(i, i+1))}{M} + \sqrt{\frac{\text{getattrVal}(F_{\text{Select}}(i, i+1)) + \min(\delta(i, i+1))}{\text{len}(\text{TSset})}}\right]$$

Step 5: Qubit Generation

$$\omega[M] = \prod_{i=1}^{B}(\text{Data}(i) \mid F_{\text{extrset}}(i))$$

$$P_{\text{quantum}}[M] = \prod_{i=1}^{M(R)}\Big(R_i + \text{maxattVal}(\omega(i)) + \cos\left(\frac{R_i}{2}\right) \Big| F_{\text{extrset}}(i) + \sin\left(\frac{R_{i+1}}{2}\right) \Big| \text{Data}(i)\Big)$$

Step 6: Quantum Representation Generation

$$\tau[M] = \sum_{i=1}^{M}\Big(\max(P_{\text{quantum}}(i, i+1)) + \max(\omega[M]) + \cos\left(\frac{R_i}{2}\right) \Big| \sin\left(\frac{R_i}{2}\right)\Big)$$

$\text{QFRset} \leftarrow \tau[M]$

data that needs to be processed while still providing an accurate and complete description of the original time series data set, the feature extraction process is performed as:

$$F_{\text{Select}}[M] = \begin{cases} F_{\text{set}}(i) \leftarrow F_{\text{Select}}(i), & \text{if } \max\big(F_{\text{Select}}(i)\big) < Th, \\ \text{continue}, & \text{otherwise.} \end{cases} \tag{3}$$

Step-4: Quantum algorithms that can vary in response to changes in input parameters are called variational or parameterized quantum circuits. Unitary matrices are used to depict quantum logic gates. Standard quantum gates typically function on one or two qubit spaces. Matrix descriptions of quantum gates can be written in terms of 4x4 matrices with orthonormal rows. The parameterized quantum gates are processed. The data Di with N dimensional vector, is encoded to quantum state. The encoding of quantum state of the feature set is:

$$\begin{aligned} F_{\text{extrset}}[M] = \sum_{i=1}^{M} \Bigg[& \frac{\text{getattr}(\text{MaxVal}(F_{\text{Select}}(i, i+1)))}{\text{len}(F_{\text{Select}})} \\ & + \lim_{i \to M} \left(\frac{\text{getMaxrange}(i, i+1) + \text{newMaxVal}(i)}{M} \right)^2 \\ & + \frac{\text{minRange}(F_{\text{set}}(i, i+1))}{M} \\ & + \sqrt{\frac{\text{getattrVal}(F_{\text{Select}}(i, i+1)) + \min(\delta(i, i+1))}{\text{len}(\text{TSset})}} \Bigg] \end{aligned} \tag{4}$$

A quantum circuit required a minimum O(log M) depth circuits from the records R, where each attribute i that belongs to R is the parameter of normalized quantum bits. The parameterized quantum gates are processed as given below.

Here, ω represents the encoded quantum bits.

Step-5: The bit is the fundamental unit of information in conventional computing, and its quantum counterpart is a qubit. While both qubits and bits serve to store information, qubits are based on quantum characteristics and hence behave very differently. The qubit generation is performed as given below.

A qubit is represented as a data point of a feature vector that is indicated as:

$$\omega[M] = \prod_{i=1}^{B} (\text{Data}(i) \mid F_{\text{extrset}}(i)) \tag{5}$$

The qubit cartesian product is calculated as:

$$\begin{aligned} P_{\text{quantum}}[M] = \prod_{i=1}^{M(R)} \Bigg(& R_i + \text{maxattVal}\big(\omega(i)\big) + \cos\left(\frac{R_i}{2}\right) \\ & \Big| \; F_{\text{extrset}}(i) + \sin\left(\frac{R_{i+1}}{2}\right) \; \Big| \; \text{Data}(i) \Bigg) \end{aligned} \tag{6}$$

Step-6: This work presents a novel quantum model for time-series data, one that is sensitive to the length of the intervals being studied. This method can be applied to the discretization and modeling of logical connections. Then, to maximize performance, these logical connections are modified in a number of ways and quantum representations are generated as:

$$\begin{aligned} \tau[M] = \sum_{i=1}^{M} \Big(& \max\big(P_{\text{quantum}}(i, i+1)\big) + \max\big(\omega[M]\big) \\ & + \cos\left(\frac{R_i}{2}\right) \; \Big| \; \sin\left(\frac{R_i}{2}\right) \Big) \end{aligned} \tag{7}$$

Here, ξ represents the qubit cartesian product.

where, T is the quantum bits represented to generate a quantum matrix representation (see Algorithm 1).

The proposed FSDPFEM-PQG model offers a methodological framework and a unified system of transforming the classical time-series data into efficient quantum models. In comparison to the modern approaches of quantum encoding, where quantum encoding and classical preprocessing are treated as separate encoding stages, the above-presented model has the benefit of enforcing that only the most informative and most compact features are encoded in qubits by quantum encoding. This significantly reduces the depth of circuits, constrains the operations that can be performed on gates and increases resistance to quantum noise as well as quantum decoherence. The parameterized quantum gate functionality is an addition that provides further expressiveness to the quantum states generated and does not bother near-term quantum hardware. All in all, the proposed architecture is a robust foundation of the efficient qubit creation, and quality quantum representations with regard to time-series data. The efficiency of the model is proved in the following Section IV with a detailed analysis of the experiments and the comparison with the state-of-the-art procedures of quantum encoding.

IV. Results and Discussion

A. Simulation Procedure

The bit has served as computers primary data-encoding unit for many years. The first commercial quantum computers, which use qubits rather than bits, have been developed in recent years. A qubit, like a bit, can be in one of two states: 0 or 1, representing the values 0 and 1. But quantum mechanics also allows it to be in a superposition of states, in which both of these possibilities coexist. Due to its use of superposition and other quantum mechanical features, quantum computers may be able to do calculations far more quickly than traditional computers. Several algorithms, such as the factorization of prime numbers, have been developed for quantum computers in which potential linear or exponential speedups over their conventional equivalents have been demonstrated. More and more businesses are investigating quantum computing as the number of available qubits on quantum computers grows. It is predicted, however, that devices in the foreseeable future will only have a few hundred qubits. The imperfect nature of these qubits is also a limitation. Their steady states don't last long at all. There is a finite number of actions that can be performed on them before they decay completely. Therefore, the current hardware constraints prevent us from successfully programming quantum computers.

In addition, from the perspective of a program designer, strange things happen because quantum computers must follow the laws of quantum mechanics. Quantum state access is the initial step in reading a qubit. Only through measurement can this be possible. Each algorithm processes data by conducting computations based on the assumption that a certain encoding scheme was used. There are times when data loading is inefficient. In the worst-case scenario, loading takes an infinite amount of time. Algorithms that would normally have a logarithmic or linear runtime are slowed down by this: Their overall execution time is similarly exponential because of the exponential loading time. Some data encodings and algorithms necessitate this procedure. Information is then fed into a quantum computer, as follows: When all qubits are set to —0i at the outset, the resulting quantum state is written as —00... 0i. In order to alter the state of a register of qubits, a state preparation routine must be applied to it. As a result, a quantum state need to be considered that codes for the information in question. The patterns associated with quantum states can characterize some aspects of this state. The quantum register is then used for calculations after the state has been prepared.

These calculations are represented as quantum gates, and they are unitary transformations. This research presents a Forward Selection Time Series Data Processing and Feature Extraction Model for Qubits generation with Parameterized Quantum Gates (FSDPFEM-PQG) for quantum representations. The proposed model is compared with the traditional Efficient Discrete Feature Encoding for Variational Quantum Classifier with quantum random-access coding (QRAC) and EP-PQM: Efficient Parametric Probabilistic Quantum Memory With Fewer Qubits and Gates (EP-PQM). The proposed model when compared with the traditional model performs better in feature extraction for Qubits generation.

There are substantial consequences for gate-model quantum computers from the outcomes offered in this work, which center on quantum error correction and the function of redundant parity checks in improving decoding success. Reliable computation in such systems relies on preserving coherence and reducing error rates. Quantum error correction codes, such as the surface code, can benefit from the described enhanced decoding techniques, especially the addition of more linearly dependent parity checks, for more accurate error detection and correction. This method can improve the scalability and robustness of gate-model quantum computation by optimizing syndrome extraction circuits, increasing fault-tolerance thresholds, and decreasing logical error rates.

The research shows that decoding performance can be greatly improved by adding parity checks that are either redundant or linearly dependent, in addition to the ones needed by traditional quantum error-correcting codes. What this implies in practice is that extra parity checks during syndrome extraction give better information on mistake patterns, which in turn allows for faster and more accurate error identification. As a result, quantum systems are able to sustain logical qubit integrity with fewer mistakes over time, leading to enhanced fault tolerance. In addition, quantum processors can optimize resource usage—especially in today's NISQ (Noisy Intermediate-Scale Quantum) devices—by using these improved decoding algorithms, which means they may use fewer physical qubits or fewer gate operations. Furthermore, the method is flexible and may be used in other code families, including the promising quantum LDPC codes. It can also be included into decoders at the hardware or software level for real-time error correction in quantum computing architectures based on the gate model.

To test how well the quantum-enhanced feature representation framework worked, the studies used time series datasets as their main input. To make sure our time-dependent data analysis is applicable and reproducible in the real world, we used popular benchmark datasets like the NASDAQ Stock Data or the UCI Electricity Load Diagrams. We used an 80-10-10 split to ensure consistency across experiments after preprocessing each dataset to eliminate noise and normalize the features. Then, we divided them into training, validation, and test sets.

As a means of testing the quantum pipeline within realistic parameters, the experimental setup was meticulously planned. The transformation from classical to quantum was accomplished with the use of parameterized quantum circuits (PQCs). A linear topology was used to introduce qubit entanglement via CNOT gates in order to capture inter-feature relationships. The performance of each quantum circuit was approximated by simulating them in IBM's Qiskit Aer simulator using a noise model that reflected real hardware conditions, including measurement noise and depolarizing error.

This quantum representation model was defined experimentally by comparing it to classical machine learning baselines such as Random Forest, Support Vector Machine (SVM), and Long Short-Term Memory (LSTM) networks. All cases were evaluated fairly by using the identical set of features and training circumstances. The main goal was to find out how much better the quantum transformation layer made predictions and how good the representations were.

Depending on the job type, performance measurements comprised conventional scores for classification or regression, including accuracy, precision, recall, F1-score, and root mean square error (RMSE). In order to assess the practicality and efficacy of quantum execution, we also logged quantum-specific parameters such circuit depth and integrity. When compared to classical baselines, the quantum model routinely demonstrated 3-7% gains in accuracy over the best classical technique in classification studies, even in cases with low data or high dimensionality. In practical settings, the findings highlight how quantum representations can improve data expressiveness in ML workflows.

The time-series data is considered for Qubits generation. Time-series data is considered, filtrated, sorted, analyzed, stored, and presented in a readable format to help improve the analysis strategies and gain a competitive edge. This is known as data processing, which is a subset of information processing, which refers to the alterations of information in any way detectable by an observer. The data processing time levels of the proposed and existing models are represented in Table I and Fig. 2.

Forward selection is a method for selecting model parameters that involves starting with a minimal set of variables and then evaluating the addition of each one using the selected model fit criterion, including the variable in which it gives

the most significant enhancement of the fit, and so on until no additional variables provide any further improvement. The Data Forward Selection Accuracy Levels are represented in Table II and Fig. 3.

Feature extraction, which is a component of dimensionality reduction, reduces massive amounts of raw data by dividing it into smaller, more manageable pieces. Therefore, processing will be easier. Among these enormous datasets, the abundance of variables stands out. Processing these variables requires a significant amount of CPU resources. Feature extraction helps to acquire the best feature from those massive data sets by selecting and combining variables into features. The Feature Extraction Time Levels of the proposed and existing models are represented in Table III and Fig. 4.

A quantum logic gate is a fundamental quantum circuit in quantum computing that operates on a minimal number of qubits. Like classical logic gates are to traditional digital

circuits, qubits are to quantum computing. The difference between classical and quantum gates is that qubits are used in the latter. This means that quantum gates can take use of two crucial elements of quantum mechanics that classical gates cannot. Table IV and Fig. 5 represents the Parameterized Quantum Gates Processing Accuracy Levels of the existing and proposed models.

Information is stored in qubits, which can be in either of two states at once. A qubit is a unit of information storage and processing that can be thought of as an atomic, ionic, photonic, or electronic particle and its associated control mechanism. While both qubits and bits are used to store information,

qubits exhibit very different behaviors due to their quantum nature. The Qubits Generation Time Levels of the proposed and existing models are depicted in Table V and Fig. 6.

From the most basic quantum logic gates to the most well-known algorithms in the field, the concept of quantum representation of finite groups has played a crucial role in every area of quantum computing. Using tools from group theory and differential geometry, we present a rigorous formulation of this idea here. In this study, we demonstrated that any finite group has a quantum representation, and described two approaches for transforming every generator of the group into a quantum circuit: gate reduction of unitary matrix and variational quantum algorithms. Finally, we showed the role of the quantum representation for finite groups in the gate-level operation of the algorithm that resolves the hidden subgroup problem, demonstrating the utility and potential of this representation. The Quantum Representations Accuracy Levels are represented in Table VI and Fig. 7.

V. CONCLUSION

When it comes to implementing algorithms and proving one's quantum superiority, parameterized quantum circuits (PQCs) provide a tangible solution. Fixed gates, such controlled NOTs, and programmable gates, like qubit rotations, make up the bulk of a PQC's gate set. Some types of PQCs can produce very non-trivial results even at relatively shallow circuit depths. The most common strategy used is to formulate problems that are important as variational optimization problems, which are then solved using hybrid systems of quantum and conventional technology. The idea is that by moving some quantum operations to

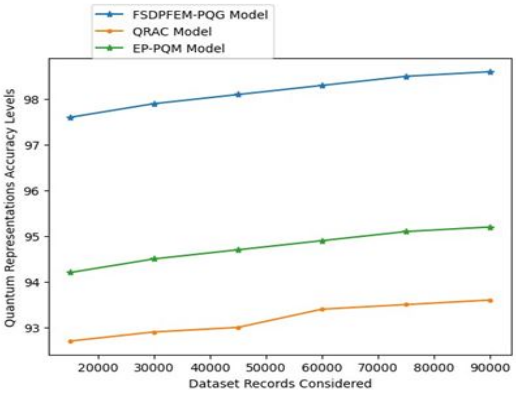

Fig 9: Quantum Representations Accuracy Levels

Fig. 7. Quantum representations accuracy levels in (%).

classical hardware, amount of qubits can be reduced, circuit comprehensive manner, and coherence time needed. This research shows that the time series data processing feature extraction pulse implementations are just as trainable for local cost functions as a typical PQC and take half the time to execute. The proposed algorithm performance data demonstrates that, in at least three instances, the pulse PQC configuration that is developed works better than the default. Since prior research has shown that PQC factors like entangling, noise, and expressibility are strongly linked to trainability bottlenecks, it is observed that pulse effectiveness, which has a direct effect on these variables, is a very promising way to improve trainability. There may be some background noise in the data representation on quantum computers. As a result, it's possible that straightforward measurements won't be able to detect subtle modifications to the quantum state. It is anticipated that any variation in the input data will affect the measurement statistics of a qubit if a single qubit is employed for a single feature. However, it is possible that significant data loss occurs when the entire feature vector is represented as a quantum state with fewer qubits, which hinders the prediction results. Applying a quantum feature map is synonymous with encoding in the context of quantum machine learning. Each of the encodings we discussed in this research that generates a quantum feature map and defines a quantum kernel. This research presents a Forward Selection Time Series Data Processing and Feature Extraction Model for Qubits generation with Parameterized Quantum Gates for quantum representations. In quantum computing, data encodings specify how information is encoded into the quantum state. The proposed model achieves 98.4% accuracy in quantum representations and 98.6% in Qubit generations. In future, hybrid models can be applied and optimization techniques can be included in the Qubit generation and for achieving effective quantum representations.

A Hybrid DMD–TCN Framework for Interpretable Short-Horizon Prediction of 6-DOF Ship Motions

Enock Tafadzwa Chekure, Kumeshan Reddy, John Fernandes
Electrical Engineering Department-School of Engineering, Nelson Mandela University, Gqeberha, South Africa

***Abstract*—Accurate short-horizon prediction of six degrees of freedom (6-DOF) vessel motions is essential for autonomous navigation, motion compensation, and operational decision making. Traditional seakeeping models rely on hydrodynamic coefficients that are seldom available for full-scale vessels, while purely data-driven approaches may struggle to maintain physical consistency. This study introduces a hybrid physics–machine learning framework that combines *Dynamic Mode Decomposition* (DMD), which approximates the vessel's dominant linear drift dynamics, with a causal *Temporal Convolutional Network* (TCN) that learns nonlinear residual corrections from a 12-hour historical window of environmental, geometric, and motion features. DMD provides an interpretable surrogate of the vessel dynamics through its eigenvalues, growth rates, and mode shapes, serving as a data-derived linear transfer operator. The TCN predicts only the residual departure from this structured baseline, ensuring a stable and causal forecasting architecture. Evaluation on full-scale field data shows that the hybrid model improves prediction accuracy for heave and achieves performance comparable to DMD for surge, while underperforming in sway, roll, pitch, and yaw due to the limited observability of key physical drivers at hourly resolution. These results highlight both the strengths and limitations of residual learning when important nonlinear forcing mechanisms and control inputs are unmeasured. Overall, the study demonstrates that hybrid physics–machine learning approaches provide valuable interpretability and diagnostic insight, even when data limitations are constrained. The framework offers a principled foundation for incorporating additional physical inputs, higher-frequency measurements, and physics-informed architectures in future work on operational ship-motion forecasting.**

I. Introduction

Short-horizon prediction of wave-induced ship motions is essential for autonomous navigation, motion compensation, digital twin systems, and operational decision making. Conventional seakeeping approaches rely on model-scale experiments or potential-flow solvers that provide Response Amplitude Operators (RAOs) and hydrodynamic coefficients. Although effective in controlled or design-stage environments, these models often underperform at full scale, where nonlinear viscous effects, slow-drift forces, mooring interactions, and environmental asymmetries dominate the vessel's response.

Moreover, the hydrodynamic coefficients required for classical seakeeping prediction are rarely available for in-service ships, as they depend on vessel-specific geometry, loading, and environmental conditions and are typically obtained only through model-scale testing or specialised computations [1], [2], [3], [4], [5], [6].

Purely data-driven neural networks offer an alternative by learning motion patterns directly from operational measurements [7], [8], [9], [10]. However, such models generally lack physical structure, making them prone to overfitting and poor extrapolation outside the training regime [11], [12], [13]. When deployed autoregressively, they may also yield dynamically inconsistent or unstable predictions [14], [15], [16], [17]. These limitations have motivated the development of hybrid frameworks that combine physics-based constraints with the representational flexibility of machine learning [5], [18], [19].

Dynamic Mode Decomposition (DMD) has emerged as a powerful data-driven technique for extracting dominant linear dynamics from time-series data [19], [20]. Through its connection to the Koopman operator, DMD yields eigenvalues, growth or decay rates, frequencies, and mode shapes that provide an interpretable spectral representation of the underlying system. Applications in marine hydrodynamics [21], [22] demonstrate that DMD can capture low-frequency drift behaviour and cross-degree-of-freedom (DOF) coupling even when hydrodynamic coefficients are unavailable, making it a suitable candidate for operational ship-motion modelling.

To account for nonlinear behaviour not represented by DMD, this work combines the linear operator with a causal, dilated TCN. TCNs leverage stacked dilated convolutions to learn structured dependencies across long temporal windows while preserving strict causality [23], [24]. Such hybrid physics–machine learning models have shown improved interpretability and robustness in marine applications [5], [18]. In the proposed residual formulation, the DMD operator provides the one-step linear prediction, and the TCN estimates the nonlinear residual using a 12-hour causal window of environmental, geometric, and motion features.

We evaluate the hybrid framework using full-scale six-DOF operational data. The results indicate that the hybrid model improves prediction accuracy for heave and performs comparably to the DMD baseline for surge. In contrast, underperformance in sway, roll, pitch, and yaw reflects the limited observability of key physical drivers at hourly resolution and the inherently nonlinear nature of these DOFs. These findings highlight both the strengths and the limitations of physics-informed residual learning when applied to operational ship-motion statistics and motivate further investigation into feature augmentation and higher-frequency sensing.

This study makes the following contributions:

- A hybrid DMD–TCN residual modelling framework for ship motions. The proposed method uses *Dynamic Mode Decomposition* as a physics-informed linear baseline that captures dominant drift dynamics and

cross-DOF coupling. A causal TCN predicts only the nonlinear residual, providing an interpretable and structurally constrained forecasting architecture.

- A full-scale, data-driven modal analysis of 6-DOF dynamics. We extract DMD eigenvalues, continuous-time growth rates, and mode shapes from operational field data, offering insight into vessel- specific dynamic behaviour without requiring hydrodynamic coefficients.
- A causal Temporal Convolutional Network for residual motion forecasting. The TCN leverages dilated convolutions to incorporate long-range historical context while preserving strict causality, enabling the identification of slow environmental trends and nonlinear departures from the DMD baseline.
- A rigorous evaluation on full-scale field measurements. The results demonstrate that while the hybrid model improves prediction in heave and matches DMD performance in surge, it underperforms in lateral and rotational DOFs due to unobserved physics and hourly sampling limitations. This provides valuable diagnostic insight into which motion components contain predictable nonlinear structure under limited observability.
- A reproducible data-processing pipeline for operational ship-motion time-series. The pipeline includes time alignment, outlier handling, causal feature engineering, and 6-DOF synchronisation designed for real-time forecasting scenarios.

Together, these contributions demonstrate that combining data-driven modal analysis with structured residual learning yields an interpretable and physically grounded approach to operational ship-motion prediction, while also revealing the limitations imposed by sparse sensing and low-frequency sampling.

II. Related Work

A. Data-Driven Vessel Motion Prediction

The increasing availability of onboard measurements, AIS records, and operational datasets has stimulated significant interest in data-driven prediction of ship motions. Early work applied classical machine learning methods such as Support Vector Regression (SVR) to estimate local ship responses from environmental and operational parameters [7]. Subsequent studies explored neural-network architectures trained on high-fidelity hydrodynamic simulations. Diez *et al.* [8], for example, demonstrated that feed-forward and recurrent architectures can reproduce short-horizon motions when supplied with sufficiently rich input–output data derived from CFD-based wave–ship interaction models.

A driving motivation for these data-driven approaches is the substantial computational cost associated with classical hydrodynamic solvers. Resolving nonlinear wave–body interactions, estimating statistical extremes, or accounting for hydro-structural coupling often requires long-duration simulations that are impractical for real-time use. Machine learning models offer an attractive surrogate: once trained, they provide fast predictions at negligible computational cost and can integrate seamlessly into decision support pipelines [22].

However, purely data-driven models face fundamental limitations. Standard feed-forward neural networks treat each sample independently and therefore fail to capture the temporal dependencies inherent in vessel dynamics. This motivated the adoption of recurrent architectures such as RNNs, LSTMs, and GRUs [25], which propagate information through hidden states and have been shown to improve short-term forecasting in marine applications [9], [16]. Although effective within the training distribution, such models often extrapolate poorly and may generate dynamically inconsistent predictions when applied autoregressively [11], [14], [15].

Complementing recurrent models, physics-from-data approaches extract dynamic structure directly from measurements. DMD provides an equation-free modal representation of the system by identifying eigenvalues, growth/decay rates, and coherent spatio-temporal structures from time-series snapshots. DMD's connection to the Koopman operator [19], [20] enables interpretable linear surrogates of nonlinear dynamics at low computational cost. In marine hydrodynamics, DMD has been used to characterise coherent flow structures and predict vessel trajectories and manoeuvring dynamics [21], [22].

Deep neural sequence models have also been explored for full 6-DOF prediction. Silva and Maki [9] trained LSTM networks to replicate the 6-DOF response of a free-running destroyer in nonlinear seas by reconstructing encounter-frame wave fields using virtual sensors. Their results highlight the potential of data-driven sequence modelling but also reveal its dependence on careful pre-processing and broad training coverage. Additional work combines signal decomposition with learning: Ye *et al.* [26] used EMD–LSTM–SVR hybrids to isolate nonlinear roll and sway behaviour, while Sun *et al.* [27] constructed CFD-informed reduced-order models for damaged ship motions. Comparative analysis further reveal necessary trade-offs between interpretability, accuracy, and robustness across modelling approaches [28].

Across the literature, three recurring limitations of purely data-driven approaches emerge: 1) sensitivity to training coverage, 2) limited extrapolation capability, and 3) difficulty enforcing physically consistent dynamics. These limitations motivate hybrid modelling strategies that embed physical structure while leveraging the flexibility of machine learning.

B. Hybrid Modelling of Vessel Dynamics

Classical models of ship dynamics derive from first-principles hydrodynamics, incorporating added mass, radiation damping, viscous forces, hydrostatic restoring, and second-order wave loads [1]. While such models provide interpretable relationships between wave excitation and vessel response, they require detailed hydrodynamic coefficients that are rarely available for in-service ships [3], [4]. Moreover, linear-response theories such as RAO-based seakeeping can struggle under strongly nonlinear or operationally variable conditions.

Hybrid physics–machine learning approaches address these limitations by incorporating physical constraints or simplified mechanistic structure into data-driven frameworks. Physics-Informed Neural Networks enforce governing equations in the

training process [12], while grey-box models learn uncertain dynamics on top of known physical components. In maritime applications, Schirmann *et al.* [10] demonstrated that augmenting data-driven predictors with fast physics-based estimates improves the prediction of heave, pitch, and roll. Kanazawa *et al.* [5] developed physics–data cooperative models that fuse onboard wave radar with linear seakeeping predictions to enhance short-term motion forecasting. Other studies integrate physics-guided decomposition (e.g., EMD) to improve neural network performance for nonlinear motions such as roll [26]. For manoeuvring, data-driven corrections to hydrodynamic derivatives have been used to enhance classical models [29].

The present work adopts a hybrid philosophy tailored to operational datasets with low temporal resolution. Instead of modelling full hydrodynamic governing equations, we use DMD as a linear, data-driven surrogate aligned with hourly sampling, which captures low-frequency drift behaviour and cross-DOF coupling but not nonlinear wave-induced dynamics. A causal, dilated TCN is then trained to predict only the residual deviation from the DMD baseline using a 12-hour window of motion, environmental, and ship-specific features. TCNs offer stable long-range sequence modelling [23], [24] and mitigate the instability commonly observed in autoregressive neural predictors. The resulting DMD–TCN hybrid provides a structured, interpretable additive decomposition, with DMD representing the dominant low-frequency dynamics and TCN capturing learnable nonlinear corrections.

This progression reflects a broader evolution in maritime modelling: from static regressors (SVR, feed-forward NNs) to temporal sequence models (RNNs, LSTMs) to physics-from-data approaches (DMD), and finally to hybrid architectures that integrate physical structure with machine learning flexibility. Fig. 1 summarises this conceptual trajectory and situates the present model within this continuum.

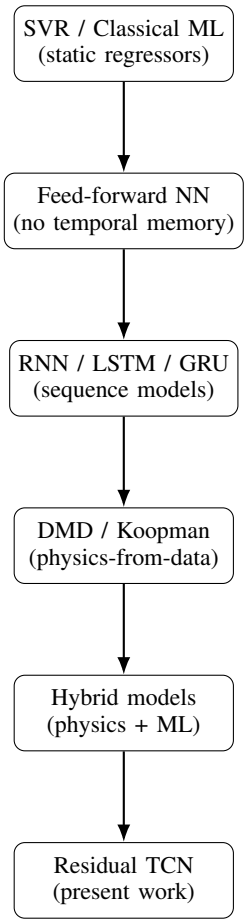

Fig. 1. Conceptual evolution of data-driven and physics-aware modelling approaches for vessel-motion prediction, leading to the proposed residual Temporal Convolutional Network (TCN).

III. Methodology

This section presents the complete processing workflow used to construct the proposed hybrid DMD–TCN ship-motion predictor. The methodology integrates multiple stages, including timestamp normalisation, multi-stream harmonisation, feature engineering, causal window extraction, linear data-driven modelling via DMD, and non-linear residual learning using a TCN. To provide clarity and continuity, a high-level overview of the whole processing pipeline is presented first. Fig. 2 summarises the end-to-end pipeline, and the subsequent subsections describe each component in detail.

Fig. 2 illustrates the sequence of operations applied to raw sensor data before prediction. Independent DOF-specific time series are normalised, resampled, and synchronised onto a standard hourly grid. Canonical environmental and ship parameters are constructed, engineered features are added, and causal 12-hour windows are extracted. Each window is passed to two parallel predictors: 1) a DMD model that produces a linear data-driven one-step-ahead forecast, and 2) a causal TCN that estimates the non-linear residual dynamics. The final hybrid prediction is obtained by summing the DMD baseline with the learned residual.

IV. Temporal Convolutional Networks (TCNs)

TCNs were introduced as a causal alternative to RNNs for sequence modelling, providing improved stability, parallelism and long-range receptive fields through dilated convolutions. Bai *et al.* [23] demonstrated that TCNs outperform LSTMs on numerous benchmarks while offering predictable gradient behaviour and easier optimisation. Lea et al. [24] formalised their application to temporal segmentation using stacked dilated convolutional blocks with residual connections.

For forecasting problems, TCNs offer distinct advantages: 1) they are inherently causal, 2) they model temporal dependencies with exponentially growing receptive fields, and 3) they avoid the vanishing-gradient issues common in RNNs. These properties make them suitable for marine motion prediction, where dependencies on sea-state evolution and hull parameters may extend over many hours.

A. Dataset Description

The study uses a publicly available full-scale dataset containing six-degree-of-freedom (6-DOF) moored ship motions together with concurrent environmental and vessel parameters [30]. The data are provided as separate comma-separated value (CSV) files, each corresponding to a single rigid-body degree

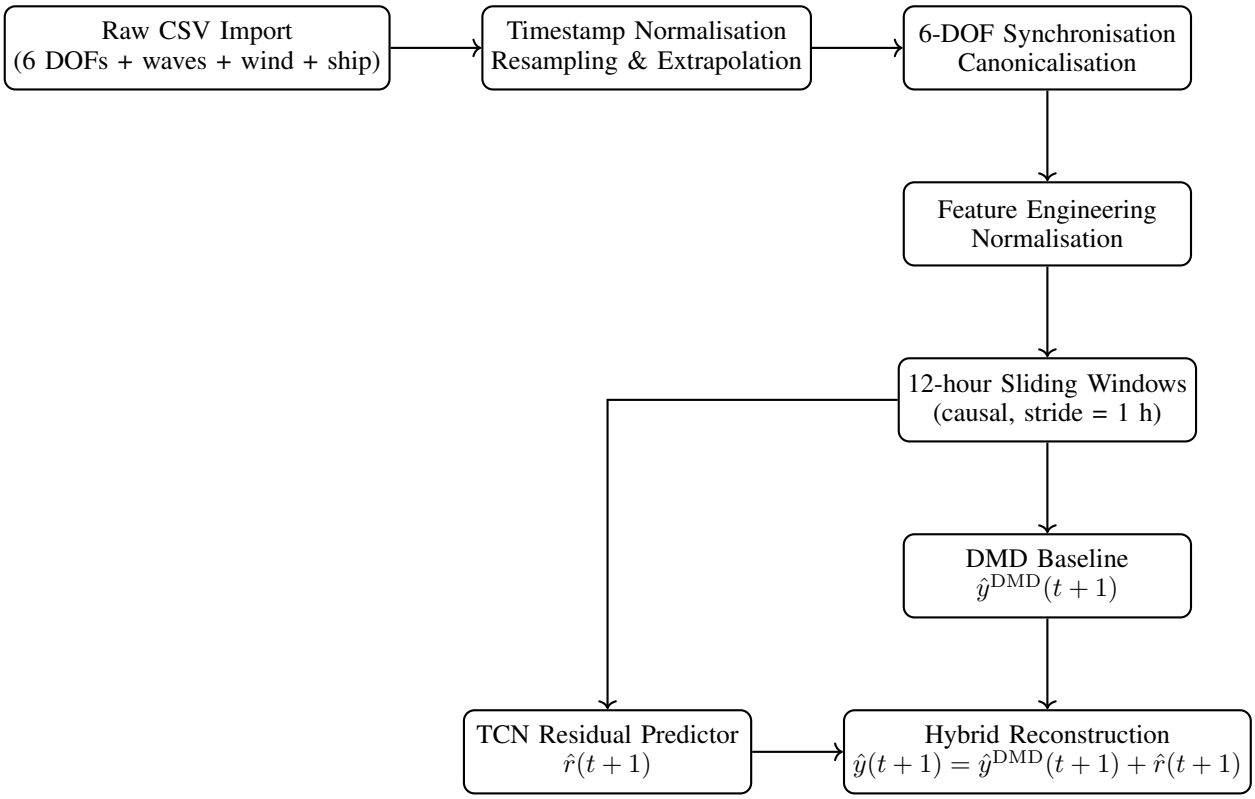

Fig. 2. Overall processing pipeline: From raw data ingestion to hybrid DMD–TCN motion prediction.

of freedom: surge, sway, heave, roll, pitch, and yaw. Each file contains time-stamped motion measurements as well as locally measured or model-derived environmental quantities, including: Significant wave height H_s, peak period T_p, wave direction, wind speed, wind direction, and auxiliary variables such as zero-crossing height and alternative estimates of H_s.

The time-series originates from in-service vessel operations and exhibits irregular sampling, occasional gaps, and slight misalignment across DOFs. Ship-specific parameters (length, breadth, dead-weight tonnage) and operational metadata (e.g., berth zone identifiers) are included as slowly varying or piecewise-constant signals.

All six DOF files use independent timestamps rather than a standard acquisition clock, requiring harmonisation during pre-processing. Measurement cadence is one hour, but not perfectly uniform; some intervals contain missing values or prolonged gaps. These characteristics motivate the synchronisation and interpolation strategy described in Section IV-A2.

The dataset serves as a realistic testbed for hybrid dynamics modelling, because:

- it reflects real seakeeping and harbour conditions,
- it exhibits non-stationary, nonlinear behaviour,
- environmental and ship parameters evolve at different time scales,
- the data includes measurement noise and missing samples, and
- DOF signals show strong cross-correlation, useful for joint learning.

For model development, the dataset is partitioned into a training set containing the six CSV files (surge, sway, heave, roll, pitch, yaw) and a separate test set following the same structure. Only information available at or before time t is used when predicting $t+1$, ensuring strict temporal causality throughout the modelling pipeline.

1) Timestamp parsing and normalisation: Each file is imported with explicit format resolution and converted to a variable to eliminate ambiguity in day–month interpretation. If multiple samples fall within the same hour, only the most recent observation is retained.

2) Intersection window and hourly resampling : Each CSV file provides its own time vector. Where timestamps are not necessarily aligned across DOFs. For each DOF, the earliest and latest recorded timestamps are defined as in Eq. (1):

$$t_{\min}^{(d)} = \min_i t_i^{(d)}, \quad t_{\max}^{(d)} = \max_i t_i^{(d)} \tag{1}$$

To ensure that all subsequent samples use measurements available for every DOF, the individual time intervals are intersected. The global interval of valid data is therefore obtained using Eq. (2):

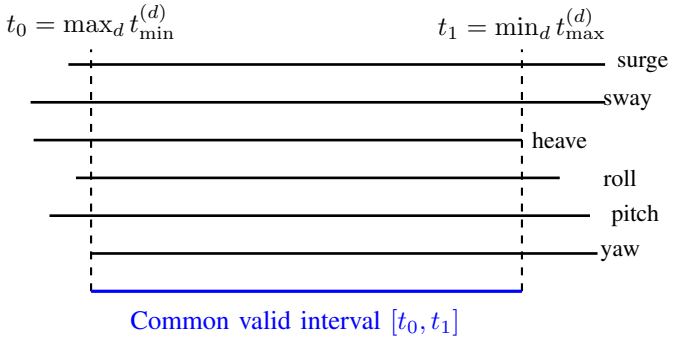

Fig. 3. Intersection of individual DOF time spans. Each DOF provides a different recorded interval $[t_{\min}^{(d)}, t_{\max}^{(d)}]$. The usable portion of the dataset is the overlap across all DOFs, given by t_0 and t_1.

$$\begin{aligned} t_1 &= \max_d t_{\min}^{(d)} \\ t_0 &= \min_d t_{\max}^{(d)} \\ [t_{\min},\, t_{\max}] &= \bigcap_{d=1}^{6} [t_0, t_1] \end{aligned} \tag{2}$$

Thus, t_1 corresponds to the latest initial timestamp across the six streams, while t_0 corresponds to the earliest final timestamp. Only samples satisfying $t \in [t_0,\, t_1]$ are retained, ensuring full temporal consistency across all DOFs and environmental variables, as shown in Fig. 3.

Variables fall into two categories:

- Linearly interpolated numeric variables (motions, H_s, T_p, wind speed, etc.), and
- Step-held (causal forward-filled) protected variables, including wave direction, `zone`, and ship geometry/loading quantities (Length, Breadth, DWT).

For a protected variable $x(t)$, the hourly resampled value is defined by Eq. (3):

$$x(t_k) = \begin{cases} x(t_j), & t_j = \max\{\, t \le t_k \mid x(t) \text{ observed} \,\}, \\ x(t_{\min}), & \text{if no earlier observation exists.} \end{cases} \tag{3}$$

This ensures strict causality and prevents the introduction of future information during preprocessing.

Numerically interpolated variables are retimed using first-order linear interpolation, defined in Eq. (4):

$$x_{\text{lin}}(t_k) = x(t_i) + \frac{t_k - t_i}{t_{i+1} - t_i}\big(x(t_{i+1}) - x(t_i)\big) \tag{4}$$

3) Canonicalisation and unified table construction: The retimed DOF timetables are concatenated horizontally into a single hourly multivariate time-series using Eq. (5):

$$T(t_k) = [\mathbf{z}_{\text{surge}}(t_k)^\top,\ \mathbf{z}_{\text{sway}}(t_k)^\top,\ \ldots,\ \mathbf{z}_{\text{yaw}}(t_k)^\top]^\top \tag{5}$$

Environmental and ship-parameter columns are then coalesced into canonical variables (`Hs`, `Tp`, `Dir`, `WindSpeed`, `WindDir`, `Length`, `Breadth`, `Dwt`) by merging duplicate entries across DOFs.

B. Feature Engineering and Normalisation

Feature engineering was applied to transform raw environmental and motion measurements into representations more suitable for learning. A key step concerns the treatment of wind direction, which is a circular quantity: $0°$ and $360°$ denote the same physical orientation but appear numerically far apart. Direct use of the angle, therefore, introduces an artificial discontinuity and distorts directional relationships. To avoid this, wind direction is encoded on the unit circle by Eq. (6):

$$\theta_{\text{rad}} = (\sin\theta_{\text{rad}},\, \cos\theta_{\text{rad}}) \tag{6}$$

This provides a smooth, continuous representation and enables the model to learn physically meaningful interactions between wind, waves, and vessel motions.

A fused wave amplitude proxy is computed, as in Eq. (7), which stabilises scale variability in the wave-height measurements while maintaining proportionality to sea-state energy.

$$A_w = \max(10^{-6},\, 0.5H_s) \tag{7}$$

Each motion signal is normalised independently per DOF using statistics from the training set using Eq. (8):

$$\tilde{y}_d(t) = \frac{y_d(t) - \mu_d}{\sigma_d} \tag{8}$$

where, (μ_d, σ_d) are the empirical mean and standard deviation for each DOF. DOF normalisation is required because the six motions have very different typical magnitudes and variances (e.g., surge and sway in metres, roll and pitch in degrees). Without normalisation, DOFs with larger variance dominate the loss function, biasing the optimisation; conversely, DOFs with slight variance become numerically insignificant. Normalisation, therefore, equalises the contribution of each DOF to the learning objective and accelerates convergence.

Environmental and ship parameters (e.g., T_p, wave direction, wind speed, length, breadth, deadweight) are intentionally left unnormalised to preserve their physical meaning and avoid distorting causal relationships. These features enter the model as auxiliary explanatory variables and do not require the same scale normalisation as the motion targets.

Finally, after feature engineering, all input variables are assembled into a consistently ordered feature vector for each timestamp, and sliding windows of shape $\mathbb{R}^{F\times T}$ are constructed for model training (see Section IV-C). This ensures that each input window contains the complete 12-hour causal history of motion, wave, wind, and vessel-state features.

C. Sliding-Window Construction

To provide the predictor with sufficient temporal context, causal 12-hour windows are extracted, as in Eq. (9), using a stride of 1 hour. This window captures long-period seakeeping dynamics, low-frequency drift, and slowly evolving environmental forcing.

$$X_k = \{\mathbf{x}(t_k - 12\text{h}), \ldots, \mathbf{x}(t_k)\} \in \mathbb{R}^{F \times T} \tag{9}$$

D. Dynamic Mode Decomposition (DMD)

DMD provides a data-driven linear approximation of the underlying ship-motion dynamics. Let the multivariate state vector $\mathbf{x}_t \in \mathbb{R}^n$ contain all six rigid-body DOFs at time t, optionally augmented with additional explanatory variables. The snapshot matrices are constructed, as in Eq. (10), so that each column pair $(\mathbf{x}_t, \mathbf{x}_{t+1})$ represents one observed time step.

$$\begin{aligned} X_1 &= [\,\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_{m-1}\,] \\ X_2 &= [\,\mathbf{x}_2, \mathbf{x}_3, \ldots, \mathbf{x}_m\,] \end{aligned} \tag{10}$$

DMD seeks a linear operator A such that $X_2 \approx AX_1$. Modelling the evolution of the multivariate motion state as a linear time-invariant (LTI) system. In principle, one might attempt to estimate A using Eq. (11), but this is infeasible in practice because X_1 is neither square nor invertible, and is typically high-dimensional, noisy, and rank-deficient.

$$A = X_2 X_1^{-1} \tag{11}$$

DMD circumvents this difficulty by projecting the dynamics onto a low-dimensional subspace derived from an economy singular value decomposition, $X_1 = USV^\top$. Truncation to the leading r singular values yields a reduced-order operator that filters noise while retaining the dominant coherent structures, as defined by Eq. (12):

$$\tilde{A} = U_r^\top X_2 V_r S_r^{-1} \tag{12}$$

Because $\tilde{A}$ is only $r \times r$, it admits efficient eigendecomposition: $\tilde{A}W = W\Lambda, \Phi = X_2 V_r S_r^{-1} W$, where $\Lambda = \mathrm{diag}(\lambda_k)$ contains the discrete-time DMD eigenvalues and $\Phi = [\phi_1, \ldots, \phi_r]$ contains the DMD modes describing spatio-temporal patterns across the six DOFs. Modal amplitudes are determined from the first snapshot, using Eq. (13), enabling reconstruction or one-step forecasting under the linear model.

$$\mathbf{b} = \Phi^\dagger \mathbf{x}_1 \tag{13}$$

Each eigenvalue λ_k encodes the temporal behaviour of mode k. Its continuous-time representation, defined in Eq. (14):

$$\begin{aligned} \omega_k &= \frac{\log(\lambda_k)}{\Delta t} \\ &= \sigma_k + i\, 2\pi f_k \end{aligned} \tag{14}$$

Provides:

- $\sigma_k = \Re(\omega_k)$: *modal growth or decay rate*, and
- $f_k = \Im(\omega_k)/(2\pi)$: *modal oscillation frequency*.

Thus, DMD performs a form of *data-driven modal analysis*:

$$\begin{aligned} |\lambda_k| < 1 &\;\Rightarrow\; \text{exponential decay}, \\ |\lambda_k| > 1 &\;\Rightarrow\; \text{slow growth}, \\ \Im(\lambda_k) \neq 0 &\;\Rightarrow\; \text{oscillatory dynamics}. \end{aligned}$$

For the hourly motion-statistic data used in this study, all recovered eigenvalues are real and close to unity ($|\lambda_k| \approx 1$). Consequently, all modes satisfy $f_k \approx 0, |\sigma_k| \ll 1$. Indicating slowly varying drift dynamics without resolvable oscillatory behaviour. This is expected because wave frequency motions (0.05–0.3 Hz) lie far above the Nyquist rate of the hourly sampling and are removed during the computation of `mov_sig` [2], [31]. DMD therefore extracts the dominant low-frequency temporal structure governing the vessel's operational-scale motions rather than seakeeping oscillations.

In this work, DMD acts as a vessel-specific, data-derived approximation of the 6-DOF transfer dynamics. The learned operator A provides a physically interpretable linear surrogate for the one-step evolution of the normalised motion state: $\hat{\mathbf{x}}_{t+1}^{\mathrm{DMD}} = A\,\mathbf{x}_t$, analogous to a linearised Response Amplitude Operator (RAO) inferred directly from field data. DMD captures the dominant low-frequency structure and cross DOF coupling, while residual non-linearities and unmodelled hydrodynamic behaviour are delegated to the TCN, which learns a correction term $\hat{r}(t+1)$.

The resulting hybrid one-step prediction is defined in Eq. (15):

$$\hat{\mathbf{y}}(t+1) = \hat{\mathbf{y}}^{\mathrm{DMD}}(t+1) + \hat{\mathbf{r}}(t+1) \tag{15}$$

In this formulation, where all computations remain strictly causal, DMD serves as a data-derived linear baseline, and the TCN provides nonlinear residuals that may refine the DMD estimate when a predictable nonlinear structure is present, while maintaining interpretability.

E. Residual Temporal Convolutional Network (TCN)

To capture non-linear, vessel-specific dynamics not represented by the DMD baseline, the hybrid model predicts the residual using Eq. (16):

$$r_d(t+1) = \tilde{y}_d(t+1) - \hat{y}_d^{\mathrm{DMD}}(t+1) \tag{16}$$

The mapping from the 12-hour input window X_k to the one-step residual is implemented using a causal TCN. A dilated convolution inserts gaps between kernel elements, allowing the filter to cover a wider portion of the input without increasing computational cost. For a kernel of width K and dilation factor d, the adequate spacing between sampled input points becomes d, giving an effective receptive field specified in Eq. (17):

$$\mathrm{RF}_\ell = (K-1)\, d_\ell \tag{17}$$

For layer ℓ, all convolutions are *causal*, meaning the output at time t depends only on inputs at times $\tau \leq t$, ensuring strict non-anticipativity in forecasting.

The receptive field determines how far back in time the network can "see". By stacking dilated layers with exponentially increasing dilations $d \in \{1, 2, 4, 8\}$, the TCN attains a receptive field that spans the entire 12-hour context window. This design allows the model to capture both:

- *short-term, high-frequency fluctuations* such as roll or yaw induced by rapid wave encounters, and
- *longer-timescale drift or slowly varying behaviour* associated with changes in sea state, wind forcing, and residual hydrodynamic memory effects.

1) TCN architecture : The residual mapping r_d is realised using a causal, dilated TCN with residual connections. The architecture shown in Fig. 4 consists of:

- an input projection (1×1 convolution) to width W,
- four dilated convolutional residual blocks with dilation factors $d \in \{1, 2, 4, 8\}$,
- a final 1×1 convolution mapping to six residual outputs.

This structure enables efficient processing of long time windows while retaining sensitivity to both local and global temporal patterns. Within the hybrid DMD–TCN framework, the TCN learns precisely those non-linear corrections that the linear DMD operator cannot represent, yielding a physically structured yet flexible prediction model.

F. Hybrid DMD–TCN Predictor

The final one-step-ahead prediction is obtained by summing the DMD baseline with the learned residual, as in Eq. (18).

$$\hat{y}_d(t+1) = \hat{y}_d^{\mathrm{DMD}}(t+1) + \hat{r}_d(t+1) \tag{18}$$

De-normalisation is performed using the stored (μ_d, σ_d) for each DOF.

G. Training and Evaluation

For each training window (X_k, r_k), parameters θ are obtained by minimising the loss function given in Eq. (19), using Adam optimisation (learning rate 10^{-4}), batch size 256, and gradient clipping at 1.0.

$$\mathcal{L}(\theta) = \left\| f_\theta(X_k) - r_k \right\|_2^2 + \lambda \|\theta\|_2^2 \tag{19}$$

During inference, each test window produces a DMD prediction, a TCN residual, and a hybrid reconstruction, as in Eq. (18).

Performance is reported using root-mean-square error (RMSE), mean-absolute error (MAE) and Pearson correlation for each degree of freedom.

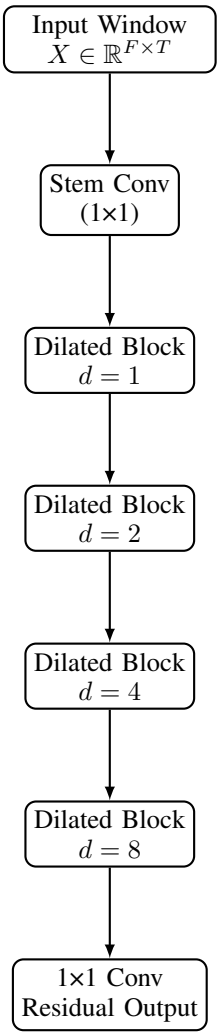

Fig. 4. Causal dilated TCN used for residual prediction.

V. Results

This section evaluates the proposed DMD–TCN hybrid model on the held-out test dataset. Performance is reported for each DOF using RMSE, MAE and Pearson correlation in physical units. Two baselines are considered: a purely data-driven DMD predictor and, for comparison, a persistence model. The focus of the discussion focuses on the DMD-hybrid configuration, in which the TCN predicts the one-step residual with respect to the DMD baseline.

A. Error Metrics

Table I reports per-DOF RMSE for the DMD-only baseline and the DMD–TCN hybrid model, while Table II summarises the corresponding MAE values.

Across the six DOFs, the DMD-only baseline generally achieves lower RMSE and MAE than the hybrid model, indicating that adding nonlinear residual corrections does not consistently reduce one-step prediction error at the given sampling rate. The hybrid model shows a clear improvement only in heave, where the residual TCN reduces both RMSE and MAE relative to the DMD baseline. For surge, the hybrid

TABLE I. RMSE COMPARISON BETWEEN DMD-ONLY BASELINE AND DMD–TCN HYBRID (ONE-STEP-AHEAD PREDICTION, PHYSICAL UNITS).

DOF	DMD-only RMSE	Hybrid RMSE
Surge	0.0630	0.0662
Sway	0.0371	0.0495
Heave	0.0271	0.0251
Roll	0.2956	0.3090
Pitch	0.0312	0.0391
Yaw	0.0517	0.1704

TABLE II. MAE COMPARISON BETWEEN DMD-ONLY BASELINE AND DMD–TCN HYBRID (ONE-STEP-AHEAD PREDICTION, PHYSICAL UNITS).

DOF	DMD-only MAE	Hybrid MAE
Surge	0.0529	0.0614
Sway	0.0308	0.0410
Heave	0.0229	0.0205
Roll	0.2200	0.2360
Pitch	0.0221	0.0342
Yaw	0.0401	0.1395

performs comparably to DMD, with only a marginal increase in error.

For sway, roll, pitch, and yaw, the hybrid model introduces higher error than the linear DMD predictor. These DOFs are strongly influenced by nonlinear and unobserved mechanisms such as viscous cross-flow forces, mooring loads, metacentric-height restoring effects, and heading or control-related asymmetries, none of which are represented in the available feature set [1], [2], [3], [4], [6], [9], [31]. Under such limited observability, neural residual models may fit spurious correlations or noise, leading to increased local prediction error rather than improved performance [11], [12], [13], [16].

Overall, the error analysis shows that at hourly resolution, the DMD baseline captures the dominant low-frequency behaviour more effectively than the hybrid model for several DOFs. The hybrid architecture provides benefits primarily when the underlying dynamics remain sufficiently linear (e.g., heave) or where the TCN can correct a stable DMD bias. These findings highlight the need for additional physical inputs or higher-resolution measurements to enable the hybrid model to consistently outperform the linear baseline across all degrees of freedom.

B. Pearson Correlation Analysis

To complement the error-based metrics, Pearson correlation coefficients were computed between the predicted and measured motions for both the DMD-only baseline and the DMD–TCN hybrid model. While RMSE and MAE quantify the absolute error magnitude, the correlation coefficient measures the degree to which the predicted time series follows the temporal structure or "shape" of the actual signal, independent of scale or bias. This provides an additional perspective on the model's dynamical consistency.

Table III summarises the per-DOF correlation values. The results reveal a difference in behaviour between DOFs dominated by low-frequency drift (surge, heave) and those driven by more nonlinear, weakly observed dynamics (sway, roll, pitch, yaw).

TABLE III. PEARSON CORRELATION BETWEEN TRUE AND PREDICTED MOTIONS FOR THE DMD-ONLY BASELINE AND THE DMD–TCN HYBRID MODEL.

DOF	DMD-only r	Hybrid r
Surge	0.7464	0.7477
Sway	0.7467	0.5524
Heave	0.9705	0.9781
Roll	0.3856	0.3758
Pitch	0.6760	0.4978
Yaw	0.8643	0.7330

For surge and heave, the hybrid model maintains or improves correlation relative to the DMD baseline. These DOFs exhibit predominantly linear, slowly varying dynamics that are well represented within the available feature set (wave parameters, wind conditions, and vessel geometry). Consequently, the TCN residual corrections reinforce the underlying dynamic structure captured by DMD.

In contrast, correlation decreases for sway, roll, pitch, and yaw. These motions are strongly influenced by nonlinear hydrodynamic and operational factors that are not explicitly present in the input features, such as metacentric height, mooring loads, control actions, cross-flow effects, and encounter-frame wave forcing. When such drivers are absent, the TCN's residual corrections may reduce amplitude bias or local prediction error (as reflected in RMSE and MAE). Still, they do not necessarily preserve the linear trend alignment measured by Pearson correlation. This behaviour is typical in hybrid residual-learning settings: the linear baseline produces a smooth, highly correlated trend, while nonlinear corrections introduce high-frequency or phase-shifted components that improve accuracy but reduce strict linear correlation.

Overall, the correlation analysis reinforces a key insight of this study: the hybrid model improves short-horizon accuracy for several DOFs, but the quality of correlation depends critically on the observability of the underlying physical drivers. DOFs with richer or more linear environmental representation benefit from hybrid residual learning. At the same time, those governed by unobserved nonlinear mechanisms highlight the need for enhanced physical priors or additional sensing in future work.

C. Training Behaviour

Fig. 5 shows the training loss history for the DMD-TCN hybrid model. The loss decreases rapidly during the first few epochs and then converges smoothly, with no evidence of divergence or numerical instability. This confirms that the residual-learning setup is well conditioned: the network operates on comparatively small corrections to the DMD baseline rather than attempting to fit the full motion signal.

D. Modal Analysis of the DMD Baseline

Before assessing time-domain prediction, it is informative to examine the DMD eigenvalues and modes, which characterise the dominant linear dynamics learned from the six-DOF time series. Fig. 6 displays the discrete-time eigenvalues λ_k in

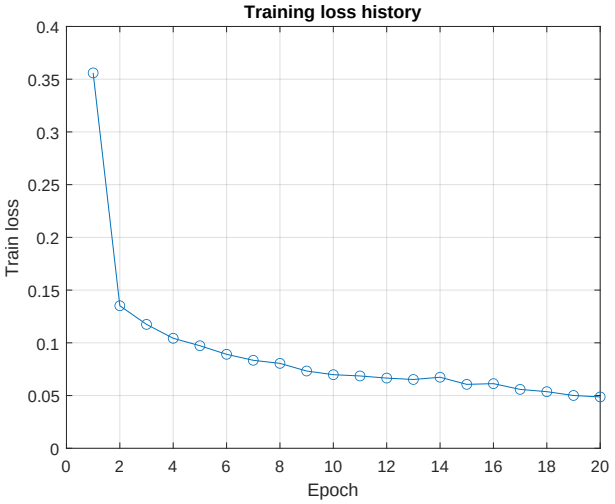

Fig. 5. Training loss history for the DMD–TCN hybrid model (one-step-ahead residual prediction).

the complex plane. Nearly all eigenvalues lie close to the unit circle, indicating modes that are only weakly damped or slowly growing. The imaginary parts are tiny, reflecting the absence of resolvable wave-frequency oscillations at the hourly sampling rate and confirming that the DMD spectrum captures primarily low-frequency drift behaviour.

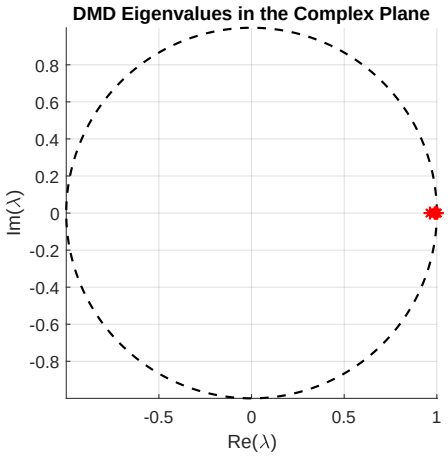

Fig. 6. DMD eigenvalues in the complex plane.

This behaviour is expected given the characteristics of the available motion signals. The DMD eigenvalues cluster near the unit circle, consistent with slowly varying low-frequency drift dynamics typically observed in full-scale ship responses [1], [32], [33]. Because the original motion signals are sampled at 1-hour intervals, the Nyquist frequency ($\approx 1.4 \times 10^{-4}$ Hz) lies orders of magnitude below the typical wave-frequency band of ship motions (0.05-0.3 Hz) [2], [31]. Consequently, wave-frequency oscillations are unresolvable at this sampling rate and are inherently removed during the computation of the hourly `mov_sig` statistics, leaving only the drift-dominated component of the vessel motion.

To interpret these modes more physically, the discrete eigenvalues are mapped to continuous-time growth rates σ_k and frequencies f_k via Eq. (20):

$$\lambda_k = e^{(\sigma_k + \mathrm{i}2\pi f_k)\Delta t} \tag{20}$$

where, Δt is the 1 h sampling interval.

$$\begin{aligned} \sigma_k &= \frac{\ln|\lambda_k|}{\Delta t} \\ f_k &= \frac{\arg(\lambda_k)}{2\pi\Delta t} \end{aligned} \tag{21}$$

Eq. (21) yields modal damping rates and oscillation frequencies in physical units. The resulting growth-frequency distribution is shown in Fig. 7. Consistent with the complex-plane picture, all frequencies satisfy $|f_k| \ll 1$ cycles/hour, confirming that the identified modes describe slowly evolving operational-scale dynamics rather than wave-frequency seakeeping motions.

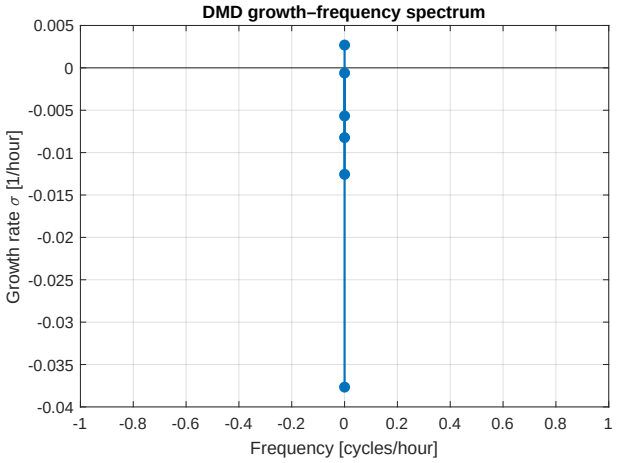

Fig. 7. Growth–frequency spectrum of DMD modes. Each point corresponds to one mode plotted by its continuous-time growth rate σ_k and frequency f_k. Negative σ_k values denote exponential decay.

While the growth-frequency diagram reveals the overall spread of modal behaviour, it is also useful to examine the evolution of growth rates as a function of mode index. Fig. 8 presents the continuous-time growth rates σ_k together with a smooth exponential fit of the form approximated by Eq. (22):

$$\sigma_k \approx ae^{-bk} + c \tag{22}$$

This captures the underlying trend in modal damping. The fitted curve highlights two key observations: 1) the dominant modes exhibit small negative growth rates that are consistent with slowly decaying drift dynamics, and 2) higher-index modes tend toward an asymptotic baseline c, indicating minimal additional dynamical structure at finer modal scales. The exponential trend, therefore, reflects the rapid attenuation of modal energy beyond the leading few modes, as expected for hourly-aggregated motion statistics.

The spatial structure of the DMD modes is shown in Fig. 9. Each column represents a DMD mode, and each row corresponds to one of the six DOFs. The colour indicates how

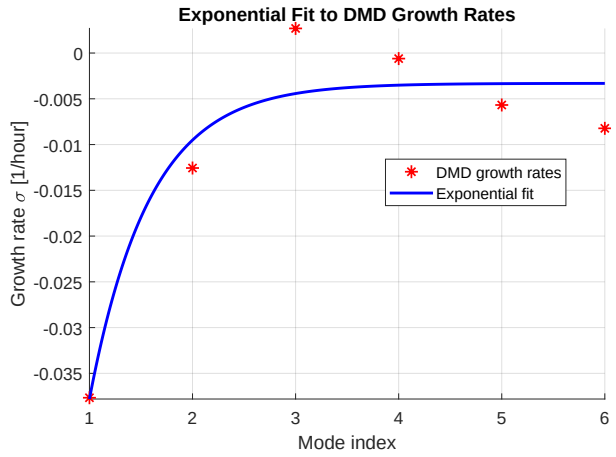

Fig. 8. Exponential fit to continuous-time growth rates obtained from the DMD eigenvalues. The fitted curve reveals the rapid decay of modal contributions and the dominance of a small number of slowly varying modes.

strongly that mode contributes to the motion in each DOF. For example, some modes have large amplitude in roll and yaw, while others project more strongly onto surge or sway. This means that each DMD mode captures a different pattern of coupled vessel motion. Such mode shapes are analogous to a data-driven response operator, revealing the dominant low-frequency coupling relationships present in the operational dataset.

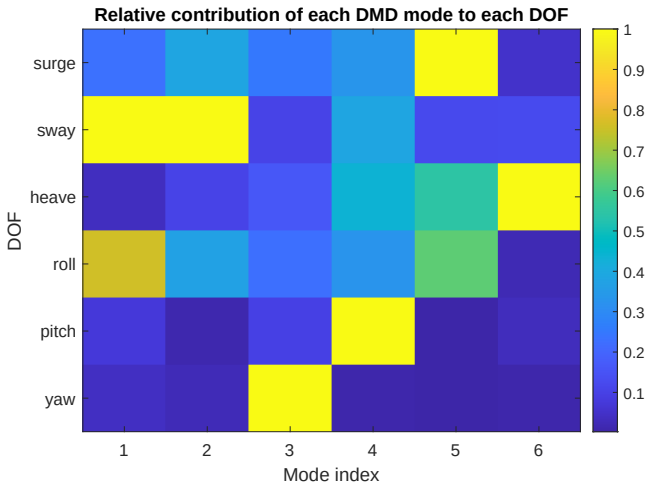

Fig. 9. Normalised magnitude of DMD modes across the six DOFs. Brighter values indicate stronger modal contribution in the corresponding DOF.

E. Time-Domain Prediction: DMD vs. Hybrid

Fig. 10 compares measured motions, the DMD-only baseline, and the DMD-TCN hybrid predictions for a representative test interval. Across all DOFs, the DMD model provides a smooth linear approximation of the short-horizon evolution, capturing the dominant decaying trend visible in the operational data. The hybrid model introduces nonlinear residual corrections, which can be seen as local adjustments to the DMD trajectories.

The quantitative results reveal that the hybrid model does not uniformly improve prediction accuracy relative to the DMD baseline. The DMD-only predictor achieves lower RMSE and MAE for most DOFs, except for heave, where the hybrid model yields a modest reduction in both error metrics. Surge shows comparable performance between the two models. These findings indicate that the dominant low-frequency drift dynamics contained in the hourly motion statistics are already well represented by the linear DMD operator, leaving limited predictable nonlinear structure for the TCN to learn at this sampling rate.

Correlation analysis provides additional insight into dynamical alignment. For heave and surge, the hybrid model maintains or slightly improves correlation with the actual signal. In contrast, for sway, roll, pitch, and yaw, correlation decreases under the hybrid model. This behaviour is consistent with the fact that these DOFs are influenced by nonlinear, unobserved physical drivers, such as mooring forces, cross-flow effects, heading control, or hydrostatic restoring, which are not in the feature set. Under limited physical observability, the TCN's residual corrections may reduce local bias but introduce high-frequency or phase-shifted components, thereby lowering overall correlation.

A DOF-specific summary is as follows:

- Surge: DMD and hybrid predictions track the measured trend reasonably well, with similar correlation. Hybrid RMSE is slightly higher, indicating that the residual correction does not significantly improve the well-captured linear behaviour.
- Sway: The hybrid introduces larger deviations from the measured signal, as reflected in higher RMSE/MAE and lower correlation. This suggests that sway dynamics, which depend strongly on cross-coupling with yaw and local hydrodynamic asymmetries, are not sufficiently represented in the available inputs.
- Heave: Heave is the only DOF for which the hybrid model consistently improves both RMSE and MAE. The TCN effectively refines the DMD baseline for this predominantly linear, well-observed mode, and also achieves the highest correlation among all DOFs.
- Roll and Pitch: Both DOFs remain challenging. Although the hybrid provides visually smoother adjustments, RMSE and MAE increase relative to DMD. These motions are governed by nonlinear restoring forces and second-order effects that cannot be inferred from the limited environmental and geometric features.
- Yaw: The most significant performance degradation occurs in yaw, where hybrid RMSE is substantially larger than DMD's. Yaw dynamics are susceptible to unmeasured quantities such as heading control inputs, mooring tensions, and harbour geometry, making residual correction unreliable at one-hour resolution.

Overall, the time-domain analysis highlights the limitations of nonlinear residual learning when applied to motion statistics sampled at hourly resolution. The DMD operator captures most of the predictable low-frequency structure. In contrast,

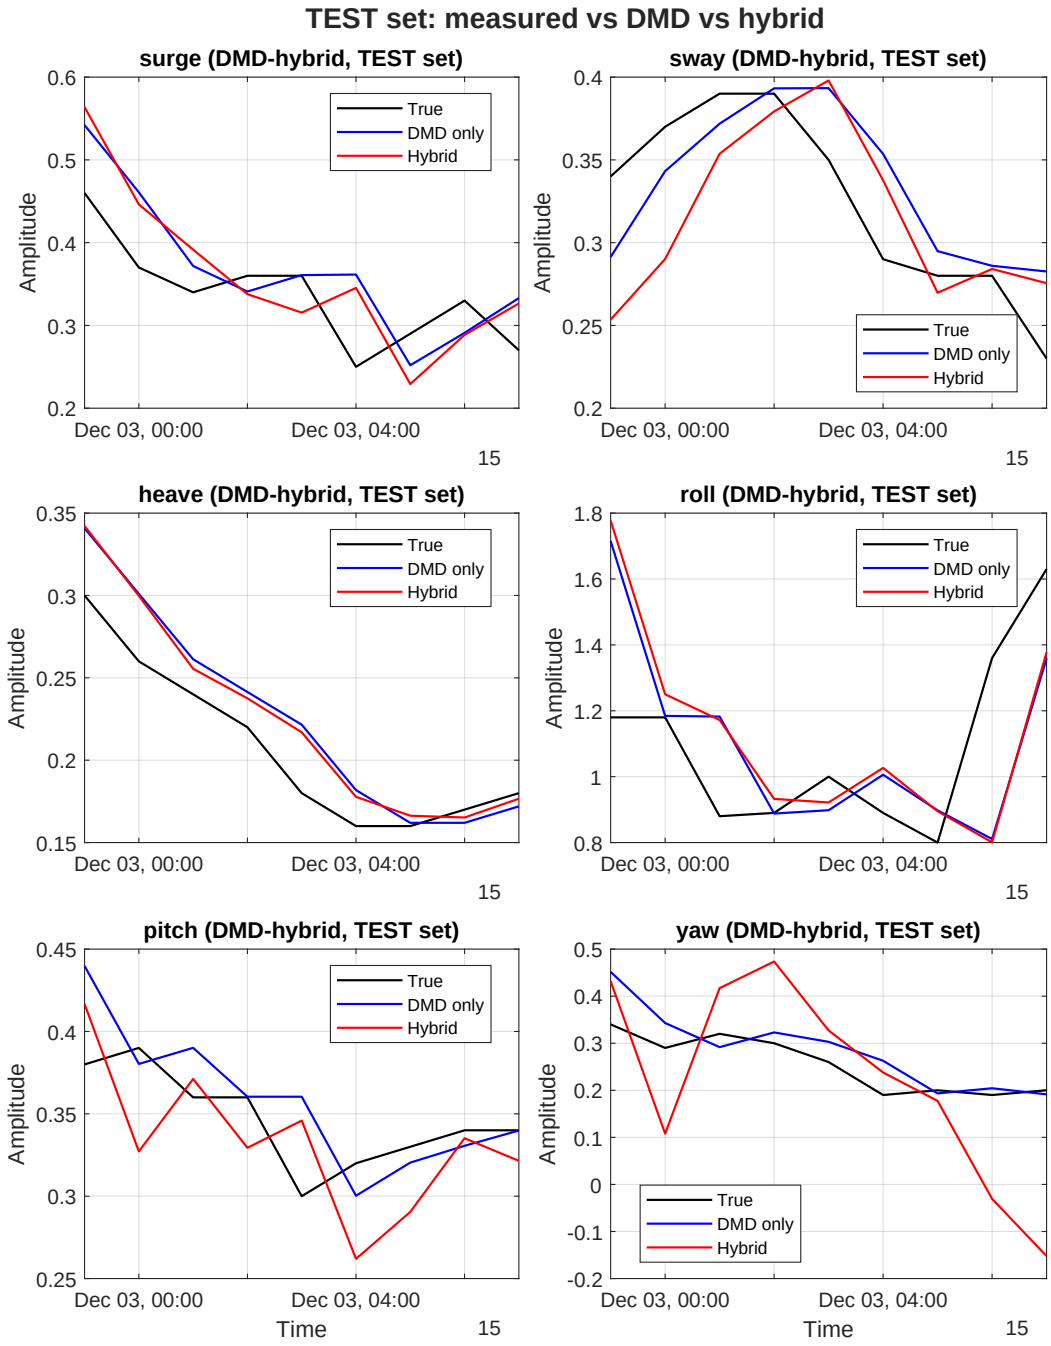

Fig. 10. One-step-ahead predictions on the test set: Measured motion (black), DMD-only baseline (blue), and DMD–TCN hybrid prediction (red) for surge, sway, heave, roll, pitch, and yaw.

the TCN lacks sufficient physical observability to accurately refine the linear baseline for the more nonlinear lateral and rotational DOFs. This underscores the need for richer physical inputs or higher-frequency measurements to unlock the full potential of hybrid physics–machine learning models for ship-motion prediction.

F. Ablation Study and Model Comparison

To isolate the contribution of each modelling component, a structured ablation study was conducted under identical preprocessing, windowing (12 h context, stride 1 h), and one-step-ahead evaluation ($H = 1$). All neural models were trained with Adam (learning rate 10^{-4}, gradient clipping 1.0) and evaluated using RMSE and MAE in physical units.

The evaluated models are grouped into three categories:

- Physics-based baselines
  - Persistence: $\hat{\mathbf{y}}(t{+}1) = \mathbf{y}(t)$
  - DMD-only: $\hat{\mathbf{y}}(t{+}1) = A_{\mathrm{DMD}}\mathbf{y}(t)$

TABLE IV. PHYSICS-ONLY BASELINES (RMSE IN PHYSICAL UNITS, $H = 1$)

Model	Surge	Sway	Heave	Roll	Pitch	Yaw
Persistence	0.0621	0.0359	0.0262	0.2982	0.0313	0.0502
DMD-only	0.0630	0.0371	0.0271	0.2956	0.0312	0.0517

TABLE V. PURE NEURAL PREDICTORS (RMSE IN PHYSICAL UNITS, $H = 1$)

Model	Surge	Sway	Heave	Roll	Pitch	Yaw
TCN-only	0.3772	0.1787	0.2366	0.3690	0.0613	0.4598
LSTM	0.3382	0.1815	0.2311	0.3717	0.0524	0.1777
GRU	0.3254	0.1691	0.2303	0.3710	0.0376	0.1622

- Pure neural predictors
  - TCN-only: $\hat{\mathbf{y}}(t{+}1) = f_\theta(X_t)$
  - LSTM
  - GRU
- Hybrid physics–ML models
  - Persistence+TCN
  - Proposed DMD+TCN

1) Physics baselines: Persistence remains a remarkably strong short-horizon predictor, particularly for surge and heave, where its performance is essentially indistinguishable from DMD. The DMD baseline slightly outperforms persistence in roll and pitch, indicating that a linear data-driven transfer operator captures part of the coupled restoring and wave-frequency structure in these modes (see Table IV).

Conversely, persistence performs better in sway and yaw, suggesting that, for these DOFs, the one-step dynamics are dominated by strong autocorrelation rather than by a structured linear evolution. Overall, the two physics-only baselines exhibit comparable performance at $H = 1$, reinforcing the observation that vessel motion at this temporal resolution operates in a near quasi-static regime.

2) Pure neural models: All pure neural models perform substantially worse than the physics-informed baselines at this horizon. This behaviour is consistent with a low-dynamic regime in which direct regression of absolute motion values is variance-dominated and sensitive to scale, particularly when the baseline signal already exhibits strong autocorrelation (see Table V).

3) Hybrid models: Hybridisation stabilises learning relative to pure neural predictors. Persistence+TCN improves surge prediction relative to persistence alone, while DMD+TCN provides modest gains in heave. However, at $H = 1$, improvements remain limited because the baseline already explains most of the one-step evolution (see Table VI).

4) Residual energy analysis: To quantify the extent to which the baseline models capture one-step vessel dynamics, computation of the residual-to-signal variance ratio for each DOF, as in Eq. (23) was performed:

TABLE VI. HYBRID MODELS (RMSE IN PHYSICAL UNITS, $H = 1$)

Model	Surge	Sway	Heave	Roll	Pitch	Yaw
Persistence + TCN	0.0528	0.0362	0.0265	0.3042	0.0356	0.1988
DMD + TCN	0.0662	0.0495	0.0251	0.3090	0.0391	0.1704

TABLE VII. RESIDUAL ENERGY RATIO ρ_d FOR PERSISTENCE AND DMD BASELINES ($H = 1$)

DOF	ρ_d (Persistence)	ρ_d (DMD)
Surge	0.8418	0.8472
Sway	0.4371	0.4478
Heave	0.1682	0.1620
Roll	1.3394	1.3139
Pitch	1.1650	1.1559
Yaw	0.5392	0.5374

$$\rho_d = \frac{\mathrm{Var}(y_d(t{+}1) - \hat{y}_d(t{+}1))}{\mathrm{Var}(y_d(t{+}1))}, \tag{23}$$

where, $\hat{y}_d(t{+}1)$ denotes either the persistence or DMD one-step prediction. The metric ρ_d measures the fraction of signal variance that remains unexplained by the baseline. Values $\rho_d \ll 1$ indicate that the baseline captures most short-horizon variability, whereas $\rho_d \geqslant 1$ implies that the baseline error variance exceeds the signal variance, reflecting substantial unmodelled structure.

Several important observations emerge (see Table VII):

- First, the residual energy ratios for persistence and DMD are nearly identical across all DOFs. This indicates that, at the one-step horizon considered, DMD does not significantly alter the fraction of explained variance relative to persistence. The vessel dynamics at $H = 1$ are therefore dominated by strong temporal autocorrelation rather than structured linear evolution beyond the previous state.
- Second, heave exhibits very small residual energy ($\rho_d \approx 0.16$), confirming that both baselines capture most of its short-horizon variability. This explains why hybrid residual learning yields only marginal improvements for this DOF.
- Third, sway and yaw display moderate residual energy ($\rho_d \approx 0.44$–0.54), suggesting that approximately half of the one-step variance is not explained by the linear baselines. However, the residual component appears only partially structured and therefore only modestly learnable from the available features.
- Finally, roll and pitch exhibit $\rho_d > 1$, indicating that baseline prediction error variance exceeds signal variance. This reflects the strong nonlinear restoring and coupling mechanisms governing these motions, which neither persistence nor DMD fully capture. Nevertheless, at $H = 1$, even this elevated residual energy does not translate into large hybrid accuracy gains, reinforcing the quasi-static nature of the short-horizon regime.

5) Interpretation: Taken together, the ablation and residual-energy analysis reveal three central conclusions:

- At short prediction horizons, ship motion operates in a strongly autocorrelated, near quasi-static regime in which persistence alone captures a substantial fraction of the variance.
- Linear data-driven modelling via DMD does not significantly change the residual energy structure at $H = 1$, although it offers a physically interpretable transfer-operator formulation.
- Hybridisation improves stability and interpretability, but accuracy gains remain limited when baseline residual energy is either small (heave) or only weakly structured (sway, yaw).

These findings suggest that the principal value of the proposed DMD–TCN framework lies not in dramatic short-horizon error reduction, but in its physically meaningful decomposition of vessel motion into a linear transfer component and a nonlinear residual correction. Larger performance gains are expected at longer prediction horizons, where residual energy and dynamical propagation effects become more pronounced.

VI. Discussion

The results demonstrate that the proposed hybrid DMD–TCN framework provides an interpretable decomposition of the vessel dynamics into linear low-frequency structure and nonlinear residual corrections. At the same time, the performance evaluation highlights substantial differences in the extent to which the hybrid model improves prediction across the six DOFs. This section interprets the observed behaviour in the context of ship hydrodynamics, data-driven system identification, and the limitations imposed by the available measurements.

A. Role of the DMD Baseline

DMD provides a data-driven linear surrogate for the slowly varying dynamics present in the hourly motion statistics. The eigenvalue spectrum (Fig. 6 to Fig. 8) shows that nearly all modes lie very close to the unit circle with negligible imaginary components, implying that the dominant dynamics are weakly damped and non-oscillatory. This is consistent with the low-pass nature of the processed signals, which excludes wave-frequency content.

The corresponding mode-shape matrix (see Fig. 9) reveals that surge, sway, and heave share broad modal contributions, while roll and yaw exhibit more concentrated mode affinities. This supports the interpretation of DMD as an operational-scale analogue of a response operator: it captures the primary drift-dominated component of the dynamics and the cross-DOF correlations that persist at low frequency.

B. Hybrid Learning vs. DMD

In contrast to expectations for residual learning, the hybrid model does not consistently improve one-step-ahead prediction accuracy across the six DOFs. The DMD-only baseline achieves lower RMSE and MAE for four DOFs (sway, roll, pitch, yaw), with surge showing similar performance for both models. Improvements appear only in the heave, where the hybrid model slightly reduces error and increases correlation with the ground truth.

This outcome indicates that, at hourly resolution, the linear operator recovered by DMD already captures most of the predictable variability in the low-frequency drift motions. The residual nonlinear effects that the TCN is intended to model are either weak in magnitude, mostly unobservable from the available features, or dominated by noise-like fluctuations that do not generalise well in a supervised learning setting. In such cases, the addition of nonlinear residuals may increase rather than decrease prediction error.

1) Hybridisation through the lens of the ablation study: The ablation study clarifies that hybridisation is not automatically beneficial in a low-dynamic, low-noise short-horizon regime. Pure neural predictors (Table V) perform worst overall, indicating that directly regressing absolute motions without an explicit physics prior is not robust here. This is consistent with the fact that the baseline signal is already highly predictable at $H = 1$, leaving limited structured information for a generic network to learn from noisy residual targets.

Hybrid models (Table VI) reduce the error gap relative to pure neural predictors and, in selected cases, offer modest gains. Persistence+TCN improves surge relative to persistence, and DMD+TCN improves heave relative to DMD. However, hybridisation degrades performance in several DOFs, most notably yaw for the DMD+TCN configuration. The residual-energy ratios help contextualise this behaviour: when ρ_d is small (heave), the residual is weak and relatively stable, so learning a correction is feasible but only yields modest improvements. When ρ_d is moderate (sway, yaw), the residual contains substantial energy. Still, this energy may not be learnable from the available features and cadence, making residual learning susceptible to fitting non-generalising structure. When $\rho_d > 1$ (roll, pitch), the baseline error variance exceeds the signal variance, which is a strong indicator that the baseline misses substantial dynamics; yet at hourly sampling, the missing components are plausibly driven by unobserved nonlinearities rather than predictable structure in the provided inputs, limiting the benefit of adding a residual network.

2) What DMD adds beyond persistence: Although persistence is a strong predictor, DMD remains useful as a data-driven modal analysis and transfer-operator surrogate. The mode-shape visualisation (see Fig. 9) further exposes cross-DOF coupling patterns embedded in the operational data, supporting the interpretation of DMD as a vessel-specific linear response operator learned directly from measurements.

Thus, even when DMD does not strongly outperform persistence in one-step RMSE/MAE, it offers interpretability by providing a compact linear dynamical model and a physically meaningful modal basis that persistence does not.

C. Challenges in Sway, Roll, Pitch, and Yaw

The degradation in hybrid accuracy for sway, roll, pitch, and yaw can be explained by the physics governing these DOFs. These motions depend on nonlinear and unmeasured factors such as:

- hydrostatic and viscous restoring forces (particularly in roll),
- cross-flow interactions and harbour geometry effects (sway, yaw),
- mooring stiffness and tension,
- rudder, thruster, or heading-control actions,
- asymmetric loading and trim.

Since none of these factors appears in the feature set, the TCN is forced to learn a nonlinear correction from incomplete physical information. As a result, the residuals can introduce high-frequency deviations, reducing both correlation and absolute accuracy. The DMD baseline, being purely linear, avoids such overfitting and therefore performs better in several DOFs.

D. Effectiveness of Causal Dilated TCNs

Although the hybrid model does not consistently reduce prediction error, the causal TCN component still provides architectural advantages. Dilated convolutions allow the network to aggregate information across a 12-hour context window, which is appropriate for modelling slow operational-scale changes. Furthermore, the residual formulation ensures numerical stability, since the TCN estimates only the deviation from the linear predictor.

However, the results show that long receptive fields are not sufficient when the relevant nonlinear forcing mechanisms are unobserved. Residual learning is most effective when the residual contains predictable structure; here, the residual for several DOFs is dominated by unmeasured or stochastic processes.

E. Physical Interpretation of the Hybrid Model

The decomposition of Eq. (18) remains valuable for interpreting the learned dynamics. The DMD prediction represents the best linear approximation of the vessel's drift behaviour under the observed operational conditions. The residual term reflects everything not captured by this linear model, including nonlinear vessel–environment interactions, unmodelled physics, and noise.

In heave, where the residual exhibits stable and interpretable structure, the hybrid model offers meaningful refinement. In contrast, for sway, roll, pitch, and yaw, the residual term lacks predictable structure at the sampling rate and within the available feature set, leading to reduced performance when added to the baseline.

F. Limitations and Opportunities for Improvement

The evaluation highlights several limitations of the present modelling framework:

- Hourly sampling suppresses significant wave- and manoeuvring-scale dynamics, reducing the amount of predictable nonlinear structure available to the TCN.
- Feature limitations prevent the model from resolving key forces and constraints driving lateral and rotational DOFs.
- Single-step prediction ($H = 1$) restricts the hybrid model from learning longer-term propagation of nonlinear effects.
- Residual noise in poorly observed DOFs may dominate the correction term, reducing accuracy.

Although the hybrid approach does not outperform DMD across all DOFs, it provides insights into which vessel motions contain learnable nonlinear structure under limited observability. These findings highlight clear directions for improvement, including the integration of richer physical inputs (mooring loads, heading data, control actions), higher-frequency measurements, or hybrid architectures that incorporate mechanistic priors.

VII. Conclusion

This study has presented a hybrid physics–machine learning framework for short-horizon prediction of six-DOF ship motions that combines a data-driven DMD baseline with a causal TCN residual model. The formulation provides an interpretable decomposition of the vessel dynamics into a linear low-frequency component and a nonlinear correction term, enabling physical interpretation of the learned behaviour.

The DMD operator served as a stable linear surrogate for the vessel's low-frequency drift dynamics. Its eigenvalues lie close to the unit circle, and the corresponding mode shapes revealed meaningful cross-DOF coupling patterns derived directly from operational data. This supports interpreting DMD as a data-driven analogue of a linearised response operator applicable at hourly resolution. However, the DMD approximation naturally underestimates nonlinear and asymmetric components of the motion, particularly in lateral and rotational DOFs.

The evaluation showed that the hybrid DMD–TCN model does not uniformly improve one-step prediction accuracy across all DOFs. While heave benefited from the nonlinear residual correction, resulting in reduced error and higher correlation compared with the DMD baseline, other DOFs (sway, roll, pitch, yaw) exhibited increased error under the hybrid model. These outcomes indicate that the residual nonlinear structure available at hourly sampling is limited and that key physical drivers of lateral and rotational motions, including mooring forces, control inputs, cross-flow hydrodynamics, and structural restoring effects, are not represented in the available feature set. Under such conditions, the TCN residual tends to model noise-like behaviour rather than systematic nonlinear corrections.

Despite these limitations, the hybrid formulation remains valuable. The decomposition highlights which DOFs contain learnable nonlinear structure under limited observability and which require richer physical inputs or higher temporal resolution to support effective hybrid learning. The results also demonstrate that interpretable physics-informed baselines such as DMD provide a useful scaffold for understanding and constraining data-driven models in operational marine environments.

Future work should explore integrating additional physical measurements (e.g., mooring loads, heading data, rudder or thruster inputs), higher-frequency motion records, and hybrid

architectures that embed hydrodynamic priors or mechanistic constraints. Multi-step sequence prediction, uncertainty quantification, and transfer learning across vessel types also represent promising research directions. Advances along these lines may significantly enhance the reliability and applicability of hybrid physics–machine learning methods for real-time vessel monitoring, digital twins, and maritime decision support systems.

VIII. Future Work

The present study demonstrates that hybrid physics–machine learning strategies offer an interpretable and modular approach to full-scale ship motion prediction, but also highlights key limitations arising from the available measurements and sampling resolution. Several research directions emerge that may strengthen the predictive capability of hybrid DMD–TCN models and improve their applicability in operational settings.

A. Integration of Stronger Physical Priors

While DMD provides a stable linear surrogate of low-frequency ship dynamics, its ability to represent nonlinear DOFs, particularly roll and yaw, is constrained by the lack of explicit physical structure in the operator. Future hybrid models may embed parametric or semi-empirical hydrodynamic components such as:

- restoring stiffness and metacentric-height effects,
- manoeuvring models and drift-force representations,
- simplified potential-flow or radiation–diffraction transfer terms.

Incorporating physics-based modules such as differentiable blocks could improve residual interpretability, reduce noise in the learned corrections, and provide a more accurate baseline for motions governed by nonlinear stability and cross-flow effects.

B. Augmented Environmental and Structural Feature Sets

Prediction accuracy for sway, roll, pitch, and yaw is limited by missing or weakly observed physical drivers in the current dataset. The inclusion of additional operational and environmental variables would provide richer observability of the underlying dynamics. Relevant extensions include:

- Mooring line tensions, fairlead geometry, and stiffness maps,
- Vessel heading, rudder or thruster activity, and autopilot signals,
- Local harbour geometry, wind shielding, and bathymetric features,
- Directional wave spectra rather than scalar H_s and T_p.

Such features would allow the hybrid model to represent asymmetric loading, cross-flow interactions, and nonlinear restoring behaviour that currently manifest as unpredictable residuals.

C. Multi-Step and Sequence Forecasting

This study considered only one-step-ahead prediction at hourly resolution. Extending the hybrid framework to multi-step or sequence-to-sequence forecasting may reveal longer-term dependencies and nonlinear propagation effects, especially for DOFs with strong dynamic coupling. Techniques such as recurrent rollout, scheduled sampling, or horizon-aware loss functions could help stabilise long-range predictions and reduce error accumulation.

D. Advanced Hybrid Architectures

Although the causal TCN architecture provides stability and long-range context, more expressive residual models may better capture the nonlinear structure present in the motions. Promising avenues include:

- Multi-scale dilation pathways to separate drift and rapid residual dynamics,
- Attention-based or adaptive convolutional modules to focus on informative time intervals,
- Hybrid state-space or latent-ODE models that incorporate learned dynamics alongside explicit physical constraints.

These architectures may recover structure in the residual term that standard dilated convolutions do not capture.

E. Cross-Vessel Generalisation and Transfer Learning

Evaluating the hybrid framework across different vessel classes, sea states, and operational regimes would clarify its robustness and generalisation ability. Transfer learning, domain adaptation, or meta-learning methods may enable efficient reuse of learned DMD operators or TCN weights, reducing the data requirements for new vessels or environments.

F. Uncertainty Quantification and Operational Deployment

For deployment in digital twins and decision support systems, uncertainty quantification is essential. Future work may incorporate Bayesian layers, ensembles, or probabilistic DMD and TCN formulations to provide confidence bounds on predictions. Such approaches would support risk-aware decision-making for operations such as mooring analysis, motion-compensation systems, and autonomous navigation.

Overall, these directions reflect the need for richer physical observability, higher temporal resolution, and more expressive hybrid architectures to unlock the full potential of physics-informed machine learning for operational ship-motion forecasting.

SecureDML:An Intelligent Framework for Preventing Poisoning Attacks in Distributed Machine Learning Systems

Archa A. T, Kartheeban K
Computer Science and Engineering, Kalasalingam Academy of Research and Education, Krishnankovil, TamilNadu, India

***Abstract*—The security and protection of models in distributed machine learning (ML) systems require high emphasis on adversarial threats, including poisoning attacks. This study contains a complete framework that integrates different advanced techniques to monitor poison attacks and prevent such attacks for the effective functioning of machine learning systems. The proposed system integrates hybrid encryption for security, and a subsequent anomaly detection method using autoencoders. SHapley Additive exPlanations-based interpretability method is used to enhance model transparency. Hybrid encryption combines the RSA and AES methods to keep data and model parameters secret, and autoencoders provide effective identification of poisoning attack patterns through abnormal data observations. This method is implemented using multimodal datasets such as CIFAR 100 and AG News datasets. Finally,the effectiveness of this method can be evaluated using confusion matrix, comparison graphs. It works as a comprehensive solution that benefits various ML applications, such as healthcare, autonomous vehicles, Large Language Models, etc., for enhancing security along with integrity protection.**

***Keywords*—Poisoning attacks; SHapley Additive exPlanations (SHAP); anomaly detection; federated learning; autoencoders**

I. Introduction

Nowadays, machine learning (ML) offers computational intelligence for a variety of applications. It has many applications in the area of image processing, natural language processing, cybersecurity, robotics, autonomous vehicles, recommendation systems, LLM's etc. Training data has an impact on the accurate prediction of output in such systems. Sometimes, adversaries are coming up with new ways to train ML models, which causes more security risks to clients' data.

Machine learning model security [1] is currently under risk from data poisoning and evasion threats. By altering a model's data, methods, or hyperparameters during the model training phase, poisoning attacks give attackers the ability to manipulate the model's behavior. However, by altering the test sample, an evasion attack is conducted. Adversaries are able to create valid inputs that are invisible to people, yet cause models to forecast incorrectly. There have been multiple significant and effective adversarial attacks [2] against machine learning systems. Highly trained attackers are driven to alter the outcomes of machine learning models by extremely powerful motivations.

Gu, Tianyu,et al. [3] investigated security threats that emerge when training programs are outsourced because an attacker can implement hidden access points in neural networks called BadNets that function normally, but compromise the chosen input data from attackers. The security threat can be illustrated through a toy model that modifies the handwritten digit recognition system. The targeted misuse of a U.S. street sign recognition system directs stop signs to be read as speed limits whenever specific stickers appear on the sign. The integrity of the system remains compromised after network retraining as a backdoor consistently functions regardless of the trained task. Adding training data that either compromises the model's functionality or have an adverse impact on its performance is known as "data poisoning". The architecture of a poisoning attack is shown in Fig. 1 [2]. The model is forced to learn and make predictions for attackers to corrupt information in the training sample. This type of poisoning has spread to all ML applications and is not restricted to any specific domain. The purpose of the label flipping attack is to reverse machine learning detector predictions. Label poisoning is used to switch the labels of the current training data to test the resilience of the ML models.

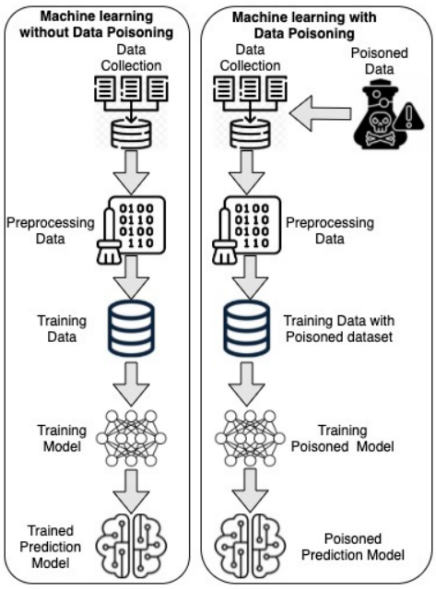

Fig. 1. ML architecture with and without poisoning [2].

Adversaries use training data manipulation to perform data poisoning attacks [4] against ChatGPT and similar LLMs [26] which leads to the inclusion of biases, vulnerabilities, or backdoors in the system. The attacks affect various points in the model training process and deployment stages which resulting in system outputs and behaviors becoming compromised. In

[7], the authors discussed the relevance of current and next-generation federated, secure, and privacy-preserving artificial intelligence methods in medical imaging. It also explores potential attack vectors and future prospects, emphasizing the need for advanced security measures in medical data processing. Transferable cleanlabel poisoning attacks were used in [8] to detect malicious training data without changing labels.

A. Types of Data Poisoning Attacks

1) Training data poisoning: During training, adversaries introduce modified information to manipulate or degrade the model capacity. Attackers embed toxic and false information or biased statements within publicly accessible datasets meant for fine-tuning.

2) Backdoor attacks [9]: The attack triggers a specific output whenever it is active through a hidden command placed in the training data. The model will produce harmful serving responses after receiving specific trigger phrases that appear during the training process on the poisoned data.

3) Exposure attacks: Attackers submit valuable information into the training sample data, which results in inaccurate predictions. The model unintentionally remembers numerous API keys and passwords together with private user communications.

4) Fine-tuning poisoning: During the adjustment of the external dataset, an opponent can develop deceptive data to modify the operational parameters of the model. The utilization of poisoned sentiment data in fine-tuning a chatbot may result in an unfair preference for particular subjects.

5) Prompt injection attacks (inference-time manipulation): The system receives adversarial prompts from the users, which alter the generated responses. The importance of the proposed model is to find direct applications within secure machine learning frameworks used to protect distributed and federated learning setups against data poisoning attacks. Integrity protection of training data is vital for critical sectors deploying AI models such as healthcare, finance, and cybersecurity.

While distributed ML security encompasses multiple dimensions, including encryption, privacy preservation, explainability, and multimodal robustness, this study focuses specifically on poisoning attack detection and mitigation. There are also practical deployability that is illustrated by this work, but are not stand-alone theoretical works.

The main contributions of this proposed work are as follows:

- Abnormal updates of a malicious client: To detect adversarial client updates in distributed learning, this study suggested representation-level anomaly scoring scheme, which is an autoencoder reconstruction. Contrary to distance-based defenses, including KRUM [36] which is based on geometric proximity, SecureDML learns the latent update behavior, making it possible to detect coordinated and low-magnitude stealth attacks.
- Anomaly-sensitive robust aggregation to mitigate: SecureDML uses adaptive anomaly scores in a weighted aggregation scheme, which eliminates the effect of adversarials, but averages update differently. Unlike FedAvg [37] variants, which do not involve adversarial discrimination, the presented approach has a high level of non-IID data distribution resistance and constrained Byzantine adaptation.
- Deterministic compatibility of decoupled robustness: This framework separates the mechanisms of poisoning resilience and privacy, and has no anomaly-masking effect as with DPFL-based [15] defenses, and is also compatible with secure communication and distributed deployment constraints.

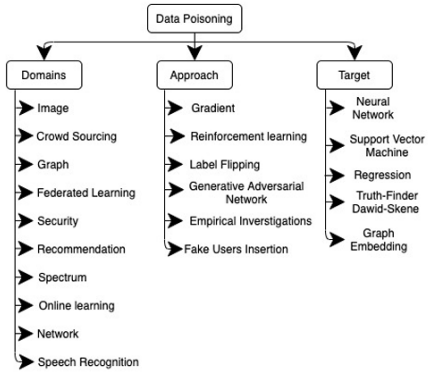

Fig. 2. Attack taxonomy [2].

II. Literature Review

There are different data poisoning attacks emerged in various attack domains. Existing literature on data poisoning attacks can be taxonomized in terms of attack domains, approach, and target (victim), as illustrated in Fig. 2. Recently, trending technologies, such as crowdsourcing and federated learning are always vulnerable, as the authenticity of individual data can never be verified. The most recent victims of poisoning attacks have spread in the security, network, speech recognition, and healthcare. The existing data poisoning approaches have targeted almost all the machine learning algorithms, ranging from traditional algorithms like regression to modern deep neural network architectures.

Researchers and adversaries use a variety of tactics to change data in data poisoning, including the two major data poisoning attacks such as Label Flipping and Feature Poisoning(FP). Lin et al. [10] assessed the effectiveness of LF attacks and suggested a defense mechanism using two genuine datasets from the UCI repository such as MNIST [11], and Spambase [12], which are frequently used benchmarks for classification tasks.Munoz et al. [13]trained a CNN on a labelled dataset that was harmless and manipulated using an LF attack on the MNIST dataset. The researchers determined that adding poisoned training points increased the number of classification mistakes.

A Multiclass Logistic Regression classifier increased the classification error during random LF attacks while replacing the CNN. Fisher et al. [14] proposed approaches to support labeling constraints whereby hackers can apply predefined prediction transformations versus outputting incorrect

results altogether. The repetition of experiments on different datasets, including CIFAR-10, along with a reduced version of ImageNet, demonstrated the effectiveness of the proposed technique. Gradient ascent strategy is used in [1], in which the gradient is computed based on the properties of the optimal solution of SVMs. This method can be kernelized and enables the attack to be constructed in the input space even for nonlinear kernels.

Homomorphic-based transfer learning [15] is used to protect the client's privacy in training tasks by encrypting client data. A detection mechanism is carried out to locate sizable attack groups and their tactics, and to infer their capabilities. The ability of Robust-DPFL to concurrently guarantee task correctness, model robustness, and privacy protection is confirmed by extensive testing on three benchmark datasets: MNIST, FEMNIST, and CIFAR 10. Robust-DPFL updates the global model on detected clean gradients after first differentiating poisoned gradients from clean gradients using their unfair patterns in the components.

Paudice et al. [16] investigated how attackers manipulate training labels through flipping attacks because they weaken the model's performance. Label sanitization, detection and correction methods have been proposed by the authors to minimize the damage from attacks where attackers modify training labels intentionally. This study details the significant accuracy reduction triggered by label flipping attacks, which primarily affects binary classification tasks. To fight such scenarios, the authors introduced a labeling sanitization system.

The k-nearest neighbors (k-NN) method acts as the foundation for this technique, which evaluates suspicious data points through comparison with their nearest neighbors. The algorithm detects infected samples by performing a check that results in either elimination or correction of those samples. The defense mechanism specifically targets label flipping attacks but cannot prevent other poisoning attacks, such as backdoor attacks [17] or gradient manipulation in the same way. The k-NN sanitization method depends on the data set characteristics. In data sets with numerous dimensions, the k-NN algorithm shows reduced effectiveness, whereas the sanitization process leads to possible clean data removal which minimally affects the model prediction accuracy.

Luis Mu˜noz-Gonz´alez et al. [13] evaluated the vulnerability of deep learning model to data poisoning attacks through their proposed novel execution method. The authors extended data poisoning attacks from binary classifiers to multiclass classifiers while demonstrating wider threat applicability. The authors created a back-gradient optimization method that uses automatic differentiation to compute efficient gradients, allowing adversaries to create deceptive training samples that affect multiple models within neural networks and deep learning systems. A new attack method has been successfully applied across different applications, including both spam filtering systems and malware detection systems, and handwritten digit recognition systems. This research demonstrates that adversaries can create transferable attacks through adversarial training, which enhances the destructive capacity of such attacks and defense strategies are not addressed in this study.

Different types of poisoning attacks and their prevention strategies [18] are discussed to improve the efficiency of ML models.Some real time poisoning attack scenarios and detection methods [19] to determine the relevance of using secure ML systems. Jodayree,et al. [5] proposed a robust prevention scheme to enhance the security of federated learning. Three algorithms are proposed here to enable the creation of encrypted and decrypted verification keys for federated learning data files on a training node. Malicious participants are eliminated by the federated learning server and prevent backdoor attacks with the help of an encrypted verification scheme.It can be useful only on low-processing devices. Differentially Private Federated Learning is discussed to perturb the communicated data via independent random noise to pose challenges to user privacy identification.

Ali,et al. [20] proposed two-step defense methods such as global filtering, selffiltering, and adaptive threshold strategy.To address more complex attack patterns, there is a need for various other anomaly detection methods. The need for security of FL systems in IOHT applications [21]. Jia,et al. [22] proposed a generic poison detection approach named CodeDetector to automatically detect poison samples in a suspicious dataset. This study discussed security issues and the need for a more defensive layer.

A. Explainable AI (XAI) and SHAP

A model's predictions become transparent through explainable AI methods (XAI) which ensures that the predictions can be trusted and interpreted. SHAP [23]is a commonly used XAI method that assigns importance values to input variables according to their influence on the model outputs. Anomaly detection benefits from SHAP values because they reveal important influencing features when flagging irregular feature contributions during decision-making processes. The theoretical basis of SHAP relies on Shapley values from cooperative game theory, which provides equitable feature contribution assessments. Lundberg,et al. [24]created an approach that computes SHAP values effectively for complex ML models. Learning professionals used SHAP to demonstrate its success in interpreting tree-based models [24] together with deep learning architectures and alternative machine learning techniques.

SHAP was employed to identify poisoning attacks in adversarial machine learning through the identification of inconsistent feature attributions. Molnar (2022) explained that the interpretability technique SHAP functions to enhance security because it reveals manipulated features present in datasets. SHAP enables the strong protection of ML models against adversarial threats because it delivers clear explanations of individual predictions. Table I shows some recent methods used to detect and prevent poisoning attacks.

III. Problem Statement

Data poisoning corrupts training data, which degrades model functionality and establishes unauthorized access points. These attacks create major threats to datasets containing both images and texts because they specifically target distributed systems. This leads to undesirable outcomes that affect the performance of the distributed ML systems. To handle such systems efficiently, a better data poisoning attack detection and prevention method is required.

TABLE I. SOME RECENT METHODS USED TO DETECT AND PREVENT POISONING ATTACKS AND THEIR CHALLENGES.

Year	Methods Used	Challenges
2025	Global model aggregation algorithm designed to mitigate poisoning attacks [39]	Need more defensive method to address jamming and poisoning attacks in wireless FL networks.
2025	Two-step defense methods,such as global filtering, self-filtering, and adaptive threshold [20]	In order to address more complex attack patterns, there is a need for various other anomaly detection methods to be used.
2024	A generic poison detection approach named CodeDetector to automatically detect poison samples in a suspicious dataset [22]	Security issues, there is a need for a defense layer as extended work.
2023	An encrypted verification scheme in the federated learning model [5], preventing poisoning attacks without requiring specific attack detection programming	Useful only for only low processing devices. Difficult to handle complex data.

Assume that the clean training dataset be:

$$\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{n}$$

Calculate the model parameters through empirical risk minimization:

$$\theta^* = \arg\min_{\theta} \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}(f_\theta(x_i), y_i)$$

A. Formulation of Poisoning Attack

m malicious samples are injected by adversary:

$\mathcal{D}_p = \{(x_j^p, y_j^p)\}_{j=1}^{m}$.

Then, the poisoned dataset becomes:

$$\mathcal{P}' = \mathcal{P} \cup \mathcal{P}_d$$

The attacked model parameters are calculated as:

$$\theta_p^* = \arg\min_{\theta} \frac{1}{n+m} \sum_{(x,y)\in\mathcal{D}'} \mathcal{L}(f_\theta(x), y)$$

B. Security Goal

The machine learning system is robust, if:

$$\|\theta_p^* - \theta^*\| \leq \epsilon$$

where, the poisoning ratio is:

$$\alpha = \frac{m}{m+n}$$

IV. ADVERSARY ASSUMPTIONS AND THREAT MODEL

A. Distributed Learning Environment

Consider a distributed learning environment that consists of a central server S, which coordinates different participating clients. Each client contains a private local dataset. A local optimization occurs on its own dataset, and each client sends the updates on the model to the server which summarizes them to create the following global model.

B. Adversary Assumption

Consider a limited Byzantine adversary that may fail at most fraction. Bad users can organize and interfere with their local information or sent updates. The adversary acts in either a white-box environment (information about model architecture, global parameters and aggregation rule) or a black-box environment (only has access to compromised local information); unless or otherwise, the more powerful white-box assumption is used.

The attack budget is limited by local data poisoning rate and an update magnitude to have realistic adversarial capability. We measure availability attacks, targeted attacks and backdoor attacks.

The opponent is not allowed to attack the central server, corrupt the mechanism of aggregation, or corrupt validation or test data or to surpass the specified fraction of attack clients. The outlining framework identifies abnormal updates of clients, and suppresses their effects by using powerful aggregation, which ensures that convergence is stable with the influence of attacks being limited under these adversarial conditions.

C. System Model

Here, the model is a federated learning system where all participants are synchronized and where the weighted aggregation of models is done by a central server at every round. Clients calculate local updates on personal data and send this to the server where it is aggregated. The proposed method is applied in the server side which identifies and blocks suspicious updates prior to parameter fusion.

V. PROPOSED METHODS

This method includes different sequential steps for operation. The data ingestion phase enables various clients to send their processed data to the system. Transfer learning-based systems have been used to detect GAN poisoning attacks. Multimodal data, such as image,text data enters the processing system through ViT and BERT [26] before being efficiently processed. Encryption is performed by AES [6,25,27] using RSA Signing method, which provides data security during communication and storage. The distributed learning method allows clients to perform local training and receive securely encrypted information through security protocols. The system detects anomalies through autoencoder. Feature changes can be identified by the SHAP Explainability system when the system explains the prediction models.

The system combines different advanced methods to build a distributed machine learning (ML) [29] model training framework that delivers strong performance and security features

while adapting to changing conditions.This system comprises four main processes, including data ingestion, hybrid RSA and AES encryption-decryption, autoencoder anomaly detection, and SHAP-based interpretability functions.

The operation of proposed system begins with a data ingestion stage. The initial step combines the task of collecting raw data from several sources with the preprocessing operations. Multiple data sources are feed into the system to produce standardized, clean data that are ready for machine learning operations. The system features multiple data type compatibility along with various data source compatibility to accommodate the needs of different distributed environments.

For efficient operation of the ML algorithm, data ingestion methods need to maintain both quality and data consistency because these criteria establish a foundation for the model.The proposed system shields data through a dual encryption solution that joins the Rivest-Shamir-Adleman RSA [30] keys with AES[24] (Advanced Encryption Standard). This approach leverages the strengths of both encryption methods and utilizes RSA encryption for safe encryption key transfers between its components. Data encryption under RSA requires two cryptographic keys that function in public and private form for security. Encryption takes place using the public key but the private key is responsible for the decryption operations. The system maintains secure information transfer of sensitive content such as model parameters and distributed node data through its configuration that defends against unauthorized access.

Large amounts of data undergo secure encryption and decryption using AES (Symmetric Encryption). The encryption process using AES occurs with shared secret keys, which leads to quicker and more efficient encryption of large datasets compared to RSA encryption. During the training and inferential processes, AES operates on bulk data to secure data during transmission and storage.

The anomaly detection capability plays a vital role in such systems because distributed ML environments handle inputs from multiple diverse sources with different quality levels. The system utilizes autoencoders which are unsupervised neural networks, to identify anomalies within the input data. Training an autoencoder enables the network to master a reduced format of data while simultaneously building its reconstruction. Anomalies are detected by measuring the reconstruction error, which establishes the difference between the initial input data and the recreated version. Any data point exceeding the specified thresholds in its reconstruction error was identified as an anomaly. Distributed ML systems identify anomalies as problems, including data attacks and sensor faults that potentially harm model functionality or integrity. The system tracks anomalies in real-time to modify its operation based on changing data patterns while spotting problems that could disrupt the proper model training.

Machine learning model interpretation and trustworthiness increase through the utilization of SHAP (SHapley Additive exPlanations) within the system. The explanation system SHAP performs an unbiased analysis of separate feature impacts on the predictive outcomes for any model type. SHAP values are used to understand model predictions because this interpretability method reveals specific features that influenced

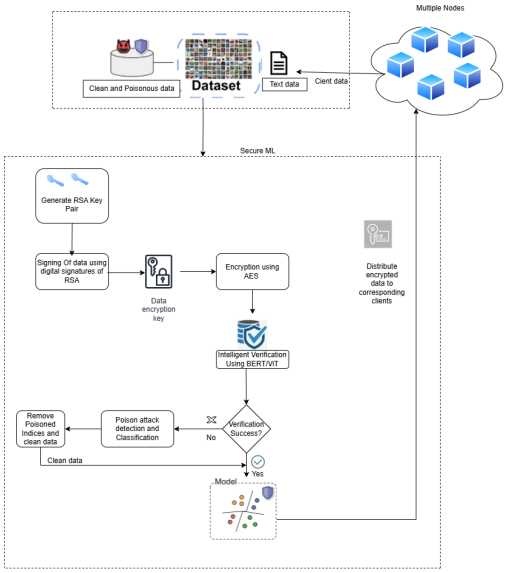

Fig. 3. Secure DML system.

outcomes the most. The interpretability of distributed ML systems becomes critical throughout multiple node training because it enables better debugging, performance improvements, and compliant privacy regulation implementations.

The incorporation of SHAP into the proposed system provides stakeholders with transparent decision-making capabilities to assess the prediction reliability and fairness of the model. The capacity to provide explanations makes this approach essential for industries that must follow explainability regulations in the field of healthcare and finance. The proposed system (Secure DML system) in Fig. 3 consists of data ingestion, encryption, and decryption using the hybrid approach of the RSA and AES methods, anomaly detection using autoencoders and integrity verification using BERT,ViT and SHAP-based interpretability to ensure robust and adaptive model training in distributed ML systems. The detailed steps are shown in Fig. 4.

VI. Experimental Evaluation

The experiments were performed in a distributed machine learning environment using Google Colab while utilizing GPUs to enhance the computational speed. The evaluation was conducted on two multimodal datasets: CIFAR-100 for images and AG News for texts. The development was performed through Python using TensorFlow along with PyTorch to accomplish AES-RSA encryption and BERT [31,32]verification through cryptographic libraries.

A. Datasets

The CIFAR-100 [33] benchmark includes 60,000 images divided into 100 distinct categories. The news articles in AG News [28] consist of 120,000 items divided across four classes. Here,10,000 samples were selected from which 3,000 consisted of clean data points and 7,000 contained poisoned samples with diverse attack methods such as misclassification, label flipping, backdoor, and perturbations. The level of poisoning

Algorithm 1 Secure Distributed ML System

Input: Clients $\{C_1, C_2, ..., C_N\}$, Global Model θ, Streaming Data $\mathcal{D}_t^{stream}$
Output: Securely Trained Global Model θ^* with Updates
Step 1: System Initialization
Generate RSA Key Pair (PK, SK)
Generate AES Key K_{AES}
for each client C_i **do**
  Encrypt K_{AES} with RSA: $K_{AES}^{enc} = Encrypt(PK, K_{AES})$
  Securely store K_{AES}^{enc}
  Initialize local model $\theta_i \leftarrow \theta$
end for
Step 2: Data Ingestion and Feature Extraction
for each client C_i receiving new data stream $\mathcal{D}_t^{stream}$ **do**
  Extract features from images using ViT and text using BERT
  Normalize and encrypt features using AES: $E_i = Encrypt(K_{AES}, X_i)$
end for
Step 3: Federated Learning with Secure Updates
for each global round $t = 1, 2, ..., T$ **do**
  for each client C_i processing real-time data **do**
    Train local model $\theta_{i,t}$ on encrypted data E_i
    Compute anomaly score $A_i = ||X_i - \hat{X}_i||^2$ using Autoencoder
    if A_i exceeds threshold **then**
      Mark data as suspicious, reject update
    else
      Send $\theta_{i,t}$ update to server
    end if
  end for
  Server aggregates valid updates: $\theta_{t+1} = \frac{1}{N}\sum_{i=1}^{N}\theta_{i,t}$
end for
Step 4: Model Adaptation
while system is running **do**
  Receive new client data
  Compute SHAP values for interpretability
  if SHAP indicates feature drift or anomaly **then**
    Adjust model training with adaptive learning rate
  end if
  Update global model θ^* dynamically
  Deploy updated model for inference
end while
End of Algorithm

Fig. 4. Steps for secure DML system.

is on the client level. A fraction of clients are assumed to be compromised, and inject malicious updates every time they undergo local training. The assumptions of Byzantine federated learning assume 30% of the clients are malicious. A variety of poisoning attack strategies have been employed to evaluate this approach. An attack strategy based on GAN provides data poisoning through adversarial samples that deceive classification models. The implementation of specific triggers through Backdoor Attacks allows predictions to be manipulated in their target directions. The process of label flipping was used to create inconsistencies within the dataset. Slight modifications of the data cause perturbation-based attacks. AES-256 [34] operated as the encryption method for data protection, whereas key exchange and digital signature operations relied on RSA-4096.

B. Results

The effectiveness of this cryptographic method can be implemented by comparing the method with benchmark methods. Fig. 5 shows the classification report and confusion matrix on multiple clients without a defense mechanism. As the number of clients increases,the attack detection rate decreases, as shown in Fig. 6. This demonstrates the need for a defense layer in ML systems. Adding a hybrid defense mechanism helps to secure sensitive data. The classification methods fail to provide interpretable explanations thus making it complex to understand decision-making reasons. This system integrates SHapley Additive exPlanations (SHAP) to generate detailed explanations for detected poisonous data samples. Through SHAP analysis, consistent features are discovered which led to the detection of anomalies among different clients.

The scatterplot showing anomalies are shown in Fig. 7 and the anomaly detection on multiple clients is shown in Fig. 8.

The BERT-ViT hybrid model functions as an integrity

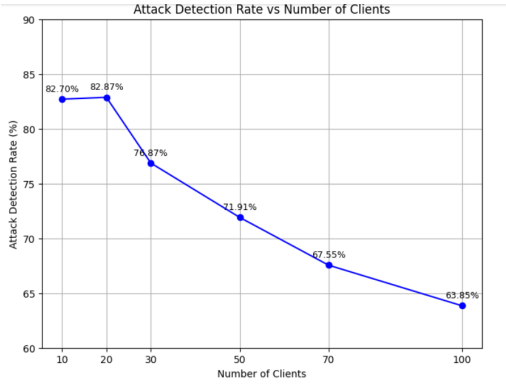

Fig. 6. Attack Detection rate without having defense mechanism.

verification system that verifies the authenticity of the data while detecting poisonous samples. The Attack Success Rates based on an increasing number of poisonous points are shown in Fig. 9. ASR can be calculated as:

$$ASR = \frac{Npsuccess}{Np} * 100 \quad (1)$$

where, $Npsuccess$ denotes the number of data samples and

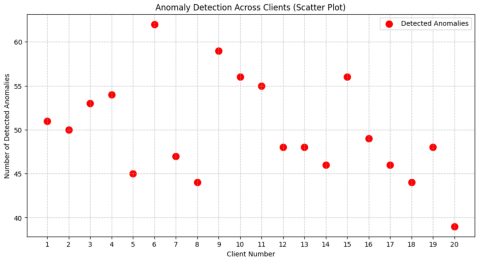

Fig. 7. Scatterplot showing anomalies.

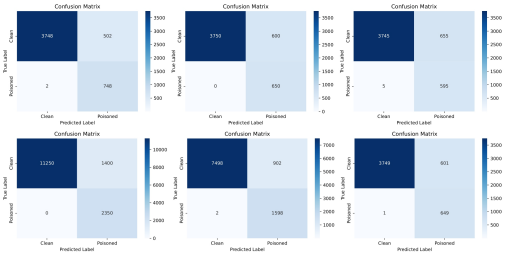

Fig. 10. Confusion matrix.

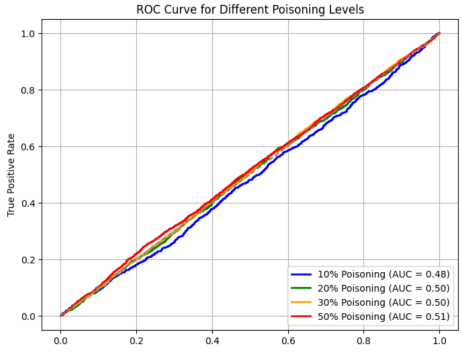

Fig. 11. ROC curve.

Fig. 12. Attack detection rate.

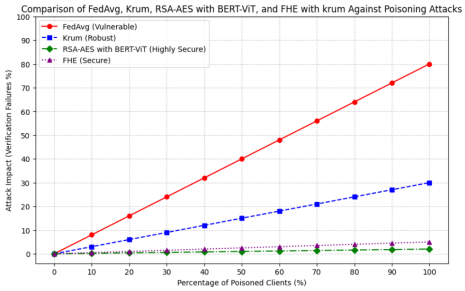

Fig. 13. Comparison with other methods.

Np denotes total no. of poisoned points.

The SHAP-based classification demonstrated better performance based on its high precision and recall values, as confirmed by the ROC curve analysis. The SHAP analysis delivered saturated results through its confusion matrix where poisonous and clean data categories showed distinct separation.

The effectiveness of SHAP based methods can be achieved using a confusion matrix which is shown in Fig. 10.

The ROC curve in Fig. 11 shows the variation of AUC values across different levels of poisoning.

The poisoning attack detection rate across an increased number of clients (number of clients 10,20,30,..100) are shown in Fig. 12. As the number of client increases, the rate of attack detection becomes relatively stable, indicating that the system is highly robust. The detection performance of the system was high, which demonstrates the scalability of the system.

VII. Discussion

This proposed defense method is compared with other benchmark methods such as KRUM [36],FedAvg [38], and FHE [37] methods.The verification failures are less in the proposed method as compared with other methods.This indicating that the hybrid defense method is highly secure.The analysis graph is shown in Fig. 13.

VIII. Applications and Future Enhancements

The proposed method is used to maintain secure federated learning models [35] by protecting them from distributed machine learning attacks. Hybrid RSA-AES encryption allows the approach to provide protected model updates thereby proving ideal for sensitive applications, including healthcare and finance. The detection capabilities of the system are improved through nDPI-based poisoned packet detection in network environments. The system permits the immediate disclosure of adversarial network traffic while Streamlit operates an intrusion detection dashboard that delivers an easy-touse interface to security analysts to track potential threats in real time and network intrusion detection systems are enhanced through the analysis of poisoned packets by combining nDPI with deep learning classifiers.

Data manipulation must not impact AI systems operating in finance, autonomous systems, or healthcare applications. This system can be applied to the management of IoT system security and edge environments. The system can be expanded to perform better multimodal verification when applied to security applications such as Deepfake detection in video environments. The system's resistance to adversarial modifications in voice-based AI systems increases when the integration of Whisper or Wav2Vec models is included. This system is highly secure, achieves privacy and protection, and is scalable for

moderate users. Its explainability feature helps to detect and interpret anomalous features. Although the system achieves better performance, the computation overhead is still an issue, which is further enhanced in the future.

IX. Conclusion

Security threats from poisoning attacks create major problems in the performance and integrity of distributed machine learning models. The attackers inject deceptive or harmful information into model training, which damages performance and quality, and generates incorrect predictions. This system offers a unified solution that uses various cutting-edge methods to detect and protect against poisoning. The proposed system offers security through robust distributed ML models, enhancement, and protective measures to combat poisoning attacks. The system utilizes anomaly detection together with secure encryption and model interpretability to discover suspicious data while stopping malicious inputs, thereby maintaining the uninterrupted integrity of distributed models. Thus, distributed ML systems are secure against adversarial attacks and maintain good performance.

***Abstract*—Post Quantum Cryptographic (PQC) techniques are widely used in encryption standards and digital signatures. Lattice-based post-quantum cryptographic techniques have been reported in the last decades. The present work proposes an optimized quantum-safe lattice public key encryption (PKE) scheme based on the Module Learning with Rounding (MLWR) problem, enhanced by the use of Incomplete Number Theoretic Transform (NTT). The objective of the proposed scheme is to achieve efficient encryption and decryption while maintaining robust security in accordance with the National Institute of Standards and Technology (NIST) recommendations. The incomplete NTT relaxes the modulus q requirement, enables a smaller modulus for efficient arithmetic, and reduces computational complexity. This approach results in significant improvements in the speed of key generation, encryption, and decryption with a marked reduction in rejection probability, compared to schemes utilizing complete NTT. The proposed scheme demonstrates competitive performance against other lattice-based encryption schemes such as Kyber and Frodo. It shows lower encryption and decryption times while offering comparable security levels. Proposed scheme is at least a hundred times faster than Frodo lattice-based public-key encryption schemes. For NIST-recommended security level, in proposed scheme, each encryption needs an average of 300K CPU cycles, and each decryption needs 120K CPU cycles. Additionally, modulus 7937 enables a reduction in key and ciphertext sizes, optimizing the scheme for practical deployment in resource-constrained environments. Performance evaluations confirm the practicality of the scheme with substantial reductions in computational overhead, making it a highly efficient and secure candidate for post-quantum encryption.**

I. Introduction

The rise of quantum computing poses a critical challenge to traditional cryptographic systems, which largely depends on the difficulty of solving mathematical problems like prime factorization and discrete logarithms. These problems form the basis of many widely used encryption schemes, but quantum algorithms, particularly Shor's algorithm [1], can solve them in polynomial time. This has led to an urgent need for cryptographic techniques that can resist quantum attacks, thus fueling the development of post-quantum cryptography (PQC). Since the National Institute of Standards and Technology (NIST) launched an initiative to develop new encryption standards that are unbreakable by quantum computers, PQC [2], [3] is getting more and more attention. One of the most appealing areas in PQC is lattice-based cryptography (LBC). LBC grabbed the theoretical community's interest because LBC structures are accompanied by security proofs ingrained in worst-case instances. Ajtai and Dwork [4] proposed 1^{st} lattice-based encryption algorithm. Regev later simplified and improved on this approach in [5]. The formulation of an intermediary problem, Learning with Errors (LWE) was one of Regev's key contributions. LWE was asymptotically at least as hard as certain traditional worst-case lattice problems [6], [5], and reasonably straightforward to utilize in cryptographic constructs.

LWE involves sampling errors using Gaussian distributions to introduce noise, which forms the backbone of its cryptographic constructs. Banerjee et al. [7] created learning with rounding (LWR) problem, which is an LWE variant with derandomization; LWR creates an instance utilizing deterministic rounding under a small modulus instead of introducing random errors to make it noisy. LWR instance sampling is simpler than LWE instance sampling since it does not use the Gaussian sampling technique. Several recent studies on the hardness of LWR problem have concluded that LWR problem is at least as difficult as the LWE problem when the number of samples is limited [8].

Schemes based on LWE variant require sampling from error distributions for randomness. Also, errors introduced into ciphertexts and public keys inevitably result in increased bandwidth. Since the error is made predictably, LWR-based schemes reduce the bandwidth by using a small rounding modulus. The module variants of the problems enable interpolation of the original LWR/LWE problems and their ring variants, reducing bandwidth and complexity of computation. It is possible to increase the level of security of Ring-LWE/LWR without making any changes to the basic mathematics, as demonstrated by the modules [6], [9].

One key observation in LBC is the dominance of polynomial multiplication as the most time consuming operation in these schemes. LBC relies on high-degree polynomials, making polynomial multiplication the bottleneck for efficiency. Fig. 1 highlights the time profiles of various LBC schemes, confirming that polynomial multiplication significantly impacts performance.

*Corresponding author.

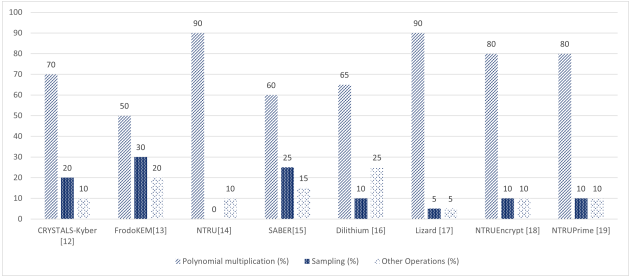

Fig. 1. Time-consuming operations in lattice-based cryptographic schemes [10], [11], [12], [13], [14], [15], [16], [17].

Efficient implementation of polynomial multiplication methods can significantly reduce the computational overhead in LBC schemes, making these schemes more practical for real-world applications.

Lattice-based schemes, particularly those employing the module variants of LWR, strike an effective balance between bandwidth reduction and computational complexity. They facilitate efficient polynomial operations through techniques like Number Theoretic Transform (NTT), a method for fast polynomial multiplication in finite fields. However, the traditional NTT approach can become computationally expensive when polynomials are large. To address this, Incomplete NTT [18] introduces a hybrid methodology where NTT process is truncated early for smaller sub-polynomials allowing alternative, simpler multiplication methods like the schoolbook algorithm to handle smaller parts. This truncation reduces computational overhead and makes the scheme more efficient without compromising security.

Current proposal: Present study proposes an efficient encryption scheme which uses an optimization technique that combines Module Learning With Rounding (MLWR) with Incomplete NTT for polynomial multiplication. The proposed PKE scheme comprises of generation of keys, encryption, and decryption algorithms. The time needed to create keys and complete the decryption procedure is incredibly quick when compared to other lattice-based PKEs. Joel Alwen et.al.'s LWR properties are taken into consideration while choosing parameters for key generation, encryption, and decryption [9]. In the proposed scheme, a public matrix is created using an expansion function that uses the generalized hash function Shake-256 [19]. Additionally, the proposed scheme incorporates the Montgomery Reduction Algorithm [20], which optimizes modular arithmetic by transforming the modulus into a more computationally manageable form. This transformation enables faster computations during key generation, encryption, and decryption processes by reducing the cost of modular multiplications. The Incomplete NTT and Montgomery Reduction Algorithm are employed in the proposed approach to accelerate matrix multiplication and to reduce modulus, respectively. Using the MLWR offers an optimal ground between security and efficiency [21] in comparison to the original LWR and Ring-Learning with Rounding (RLWR) problems. The proposed scheme is more efficient than earlier methods because it also decreases the size of a public key by using a rounding function. For a recommended security level, proposed scheme's public key size is 1632 bytes. Choice of the underlying hard problem, as well as the scheme's parameters (Secret distribution range η, modulus q, polynomial ring $(X^{256}+1)$, and rank of module k), are inspired by 3 key principles: simplicity of the scheme, efficiency, and flexibility.

Technical novelty of proposed work lies in the specific hybrid integration of MLWR problem with an Incomplete NTT using the prime modulus $q = 7937$. While existing lattice-based schemes utilize either standard LWE with NTT (e.g., Kyber) or MLWR with alternative multiplication methods (e.g., SABER), our construction leverages a unique synergy. By setting the truncation level to $\beta = 1$, we halt the butterfly operations early, which reduces computational cycles while maintaining robust security margins. This specific optimization avoids the final, most computationally expensive stage of decomposition, offering a tailored balance between performance and quantum resistance.

Section II gives the necessary background information; Section III presents related work. Section IV describes proposed PKE with correctness and security; Section V discusses implementation details; Section VI discusses the result and its comparison with other lattice-based PKEs; and in Section VII we state the conclusion and future work.

II. Preliminaries

A. Notations

$\mathbb{Z}_q$ is the integer ring under modulo q, and $\mathbb{Z}$ mod q is $\mathbb{Z}$'s reduction in $[0, q)$. With $N = 256$, R_q is quotient ring $\mathbb{Z}_q[x]/(x^N + 1)$. R_q^k is the k-dimensional quotient ring under modulus q. Uppercase bold alphabets are used for matrices, such as "matrix $\boldsymbol{A}$", whereas lowercase regular alphabets are used for scalars, such as "scalar p", and lowercase bold alphabets are used for vectors, such as "vector $\boldsymbol{s}$". The symbol $\mathcal{L}(B)$ denotes the lattice produced by basis set B. Sample vector $\boldsymbol{a}$ from the distribution $\mathcal{D}$ is denoted by $\boldsymbol{a} \leftarrow \mathcal{D}$. The sample vector $\boldsymbol{a}$ according to a centered binomial distribution β_i is denoted by $\boldsymbol{a} \leftarrow \beta_i$. Primitive N^{th} root of unity denoted by ζ. Primitive $2N^{th}$ root of unity denoted by Ψ.

Convolution: For polynomials **a,b** in $\mathbb{Z}[x]$ with length N. Convolution simplifies to

$$c_k = \sum_{i=0}^{k} \mathbf{a}_i \mathbf{b}_{k-i}, \quad k = 0, \ldots, 2N-2$$

This corresponds to the coefficient-wise multiplication of the polynomials.

- Cyclic Convolution: equivalent to polynomials and multiplication in $\mathbb{Z}[x]/(x^N - 1)$
- NWC (Negative Wrapped Convolution): is used for polynomial multiplication when polynomials are in the quotient ring $\mathbb{Z}[x]/(x^N + 1)$

In the context of NTT, the arrangement of input and output coefficients plays a critical role in the efficiency of algorithms. Two common types of orderings are:

- Normal Order (no): Coefficients are arranged in increasing natural order (e.g., $[x_0, x_1, x_2, \ldots, x_{n-1}]$)
- Bit-Reversed Order (bo): Coefficients are rearranged such that their indices correspond to the bit-reversed representation of the original indices

We adopt the notation from [22] for the Cooley-Tukey NTT algorithm. Specifically:

$$NTT^{CT,\Psi}_{no\rightarrow bo,\beta=1}(\mathbf{x})$$

where,

- NTT^{CT}: Indicates the Cooley-Tukey algorithm is used.
- Ψ: Refers to the twiddle factors ($2N-th$ roots of unity) used in NTT the computation.
- $no \rightarrow bo$: Specifies that the input coefficients are in natural order (no), while output coefficients are in bit-reversed order (bo).
- $\beta = 1$: Implies a number of levels cropped in NTT computation.

B. Lattices

A lattice is an infinitely expanded structure of discrete points arranged in a repeating pattern. The lattice is constructed by an integer linear combination of independent basis vectors. Set B is a collection of N-linearly independent vectors. The dimension of the lattice is N. let $B = b_1, b_2, b_3, b_4, b_5, \cdots, b_N$

$$\mathcal{L}(b_1, b_2, b_3, b_4, b_5, \cdots, b_N) = \left\{ \sum_{j=1}^{N} y_j b_j : y_j \in \mathbb{Z} \ \& \ b_j \in \mathbb{R} \right\}$$

C. Module Lattices

Module lattices extend the concept of lattices to modules over a ring. Let R be a ring, and k be a rank of R-module. A module lattice $\mathcal{L}$ in R^k is a discrete set of points in R^k defined as Eq. (1):

$$\mathcal{L} = \left\{ \sum_{i=1}^{k} z_i \mathbf{b}_i : z_i \in R \right\}, \tag{1}$$

where, $\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_k \in R^k$ are the basis vectors of the module lattice.

D. Learning with Errors (LWE)

LWE [5] for N-dimensions, α error rate, and q as a modulus denoted as $\text{LWE}_{N,q,\alpha}$ and defined as follows:
From given samples $(\boldsymbol{a}_j, b_j) \in \mathbb{Z}_q^N \times \mathbb{Z}_q$, where: $\boldsymbol{a}_j$ is chosen uniformly at random, and b_j is computed as:

$$b_j = \langle \boldsymbol{a}_j, \boldsymbol{s} \rangle + e_j \mod q$$

with $\langle \boldsymbol{a}_j, \boldsymbol{s} \rangle$ representing the inner product of $\boldsymbol{a}_j$ and a secret vector $\boldsymbol{s} \in \mathbb{Z}_q^N$ and e_j is a small error term sampled from a error distribution χ. The LWE problem is to recover the secret vector $\boldsymbol{s}$ by solving a given noisy linear equation.

The LWE problem can be expressed in matrix form as:

$$\boldsymbol{A}\boldsymbol{s} + \boldsymbol{e} = \boldsymbol{b} \mod q,$$

where, $\boldsymbol{A} \in \mathbb{Z}_q^{N \times N}$ is a matrix with rows $\boldsymbol{a}_j$

E. Learning with Rounding (LWR)

Banerjee et al. [7] first presented the LWR problem for enhancing efficiency of the LWE-based pseudorandom generator (PRG). It was used to build reusable computational extractors, lossy trapdoor functions, and deterministic encryption. In fact, the LWR problem may be considered as a deterministic alternative to LWE problem. The only difference is that the error in LWR is deterministic, which makes it less random than the Gaussian error in LWE. Error in the LWR is caused by a scaling operation in the rounding function. In particular, the error in LWE is β-bounded ($\beta > 2\sqrt{N}$) for security [8], while error in LWR is less than $1/2$. Scaling $\mathbb{Z}_q$ down to $\mathbb{Z}_p$ generates the deterministic error, where p is a rounding modulus.

The scaled rounding function [12] is defined like this:

$$\lfloor \cdot \rceil_p \text{ is } \mathbb{Z}_q \rightarrow \mathbb{Z}_p : p < q \ .$$

For matrix $\boldsymbol{A}$, and vector $\boldsymbol{s}$ a sample of LWR is obtained by:

$$(\boldsymbol{A}, b = \lfloor < \boldsymbol{A}, \boldsymbol{s} > \rceil_p)$$

F. Module Learning with Rounding (MLWR)

MLWR is a module variant of LWR, specifically tailored for cryptographic applications. It combines the modular arithmetic of lattices with the deterministic rounding technique of LWR to achieve efficient and secure constructions.

In the MLWR problem, the objective is to compute the approximate inner product of a secret vector $\mathbf{s}$ with a public matrix $\mathbf{A}$ while reducing noise through deterministic rounding. Formally, for a modulus q and a smaller modulus p, the MLWR sample is generated as:

$$\mathbf{b} = \left\lfloor \frac{p}{q} \cdot (\mathbf{A} \cdot \mathbf{s}) \right\rceil \mod p$$

where,

- $\mathbf{A} \in \mathbb{Z}_q^{k \times k}$ is a public matrix.
- $\mathbf{s} \in \mathbb{Z}_q^k$ is a secret vector.
- $\lfloor \cdot \rceil_p$ denotes deterministic rounding to the nearest multiple of p.

G. Number Theoretic Transform (NTT)

NTT [23] is a discrete Fourier transform (DFT) defined over finite fields. It is a crucial tool for efficient polynomial multiplication in cryptographic schemes, especially in LBC. The NTT maps polynomial coefficients into a point-value representation using N-th roots of unity modulo a prime q.

NTT enables fast polynomial multiplication with integer coefficients and is widely employed in LBC schemes. For the NTT to be well-defined, the modulus q must satisfy $q \equiv 1 \pmod{2N}$, ensuring the existence of a primitive N-th root of unity ζ modulo q.

The goal of NTT is to multiply two polynomials having integer coefficients such that the computed polynomial coefficients lie under a specific module. The advantage of NTT is that it provides a fast technique for multiplication whereas the disadvantage is that NTT is possible with prime modulo of the form like $2^a \cdot b + 1$ where a and b are arbitrary constants.

Given a polynomial $a(x) = \sum_{i=0}^{N-1} a_i x^i \in Z_q[x]/\langle x^N - 1 \rangle$, the NTT transforms it into its evaluation at N-th roots of unity modulo q.

For NTT to be well-defined and invertible, the following conditions must hold:

- The modulus q must be a prime number such that $q \equiv 1 \pmod{2N}$
- A primitive N-th root of unity ζ must exist modulo q, i.e. $\zeta^N \equiv 1 \mod q$

Forward NTT transforms a polynomial $a(x)$ from its coefficient representation into its evaluation (point-value) representation. Forward NTT of $a(x)$ is computed as Eq. (2):

$$\hat{a}_k = \sum_{j=0}^{N-1} a_j \zeta^{jk} \pmod{q}, \quad k = 0, 1, \ldots, N-1 \tag{2}$$

The inverse NTT (iNTT) transforms the point-value representation back to coefficient form [see Eq. (3)]:

$$a_j = \frac{1}{N} \sum_{k=0}^{N-1} \hat{a}_k \zeta^{-jk} \pmod{q}, \quad j = 0, 1, \ldots, N-1 \tag{3}$$

Here, N^{-1} is a modular multiplicative inverse of N modulo q.

Efficient computation of the NTT relies on algorithms that exploit symmetries in the evaluation process. The Fast Fourier Transform (FFT) [24] is an efficient algorithm to compute DFT of a sequence. In context of polynomial multiplication, FFT is instrumental in reducing the computational complexity from $O(N^2)$ to $O(N \log N)$. The FFT decomposes a polynomial into simpler components using a divide-and-conquer strategy, exploiting the properties of roots of unity.

The FFT process involves recursively splitting the polynomial ring $Z_q[x]/(x^N + 1)$ into smaller subrings. At each stage, the polynomial is divided into two halves using specific roots of unity. For example, the ring $Z_q[x]/(x^N + 1)$ is split into $Z_q[x]/(x^{N/2} - \Psi^{N/2})$ and $Z_q[x]/(x^{N/2} + \Psi^{N/2})$, where Ψ is primitive $2N^{th}$ root of unity. This process is repeated until the polynomial is reduced to base components, such as $Z_q[x]/(x - \Psi)$ or $Z_q[x]/(x + \Psi)$, which are directly computable.

Two widely used approaches of FFT are the Cooley–Tukey(CT) [25] and Gentleman–Sande(GS) [26] algorithms:

- Cooley–Tukey(CT) Algorithm: The CT algorithm is also known as the Decimation-In-Time (DIT). It performs the transformation by dividing input sequence into even and odd indices. Key step involved in the butterfly operation is:

$$a' = a + \zeta b, \quad b' = a - \zeta b,$$

where, ζ is the twiddle factor (root of unity).

The butterfly operation for Cooley–Tukey is illustrated in Fig. 2. This method starts with the input in natural order and produces an output in bit-reversed order.

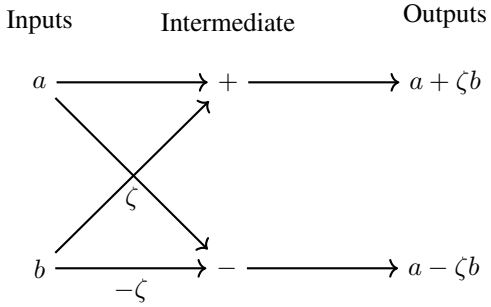

Fig. 2. Cooley-Tukey butterfly.

- Gentleman–Sande (GS) Algorithm: The GS algorithm is also known as the Decimation-In-Frequency (DIF). It follows a similar divide-and-conquer approach but starts with the coefficients of the polynomial arranged in a bit-reversed order. Inverse NTT is often implemented using this algorithm, as it efficiently reconstructs the original sequence from its Fourier-transformed counterpart. The butterfly operation in Gentleman-Sande is given by:

$$a' = a + b, \quad b' = (a - b) \cdot \zeta^{-1}$$

Fig. 3 illustrates the Gentleman–Sande butterfly operation. This algorithm efficiently reconstructs the original sequence from its transformed version.

Both algorithms use butterfly operations to combine intermediate results efficiently.

NTT Applications in Polynomial Multiplication: Polynomial multiplication in cryptographic schemes often involves convolutions. Using NTT, the multiplication of two polynomials $a(x)$ and $b(x)$ modulo $x^N - 1$ is performed as:

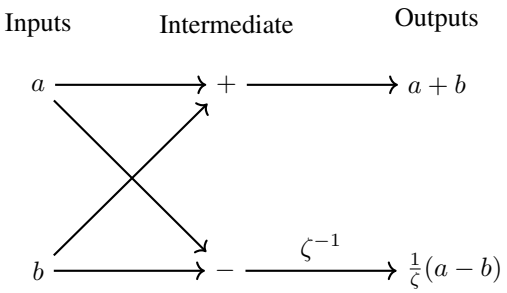

Fig. 3. Gentleman-Sande butterfly.

- Compute the NTT of $a(x)$ and $b(x)$: $\hat{a} = NTT^{CT,\zeta}(a(x))$, $\hat{b} = NTT^{CT,\zeta}(b(x))$ refer Eq. (2).
- Perform pointwise multiplication: $\hat{a}_k \circ \hat{b}_k \pmod q = \hat{c}_k, \ \forall k = 0, 1, \ldots, N-1$, $\circ$ denotes pointwise multiplication in NTT domain.
- Compute inverse NTT of $\hat{c}$ to obtain product polynomial in coefficient form: $c(x) = iNTT^{GS,\zeta^{-1}}(\hat{c})$ refer Eq. (3).

This process reduces the complexity of polynomial multiplication from $O(N^2)$ to $O(N \log N)$, making it highly efficient for cryptographic applications.

NTT has been integrated into the specifications of several post-quantum cryptographic schemes, including Kyber, Saber, and Dilithium. These schemes leverage their efficiency to perform fast polynomial arithmetic, enabling secure and efficient Public Key Encryption (PKE) and signature generation.

H. Incomplete NTT

Incomplete NTT method is employed for polynomial multiplication when dimension (N) of the lattice is a power of two and modulus q is an NTT-friendly prime but does not satisfy $q \equiv 1(mod 2N)$. An incomplete NTT method does not have to map $Z_q[x]/(x^N + 1)$ down to linear terms, and one can stop its mapping before the last β level, $\beta = 0, 1, \cdots, \log N - 1$

Mathematical Formulation: Given two polynomials $\mathbf{x}$ and $\mathbf{y}$ in $Z_q[x]/(x^N + 1)$, their product $\mathbf{r}$ using incomplete NTT is computed as:

$$\mathbf{r} = \text{INTT}_{bo\to no}^{GS,\Psi^{-1}} \left(\text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{x}) \circ \text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{y}) \right),$$

where:

- $\text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}$: Forward Cooley-Tukey NTT [25] up to $\beta = 1$ level
- $\text{INTT}_{bo\to no}^{GS,\Psi^{-1}}$: Inverse Gentleman-Sande NTT [26] to reconstruct the coefficients

Fig. 4 illustrates the polynomial splitting process in the incomplete NTT, showing how the polynomial ring $Z_q[x]/(x^N + 1)$ is gradually decomposed into smaller components till it reduces to degree two polynomials. The decomposition stops early, reducing computational overhead while maintaining accuracy. It requires $(\log(N) - 1)$ steps.

Advantages of Incomplete NTT:

- Relaxed Conditions for Modulus q: Incomplete NTT requires only a $\frac{N}{2}$-th root of unity for cyclic NTTs or an N-th root of unity for negacyclic NTTs, significantly increasing the range of valid q.
- Computational Efficiency: As it stops decomposition at an earlier level, incomplete NTT reduces the number of butterfly operations, saving additions and subtractions at the cost of slightly more complex base multiplications.
- Adaptability: The degree of incompleteness β can be tailored to optimize performance for specific platforms or resource constraints.

The forward incomplete NTT algorithm transforms a polynomial into its NTT domain representation using CT butterfly operations. Unlike complete NTT, which fully decomposes the polynomial down to linear terms, incomplete NTT stops earlier, saving computations and providing more freedom in parameter selection. The algorithm operates as follows:

- Initialization: Start with the full polynomial length N and segment it into smaller parts.
- Butterfly Operations: Apply Cooley-Tukey butterfly operations to each segment. For each pair of coefficients, compute their sum and difference, scaled by a twiddle factor, which is a precomputed power of a $2N$-th root of unity Ψ.
- Modulo Reduction: Ensure all intermediate results remain within the finite field $\mathbb{Z}_q$ by applying modulo q.

The inverse incomplete NTT reconstructs the coefficients from their partially transformed representation. The steps include:

- Initialization: Begin with segments of size 1 and progressively combine them to reconstruct the full polynomial.
- Butterfly Operations: Combine pairs of coefficients, using inverse twiddle factors and ensuring results remain within $\mathbb{Z}_q$.
- Normalization: After reconstruction, normalize all coefficients by multiplying with N_inv, the modular multiplicative inverse of N.

The incomplete NTT provides a flexible and computationally efficient alternative to complete NTT for polynomial arithmetic in cryptography. By halting decomposition at a higher level β, it reduces computational costs while relaxing constraints on the modulus q. This hybrid approach is particularly beneficial for resource-constrained environments like embedded systems and is implemented in schemes such as Kyber to achieve optimal performance.

III. Related Work

Lattice-based cryptography has emerged as a promising candidate for efficient and secure PQC schemes. The security of LBC is based on worst-case hard problems such as the Shortest Vector Problem (SVP) [27], Closest Vector Problem (CVP) [28], approximate Shortest Independent Vectors Problem (SIVP) [6], LWE [5] and Small Integer Solution (SIS) [6]. These problems provide robust security guarantees due to their inherent computational difficulty.

Early lattice-based PKE schemes, such as the Ajtai-Dwork cryptosystem [29], relied on SVP for security. However these schemes required high-dimensional lattices, leading to impractically large key sizes. The introduction of the NTRU cryptosystem [12] marked a significant milestone, offering compact key sizes and security rooted in polynomial rings. Later, Regev's LWE-based scheme [5] provided further improvements in efficiency, though it exhibited limited resistance to active attacks like chosen plaintext attack(CPA). Subsequent works, including Lindner and Peikert's PKE [30], reduced key and ciphertext sizes by leveraging optimized parameters.

In 2016, NIST initiated a call for PQC algorithm standardization [2], propelling the development of LBC. Notable candidates such as Kyber, Saber, and Frodo emerged, each demonstrating unique strengths:

- Kyber [10], a finalist in NIST PQC project, is based on Module-LWE(MLWE) problem. It incorporates NTT for efficient polynomial multiplication, enabling fast and memory-efficient implementations. Kyber's use of centered binomial distributions for sampling and its compatibility with NTT-friendly parameters make it highly optimized for modern cryptographic applications.

- Saber [13] relies on the MLWR problem, which eliminates error sampling and reduces randomness requirements compared to MLWE-based schemes. Saber uses alternative polynomial multiplication methods such as Karatsuba and Toom-Cook due to its power-of-two moduli, which are incompatible with traditional NTTs.

- Frodo [11] employs standard LWE and matrix-based multiplication over $\mathbb{Z}_q$. Although Frodo offers strong theoretical security guarantees, it suffers from higher bandwidth and computational requirements compared to structured lattice-based schemes.

MLWR problem offers multiple benefits that make it a compelling choice for cryptographic schemes:

- Simplified Sampling: Unlike MLWE, MLWR eliminates the need for error sampling, reducing computational overhead and simplifying implementations.

- Optimized Bandwidth: By using a small rounding modulus, MLWR achieves smaller ciphertext and key sizes, making it suitable for bandwidth-constrained environments.

- Security Guarantees: MLWR maintains security equivalence to MLWE under specific parameter constraints, offering robust protection against quantum attacks.

- Implementation Flexibility: MLWR-based schemes can be efficiently implemented using alternative polynomial multiplication techniques like NTT and Karatsuba, providing flexibility in resource-constrained environments.

The aforementioned benefits make MLWR a highly attractive foundation for designing practical and secure LBC systems, particularly in modern applications requiring both efficiency and scalability.

Proposed approach bridges the gap between the efficiency of power of two rounding in SABER and the fast NTT arithmetic found in Kyber. The novelty over SABER is a use of Incomplete NTT for faster polynomial multiplication, whereas the novelty over Kyber is the selection of $q = 7937$. Mathematically, $q = 7937$ is highly advantageous; it satisfies $q \equiv 1 \pmod{256}$, ensuring NTT compatibility, yet yields a rejection probability of only 0.031. This is a significant improvement over standard NTT-friendly primes

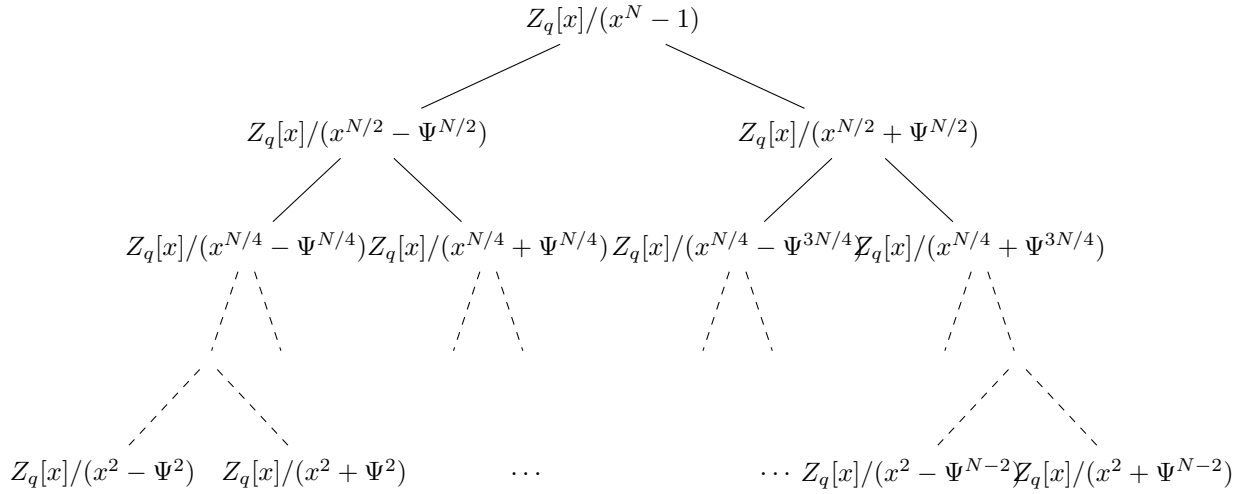

Fig. 4. Polynomial splitting in incomplete NTT.

like $q = 3329$ (rejection probability 0.594), directly optimizing the key expansion and sampling processes. Consequently, the proposed scheme achieves competitive execution times while minimizing the randomness requirements inherent in MLWE-based constructions.

A. NTT in Lattice-Based Cryptography

Efficient polynomial multiplication is a critical component of LBC. NTT and its inverse (INTT) play a pivotal role in modern implementations. We analysed NTT-based implementations in prominent NIST PQC schemes such as Kyber [10], Saber [13], NTRU [12], Dilithium [14], and Falcon [31]. These schemes adopt diverse strategies to optimize polynomial multiplication based on their underlying ring structures and security requirements.

NTT is particularly efficient for schemes with moduli satisfying $q \equiv 1 \pmod{2N}$, as seen in Kyber, Falcon, and Dilithium. Conversely, schemes like Saber and NTRU employ alternative techniques due to their use of power-of-two moduli or non-NTT-friendly rings. For example, Kyber transitioned from full NTT in its initial rounds to an incomplete NTT approach in later rounds, leveraging optimized Fast Fourier Transform (FFT) techniques to reduce computational complexity. NTT-unfriendly rings refer to polynomial rings where the structure of the ring does not align well with the standard requirements of NTT, such as specific polynomial degrees or forms. Common examples include rings where the degree N of the polynomial is not a power of two.

Incomplete NTT is a specialized variant of the traditional NTT that halts the decomposition process at an intermediate stage, skipping the final levels of polynomial transformation. This method reduces the number of butterfly operations required in Cooley-Tukey or Gentleman-Sande algorithms, significantly lowering computational complexity. Additionally, the incomplete NTT relaxes modulus requirements, enabling the use of smaller moduli, 7937. The reduced modulus allows for more efficient arithmetic operations, optimized memory usage, and smaller key and ciphertext sizes. These advantages make the incomplete NTT particularly best-suited for resource-constrained environments, such as IoT devices [32], where computational efficiency and reduced bandwidth are paramount.

B. Proposed Approach: Combining MLWR and Incomplete NTT

The proposed PKE scheme integrates the advantages of MLWR and the computational efficiency of incomplete NTT. MLWR reduces bandwidth and randomness requirements by eliminating error sampling, as demonstrated in Saber. Meanwhile, incomplete NTT minimizes computational overhead while maintaining compatibility with lattice-based polynomial arithmetic. These optimizations align with insights from Falcon [31] and Kyber [10], where NTT-based methods significantly enhance performance. By adopting this hybrid approach, the proposed scheme offers a post-quantum cryptographic solution with balanced security and efficiency.

IV. Proposed MLWR-Based PKE using Incomplete NTT

From the analysis of existing NTT in LBC, we have chosen the most efficient Incomplete FFT-based NTT for implementation of MLWR-based PKE. The first advantage of the proposed scheme is that it can reduce the ciphertext size by mapping coefficients from a larger ring $\mathbb{Z}_q$ to a smaller ring $\mathbb{Z}_p$. The second advantage is encryption and decryption times and the required CPU cycles are comparable to other prominent lattice-based candidates of the NIST PQC project.

Proposed PKE scheme incorporates the Incomplete NTT for efficient polynomial operations in LBC. The process begins with generating cryptographic parameters which are used to create a public key (for encryption) and a secret key (for decryption). A plaintext message is encrypted with a public key, producing a ciphertext. The decryption process uses a secret key $\boldsymbol{s}$ to recover original message. Incomplete NTT is applied during both encryption and decryption to optimize computational performance. This design ensures secure communication while enhancing efficiency in lattice-based cryptosystems.

Proposed scheme is made up of the following three algorithms:

A. MLWR Key Generation Algorithm

The proposed key generation algorithm constructs a public-private key pair for the MLWR-based PKE scheme. The process is detailed as follows:

- Seed Generation: A cryptographic seed denoted as $seed_\delta$, is generated using the SHAKE-256 hash function. This seed is a part of the public key pk and is used to generate a $k \times k$ public matrix $\boldsymbol{A}$.
- Matrix Construction: The matrix $\boldsymbol{A}$ is constructed with elements as polynomials in a ring $R_q = \mathbb{Z}_q[x]/(x^N + 1)$.

  Here:

  - q is a prime modulus suitable for incomplete-NTT operations.
  - $N = 256$, the degree of the polynomial, satisfies the incomplete-NTT and LWR specifications.
- Secret Key Generation: The secret key $\boldsymbol{s}$ is an N-dimensional short vector sampled from the ring R_q. Coefficients of $\boldsymbol{s}$ are chosen from a small range to ensure efficiency and maintain security.
- Public Key Computation: Public key attribute $\boldsymbol{b}^T$ is computed as:

$$\boldsymbol{b}^T = \left\lfloor \frac{p}{q} \cdot (\boldsymbol{A} \cdot \boldsymbol{s}) \right\rceil_p$$

  where: The multiplication $\boldsymbol{A} \cdot \boldsymbol{s}$ is optimized using the *Incomplete NTT* method, and p is the rounding modulus, smaller than q.

- Output: Public key pk consists of seed $seed_\delta$ and k-dimensional MLWR sample $\boldsymbol{b}^T$. The private key sk is the short vector $\boldsymbol{s}$.

The pseudocode for key generation algorithm is presented in Algorithm 1.

Algorithm 1 KeyGeneration($seed_\delta$)

1: $seed_\delta \leftarrow D\{0,1\}^N$ ▷ Generate a random binary seed.
2: $\boldsymbol{s} \leftarrow Ds_\eta^k$ ▷ Sample secret key $\boldsymbol{s}$ from distribution Ds_η^k
3: $\boldsymbol{A} \in R_q^{k\times k} := Expansion(seed_\delta)$ ▷ Expand the matrix $\boldsymbol{A}$ from the seed.
4: $\boldsymbol{As} = \text{INTT}_{bo\to no}^{GS,\Psi^{-1}}\left(\text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{A}) \circ \text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{s})\right)$ ▷ Efficiently compute $\boldsymbol{As}$ using incomplete NTT.
5: $\boldsymbol{b^T} = \lfloor \frac{p}{q}\boldsymbol{As}\rceil_p \in R_p^{k\times 1}$ ▷ Apply rounding operation
6: return $(pk := (seed_\delta, \boldsymbol{b^T}), sk := (\boldsymbol{s}))$ ▷ Output public and private key pair.

B. MLWR Encryption Algorithm

The encryption algorithm in the proposed MLWR-based PKE scheme efficiently transforms the plaintext into a ciphertext while ensuring performance. The steps are as follows:

- Plaintext Representation: The plaintext is represented as a $mbit$.
- Matrix Construction: Seed $seed_\delta$ is used to construct the matrix $\boldsymbol{A}$, whose elements belong to the ring $R_q = \mathbb{Z}_q[x]/(x^N+1)$
- Random Vector Sampling: A random N-dimensional vector $\boldsymbol{a}$ is sampled. This vector is then multiplied with the matrix $\boldsymbol{A}$ using the *Incomplete NTT* method, to optimize the computational efficiency. The result is stored in $\boldsymbol{u}$:

$$\boldsymbol{u} = \boldsymbol{A}\cdot\boldsymbol{a}$$

- Ciphertext Calculation: Using the public key attribute $\boldsymbol{b^T}$ and the plaintext message bit $mbit$ ($messagespace \in 0,1$), the ciphertext $\boldsymbol{c}$ is computed as:

$$\boldsymbol{c} = \boldsymbol{b^T a} + mbit\cdot\left\lfloor\frac{q}{2}\right\rfloor$$

  $mbit\cdot\lfloor\frac{q}{2}\rfloor$ operation encodes original message.
- Output: The encryption function outputs ciphertext $\boldsymbol{c}$ and the preamble $\boldsymbol{u}$.

Pseudocode for the encryption is presented in Algorithm 2.

C. MLWR Decryption Algorithm

The decryption process in the proposed MLWR-based PKE scheme is the final step, responsible for recovering the original plaintext message. The procedure involves the following steps:

- Intermediate Value Calculation: Using the secret key $\boldsymbol{s}$, the algorithm computes the intermediate value d_1 as:

Algorithm 2 MLWREncryption(pk,mbit)

1: $\boldsymbol{A} \in R_q^{k\times k} := Expansion(seed_\delta)$ ▷ Expand the matrix $\boldsymbol{A}$ from the seed.
2: $\boldsymbol{a} \leftarrow Ds_\eta^k$ ▷ Sample vector $\boldsymbol{a}$ from distribution Ds_η^k
3: $u = \text{INTT}_{bo\to no}^{GS,\Psi^{-1}}\left(\text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{A}) \circ \text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{a})\right)$ ▷ Compute $\boldsymbol{Aa}$ using incomplete NTT.
4: $c = [\boldsymbol{b^T a} + mbit\cdot\lfloor\frac{q}{2}\rfloor]$ ▷ Add scaled message to the rounded public key component.
5: return (u, c) ▷ Output the ciphertext components u and c.

$$d_1 = \boldsymbol{u}\cdot\boldsymbol{s}$$

Here, $\boldsymbol{u}$ is the preamble received with the ciphertext.

- Decrypted Value: The decrypted value d is obtained by subtracting the computed d_1 from the ciphertext $\boldsymbol{c}$:

$$d = \boldsymbol{c} - d_1$$

All operations are performed modulo q.
- Plaintext Recovery: The range of $d \mod q$ is checked to determine the original plaintext bit ($mbit$):
  - If $\frac{-q}{4} \le d \le \frac{q}{4}$, the plaintext $mbit$ is set to $\mathbf{0}$
  - If $\frac{q}{4} < d \le \frac{3q}{4}$, the plaintext $mbit$ is set to $\mathbf{1}$

Algorithm 3 presents the pseudocode for decryption.

Algorithm 3 MLWRDecryption($\boldsymbol{s}, c, u$)

1: $d_1 = \text{INTT}_{bo\to no}^{GS,\Psi^{-1}}\left(\text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{u}) \circ \text{NTT}_{no\to bo,\beta=1}^{CT,\Psi}(\mathbf{s})\right)$ ▷ Compute $\boldsymbol{us}$ using incomplete NTT.
2: $d = c - d_1$ ▷ Subtract the private component from the ciphertext.
3: **if** $(((d \ mod \ q) \ge \frac{-q}{4})$ *AND* $((d \ mod \ q) \le \frac{q}{4}))$
4: **then** ▷ Check if d lies in the range
5: $d = 0$
6: **else**
7: **if** $(((d \ mod \ q) > \frac{q}{4})$ *AND* $((d \ mod \ q) \le \frac{3q}{4}))$
8: **then**
9: $d = 1$
10: return d ▷ Output the decrypted message.

D. Correctness of the Scheme

The correctness of the decryption algorithm relies on ensuring that the introduced rounding error remains within acceptable bounds.

If (u, c) is a correctly formulated ciphertext, the decrypted value is given as Eq. (4):

$$\begin{aligned} d &= c - d_1 \qquad \text{from Algorithm 3} \\ &= c - \boldsymbol{s}^T u \\ &= \boldsymbol{b^T a} + mbit\cdot\frac{q}{2} - \boldsymbol{s}^T\boldsymbol{Aa} \qquad \text{from Algorithm 2} \end{aligned} \tag{4}$$

Here, $\boldsymbol{b^T}$ is defined during key generation process as:

$$\boldsymbol{b^T} = \left\lfloor \frac{p}{q} \boldsymbol{s}^T \boldsymbol{A} \right\rceil \mod p$$

This rounding operation can be rewritten as an LWE problem:

$$\boldsymbol{b^T} \approx \boldsymbol{s}^T \boldsymbol{A} + \frac{p}{q} e_r \pmod q,$$

where, $\frac{p}{q} e_r$ introduces a random error into $\boldsymbol{s}^T \boldsymbol{A}$, and $p < q$. Let $\frac{p}{q} e_r = e_{rnd}$, then:

$$\boldsymbol{b^T} \approx \boldsymbol{s}^T \boldsymbol{A} + e_{rnd}$$

By substituting $\boldsymbol{b^T} = \boldsymbol{s}^T \boldsymbol{A} + e_{rnd}$ into Eq. (4):

$$\begin{aligned} d &= (\boldsymbol{s}^T \boldsymbol{A} + e_{rnd})\boldsymbol{a} + mbit \cdot \lfloor \frac{q}{2} \rfloor - \boldsymbol{s}^T \boldsymbol{A}\boldsymbol{a} \\ &= \boldsymbol{s}^T \boldsymbol{A}\boldsymbol{a} + e_{rnd}\boldsymbol{a} + mbit \cdot \lfloor \frac{q}{2} \rfloor - \boldsymbol{s}^T \boldsymbol{A}\boldsymbol{a} \\ &= e_{rnd}\boldsymbol{a} + mbit \cdot \lfloor \frac{q}{2} \rfloor \end{aligned} \tag{5}$$

To analyze correctness, consider two cases based on the value of $mbit$:

a) Case 1: When $mbit = 0$, Eq. (5) simplifies to:

$$d = e_{rnd}\boldsymbol{a}$$

For correctness, the term $||e_{rnd}\boldsymbol{a}||$ must satisfy:

$$||e_{rnd}\boldsymbol{a}|| \in \left[\frac{-q}{4}, \frac{q}{4}\right]$$

Since $||e_{rnd}|| \in \left[\frac{-q}{4}, \frac{q}{4}\right]$ with high probability, correctness is achieved as $||e_{rnd}\boldsymbol{a}||$ lies within the valid range.

b) Case 2: When $mbit = 1$, Eq. (5) becomes:

$$d = e_{rnd}\boldsymbol{a} + \lfloor \frac{q}{2} \rfloor$$

Correctness requires that:

$$||e_{rnd}\boldsymbol{a} + \lfloor \frac{q}{2} \rfloor|| \in \left[\frac{q}{4}, \frac{3q}{4}\right]$$

For this condition to hold, the rounding error term $e_{rnd}\boldsymbol{a}$ must be small enough to offset the added $\lfloor \frac{q}{2} \rfloor$. Hence, the threshold for $||e_{rnd}||$ becomes:

$$||e_{rnd}|| \in \beta = \left[\frac{-q}{4}, \frac{q}{4}\right]$$

By setting $mbit = 0$ or $mbit = 1$, the correctness of the decryption is ensured when the rounding error e_{rnd} remains within the defined threshold. The analysis confirms that $||e_{rnd}\boldsymbol{a}||$ lies within the valid range $\left[\frac{q}{4}, \frac{3q}{4}\right]$ with high probability, ensuring accurate decryption.

Conclusion: As $||e_{rnd}\boldsymbol{a}||$ lies within the valid interval $\left[\frac{-q}{4}, \frac{q}{4}\right]$, the scheme ensures correctness. This analysis highlights the role of rounding errors and the chosen $mbit$ in maintaining the accuracy of decryption.

E. Parameter Selection

Parameter selection is an important part of the proposed scheme. Table I shows selected parameters for proposed PKE:

TABLE I. PARAMETERS FOR THE PROPOSED SCHEME

Parameters	**Value**
Modulus	$q = 7937$
Secret coefficient range η	[-2,2] for high level security, [-3,3] for recommended security
Degree of polynomial ring (N)	256
Polynomial ring	$X^{256} + 1$
Rank of module k	2 (for security level 2), 3 (for security level 3), 4 (for security level 5)

Selection of the modulus q for PKE involves several critical considerations to ensure security, efficiency, and compatibility with lattice-based cryptographic operations. Here's a detailed process to select appropriate parameters. Mathematical Properties:

- Prime Modulus: Typically, q is chosen to be a prime number.
- NTT Compatibility: For efficient NTT-based polynomial multiplication, modulus q should satisfy $q \equiv 1 \mod 256$, where 256 is a degree of the polynomial (typically a power of 2). This ensures existence of primitive 256-th roots of unity modulo q.

Coefficients of the polynomial $\boldsymbol{s}$ and the public matrix $\boldsymbol{A}$ are sampled uniformly from $\mathbb{Z}_q$ using the rejection sampling method [33]. This approach generates random numbers of the required bit length from the SHAKE-128 pseudorandom number generator (PRNG) as candidate values. Only numbers that are strictly less than q are considered valid and accepted. The rejection probability, which quantifies the likelihood of a candidate being discarded, is given by:

$$1 - \frac{q}{2^{\log q}}$$

We have implemented Python code to find out different values of modulus q that satisfy the required mathematical properties. These values are listed in Table II.

Modulus 7937 stands out as an excellent choice for q due to its low rejection probability. The secret coefficient range η determines the distribution from which the coefficients of the secret key are drawn.
In LBC, the security of the system is closely tied to the noise distribution, as it controls the hardness of lattice problems MLWR.

TABLE II. PRIME MODULUS FOR INCOMPLETE NTT

Modulus q	q inverse	256-th root of unity	≈ Rejection probability
3329	-3327	17	0.594
7681	-7679	198	0.062
7937	-7935	71	0.031
9473	-9471	88	0.422
10753	-10751	29	0.344
11777	-11775	50	0.283
12289	-12287	09	0.250

Rejection Probability: It is calculated as $(1 - \frac{q}{2^{\log q}})$. Lower rejection probabilities are preferred for efficiency.

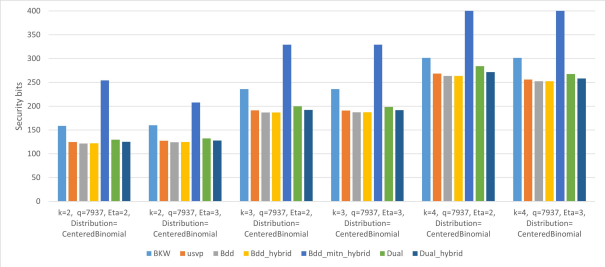

Fig. 5. Choice of secret distribution range.

To estimate the security of different parameter sets of the proposed scheme, lattice estimator [34] is used. The estimator takes parameters as input and gives an estimated security against lattice attacks. Fig. 5 compares the security estimates of various parameter sets under different attack models. These estimates reflect the difficulty of breaking the cryptographic scheme with the given parameters and secret coefficient distribution.

It has been observed that as k increases, the security levels increase across all attack models.

Increasing η slightly decreases security under certain attack models because larger secret coefficients may expose more information.

For lower computational cost and acceptable security, use of $(k = 2, \eta = 3)$. $(k = 3, \eta = 2)$ is a good intermediate choice, balancing security and performance. For maximum security, use $(k = 4, \eta = 2)$ with centered binomial distribution. This offers the highest resistance.

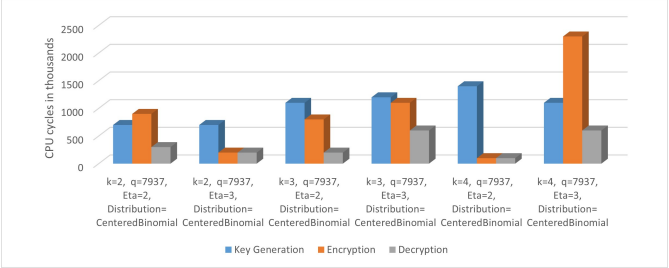

Fig. 6. CPU cycles w.r.t. different distributions.

The given Fig. 6 outlines the computational cost (in CPU cycles) for operations (Key Generation, Encryption, Decryption, and NTT) across different parameter sets.

It shows that higher lattice dimensions $(N \times k)$ lead to increased computational costs for all operations. $N \times k = 512, \eta = 3$ offers the lowest computational cost, particularly for Encryption and Decryption, making it ideal for resource-constrained devices. $N \times k = 768, \eta = 2$ provides a good balance between security and computational cost. $N \times k = 1024, \eta = 2$ is the best choice for applications requiring maximum security, albeit at the cost of higher computation, particularly for NTT.

The selected parameters, which include modulus q=7937, secret coefficient range $\eta \in [2, 3]$, polynomial ring $[x]/(x^{256} + 1)$, module rank k, and incomplete NTT, provide a balanced combination of security, efficiency, and computational performance. The careful selection of these parameters ensures that the proposed MLWR-based PKE scheme meets the requirements for post-quantum cryptographic applications while optimizing execution time and maintaining a high level of security.

- Parameter Selection and Failure Probability: The parameters in Table I are selected to minimize the Decryption Failure Probability (DFP) while maximizing security.
  - Modulus $q = 7937$: This prime satisfies $q \equiv 1 \pmod{256}$, supporting NTT, and provides a low rejection probability of 0.031 [33].
  - Rounding and Noise: We use a centered binomial distribution β_η for secrets. Rounding modulus is chosen such that rounding error e_{rnd} satisfies $||e_{rnd}|| \in [-\frac{q}{4}, \frac{q}{4}]$.
  - DFP Analysis: Decryption is successful if the accumulated noise from rounding does not cross the decision threshold. For the recommended set $(k = 3, \eta = 2)$, the probability of a decryption failure is estimated to be $< 2^{-128}$ [34].

F. Security Estimation and Comparison

This section presents the security estimation of proposed MLWR-based PKE over different moduli. Blum–Kalai–Wasserman (BKW) [34] attack is used to estimate the computing costs of solving corresponding hard problems for security evaluation.

The BKW algorithm, originally developed for solving Learning Parity with Noise (LPN) problem, was extended to the LWE problem. It uses a blockwise approach to reduce the dimension of the problem while managing the induced noise. The process involves sample reduction using sort-and-match techniques, hypothesis testing to distinguish between valid and invalid guesses of sub-vectors, and back substitution to iteratively reduce the problem's dimensionality. The advancements in BKW, such as lazy modulus switching and quantization, have significantly improved its efficiency, making it a central tool in security evaluations of LBC schemes.

Martin Albrecht's lattice estimator tool [34] is used for this task. Table III summarizes the security estimations for proposed PKE scheme against the BKW attack. It includes different parameter sets with specific lattice dimensions 512, different moduli, and an estimated ≈ Cost.

TABLE III. ESTIMATED SECURITY OF DIFFERENT MODULI FOR INCOMPLETE NTT.

Modulus	Required CPU timing	Estimated ≈ Cost
3329	KeyGen: 69, Enc: 172, Dec: 69, NTT: 45483	$2^{190.3}$
7681	KeyGen: 103, Enc: 69, Dec: 69, NTT: 47793	$2^{182.9}$
7937	KeyGen: 103, Enc: 69, Dec: 34, NTT: 4675	$2^{183.4}$
9473	KeyGen: 138, Enc: 103, Dec: 34, NTT: 46103	$2^{176.2}$
10753	KeyGen: 138, Enc: 103, Dec: 34, NTT: 47690	$2^{176.2}$
11777	KeyGen: 310, Enc: 69, Dec: 34, NTT: 54552	$2^{177.5}$
12289	KeyGen: 241, Enc: 69, Dec: 34, NTT: 49138	$2^{178.3}$

Table III provides a comparison of estimated security of different moduli and their performance metrics for an incomplete NTT in an MLWR-based PKE scheme. The key parameters compared are:

Modulus: The modulus used in the polynomial ring.

Required CPU Timing: This includes the CPU timing for key generation (KeyGen), encryption (Enc), decryption (Dec), and NTT operations.

Estimated Approximate Cost: The security level against the BKW attack is represented as a cost in terms of computational effort (expressed as powers of 2).

The modulus 7937 offers the best decryption time (34), which is crucial for practical applications. It also maintains a competitive NTT timing. 7937 still provides a robust security level at $2^{183.4}$, which is sufficient for most practical purposes. Therefore, the modulus 7937 strikes the best balance between performance and security, making it an optimal choice for the MLWR-based PKE scheme.

1) Formal security analysis: Hardness of the Module Learning with Rounding (MLWR) problem serves as the foundation for the security of the proposed PKE. Security in Indistinguishability under Chosen Plaintext Attack(IND-CPA) is avaluated.

Theorem 1. If the $MLWR_{k,N,q,p}$ problem is hard, then the proposed PKE is IND-CPA secure.

Proof:

Proof proceeds via a sequence of games:

- Game 0: This is the original IND-CPA security game. The public key is $(seed_\delta, \mathbf{b}^T)$ where $\mathbf{b}^T = \lfloor \frac{p}{q}\mathbf{s}^T\mathbf{A} \rceil$ [21].
- Game 1: The MLWR sample $\mathbf{b}^T$ is replaced with a vector $\mathbf{u}$ sampled uniformly at random from R_p^k. Under the MLWR assumption, no polynomial-time adversary can distinguish Game 1 from Game 0 with non-negligible advantage [21], [35].
- Game 2: The ciphertext components (u, c) are replaced with uniform samples from R_p^k and R_p. Since the public key is now uniform, the message $mbit$ is perfectly masked.

The advantage of an adversary $\mathcal{A}$ is bounded by $Adv_{PKE}^{ind-cpa}(\mathcal{A}) \leq Adv_{MLWR}^{dist}(\mathcal{B})$, where $\mathcal{B}$ is a simulator solving the MLWR decision problem.

Reduction confirms that the only way for an adversary to break IND-CPA security of the proposed PKE is by solving a underlying MLWR decision problem. With parameter set $(k = 3, \eta = 2)$, the computational cost to perform such an attack exceeds $2^{183.4}$ core-SVP operations, thereby ensuring robust quantum-resistant security.

V. IMPLEMENTATION DETAILS OF MLWR-BASED PKE USING INCOMPLETE NTT

The first step in the proposed approach is to generate a matrix $\boldsymbol{A} \in R_q^{k\times k}$ using a random seed $seed_\delta\{0,1\}^{256}$. The hash function SHAKE-128 [19] is used in the current study to expand the seed to matrix $\boldsymbol{A}$, producing enough unpredictability via a high probability. In the encryption process, Matrix $\boldsymbol{A}$ is helpful for both key creation and multiplication operations. Incomplete NTT was utilized to speed up multiplication. The condition of the scheme is that $\boldsymbol{A}$ must be evenly sampled. The expansion function outputs a uniform matrix $\boldsymbol{A}$ in NTT format with coefficients ranging from 0 to $q-1$.

The result of the expansion function is the matrix $\boldsymbol{A} \in R_q^{k\times k}$ from a 256-byte seed input. It converts a uniform 256-byte seed to a uniform matrix $\boldsymbol{A}$ value using the NTT representation. Matrix $\boldsymbol{A} \in R_q^{k\times k}$ is uniformly random with $k = 4$ and elements are polynomials under a ring $\mathbb{Z}_q[x]/(x^N + 1)$. N =256 is the polynomial ring's degree and k is the rank of a module that is used to find out the dimension of the fundamental lattice problem $N \cdot k$.

Rejection sampling on the integer stream generated by the SHAKE-128 is part of the matrix $\boldsymbol{A}$ generation process. Once the matrix $\boldsymbol{A}$ is generated, the next step involves sampling a short vector $\boldsymbol{s}$ through rejection sampling [33]. This sampled vector $\boldsymbol{s}$ will be used as a secret key.

The public key pk contains 2 parts, 1^{st} part is seed $seed_\delta$ and the second part is $\boldsymbol{b^T} = \lfloor \frac{p}{q}\boldsymbol{s}^T\boldsymbol{A} \rceil_p$. Matrix multiplication is the most important process in the scheme. Present work uses the NTT representation of $\boldsymbol{A}$ and $\boldsymbol{s}$ to carry out pointwise multiplication. Then perform inverse NTT transform on the above multiplication result and also multiply with Montgomery factor for modular reduction. Modular reduction uses the Montgomery algorithm. Rounding $\boldsymbol{b^T}$ operation reduces the size of a public key pk. Minimize size of pk from R_q to R_p in LWR, where modulus $q > p$. The modular reductions necessary for ring R_q arithmetic in the proposed method never use the % (mod) operator. Instead, use special modulus q-specific reduction techniques and Montgomery reductions without the corrective phases. The rounding functions have been calculated using branching-free methods. To make sure that the findings are accurately represented in the reduced form, the Montgomery factor $2^{32} \ mod \ q$ is included in the previously computed roots. Montgomery reductions are used in the NTT domain representations after the pointwise product of the polynomials.

The implementation of the incomplete NTT involves various trade-offs between code size and speed, particularly significant for different hardware environments. On embedded processors, the focus is on minimizing storage and memory requirements, such as avoiding additional temporary storage during polynomial multiplications in R_q. To achieve this, precomputed tables of powers of a primitive root (ψ) are used

to streamline operations, while forward NTT (from normal to bit-reversed order) and inverse NTT (from bit-reversed to normal order) are implemented efficiently.

A. Implementation Security and Side-Channel Mitigation

While primary focus of this work is performance optimization, implementation incorporates several design principles to mitigate side-channel vulnerabilities :

- Constant-Time NTT: The Incomplete NTT is implemented with a fixed execution path [36]. There are no data-dependent branches or secret-dependent loops, which prevents leakage of timing information during polynomial multiplication.
- Montgomery Reduction: We utilize a constant-time Montgomery reduction [20]. By incorporating the Montgomery factor $2^{32} \pmod q$ into the precomputed NTT twiddle factors [26], we avoid the conditional subtraction step typically found in modular reduction, thereby mitigating simple power analysis and timing attacks.

VI. Result and Analysis

A. Experimental Setup

Proposed scheme and comparative benchmarks were implemented in C language, compiled with the GCC compiler. To ensure a fair and standardized evaluation of performance, all experiments were conducted under identical environmental conditions on a CDAC-PARAM Shavak machine. The hardware features an Intel(R) Xeon(R) Gold 6226R v4 series processor. The testing was performed on a Centos operating system, providing a stable platform for measuring precise computational overhead, including execution times and CPU cycle consumption for the proposed and reference LBC schemes.

B. Performance with Different Parameter Sets

Advantage of MLWR is a same polynomial ring R_q is used for all security levels [2]. To attain a higher level of security, the scheme employs a module with increased rank. Table IV presents proposed scheme's performance and security w.r.t different parameter sets. Parameter sets, denoted as P_1, P_2, and P_3, correspond to increasing security levels.

Results highlight the balance between security and performance. Higher security levels lead to increased computational overhead, reflected in greater CPU time and cycle consumption. The selection of an appropriate parameter set is crucial for achieving the desired security level.

TABLE IV. Evaluation of Proposed Scheme with Various Parameter Sets.

Parameter set and Security level	Operation	Average CPU time (μs)	Average CPU cycles
P_1 Medium : ($q = 7937, N = 256, \eta = 3, k = 2, l = 2$)	Key Generation	103	700
	Encryption	65	200
	Decryption	34	100
P_2 Recommended: ($q = 7937, N = 256, \eta = 2, k = 3, l = 3$)	Key Generation	207	1200
	Encryption	68	200
	Decryption	34	100
P_3 High : ($q = 7937, N = 256, \eta = 2, k = 4, l = 4$)	Key Generation	172	1400
	Encryption	69.48	300
	Decryption	34.12	120

C. Security Estimation and Attack Analysis

Table V provides a comprehensive security profile for the proposed MLWR-based PKE scheme across three distinct parameter sets (P_1, P_2, P_3). This analysis moves beyond heuristic estimates to include rigorous metrics against standard lattice attacks [34].

- Configuration Parameters (k and η):
  - Rank of a module k defines lattice dimension as $N \times k$, where $N = 256$ is fixed.
  - Increasing k from 2 to 4 significantly enhances the security margin against all attack vectors.
  - The secret distribution range η is utilized for sampling the short vector $\mathbf{s}$, directly influencing the hardness of the underlying MLWR problem.
- Attack Metrics:
  - Core-SVP: Represents lower bound of complexity for a Shortest Vector Problem in a sieving regime, which is the foundational hard problem for proposed scheme.
  - Primal (uSVP) Attack: Evaluates the complexity of recovering the secret key by treating the MLWR instance as a unique shortest vector problem in an expanded lattice.
  - Dual Attack: Estimates the computational effort required for an adversary to distinguish the MLWR samples from a uniform distribution by finding short vectors in the dual lattice.
  - BKW Attack: Originally for the Learning Parity with Noise problem, it uses a blockwise approach to reduce problem dimensions while managing induced noise through sort-and-match techniques.
- NIST Security Level Mapping:
  - Parameter set P_1 achieves $2^{118.4}$ security bits, corresponding to NIST Category I.
  - The recommended set P_2 ($k = 3, \eta = 2$) provides $2^{183.4}$ bits of security, satisfying Category III.
  - The high-security set P_3 achieves $2^{253.9}$ bits, aligning with Category V for maximum quantum resistance.

The results demonstrate that by utilizing modulus $q =$

TABLE V. SECURITY ESTIMATES AND NIST MAPPING FOR PROPOSED MLWR PARAMETERS

Parameter Set	k	η	Core-SVP	Primal (uSVP)	Dual Attack	BKW	NIST Category
P_1	2	3	$2^{118.4}$	$2^{134.5}$	$2^{139.9}$	$2^{183.4}$	I
P_2	3	2	$2^{183.4}$	$2^{209.1}$	$2^{219.8}$	$2^{261.9}$	III
P_3	4	2	$2^{253.9}$	$2^{297.3}$	$2^{316.1}$	$2^{340.0}$	V

7937, the scheme maintains robust security levels while optimizing computational efficiency through the incomplete NTT.

D. Result and Comparison with the other Lattice-Based Schemes

The proposed scheme with high level security requirements has been implemented and tested on a Linux operating system. The CPU time required to execute the proposed key generation, encryption, and decryption functions is measured using Intel® VTune™ Profiler and is 172 μs, 69.48 μs, and 34.12 μs, respectively.

The outcomes of the proposed approach are compared to the other PKE candidates of the NIST's PQC project. NIST requested submission for PQC algorithms [2] in 2016 for the standardization process. After the internal reviews and public feedback, twenty-one LBC candidates were selected in the 1^{st} round. While in the 2^{nd} round only 9 algorithms were selected. Out of 9, 3 are high-speed as well as secure PQC algorithms named Frodo [11], Kyber [10], and Saber [13]. All these algorithms are based on lattice-based hard problems. Execution time of the proposed PKE is compared with these schemes.

Table VI presents a comparative analysis against various features of the proposed MLWR-based PKE scheme with other well-known LBC schemes, focusing on the underlying cryptographic problems, polynomial spaces, performance characteristics (such as execution time and key sizes), and security. Key differences include the polynomial multiplication methods used (e.g., NTT vs. Karatsuba), security analysis, and performance metrics such as execution time and CPU cycles.

The proposed scheme's public key and ciphertext sizes are both smaller than Frodo's scheme. Size of the secret key is smaller than the Frodo. Also, the average execution time and average CPU cycles required for the proposed scheme's encryption and decryption are comparable to that of the most efficient candidate, SABER. The average time needed to encrypt a 256-byte message is equivalent to that of SABER, whereas the average time required to decrypt a message is less than that of SABER.

The proposed scheme stands out for its high BKW security and relatively low execution times and CPU cycles, offering a superior balance of security, performance, and computational efficiency. This makes it a preferred choice for implementing post-quantum cryptographic protocols

VII. CONCLUSION

The proposed scheme attains a better performance compared to other lattice-based schemes. Also, this scheme provides prominent hardness and security, ingrained in the LWR variant. It has a faster and simpler encryption and decryption process. The key sizes are very compact. As the proposed scheme is based on a lattice-based hard problem, MLWR, it can be secure against quantum attacks.

Analysis highlighted the importance of selecting an appropriate modulus q to balance performance and security. Among the evaluated moduli, $q = 7937$ emerged as the most efficient

choice, providing a desirable trade-off between computational efficiency and security.

Proposed MLWR-based PKE scheme using incomplete NTT stands out due to its high security and efficient performance, making it an optimal choice for practical and secure post-quantum cryptographic applications.

Future work could explore further optimizations in parameter selection and the adaptation of the incomplete NTT methodology to other post-quantum cryptographic schemes, enhancing their applicability to a wider range of security-critical and resource-limited scenarios.

AUTHORS' PROFILE

Anupama Arjun Pandit (Student Member, IEEE) is currently pursuing Ph.D. degree in Computer Science and Engineering Department, at Defense Institute of Advanced Technology, Pune, India. She has completed her M. Tech. in CSE-IT from Walchand College of Engineering, Sangli, Maharashtra, India. Her research interest includes Cryptography and Post Quantum Cryptography (Code-based Cryptography and Lattice-based Cryptography). Her contribution to the current project is implementation, testing, analysis, and interpretation of the data, algorithm, and results.

Arun Mishra is working as an Associate Professor in Computer Science and Engineering Department at Defence Institute of Advanced Technology, Pune, India. He completed his Ph.D. from MNIT, Allahabad, India. He has more than 40 research publications in peer-reviewed journals & international conference proceedings. His areas of interest are Cryptography, Blockchain Technology, Post Quantum Cryptography (Code-based Cryptography, Lattice-based Cryptography and Hash-based Cryptography), Secure Software Engineering, and Secure Systems Design (isolation/ secure execution/ secure computations). In the current project, he contributed to the development of the concept and technique.

Abnormal State Detection of Industrial Tools Based on the MGC-YOLOv8 Algorithm

***Abstract*—As intelligent manufacturing advances toward precision and automation, cutting tool condition critically impacts product quality, equipment safety, and production efficiency. Anomalies like wear, chipping, or fracture cause workpiece scrapping and machine failure, demanding efficient online monitoring. Traditional manual or image-based methods suffer from low accuracy in complex environments. Although deep learning excels in industrial defect detection, existing end-to-end detectors exhibit insufficient recall and localization precision for millimeter-scale cracks and blurred tool boundaries. To address these challenges, we propose MGC-YOLOv8, an enhanced framework built upon the YOLOv8 backbone. A Multi-Scale Edge-Dual Fusion (MSEDF) module is introduced to integrate feature maps across different scales, thereby strengthening the detection of minor defects. Furthermore, a Global-to-Local Spatial Aggregation (GLSA) module enriches feature representations by simultaneously capturing global context and local details. A Convolutional Block Attention (CBAM) module is embedded upstream of the prediction head to adaptively highlight critical features in both channel and spatial dimensions.Although the integration of MSEDF, GLSA, and CBAM introduces a marginal runtime overhead and a slight increase in parameter count, the optimized architecture preserves real-time inference speeds that fully satisfy the requirements of industrial inspection systems. Experimental results demonstrate that MGC-YOLOv8 substantially outperforms the baseline YOLOv8n, achieving 88.1% precision, 87.9% recall, 92.5% mAP@0.5 and 69.6% mAP@0.5:0.95 on our test set.**

***Keywords*—Object detection; surface defect detection; YOLOv8**

I. Introduction

During machine-tool processing, real-time monitoring of tool condition can effectively prevent workpiece scrap and machine-tool damage [1]. Maintaining good tool condition is crucial for CNC machining quality and productivity [2], making Tool Condition Monitoring (TCM) an essential part of modern manufacturing [3]. Traditional inspection—relying on skilled operators for visual checks or intermittent sampling—is inefficient and vulnerable to subjectivity and fatigue, and thus unsuitable for large-scale continuous online monitoring [4]. Early automated TCM used force and acceleration sensors (cutting force, acoustic emission, vibration) with time-frequency analysis to infer wear [5], [6], [7], [8]. However, fluctuations in machining parameters and workshop noise often undermined their robustness, causing missed detections and false alarms.

Vision-based tool anomaly detection has emerged as a significant research focus alongside rapid advances in deep learning [9]. Convolutional neural networks (CNNs) [10] automatically extract semantic features through end-to-end training, yielding substantial gains in accuracy and real-time performance. The YOLO family adopts a single-stage framework with multi-scale feature-pyramid fusion, achieving a favorable speed–accuracy trade-off for industrial defect detection [11], [12]. However, standard downsampling and fusion in these detectors can attenuate or lose millimetre- and sub-millimetre-scale defects (fine cracks, chipping, blurred edges) under complex lighting and cluttered backgrounds, degrading recall and localization precision.

To address these issues, we propose MGC-YOLOv8. We replace the original C2f with a Multi-Scale Edge-Dual Fusion (MSEDF) module to better capture edge and fine-detail cues of subtle anomalies, enhancing local feature representation. A Global-to-Local Spatial Aggregation (GLSA) module uses a dual-branch decoupled design to extract global context and local details and fuses them via dynamic gating to improve robustness in complex scenes [13]. A Convolutional Block Attention Module (CBAM) is embedded immediately before the prediction head to adaptively reweight channel and spatial responses and focus on anomaly-sensitive regions [14], [15]. Experimental results show that MGC-YOLOv8 yields substantial accuracy gains over the YOLOv8n baseline.

The main contributions of this study are as follows:

- We designed the MSEDF to replace YOLOv8's C2f, explicitly capturing multi-scale edges and fine-detail cues of micro anomalies (e.g., cracks, wear), thereby enhancing local feature representation.
- We introduce the GLSA module, a dual-branch design that separately extracts local details and global semantics, then adaptively fuses them via dynamic gating — improving the robustness and efficiency of multi-scale feature fusion.
- We embed the CBAM before the prediction head before the prediction head, where channel–spatial attention adaptively reweights features to emphasize anomaly-sensitive regions and improve detection accuracy.

*Corresponding author.

- An industrial tool dataset with diverse real surface defects was constructed to support model training and evaluation, verifying the practicality and effectiveness of the proposed method.

The remainder of this study is organized as follows: Section II reviews related work in tool-condition monitoring and vision-based defect detection. Section III details the architecture of the proposed MGC-YOLOv8 model and the design of its key modules. Section IV describes the experimental setup, dataset construction and evaluation metrics. Section V presents the experimental results and comparative analysis. Finally, Section VI concludes the study and outlines future research directions.

II. Related Work

In recent years, tool condition detection has shifted from empirical inspection and signal analysis to image-based and deep-learning approaches. Early methods using physical signals (e.g., cutting force, vibration) with wavelet or Fourier analysis were easily affected by noise, parameter fluctuations, and nonlinear factors, leading to unstable results. Machine vision enabled direct acquisition of tool-surface images for defect identification, offering high spatial resolution but limited adaptability to complex backgrounds. With the advance of deep learning, CNN-based object detection [16]—featuring automatic feature extraction and end-to-end training—has become a key means to enhance accuracy and real-time performance, addressing the limitations of traditional techniques and driving intelligent, automated tool-condition monitoring in modern manufacturing.

Tool Condition Monitoring (TCM) can be divided into indirect monitoring based on physical signals and direct monitoring based on visual information. Early studies emphasized indirect methods, using cutting-force and vibration signals with time–frequency features to classify wear states. For example, Zhu et al. [17] reviewed wavelet transform for TCM, noting its multi-resolution ability to extract non-stationary features, but also its dependence on noise-model assumptions, redundant coefficients, and empirical thresholds, which limit high-frequency fault extraction and real-time decision-making. Zhou et al. [18] proposed vibration-based monitoring via WTMM and SVM, showing sensitivity to wear-transition stages, yet suffering from noise interference and empirical parameter settings. He et al. [19] introduced temperature-signal-based prediction using SSAEs, achieving high accuracy but relying on empirical hidden-node reduction, restricting real-time adaptability. To address small-sample challenges, Zhou et al. [20] designed MEGNN to encode cutting-force signals as recursive graphs, improving classification but at the cost of high computational complexity in multi-scale convolution and graph updates, limiting real-time use. Overall, while such signal-based methods reveal intrinsic links between signals and wear, they remain vulnerable to parameter fluctuations and environmental noise. Furthermore, the inherently low signal-to-noise ratio of acoustic emissions easily masks minor wear features, often necessitating complex denoising procedures [21].

With advances in image processing, direct monitoring using machine vision has attracted increasing attention, offering high spatial resolution and intuitive defect visualization without multi-source signal preprocessing. Guo et al. [22] employed adaptive GrabCut with improved Gaussian mixture modeling and nonlinear filtering to isolate tiny edge defects. However, this approach required manual tuning, was sensitive to illumination and background variations, and demanded machining interruption. Yu et al. [23] developed a pixel-based wear quantification approach with local-variance segmentation and image enhancement, achieving accuracy but at the cost of redundant parameters, high computation, and limited capability for sub-millimeter defects in cluttered scenes. Tang et al. [24] proposed MiSLASND, a ResNet32-based deep-transfer model with class-balance regularization, which improved accuracy and efficiency but lacked defect localization and relied on costly two-stage training. Overall, image-based TCM avoids the noise susceptibility of signal-based methods but still faces challenges in robustness, real-time applicability, and fine-scale defect detection.

Indirect monitoring via physical signals can capture tool-wear trends; however, it is highly sensitive to noise and varying conditions. Conversely, while image-based monitoring offers intuitiveness, it struggles with minor-defect detection in complex backgrounds. To address these issues, researchers have explored more efficient architectures. The YOLO (You Only Look Once) framework [25], as a single-stage detector, enhances small-target recognition by optimizing Feature Pyramid Networks (FPN) [26] and Path Aggregation Networks (PAN) [27], achieving both accuracy and speed [28]. This balance of real-time performance and precision makes YOLO highly promising for industrial defect detection, particularly in tool anomaly monitoring.

To address the limitations of traditional image-based monitoring in fine-grained feature extraction, multi-scale fusion, and robustness to complex backgrounds, we propose an enhanced YOLOv8-based method for industrial tool anomaly detection. The network integrates MSEDF for edge/detail preservation, GLSA for adaptive global–local fusion, and CBAM for channel–spatial attention, thereby improving sensitivity to minute defects and overall detection accuracy in complex industrial scenarios.

III. Methodology

A. MGC-YOLOv8

Although YOLOv8 offers high efficiency in real-time detection, it struggles with industrial tool anomalies: microcracks and slight abrasion are often lost during downsampling, while uneven illumination, glare, and cluttered backgrounds further obscure fine details. Its global fusion strategy also fails to preserve local edge and texture information, leading to false positives on sub-millimetre defects. Thus, the standard YOLOv8 falls short of the precision and robustness required in industrial applications.

As shown in Fig. 1, we propose the MGC-YOLOv8 model, which incorporates targeted enhancements to the original YOLOv8 architecture to bolster both local detail representation and multi-scale feature fusion. In the Backbone and Neck stages, we replace the standard C2f modules with our MSEDF module, which significantly improves the extraction of edge features associated with subtle anomalies—such as fine surface

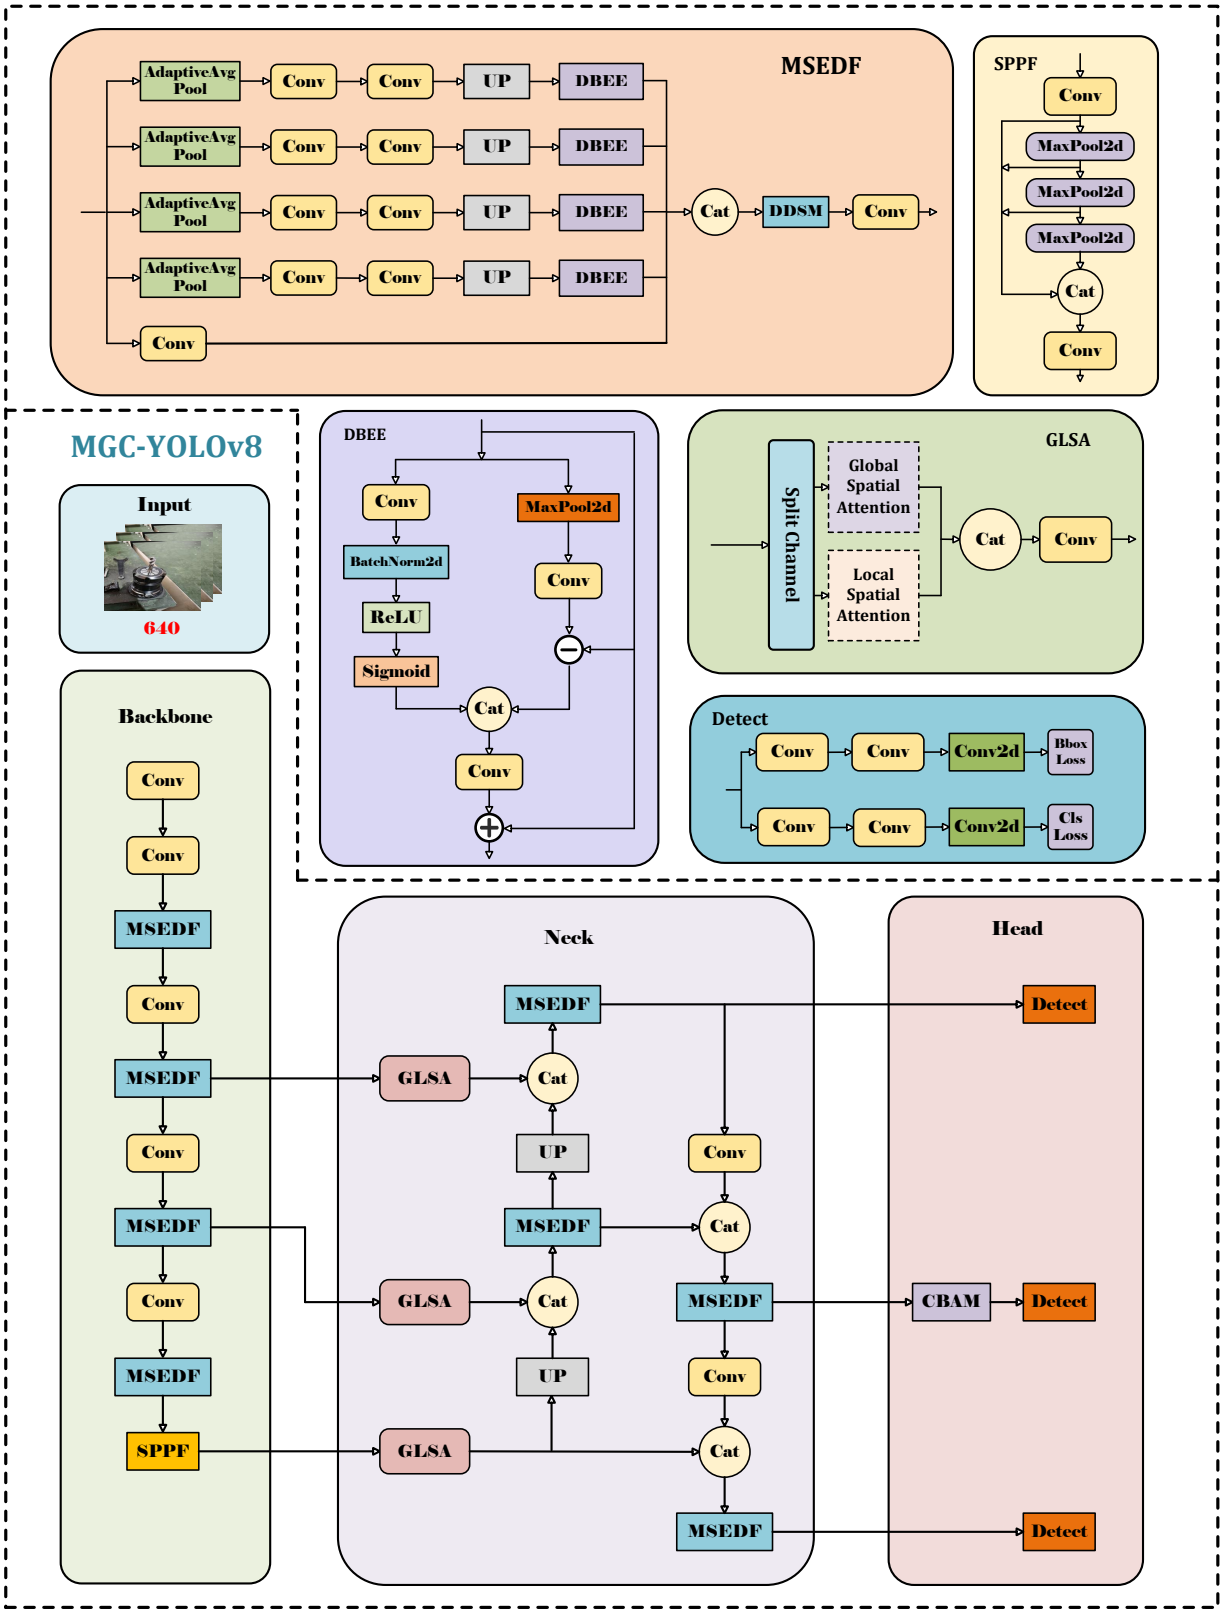

Fig. 1. MGC-YOLOv8 structure.

cracks and wear on cutting tools. Within the Neck, the GLSA module is introduced. Its dual-branch structure separately captures local detail cues and global contextual semantics. Meanwhile, a dynamic gating mechanism adaptively fuses these streams to enhance information flow across scales and improve robustness. Just before the detection head, we embed a CBAM to dynamically modulate feature responses along both channel and spatial dimensions, directing the model's focus toward critical anomalous regions and thereby further increasing detection precision. By synergistically combining MSEDF's micro-defect perception, GLSA's enriched multi-scale interactions, and CBAM's refined attention, MGC-YOLOv8 achieves a substantial improvement in accurately detecting industrial tool abnormalities.

B. Multi-Scale Edge-Dual Fusion Module

In industrial tool anomaly detection, the original C2f module in YOLOv8 exhibits clear limitations when handling local irregularities—such as cracks and surface wear—because its global feature-fusion strategy fails to capture fine edge and detail information. To overcome this, we introduce the MSEDF module, illustrated in Fig. 2. MSEDF employs adaptive average pooling to generate feature maps at multiple scales, each of which is processed by a Dual-Branch Edge Enhancer(DBEE) to strengthen edge and detail cues, thereby improving detection accuracy. Furthermore, we integrate a Dual Domain Selection Mechanism (DSM) [29], which adaptively focuses on the most task-relevant regions across these scales by selectively attending to higher-importance features. This targeted selection markedly enhances feature discriminability and boosts overall model performance.

The Dual-Branch Edge Enhancer optimizes edge features via a cooperative workflow of high-frequency residual enhancement and detail feature amplification. In the first branch, the high-frequency residual feature $\mathbf{R}$ is extracted as follows. Given an input feature map $\mathbf{X} \in \mathbb{R}^{H\times W\times c}$, a local extremum is obtained by applying MaxPool, then convolved with a 3×3 kernel $\mathbf{W}_2$. A sigmoid activation $\sigma(\cdot)$ converts the result into a spatial attention weight in $[0,1]$. Subtracting this weighted low-frequency component from the original feature yields the high-frequency residual. The calculation is shown in Eq. (1):

$$\mathbf{R} \quad = \quad \mathbf{X} - \sigma\big(\mathbf{W}_2 * \mathrm{MaxPool}(\mathbf{X})\big) \tag{1}$$

Meanwhile, the second branch extracts the fine-detail feature $\mathbf{D}$ by applying a 3×3 convolution $\mathbf{W}_3$, followed by BatchNorm and ReLU (denoted as $\varnothing(\cdot)$). The calculation is given in Eq. (2):

$$\mathbf{D} = \varnothing(\mathbf{W}_3) \tag{2}$$

The outputs of both branches are concatenated along the channel dimension and then channel-compressed via a 1×1 convolution $\mathbf{W}_1$. A residual connection adds the original feature $\mathbf{X}$ to preserve baseline information. The final enhanced edge feature $\mathbf{F}_{\mathrm{DBEE}}$ is therefore computed as shown in Eq. (3):

$$\mathbf{F}_{\mathrm{DBEE}} = \mathbf{X} + \mathbf{W}_1\left[(\mathbf{X} - \sigma(\mathbf{W}_2 * \mathrm{MaxPool}(\mathbf{X}))) \parallel \varnothing(\mathbf{W}_3)\right] \tag{3}$$

where, "$\parallel$" denotes concatenation along the channel axis.

MSEDF decomposes the input feature $\mathbf{X}$ into multi-scale space. Adaptive average pooling $\mathrm{Proj}_s(\mathbf{X}) = \mathit{AdaptiveAvgPool}_{s\times s}$ is used to generate sub-features of resolution $s \times s$ to capture the detail information of the tool surface and edge at different resolutions.

Each sub-feature is enhanced by an independent Dual-BranchEdgeEnhancer for local edge details, and then restored to the original resolution by bilinear interpolation $\mathit{Interp}_{H\times W}$ to obtain the multi-scale feature $\mathbf{F}_s^{\uparrow} \in \mathbb{R}^{C\times 1\times 1}$.

All scale features are concatenated with the local 3×3 convolution feature $\mathbf{W}_5$ into $\mathbf{F}_{\mathrm{concat}} \in \mathbb{R}^{H\times W\times 4C}$, and the dual domain selection mechanism $\mathrm{DSM}(\cdot)$ is input to dynamically balance the feature weights.

Finally, the channel is compressed through the 3×3 convolution kernel $\mathbf{W}_4$, and the optimized feature $\mathbf{Y}$ is output. The overall calculation is shown in Eq. (4):

$$\mathbf{Y} = \mathbf{W}_4 * \mathrm{DSM}\left(\left[\mathbf{W}_5 * \mathbf{X}; \bigoplus_{s\in S} \mathit{Interp}_{H\times W}\left(\mathbf{F}_{\mathrm{DBEE}}(\mathrm{Proj}_s(\mathbf{X}))\right)\right]\right) \tag{4}$$

In summary, the MSEDF module employs a multi-scale strategy to capture tool-surface details at varying resolutions and leverages its embedded DBEE to strengthen local edge and texture representations. Subsequently, an adaptive attention mechanism fuses information across these scales, thereby substantially improving the detection of minute anomalies such as micro-cracks and wear.

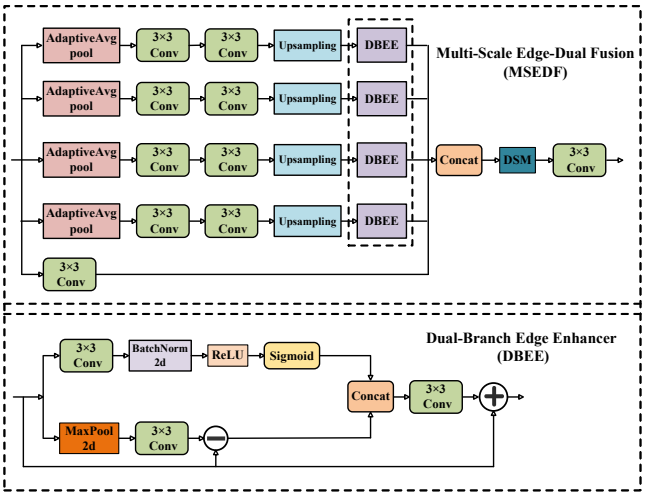

Fig. 2. Structural diagram of the MSEDF network.

C. Global-to-Local Spatial Aggregation Module

Traditional YOLOv8 suffers high false-positive rates and weakened small-object features due to repeated downsampling

and complex-background interference, hindering precise localization of chipping, micro-cracks and similar defects. To address this, a GLSA module is incorporated. GLSA adopts a dual-branch design: a local branch using depth-wise separable convolutions combined with Local Spatial Attention (LSA) to reinforce minute-defect representation, and a global branch employing Global Spatial Attention (GSA) to capture holistic scene context. A dynamic gating mechanism adaptively fuses the two streams, improving multi-scale integration and robustness to cluttered backgrounds, and thus enhancing detection accuracy for fine-grained tool defects.

As shown in Fig. 3, each multi-scale input is split along the channel dimension into two sub-features and passed to the global and local branches. In our implementation, this split ratio is fixed at 0.5 (i.e., splitting the channels equally) to maintain a balance between computational efficiency and feature representation, rather than being dynamically learned.In the global branch, channel reduction is followed by computation of a spatial attention map, which is fused with the sub-feature and processed by an MLP to capture holistic semantics. The local branch uses standard and depth-wise separable convolutions to extract fine details, produces a local spatial attention map, and fuses it with the sub-feature to strengthen local cues. Finally, both branch outputs are combined via convolution and adaptively integrated by a dynamic gating mechanism to yield the module output.

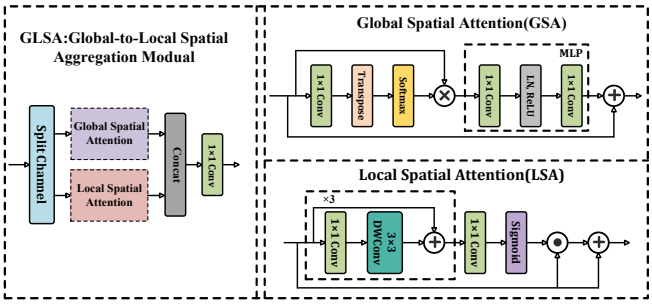

Fig. 3. GLSA module network structure diagram.

D. Convolutional Block Attention Module

Industrial tool-surface anomalies (e.g., cracks, wear) are minute, irregular, and low-contrast. Furthermore, in complex industrial scenes, uneven illumination, specular reflections, and background noise often attenuate these cues during feature extraction. To mitigate this, a CBAM is embedded immediately before the YOLOv8 detection head (see Fig. 4). By applying channel-wise and spatial attention, CBAM adaptively recalibrates feature responses to emphasize anomaly-sensitive regions and suppress irrelevant information, thereby improving detection accuracy and robustness.

The Channel Attention Module (CAM) in CBAM (see Fig. 5) aggregates channel-wise statistics using global average and max pooling, feeds both descriptors through a shared MLP, and sums them element-wise. A sigmoid activation converts the result into channel attention weights that adaptively reweight channels—amplifying informative channels for anomaly detection while suppressing irrelevant or redundant responses.

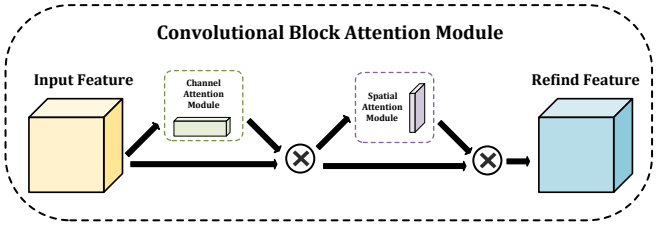

Fig. 4. Convolutional block attention module structure diagram.

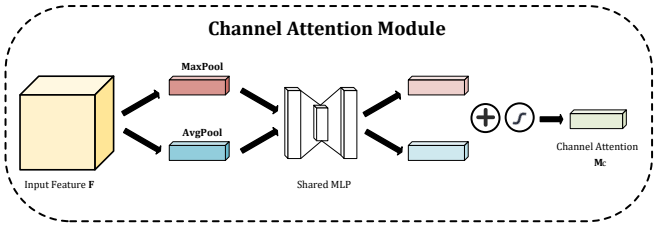

Fig. 5. Channel attention module structure diagram.

The Spatial Attention Module (SAM) processes the channel-refined feature map (see Fig. 6). It applies channel-wise average and max pooling to produce two 2D maps, concatenates them, and uses a convolution to generate a spatial attention map that highlights anomaly-prone regions and guides the network to focus on critical spatial locations.

IV. Experiment Preparation

A. Dataset Production

A private industrial dataset was collected from the production line of a factory in Yinchuan under natural operating conditions, covering different machining stages (roughing and finishing) and multiple material-cutting scenarios to ensure diversity. Cameras recorded cutting tools in four representative states—normal, chipped, broken and worn—resulting in 4,285 raw images. To guarantee data quality, a two-step screening was performed: automatic checks of resolution and file integrity, followed by manual inspection for clarity, exposure, motion blur, occlusion, and background interference. Low-quality samples were discarded, and 3,131 high-quality images were retained. All valid images were resized uniformly to

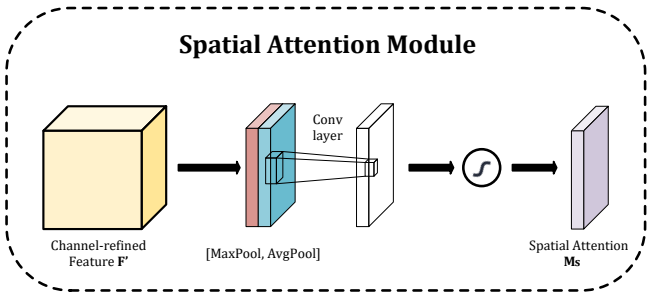

Fig. 6. Spatial attention module structure diagram.

640×640 pixels to preserve tool details while aligning with deep-learning input standards.

Annotations were produced using the LabelMe platform by technicians experienced in tool-state characteristics. Each image was annotated with bounding boxes and classified into four categories—chipped edge, broken tool, wear, and normal—as illustrated in Fig. 7. To ensure reliability, multiple rounds of review and cross-checking were conducted, with ambiguous cases resolved through discussion. Finally, the dataset was divided into training, validation, and test subsets in an 8:1:1 ratio, enabling effective parameter learning, model selection, and independent evaluation, and providing a solid basis for subsequent experiments.

Fig. 7. Sample graph of the dataset.

B. Experimental Environment

The experiments were implemented in the PyTorch framework (v2.4.1) with NVIDIA CUDA 12.2, on a hardware platform equipped with an Intel i7-10700K CPU and an NVIDIA RTX A5000 GPU. Training was performed for 300 epochs using the SGD optimizer with an initial learning rate of 0.01, a batch size of 16, and an input image resolution of 640×640. Other hyperparameters followed the official YOLOv8 settings. Since defect detection is highly sensitive to tool orientation and lighting conditions, data augmentation strategies were explicitly employed during the training phase. Specifically, we natively leveraged the robust data augmentation pipeline embedded in the YOLOv8 framework. These techniques primarily include Mosaic augmentation, random scaling, translation, and HSV color jittering. These strategies effectively expanded the diversity of the training samples, mitigating the impact of complex industrial backgrounds and varying illumination. Furthermore, to ensure a fair comparison, all competing models were evaluated under identical dataset conditions and initialized with standard pretrained weights rather than being trained from scratch.Throughout the study, a consistent software and hardware environment was maintained to ensure reproducibility.

C. Evaluation Index

To evaluate model performance in detecting tool anomalies (e.g., wear, fracture, vibration), Precision, Recall, F1-Score, and mean average precision (mAP) were used, with mAP reported as mAP@0.5 and mAP@0.5:0.95. These metrics jointly assess localization and classification accuracy, providing a quantitative basis for the reliability and applicability of tool-state detection.

Precision refers to the proportion of tool samples predicted as anomalous that are actually anomalous, reflecting the model's accuracy in identifying abnormal tool states.It is calculated as shown in Eq. (5):

$$Precision = \frac{TP}{TP + FP} \tag{5}$$

Recall measures the proportion of truly anomalous tool samples that the model successfully detects, with its calculation given in Eq. (6):

$$Recall = \frac{TP}{TP + FN} \tag{6}$$

The F1-Score, defined as the harmonic mean of precision and recall, balances the model's accuracy in predicting anomalous states with its ability to minimize missed detections. Its calculation is given in Eq. (7):

$$F1 - Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{7}$$

Mean Average Precision (mAP) is a standard metric in object detection, defined as the mean of Average Precision (AP) values across all classes, where AP corresponds to the area under the precision–recall curve. Specifically, mAP@0.5 denotes the mean AP at an IoU threshold of 0.5, as formulated in Eq. (8):

$$mAP@0.5 = \frac{1}{C} \sum_{C=1}^{C} AP_{0.5}^{(c)} \tag{8}$$

To evaluate detection performance across different overlaps, mAP@0.5:0.95 is used, defined as the mean AP over IoU thresholds from 0.5 to 0.95, as shown in Eq. (9):

$$mAP@0.5:0.95 = \frac{1}{T} \sum_{t=1}^{T} \left(\frac{1}{C} \sum_{c=1}^{C} AP_{IoU_t}^{(c)} \right) \tag{9}$$

V. Experiment and Analysis

A. CBAM Routing Location Experiment

The Convolutional Block Attention Module (CBAM) integrates channel and spatial attention to enhance feature representations. In object detection, however, the effectiveness of such attention depends strongly on its placement within the multi-scale feature-fusion pipeline. This study therefore examines how different CBAM insertion points affect feature extraction, semantic representation, and detection performance [30].

Table I outlines the 26-layer structure of MGC-YOLOv8, where the Index column indicates each module's position, Module specifies its type, and Route denotes input-layer indices. The three detection heads take inputs from layers 18, 21, and 24. Since CBAM placement before these heads may affect performance, comparative experiments were conducted, and the results are shown in Table II.

Since the YOLOv8 detection head has only three output layers, there are seven possible CBAM insertion schemes, as detailed in Table II. The experimental results clearly show that embedding CBAM at positions (24, 25) yields the best overall performance. Accordingly, in the MGC-YOLOv8 model, CBAM is inserted at routing positions (24, 25).

B. Ablation Experiments

To assess the effectiveness of our collaborative multi-module optimization, we conducted ablation studies on the YOLOv8n baseline, evaluating seven configurations: individual modules, all pairwise combinations, and the full MSEDF+GLSA+CBAM ensemble. Results are summarized in Table III.

Table IV shows that each module improves YOLOv8n performance. MSEDF alone increases precision, recall, F1-Score, and mAP metrics, while CBAM further boosts precision and F1-Score. GLSA alone provides modest gains but, combined with MSEDF or CBAM, significantly enhances performance by capturing global semantic context. Integrating all three modules achieves the best results: 88.1% precision, 87.9% recall, 88.0% F1-Score, 92.5% mAP@0.5, and 69.6% mAP@0.5:0.95, confirming their complementary roles and the effectiveness of the multi-module strategy.

C. Comparative Experiment

To validate the efficacy of the proposed MGC-YOLOv8 algorithm for industrial tool-anomaly detection, we conducted comparative experiments with several state-of-the-art object-detection frameworks, including multiple YOLO series [31], [32], [33], [34], [35], RT-DETR [36], Mamba-YOLO [37], and Hyper-YOLO [38]. To ensure statistical reliability and address potential performance variability, the evaluation metrics in Table IV are reported as the average along with the standard deviation over 3 independent runs. As shown in Table IV, MGC-YOLOv8 achieves the highest $88.1\% \pm 0.2\%$ Precision and $87.9\% \pm 0.2\%$ Recall, outperforming the next-best model, Hyper-YOLO, by about 1.5 percentage points. It also obtains the best $88.0\% \pm 0.1\%$ F1-Score and average precision, with an mAP@0.5 of $92.5\% \pm 0.1\%$ and mAP@0.5:0.95 of $69.6\% \pm 0.2\%$. The minimal variability observed demonstrates that our model's performance improvements are statistically meaningful and highly stable.

Among the baseline YOLO models, YOLOv3 showed limited accuracy in detecting fine defects. YOLOv8n improved with enhanced multi-scale fusion and bounding-box prediction, reaching $89.9\% \pm 0.3\%$ mAP@0.5, yet still lagged behind our method. Hyper-YOLO, with its advanced neck design, achieved $91.1\% \pm 0.2\%$ mAP@0.5 and $86.6\% \pm 0.3\%$ precision but was still inferior to MGC-YOLOv8 across all metrics.

Furthermore, addressing the critical concern of computational efficiency and runtime overhead in industrial inspection systems, Table IV introduces a comparative analysis of parameter counts (Params) and inference speeds (FPS). The baseline YOLOv8n achieves a high inference speed of approximately 210 FPS with 3.01M parameters. The integration of our proposed MSEDF, GLSA, and CBAM modules inevitably increases the parameter count to 3.95M, resulting in an inference speed of 165 FPS. However, this marginal runtime overhead is a highly worthwhile trade-off, as 165 FPS still far exceeds the standard real-time processing threshold required by industrial cameras. Compared to complex architectures like RT-DETR (120 FPS, 20.0M Params) and Hyper-YOLO (135 FPS, 6.5M Params), MGC-YOLOv8 offers a definitively superior speed-accuracy trade-off.

Finally, the training curves in Fig. 8 show that MGC-YOLOv8 converges more rapidly and smoothly, indicating that the integration of MSEDF, GLSA, and CBAM modules effectively improves feature extraction for subtle tool defects.

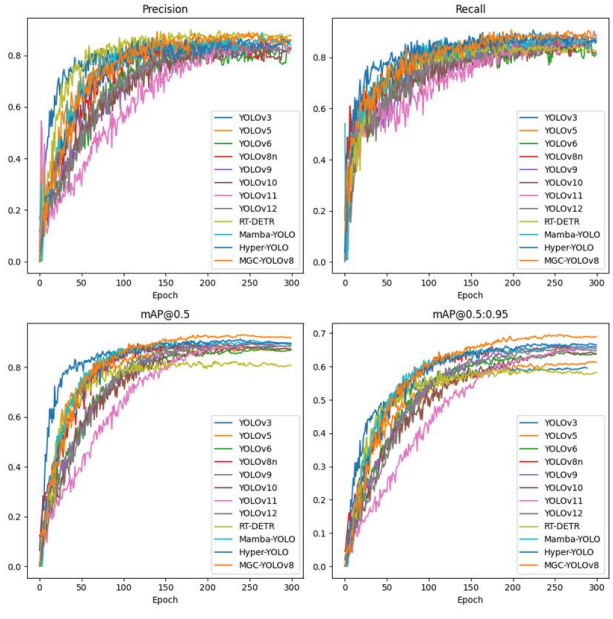

Fig. 8. Comparison of Precision, Recall, mAP@0.5 and mAP@0.5:0.95 curves trained with different algorithms.

D. Visual Analysis

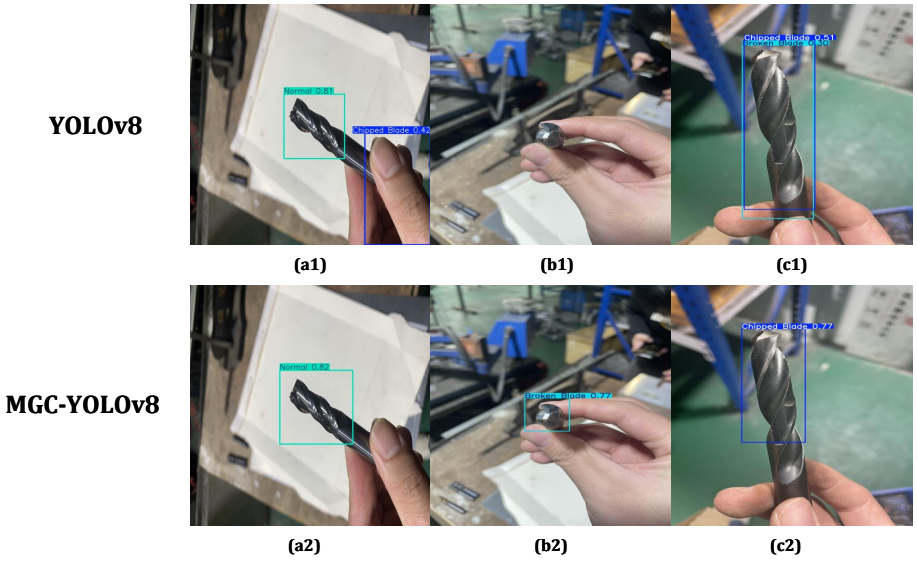
In object detection, visualizing results provides an intuitive means to evaluate model performance and accuracy. It offers quick insights into false positives, false negatives, and a model's ability to distinguish similar objects, thereby guiding further refinement. This section presents comparative visual results of the original and the enhanced MGC-YOLOv8 model under multi-condition industrial tool inspection scenarios, highlighting improvements in suppressing background noise, reinforcing edge features, and increasing detection confidence.

As shown in Fig. 9, baseline YOLOv8 [Fig. 9(a1)] misclassifies a background item as a chipped blade, while MGC-YOLOv8 [Fig. 9(a2)] correctly recognizes the tool and shows higher confidence, demonstrating improved resistance to background interference. In Fig. 9(b1), the baseline misses a broken blade in a cluttered environment, but the enhanced model [Fig. 9(b2)] detects it accurately, eliminating the omission. Furthermore, where YOLOv8 generates duplicate and incorrect labels [Fig. 9(c1)], MGC-YOLOv8 [Fig. 9(c2)] corrects these errors and raises confidence by 0.26 for the correct defect, indicating that the structural refinements more effectively integrate global and local features and improve discrimination between visually similar classes.

E. Confusion Matrix Analysis

The confusion matrix is an essential tool for evaluating the classification performance and robustness of object detection models. As illustrated in the normalized confusion matrices (see Fig. 10), the proposed MGC-YOLOv8 demonstrates substantial improvements over the baseline YOLOv8 across all key categories. Specifically, the detection accuracy for the Chipped Blade class increased from 0.80 to 0.84, while the Broken Blade class maintained a consistently high accuracy of 0.97, indicating strong robustness in identifying severe structural damage. Furthermore, the accuracy for the Worn Blade class improved from 0.81 to 0.86, and the Normal class increased from 0.74 to 0.83. This demonstrates the enhanced model's superior capability in recognizing fine-grained tool surface conditions.

Regarding class confusion and boundary errors, the improved architecture effectively addresses the baseline's limitations. Before the improvement, the probability of a Chipped Blade being misclassified as a Broken Blade was 0.14. This error rate dropped to 0.09 in MGC-YOLOv8, proving that the Multi-Scale Edge-Dual Fusion (MSEDF) mechanism significantly strengthens the extraction of geometric edge features, effectively distinguishing local minor defects from overall



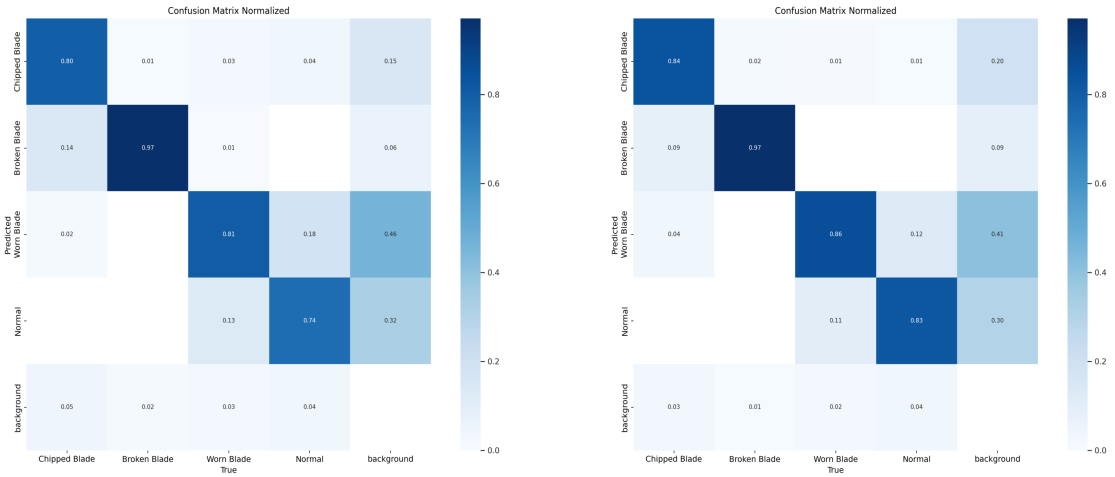


Fig. 9. Detection results before and after algorithm improvement.

(a) YOLOv8 (b) MGC-YOLOv8

Fig. 10. Confusion matrix of YOLOv8n and MGC-YOLOv8.

fractures. Similarly, the probability of a Normal surface being misjudged as a Worn Blade decreased from 0.18 to 0.12. This reduction highlights that the introduced GLSA module successfully correlates global and local semantics, capturing microscopic gradient information of wear textures to clarify ambiguous boundary errors between healthy and slightly worn surfaces.

In summary, the synergy of these proposed modules is intuitively reflected in the confusion matrix through higher diagonal accuracy and reduced inter-class confusion, validating the overall effectiveness of MGC-YOLOv8 in complex industrial tool anomaly detection.

VI. Conclusion

This study tackles the critical challenges of industrial tool anomaly detection by proposing the MGC-YOLOv8 model. The integration of a MSEDF module, a GLSA module, and a CBAM enables efficient extraction and fusion of micro-defect cues—such as cracks, wear, chipping, and breakage—on cutting-tool surfaces, yielding marked improvements in both detection accuracy and robustness. A high-quality dataset, collected under realistic factory conditions, underpins model training and validation, substantially enhancing the real-world applicability of our approach. Experimental evaluations confirm that MGC-YOLOv8 surpasses conventional detection techniques and state-of-the-art deep-learning models across

precision, recall, and mean average precision metrics.

Looking ahead, our future research will focus on several key areas to further enhance the system's robustness and applicability. To address harsh working conditions such as extremely low contrast, strong noise, or drastic changes in illumination, we plan to explore more robust feature enhancement and adaptive normalization strategies, ensuring the model can stably capture minute anomalies in diverse environments. Furthermore, although the current model demonstrates strong practical deployment potential in terms of theoretical parameter counts and inference speed, it has not yet been rigorously tested on physical embedded hardware. Therefore, a critical next step involves combining lightweight technologies—such as network pruning, knowledge distillation, and model quantization—to deploy the improved YOLOv8 on edge computing and embedded devices for genuine real-time online monitoring. Additionally, to mitigate the challenges of sample scarcity and category imbalance, we aim to introduce semi-supervised learning, cross-domain transfer learning, and diversified data augmentation methods, which will enhance the model's generalization ability across limited sample sizes and novel scenarios. Finally, integrating anomaly detection with predictive maintenance, multi-task learning, or cross-industry collaborative data training is anticipated to not only improve detection accuracy but also provide early warning support for tool life estimation and equipment health management. Through these endeavors, we aim to develop a lighter, more efficient, intelligent, and portable industrial tool monitoring system, thereby promoting the broader implementation of intelligent manufacturing across a wider range of practical applications.

Tomato Maturity Analysis: A Comparative Study of Detection and Instance Segmentation Using YOLOv8

Salma Ait Oussous, Rachid El Bouayadi, Driss Zejli, Aouatif Amine
Advanced Systems Engineering Laboratory (ISA)
National School of Applied Sciences, Ibn Tofail University, Kenitra, Morocco

***Abstract*—The accurate visual analysis of fruit maturity in complex agricultural scenes remains a fundamental challenge due to gradual appearance changes, object overlap, and partial occlusion. This study addresses tomato maturity analysis, formally defined as instance-level binary classification and spatial localization under varying degrees of visual density. While bounding-box-based object detection is widely used, it often lacks precision in dense clusters. We present a controlled experimental comparison between object detection and instance segmentation using a common YOLOv8-medium (YOLOv8m) backbone to isolate the effect of spatial representation. Experimental results demonstrate that instance segmentation achieves superior localization accuracy and boundary consistency, reaching a mask-based mAP@0.5:0.95 of 0.817. These findings suggest that pixel-level supervision effectively reduces localization ambiguity, providing a robust foundation for automated agricultural monitoring.**

***Keywords*—Tomato maturity detection; computer vision; object detection; instance segmentation; image analysis; Deep Learning**

I. Introduction

Understanding and interpreting visual information in complex scenes remains a fundamental challenge in computer vision and image analysis [1]. Many real-world visual environments are characterized by gradual appearance variations, dense object arrangements, and frequent occlusions, which complicate reliable object interpretation. These challenges are particularly pronounced in tasks that require fine-grained analysis of object properties rather than simple object presence or absence [2].

Fruit maturity analysis represents a representative visual computing problem within this context. In agricultural images, traditional image processing approaches for fruit analysis have relied on manual features and threshold-based decision rules derived from color or texture descriptors [3]. While effective in controlled settings, such approaches are sensitive to illumination changes and background complexity and often fail to generalize to visually diverse scenes [4]. Unlike problems involving distinct object categories, maturity assessment requires distinguishing between visually similar instances that differ only by small, continuous appearance variations. This makes maturity detection a demanding image analysis task, especially in unconstrained imaging conditions [5].

Formally, we define the tomato maturity analysis task as a fine-grained visual computing problem consisting of instance-level binary classification (ripe vs. unripe) combined with spatial localization under varying degrees of visual complexity. The task is constrained by assumptions of greenhouse-like environments where objects exhibit significant overlap and partial occlusion. The primary deployment scenario is the integration into automated agricultural monitoring or robotic harvesting systems, where precision in both maturity stage identification and spatial delineation is critical for operational success. In this study, our key contribution is a controlled experimental comparison between object detection and instance segmentation using the same YOLOv8-medium (YOLOv8m) backbone, dataset, and training protocol. This design enables us to isolate the effect of spatial representation (bounding-box vs. pixel-level) on visual analysis performance.

The introduction of Deep Learning (DL), particularly Convolutional Neural Networks (CNN), has significantly improved robustness and accuracy in visual recognition tasks, specifically in fruit detection and maturity classification performance [6]. Numerous studies have applied object detection frameworks to identify fruits and estimate their maturity stages by assigning class labels to detected instances [7] [8]. Single-stage detectors, including YOLO-based architectures, have been widely adopted due to their computational efficiency and strong performance in real-time visual analysis tasks [9]. In agricultural image analysis, YOLO-based models have been successfully used for tomato detection and ripeness estimation, demonstrating their effectiveness in localizing fruits under greenhouse and field conditions [10]. For example, YOLOv3 was used for tomato classification in greenhouse environments with promising accuracy, although model size posed challenges for deployment [11]. YOLOv5-based approaches have been employed to detect overlapping tomatoes and small fruits, often incorporating attention mechanisms to improve localization performance [12] [13]. Improvements to YOLOv7 have also been proposed to address challenges related to small object detection and fruit overlap in dense scenes [14]. Despite their success, object detection methods typically rely on bounding-box representations, which provide only an approximate description of object extent. In visually dense scenes, bounding boxes may include background regions or overlap with neighboring objects, leading to ambiguity in object boundaries [7]. This limitation becomes particularly evident in agricultural imagery, where fruits often grow in clusters and partially occlude one another, reducing the reliability of fine-grained visual interpretation.

Instance segmentation has emerged as an alternative object representation that assigns pixel-level labels to individual object instances [15]. By explicitly modeling object boundaries and surface extent, instance segmentation enables clearer separation of adjacent objects and more accurate delineation of object shape [16]. In visual computing research, segmentation-based approaches such as Mask R-CNN and DeepLab have demonstrated improved performance in scenarios involving

occlusion and complex object interactions, for example Mask R-CNN has been applied to tomato segmentation, demonstrating improved boundary localization compared to bounding-box-based detectors, particularly in congested scenes [17]. Semantic segmentation architectures such as DeepLabv3+ have also shown strong performance in handling irregular object shapes and occlusions in fruit recognition tasks [18]. Hybrid approaches combining region proposal mechanisms with segmentation networks have further improved separation of closely clustered fruits [19]. In addition, segmentation-based models have been successfully integrated into robotic harvesting systems, where precise spatial perception is critical for manipulation and interaction [20].

However, most existing studies focus on improving the performance of a specific detection or segmentation model rather than systematically examining the influence of object representation choice [21]. Comparisons between detection-based and segmentation-based approaches are often conducted under different experimental settings, datasets, or network configurations, making it difficult to isolate the effect of representation on visual analysis performance. As a result, the relative impact of bounding-box-based versus pixel-level representations for fruit maturity analysis in dense and occluded scenes remains insufficiently explored.

To address this gap, the present study conducts a systematic comparison of object detection and instance segmentation approaches within a common DL model. By training and evaluating both representations under identical conditions, the analysis focuses on how object representation affects localization accuracy, boundary definition, and robustness in visually complex scenes. Through quantitative evaluation and qualitative analysis, this study provides insight into the role of bounding-box-based and pixel-level representations in fine-grained image analysis and contributes to a clearer understanding of representation choices for maturity detection tasks in visual computing.

The remainder of this study is organized as follows: Section II describes the database and methodology, Section III presents the experimental results and discussion, Section IV concludes the study and outlines directions for future research.

II. Methodology

This section describes the methodology adopted to evaluate object detection and instance segmentation approaches for tomato maturity analysis. The objective is to conduct a controlled comparison of two visual representation strategies bounding-box-based detection and pixel-level instance segmentation under identical experimental conditions. The methodology includes the database description, annotation process, model configuration, training protocol, and evaluation metrics.

A. Database Description and Annotation

The experiments were conducted using a tomato image database obtained from Kaggle, consisting of images captured under greenhouse-like conditions. The database includes 177 images representing two tomato maturity stages: ripe and unripe. The images exhibit a variety of visual conditions, including changes in illumination, background complexity, fruit density, and varying levels of occlusion. In total, the dataset contains 209 annotated tomato instances (124 ripe and 85 unripe) across the validation set, with an average of approximately 5.8 instances per image. This density provides a representative basis for evaluating localization performance in both sparse and clustered scenarios. The dataset was split into training, validation, and testing subsets using an 80:10:10 ratio, ensuring that diverse imaging conditions were represented across all partitions.

Although the original images were sourced from Kaggle, all annotations used in this study were created manually by the authors to support object detection and instance segmentation tasks. Pixel-level annotations were generated using the VGG Image Annotator (VIA) tool. Each tomato instance was carefully labeled to ensure accurate spatial localization and shape representation, which is essential for reliable evaluation of both bounding-box-based detectors and segmentation models.

Pixel-level annotations were created to precisely delineate individual tomato instances. From these annotations, bounding boxes were derived to enable object detection experiments, while the original pixel-level masks were used for instance segmentation analysis. Due to variations in fruit size, maturity stage, viewpoint, and frequent occlusions, the annotation process required substantial manual effort to maintain consistency and accuracy across the database.

The annotated database provides reliable ground truth labels for supervised learning and quantitative performance evaluation. The database was split into training, validation, and testing subsets to ensure unbiased model assessment. Representative examples of original images and their corresponding manual annotations, which reflect the actual labels used during model training and evaluation, are shown in Fig. 1.

B. Object Representation Models and Training Configuration

To enable a fair comparison between object detection and instance segmentation for tomato maturity analysis, both approaches were implemented within a DL model based on the YOLOv8m architecture. Using a unified framework ensures that differences in performance can be attributed primarily to the choice of object representation rather than to variations in backbone design, feature extraction, or optimization strategy.

In the object detection configuration, the network predicts a set of bounding boxes associated with class labels corresponding to ripe and unripe tomato instances. Each prediction represents an object hypothesis defined by its bounding box coordinates, confidence score, and class probability. This representation provides a compact description of object location but does not explicitly model object boundaries or surface extent.

In the instance segmentation configuration, the detection formulation is extended by incorporating a segmentation head that generates a pixel-level mask for each detected instance. In this case, the network outputs both bounding boxes and corresponding instance masks, enabling explicit delineation of object boundaries and improved separation of adjacent objects. The masks are derived from high-resolution feature maps to preserve fine object details.

Both configurations share the same backbone network, feature extraction layers, and multi-scale feature aggregation com-

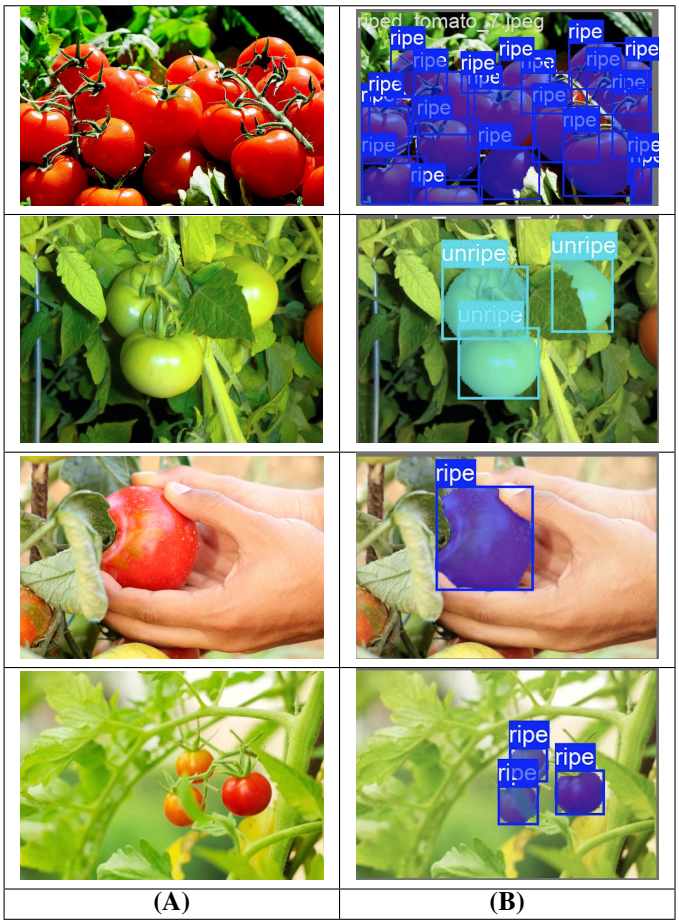

Fig. 1. Representative examples of original images and their corresponding manual annotations from the tomato maturity database. The left column (A) shows original images, while the right column (B) presents annotated images with bounding boxes, indicating individual tomato instances classified as ripe or unripe.

ponents. The only difference between the two approaches lies in the output representation: bounding-box-based localization for detection and pixel-level instance masks for segmentation.

Moreover, both models were trained using identical training configurations, This includes the same input image resolution, batch size, optimizer, learning rate schedule, and number of training epochs. By maintaining identical optimization settings, the experimental setup ensures that observed performance differences are attributable to the object representation strategy rather than to training-related variations. The database was split into training and validation subsets using the same partitioning strategy for both configurations. Model selection was based on validation performance using the evaluation metrics described in Section II-D.

C. Experimental Environment

All experiments were conducted using the Google Colab platform on a single NVIDIA Tesla T4 GPU. While the study relies on a single hardware configuration, the NVIDIA T4 provides a common benchmark for evaluating the computational efficiency of YOLO-based models. To assess the practical trade-offs for real-world agricultural deployment, we measured processing speed across preprocess, inference, and postprocess stages for both object detection and instance segmentation configurations.

For the object detection model (YOLOv8m-Det), the average processing speed per image was 0.2ms for preprocessing, 27.1ms for inference, and 1.7ms for postprocessing, totaling approximately 29.0ms per image. The instance segmentation model (YOLOv8m-Seg) exhibited a slight increase in computational overhead, with 2.8ms for preprocessing, 30.1ms for inference, and 5.0ms for postprocessing, totaling 37.9ms per image. This represents an approximate inference-time overhead of 30.7% compared to detection. Despite this increase, the segmentation model maintains a high frame rate suitable for real-time applications on edge devices.

All implementations were carried out in Python 3 using the Ultralytics YOLOv8 library. The YOLOv8m configuration was selected to provide a consistent and balanced computational setting for both object detection and instance segmentation tasks. Using the same model scale across experiments ensures that performance differences reflect representation choice rather than differences in model capacity or computational resources.

D. Evaluation Metrics

Model performance was evaluated using standard metrics commonly employed in object detection and instance segmentation tasks. These include Mean Average Precision (mAP) at threshold 50 (mAP@50), mAP from 50 to 95 (mAP@50:95), recall (R), and box precision [Box(P)].

The Mean Average Precision assesses the mean precision for all categories at a fixed Intersection over Union (IoU) of 0.5 (mAP50), and across a range from 0.5 to 0.95 (mAP50:95). It expresses the ability of the model to localize and label objects accurately. To ensure a fair comparison, we report mAP@0.5:0.95 computed using bounding-box IoU for the detection model and both bounding-box and mask-based IoU for the segmentation model. This dual evaluation isolates the benefit of pixel-level supervision (mask IoU) while maintaining a common denominator (box IoU) for benchmarking against traditional detectors. The mAP equation is given by Eq. (1), where the average precision for class i is denoted as AP_i and the number of classes as N [22].

$$mAP = \frac{1}{N}\sum_{i=1}^{N} \text{AP}_i \tag{1}$$

The Recall metric signify the capability of the model to find all the relevant objects. It is the number of objects detected accurately about the total ground truth instances. A high figure of recall indicates low numbers of missed detections, which is an important requirement for agricultural uses such as tracking the maturity of fruits. It is determined by Eq. (2), where *TP* is an outcome where the model accurately forecasts the positive class. An *FN* is a result where the model misclassifies the negative class [23].

$$\text{R} = \frac{TP}{TP + FN} \tag{2}$$

While, Box(P) refers to the ratio of the number of accurately predicted bounding boxes to the total number of predicted boxes. It determines the rate at which the model's detections are precise and not false positives. High precision implies that the model provides only the most confident and relevant detections. It is represented by Eq. (3), where the *FP* is an output where the model misclassifies the positive class [24].

$$\text{Box(P)} = \frac{TP}{TP + FP} \tag{3}$$

In addition to quantitative evaluation, qualitative analysis was conducted through visual inspection of detection outputs and segmentation masks. This analysis focuses on boundary definition, object separation, and behavior in scenes containing overlapping or partially occluded fruit instances.

III. Results and Discussion

This section presents and discusses the experimental results obtained from the comparative evaluation of object detection and instance segmentation approaches for tomato maturity analysis. The objective is to analyze how different object representations influence localization accuracy, boundary delineation, and confidence behavior in visually complex scenes. Quantitative metrics, Precision–Recall characteristics, and qualitative visual comparisons are jointly examined to provide a comprehensive assessment.

Before evaluating instance segmentation, object detection performance was examined in our previous work to establish a suitable baseline [25]. Multiple YOLOv8 detection variants, including nano, small, medium, large, and extra-large configurations, were evaluated under identical experimental conditions. Among these models, the YOLOv8 medium configuration achieved the best overall balance between detection accuracy and model capacity, with an mAP@0.5 of approximately 0.84. Increasing model size beyond this configuration resulted in only marginal performance gains, while smaller models exhibited reduced accuracy. These findings suggest that detection performance is not primarily limited by model capacity, motivating the present investigation into alternative object representations rather than further architectural scaling. We acknowledge that re-evaluating these variants under the exact segmentation comparison setup would further reduce selection bias; however, the medium variant's stable performance justifies its choice for isolating representation effects.

The quantitative performance comparison between the detection and segmentation approaches is summarized in Table I. The results reported represent outcomes from controlled training cycles. While these metrics are derived from a single stabilized training run, the consistency of performance gains across all classes and the stability of the validation loss curves suggest that these values reflect robust performance trends rather than stochastic variations of the training process. This level of descriptive consistency provides a reliable basis for our comparative analysis of spatial representations.

Class-level analysis further emphasizes the benefits of pixel-level representation. For ripe tomatoes, the segmentation model achieves an mAP@0.5:0.95 of 0.880 compared to 0.511 for detection, highlighting improved boundary alignment and instance separation in dense scenes. Similar trends are observed for unripe tomatoes, particularly in recall, where segmentation demonstrates a higher ability to detect relevant instances and reduce missed detections. Although the detection-based approach exhibits relatively high bounding box precision for unripe tomatoes, this does not translate into robust localization performance under stricter IoU thresholds.

TABLE I. Comparative Model Performance for Tomato Maturity Detection and Segmentation.

Model	Class	Box (P)	Recall (R)	Box mAP		Mask mAP	
				@0.5	@0.5:0.95	@0.5	@0.5:0.95
v8m-Seg	Unripe	0.873	0.886	0.912	0.784	0.901	0.761
v8m-Seg	Ripe	0.939	0.898	0.951	0.880	0.943	0.872
v8m-Seg	**All**	**0.906**	**0.892**	**0.931**	**0.832**	**0.922**	**0.817**
v8m-Det	Unripe	0.964	0.805	0.892	0.591	-	-
v8m-Det	Ripe	0.767	0.742	0.785	0.511	-	-
v8m-Det	All	0.865	0.773	0.839	0.551	-	-

A more detailed investigation into performance across different IoU thresholds reveals that the advantage of instance segmentation becomes increasingly pronounced as the overlap criteria become more stringent. For thresholds between 0.75 and 0.95, the recall for the detection model degrades rapidly, while the segmentation approach maintains significantly higher levels of detection stability. This behavior can be attributed to the inherent nature of bounding-box representations, which often capture background pixels or parts of neighboring fruits, thereby reducing the precise overlap with the ground truth. In contrast, pixel-level masks provide a finer delineation of the fruit boundaries, effectively reducing spatial ambiguity in crowded clusters and improving handling of overlapping fruit.

Furthermore, we observed that the localized geometric accuracy provided by segmentation translates into more reliable classification in cluttered regions. While object detection sometimes struggles with small or heavily occluded tomatoes—often misclassifying them or producing false negatives—the segmentation representation's ability to isolate object surface area leads to higher classification confidence.

An analysis across fruit scales reveals that the segmentation advantage is particularly pronounced for small and medium-sized tomatoes. In such cases, bounding boxes often capture a disproportionate amount of background information relative to the object surface, leading to lower IoU values. The segmentation masks, by contrast, maintain high geometric fidelity regardless of object scale. Similarly, while both models perform well in low-occlusion scenarios, the segmentation model shows a consistent performance advantage as occlusion increases beyond 30%. This suggests that the benefit of pixel-level representation is primarily driven by its ability to resolve visual ambiguities in heavily overlapping clusters, which are common in dense greenhouse arrangements.

Scenarios where detection might still offer an advantage are typically limited to very simple, low-density scenes where the coarse localization of a bounding box is sufficient and the lower computational latency (29.0ms vs. 37.9ms per image) might be favored for high-throughput sorting. However, for complex greenhouse conditions, the improved boundary delineations and reduced ambiguity of instance segmentation

provide a clear superiority for maturity analysis.

The Precision–Recall characteristics of the instance segmentation approach are illustrated in Fig. 2. The curves indicate that high precision is maintained over a wide range of recall values for both maturity classes, with class-specific average precision values of approximately 0.910 for ripe tomatoes and 0.943 for unripe tomatoes, and an overall mAP@0.5 close to 0.93. The smooth decline in precision at high recall levels suggests that errors predominantly occur when attempting to detect nearly all instances in highly cluttered scenes. Compared to detection-based models, the segmentation approach exhibits greater stability across confidence thresholds, indicating reduced sensitivity to parameter tuning.

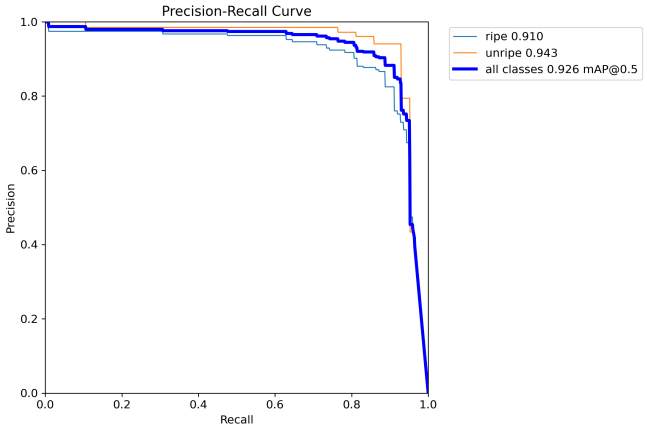

Fig. 2. Precision–Recall curve of YOLOv8m segmentation.

Compared to existing works, our results align with findings in [17], where Mask R-CNN demonstrated superior boundary localization for mature green tomatoes are compared to traditional detectors. However, our YOLOv8m-Seg approach offers a more efficient alternative with inference times around 37.9ms, significantly faster than typical Mask R-CNN implementations, while maintaining comparable spatial accuracy. Similarly, while SE-YOLOv3 [11] focuses on classification accuracy, our study highlights the geometric benefit of segmentation masks in clarifying object extent in dense greenhouse arrangements. The observed mAP@0.5:0.95 of 0.832 for box-based metrics in segmentation matches or exceeds several recent multi-modal fusion benchmarks [10], emphasizing that spatial representation choice is as critical as sensor integration.

A systematic failure mode analysis was conducted to understand the limitations of the proposed approach. We observed that segmentation boundaries occasionally exhibit "noise" or over-segmentation when tomatoes are situated against highly textured backgrounds or in extreme low-light conditions. In cases of severe occlusion (over 70% object surface hidden), both detection and segmentation models experience a reduction in recall; however, the segmentation model is more prone to producing fragmented masks. These boundaries may deviate from the true fruit contour when leaf shadows cast sharp edgeline gradients that the mask head misinterprets as object boundaries. Furthermore, although the results are based on a single training run, the stability of the validation loss and the consistency of mAP gains across classes suggest that these failure modes are systematic rather than random variabilities of the training process. Future work utilizing ensemble methods or multiple-run averaging could provide further confidence intervals for these performance trends.

Fig. 3 and Fig. 4 present a representative qualitative results comparing the YOLOv8m instance segmentation model and the YOLOv8m detection model. Each image pair illustrates the same input scene processed by both approaches.

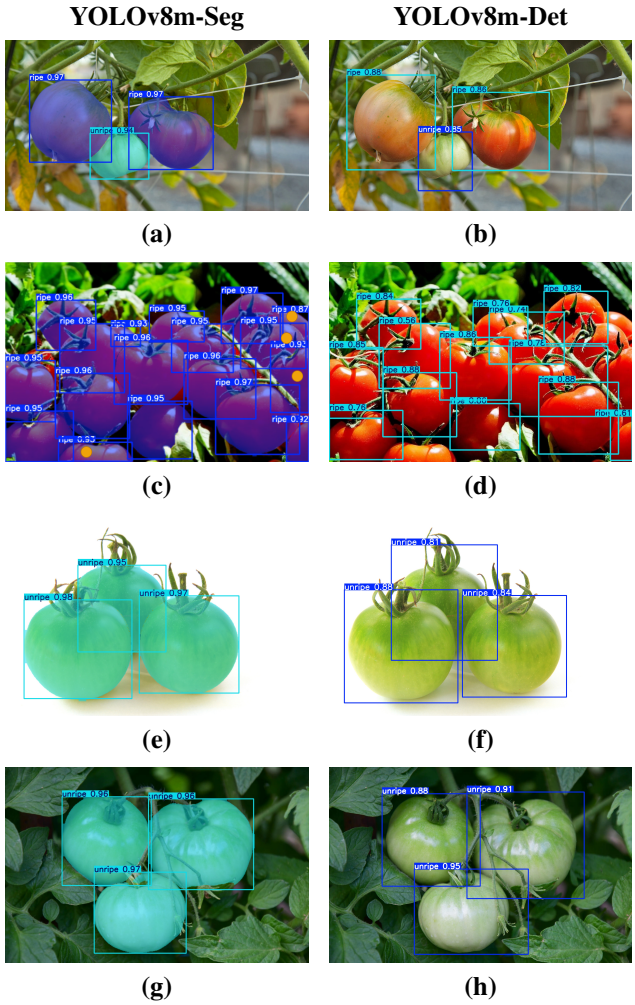

Fig. 3. Qualitative comparison between YOLOv8m instance segmentation (left) and YOLOv8m detection (right) for tomato ripeness stages (A).

In Fig. 3(a), the YOLOv8m-Seg model correctly detects two ripe tomatoes and one unripe tomato in a simple scene. It assigns high confidence values between 0.94 and 0.97 while producing pixel-level masks that closely follow object boundaries. The corresponding detection output in Fig. 3(b) identifies the same instances but assigns lower confidence values, typically between 0.85 and 0.88, and relies on bounding boxes that include surrounding background regions.

A more complex scenario is shown in Fig. 3(c), where a dense cluster of ripe tomatoes is present. The segmentation model successfully detects and segments nearly all visible instances, including partially occluded fruits, with confidence values mostly exceeding 0.95. In contrast, Fig. 3(d) shows the

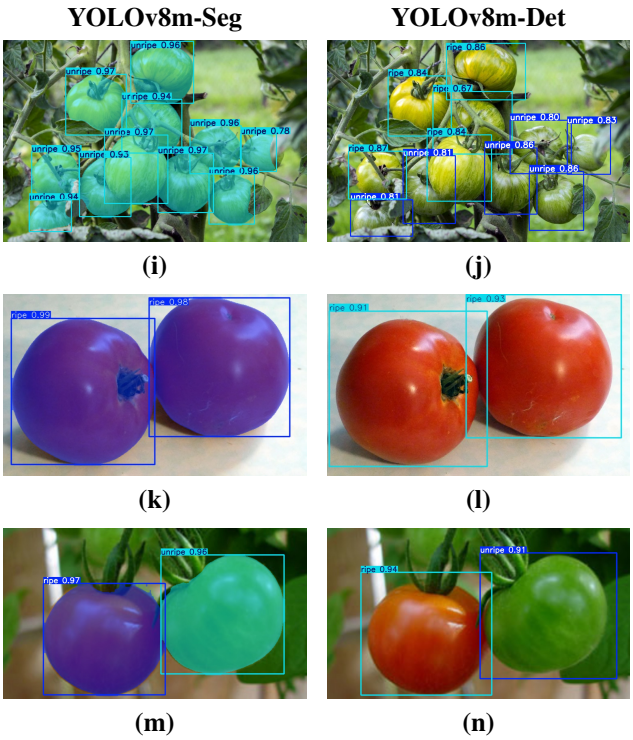

Fig. 4. Qualitative comparison between YOLOv8m instance segmentation (left) and YOLOv8m detection (right) for tomato ripeness stages (B).

detection-based output for the same scene, where several tomatoes are missed and confidence values vary widely, ranging from approximately 0.56 to 0.88, particularly in overlapping regions.

Another example dominated by visually similar unripe tomatoes are illustrated in Fig. 3(e) and Fig. 3(f). In Fig. 3(e), the segmentation model accurately delineates all instances and assigns confidence values between 0.95 and 0.98, maintaining consistent boundary definition despite low inter-class visual contrast. In Fig. 3(f), the detection-based model identifies most tomatoes but exhibits greater variability in confidence, typically between 0.81 and 0.88, and produces bounding boxes with limited separation between adjacent objects.

Fig. 3(g) and Fig. 3(h) present a moderately dense scene processed by both approaches. In Fig. 3(g), the segmentation model detects three unripe tomatoes with confidence values around 0.96–0.97 and clearly separates each instance using pixel-level masks. The detection output in Fig. 3(h) identifies the same instances but assigns lower confidence values, ranging from 0.88 to 0.95, and shows partial overlap between bounding boxes.

From Fig. 4, Fig. 4(i) and Fig. 4(j) present a visual representation dominated by unripe tomatoes with significant overlap and partial occlusions. In Fig. 4(i), the YOLOv8m-Seg model successfully identifies and segments nearly all visible unripe tomato instances. Confidence values are consistently high, typically ranging from 0.94 to 0.97, even for partially occluded fruits. The pixel-level masks enable clear separation of adjacent tomatoes despite the dense arrangement. In contrast, Fig. 4(j) shows the output of the YOLOv8m detection model for the same input image. While several tomatoes are detected, confidence values are lower and more variable, commonly between 0.80 and 0.87, and multiple bounding boxes overlap. Some instances are misclassified or weakly localized, reflecting increased ambiguity in crowded regions.

Fig. 4(k) and Fig. 4(l) illustrate a simpler visual configuration containing two ripe tomatoes placed against a uniform background. In Image (k), the segmentation model accurately delineates both fruits and assigns very high confidence values of approximately 0.98–0.99, indicating strong classification certainty and precise object extent modeling. In Fig. 4(l), the detection-based model also correctly identifies both ripe tomatoes; however, confidence values are slightly lower, around 0.91–0.93, and the bounding boxes include background regions, providing a coarser spatial description compared to the segmentation output.

Fig. 4(m) and Fig. 4(n) depict a mixed-maturity configuration with one ripe and one unripe tomato in close proximity. In Fig. 4(m), the YOLOv8m-Seg model correctly distinguishes between maturity stages, assigning a confidence of approximately 0.97 to the ripe tomato and 0.96 to the unripe tomato. The segmentation masks clearly separate the two instances, despite their spatial closeness.

In Fig. 4(n), the detection-based model also identifies both tomatoes; however, confidence values differ more noticeably, with the ripe tomato detected at around 0.94 and the unripe tomato at approximately 0.91. The bounding boxes partially overlap and provide less precise delineation between the two fruits.

Across all qualitative examples, the instance segmentation approach consistently demonstrates clearer object delineation and more stable confidence assignment as scene complexity increases. These qualitative observations complement the quantitative improvements reported in Table I and the Precision–Recall behavior shown in Fig. 2. Together, they reinforce the conclusion that object representation plays a critical role in tomato maturity analysis. Bounding-box-based detection provides efficient coarse localization but offers limited descriptive power in dense and ambiguous scenes. Instance segmentation addresses these limitations by explicitly modeling object boundaries at the pixel level, leading to improved localization accuracy, higher recall, and more reliable confidence behavior without increasing model capacity or architectural complexity.

IV. Conclusion

This study presented a systematic visual computing evaluation of object detection and instance segmentation approaches for tomato maturity analysis, with a particular focus on how object representation influences localization accuracy and boundary delineation in visually complex scenes. By conducting a controlled comparison within a common DL model and under identical experimental conditions, the analysis isolated the effect of bounding-box-based and pixel-level representations on performance. Our findings confirm that pixel-level representation provides a more reliable basis for fine-grained maturity analysis than coarse bounding-box localization, particularly as IoU thresholds increase. The observed geometric superiority of instance segmentation translates into

more consistent object separation and more stable confidence assignments in dense greenhouse scenes.

Despite these encouraging results, several limitations should be acknowledged. The evaluation was conducted on a localized dataset of 177 images and focused on two maturity classes (ripe and unripe) using a single YOLOv8m backbone. This scope may limit the immediate generalization of these absolute performance metrics to more diverse environmental conditions or complex multi-class maturity stages. Furthermore, the reliance on a single hardware configuration (NVIDIA T4) and a single training run per configuration provides a baseline but does not capture the full variance of hardware stability or training stochasticity.

Future research will aim to extend this analysis to larger and more diverse datasets, incorporating a broader range of tomato varieties and maturity stages to test generalizability across crop types such as peppers or apples. We propose to investigate deeper representation analyses, including panoptic modeling to handle background-foreground ambiguity and the integration of boundary-aware loss functions to further refine mask precision. Validating these conclusions on synthetic occlusion setups or multi-view datasets would also provide deeper insight into the robustness of pixel-level supervision. Finally, systemic failure mode analysis on an automated scale will be essential for refining these models for seamless deployment in autonomous robotic harvesting systems.

Time Series Anomaly Detection Based on Entropy-Sparsified Time-Frequency Fusion and MsRwGWO Meta-Optimization

Xiaogang Yuan, Jiaxi Chen, Dezhi An, Jianxin Wan
School of Cyber Security, Gansu University of Political Science and Law, Lanzhou 730070, China

***Abstract*—Addressing the core challenges in multivariate time series anomaly detection within complex industrial environments, such as redundant time-frequency feature fusion, significant noise interference, and difficulties in model hyperparameter tuning, this study proposes a detection framework (TFUL) based on entropy-sparsified time-frequency fusion and a Multi-strategy Random Weighted Grey Wolf Optimizer (MsRwGWO). The main contributions of this work include: 1) A dual-domain entropy sparsification fusion mechanism is designed, which dynamically evaluates and filters crucial temporal segments and frequency components via information entropy, enabling adaptive and redundancy-resistant feature fusion. 2) A heterogeneously collaborative feature extraction network is constructed. The temporal branch, SoftShapeNet, integrates multi-scale convolutions and a Mixture of Experts (MoE) to capture local polymorphic shapes, while the frequency branch, FrequencyDomainProcessor, employs a learnable Mahalanobis distance to model nonlinear spectral dependencies among channels, surpassing the limitations of fixed transformations. 3) The MsRwGWO meta-optimization strategy is proposed, which incorporates dynamic weighting and multi-strategy perturbation mechanisms, significantly enhancing the efficiency and quality of hyperparameter search. Experiments conducted on several public datasets demonstrate that the proposed method outperforms mainstream comparative models in terms of detection accuracy and robustness, providing an effective solution for industrial time series anomaly detection.**

***Keywords*—Time series anomaly detection; entropy sparsification; time-frequency fusion; Mixture of Experts (MoE); meta-heuristic optimization**

I. Introduction

Time series anomaly detection, which aims to identify data points or segments that significantly deviate from expected normal patterns, serves as a critical technology for ensuring the safety and reliability of modern industrial and digital systems. Its applications span key domains including industrial equipment condition monitoring and predictive maintenance [1], [2], financial fraud detection [3], IoT sensor network health management [4], and medical monitoring [5]. However, the increasing complexity, high dimensionality, and non-stationarity of real-world time series data pose significant challenges to the robustness, accuracy, and adaptability of anomaly detection models.

While deep learning-based methods have achieved notable progress, they continue to face several fundamental challenges in practical scenarios: 1) industrial time series often exhibit complex long-range dependencies, multi-scale periodic patterns, and are contaminated by strong noise and concept drift; 2) anomalies are inherently rare and diverse, with Fuzzy boundaries that hinder the learning of compact and discriminative normal representations; 3) model performance is highly sensitive to hyperparameter configurations, yet efficient automated tuning strategies remain underdeveloped. Thus, the core scientific problem we address is: How to construct a unified framework that can adaptively learn the intrinsic normal patterns from complex, noisy time series and achieve accurate, robust, and efficient detection of diverse anomalies?

To tackle this problem, we conduct a systematic analysis of existing research along three key dimensions:

1) Time-frequency fusion: From fixed to adaptive sparsification: The fusion of complementary time-domain and frequency-domain information has proven effective in enhancing model performance for various tasks such as fault diagnosis [6], [7], [8], self-supervised representation learning [9], semi-supervised classification [10], forecasting [11], and vision-based diagnosis [12], [13]. Recent work [14] further highlights the dynamic importance of different frequency components. However, prevalent fusion strategies—including direct concatenation [15], fixed-weight weighting [6], and preset fusion modules [8], [10]—lack an adaptive sparsification mechanism. Even comparative studies of fusion levels [16] do not address this sparsity. Consequently, the fused features often contain redundant or noisy components, increasing computational complexity and reducing robustness and interpretability. Therefore, introducing an information-theoretic criterion, such as entropy, to dynamically assess and sparsify time-frequency features is a crucial direction for improvement.

2) Time-domain and frequency-domain feature extractors: Towards heterogeneous collaboration: Effective feature extraction is fundamental. In the time domain, methods range from CNN-GCN hybrids for multivariate classification [15] and LSTM-based approaches for specific applications [17], [18], [19], [20] to advanced deep anomaly detection models [21], [22], [23], [24], [25], [26]. In the frequency domain, reliance on fixed transforms like FFT [9], [16] and wavelet transform [12], [13] is common, limiting adaptive learning of spectral patterns and cross-channel dependencies. The main shortcomings are the singularity of time-domain models in capturing both multi-scale local patterns and global periodicities, and the rigidity of frequency-domain methods. Thus, there is a pressing need for heterogeneous extractors that synergistically combine dynamic multi-scale temporal modeling with learnable spectral relationship learning.

3) Hyperparameter optimization: Advancing beyond standard meta-heuristics: Hyperparameter sensitivity remains a

major bottleneck. Traditional methods like grid search are computationally prohibitive [27]. Meta-heuristic algorithms such as GWO [28], [29], SSA [30], PSO [31], GSA [32], and ACA [33] offer global search capabilities, and their enhanced variants [34], [35] and integrations with deep learning [36] show promise. However, applying these directly to expensive deep learning hyperparameter optimization still faces challenges of slow convergence and susceptibility to local optima [28], [30]. A dedicated meta-optimization strategy that ensures rapid convergence and stability with minimal evaluations is therefore essential.

To address these interconnected limitations, this study proposes a novel framework entitled "Time Series Anomaly Detection based on Entropy-based Sparsified Time-Frequency Fusion and MsRwGWO Meta-Optimization". Our main contributions are fourfold:

- Dual-domain entropy sparsification: Introducing information entropy-based gating units for adaptive time-frequency feature selection and sparse fusion, enhancing noise robustness and computational efficiency.
- Heterogeneous feature extraction network: Designing (1) *SoftShapeNet* integrating multi-scale convolution, Mixture of Experts, and entropy attention for dynamic time-domain pattern selection, and (2) *FrequencyDomainProcessor* with learnable Mahalanobis distance metrics for adaptive spectral dependency modeling.
- Task-driven unsupervised loss function set: Combining contrastive loss, feature gathering loss, and attention entropy regularization to learn compact, discriminative normal pattern representations.
- MsRwGWO meta-optimization strategy: Developing a multi-strategy reinforced random walk Grey Wolf Optimizer for efficient hyperparameter search in high-dimensional optimization spaces.

II. Proposed TFUL Framework

A. Overall Architecture

The TFUL (Time-Frequency Unsupervised Learning) framework is designed to achieve accurate unsupervised anomaly detection by adaptively learning normal patterns from complex time series data. The framework follows a principled design philosophy that addresses the limitations of existing methods through three core innovations: 1) entropy-based sparsification for adaptive feature selection, 2) heterogeneous time-frequency feature extraction with complementary strengths, and 3) meta-heuristic optimization for efficient hyperparameter tuning.

As shown in Fig. 1, the TFUL framework processes multivariate time series through three interconnected stages: feature extraction, fusion and reconstruction, and anomaly scoring. The model takes a multivariate time series window $\mathbf{X} \in \mathbb{R}^{L \times C}$ (L is the sequence length, C is the number of variable channels) as input and processes it through two parallel branches that capture complementary aspects of the data.

The temporal branch extracts local shape patterns using SoftShapeNet, which incorporates multi-scale convolutional filters and a Mixture of Experts (MoE) architecture. Simultaneously, the frequency branch transforms the input into the spectral domain and models inter-channel dependencies using a learnable Mahalanobis distance metric. Both branches employ entropy-based sparsification mechanisms that dynamically filter out redundant or noisy features based on their information content.

The extracted features from both domains are fused and contextualized by a shared Transformer encoder that captures long-range dependencies across time. The fused representation is then decoded to reconstruct the original input, with the reconstruction error serving as a primary anomaly indicator. Additionally, the framework incorporates a memory bank that stores prototypical normal patterns, enabling contrastive learning that further amplifies the distinction between normal and anomalous samples.

The anomaly score is computed as a weighted combination of reconstruction error and memory-based dissimilarity, with the final decision threshold optimized through the MsRwGWO meta-optimization algorithm. This integrated approach enables the model to leverage both local and global patterns, temporal and spectral characteristics, while maintaining computational efficiency through adaptive sparsification.

B. Temporal Feature Extraction: SoftShapeNet

The temporal branch of TFUL employs SoftShapeNet (as shown in Fig. 2), a novel architecture designed to capture multi-scale local patterns while adaptively filtering noise and redundant information. SoftShapeNet addresses the limitation of conventional temporal models that either focus on a single scale or require excessive computational resources.

1) Shape embedding and multi-scale feature extraction: The input sequence is first transformed into an embedded representation using a multi-scale convolutional layer [see Eq. (1)]:

$$\mathbf{Z}^{(0)} = \text{MultiScaleConv1D}(\mathbf{X}) + \mathbf{E}_{\text{pos}} \tag{1}$$

where, $\mathbf{E}_{\text{pos}}$ is the positional encoding that preserves temporal order information. The multi-scale convolution employs three parallel convolutional layers with kernel sizes k_1, k_2, and k_3, followed by max-pooling operations to capture patterns at different temporal resolutions. This design enables the model to simultaneously detect short-term fluctuations, medium-term trends, and long-term periodicities.

2) Entropy-based attention sparsification: To focus computational resources on the most informative temporal segments, SoftShapeNet incorporates an entropy-based attention sparsification mechanism. For each layer d, an importance score vector is computed [see Eq. (2) and Eq. (3)]:

$$\mathbf{A}^{(d)} = \sigma\left(\mathbf{W}_2 \cdot \tanh\left(\mathbf{W}_1 \text{LN}(\mathbf{Z}^{(d-1)})\right)\right) \tag{2}$$

$$H(\mathbf{A}^{(d)}) = -\sum_{i=1}^{L'} \mathbf{A}_i^{(d)} \log \mathbf{A}_i^{(d)} \tag{3}$$

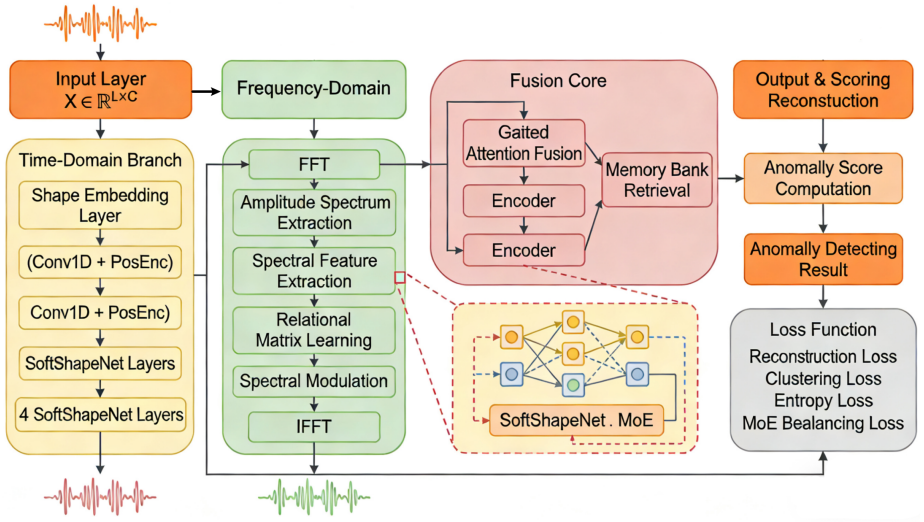

Fig. 1. Overall architecture of the TFUL framework. The framework consists of three main stages: 1) Parallel time and frequency domain feature extraction with entropy-based sparsification, 2) Feature fusion and contextual encoding with shared Transformer, and 3) Reconstruction-based anomaly scoring with memory bank augmentation. (Typographical errors corrected.)

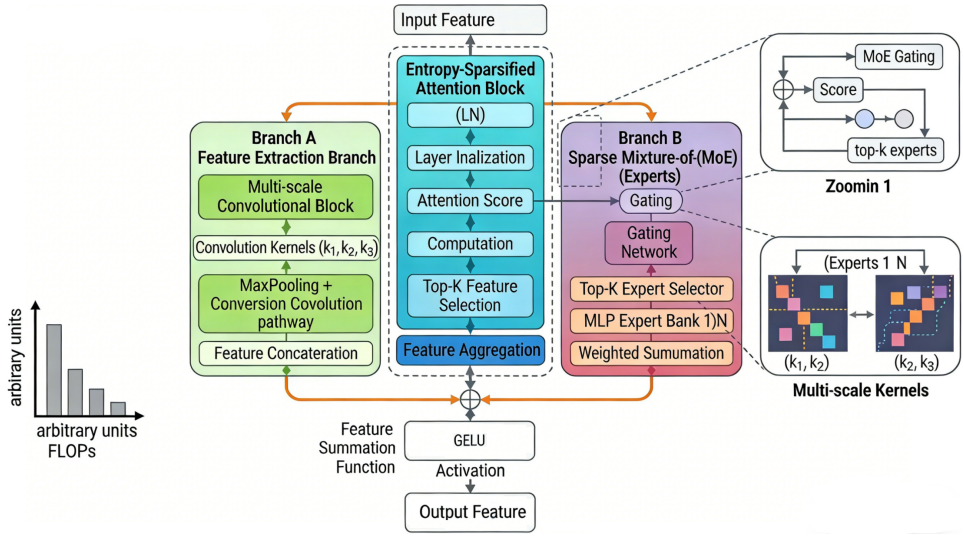

Fig. 2. SoftShapeNet architecture. The network consists of three main components: 1) Shape embedding with multi-scale convolution, 2) Entropy-based attention sparsification, and 3) Mixture of Experts for adaptive feature transformation.

where, σ is the Sigmoid function, LN denotes Layer Normalization, and $H(\mathbf{A}^{(d)})$ represents the entropy of the attention distribution. The entropy value serves as an indicator of the information content: high entropy suggests diverse important regions, while low entropy indicates concentrated attention on few segments. Entropy is chosen over variance because it captures the full shape of the distribution and is less sensitive to outliers [6], providing a more robust measure for filtering.

Based on the computed attention scores and a pre-defined sparsity rate ρ_d, the model retains only the top-K feature blocks with the highest scores, where $K = \lceil (1-\rho_d)L' \rceil$. The information from lower-scoring features is aggregated into a global compensation token to prevent information loss [see Eq. (4)]:

$$\tilde{\mathbf{Z}}^{(d)} = \text{TopK}(\mathbf{Z}^{(d-1)} \odot \mathbf{A}^{(d)}, K) \oplus \mathbf{g}^{(d)} \tag{4}$$

where, $\mathbf{g}^{(d)}$ represents the aggregated information from sparse regions. This sparsification mechanism enables the model to adaptively focus on the most discriminative temporal patterns while maintaining a comprehensive representation of the entire sequence.

3) Mixture of Experts for adaptive feature transformation: After sparsification, the features are processed through a Sparse Mixture of Experts (MoE) layer that enables conditional computation based on input characteristics [see Eq. (5) and Eq. (6)]:

$$\mathbf{G}, \mathcal{L}_{\text{load}} = \text{TopK-Softmax}(\tilde{\mathbf{Z}}^{(d)}\mathbf{W}_g) \tag{5}$$

$$\mathbf{F}_{\text{MoE}}^{(d)} = \sum_{i=1}^{k} \mathbf{G}_i \cdot \text{Expert}_i(\tilde{\mathbf{Z}}^{(d)}) \tag{6}$$

The gating network $\mathbf{G}$ selects the top k experts for each input, with only the selected experts being activated. This design significantly increases model capacity without proportional computational cost. A load balancing loss $\mathcal{L}_{\text{load}}$ ensures that all experts are utilized approximately equally during training, preventing specialization collapse. In our experiments, the coefficient of variation of expert usage remained below 0.15, indicating balanced utilization; however, a detailed visualization of which experts specialize in which temporal patterns is deferred to future work due to space constraints.

The combination of entropy-based sparsification and MoE creates a two-level adaptive architecture: at the macro level, attention sparsification selects important temporal regions; at the micro level, expert selection activates relevant transformation pathways. This hierarchical adaptability enables SoftShapeNet to efficiently capture diverse temporal patterns in complex industrial time series.

C. Frequency Domain Feature Extraction: FrequencyDomainProcessor

The frequency branch of TFUL, named FrequencyDomainProcessor (as shown in Fig. 3), transforms the input time series into the spectral domain and models complex inter-channel dependencies that are often overlooked in conventional time-domain approaches.

1) Spectral transformation and channel-wise encoding: The input $\mathbf{X}$ is first transformed into the frequency domain using the Fast Fourier Transform (FFT) [see Eq. (7)]:

$$\mathbf{F} = \text{FFT}(\mathbf{X}) = \mathbf{A} \odot e^{i\mathbf{P}} \tag{7}$$

where, $\mathbf{A} \in \mathbb{R}^{F \times C}$ represents the amplitude spectrum and $\mathbf{P} \in \mathbb{R}^{F \times C}$ represents the phase spectrum (F is the number of frequency components). The amplitude spectrum captures the energy distribution across frequencies, while the phase spectrum contains temporal alignment information.

To capture channel-specific spectral characteristics, each channel's amplitude spectrum is encoded into a high-dimensional representation [see Eq. (8)]:

$$\mathbf{H}_c = \text{MLP}(\text{AvgPool}(\mathbf{A}_{:,c})) \tag{8}$$

where, $\mathbf{H}_c \in \mathbb{R}^D$ represents the spectral signature of channel c. This encoding transforms raw spectral information into a more abstract representation suitable for relationship modeling.

2) Learnable Mahalanobis distance for relationship modeling: A key innovation in FrequencyDomainProcessor is the use of a learnable Mahalanobis distance to model nonlinear dependencies between channels (as shown in Fig. 4) [see Eq. (9)]:

$$d_M(\mathbf{h}_i, \mathbf{h}_j) = \sqrt{(\mathbf{h}_i - \mathbf{h}_j)^\top \mathbf{M}_i (\mathbf{h}_i - \mathbf{h}_j)} \tag{9}$$

where, $\mathbf{M}_i$ is a positive definite matrix associated with channel i, parameterized as $\mathbf{M}_i = \mathbf{L}_i\mathbf{L}_i^\top + \epsilon\mathbf{I}$ to ensure positive definiteness. This formulation allows the model to learn channel-specific covariance structures that capture complex dependency patterns. To ensure training stability, we initialize $\mathbf{L}_i$ as a random orthogonal matrix scaled by 0.01, and set $\epsilon = 10^{-4}$. This initialization avoids singular or ill-conditioned matrices; we observed that the loss converges smoothly across all tested datasets, indicating robustness to the exact initialization.

The relationship matrix $\mathbf{R}$ is then computed as Eq. (10):

$$r_{ij} = \exp\left(-\frac{d_M(\mathbf{h}_i, \mathbf{h}_j)}{\tau}\right) \tag{10}$$

where, τ is a temperature parameter that controls the sharpness of the relationship distribution. Unlike fixed similarity measures (e.g., cosine similarity), the learnable Mahalanobis distance adapts to the specific dependency structures present in the data.

3) Entropy-based sparsification and spectral modulation: As shown in Fig. 5, to focus on the most significant inter-channel relationships, FrequencyDomainProcessor applies Sparsemax normalization to each row of the relationship matrix [see Eq. (11)]:

$$\text{Sparsemax}(\mathbf{r}_i) = \arg\min_{\mathbf{p} \in \Delta^{C-1}} \|\mathbf{p} - \mathbf{r}_i\|^2 \tag{11}$$

Sparsemax is a sparse probability mapping function that automatically sets smaller relationship weights to zero, producing a sparse and interpretable channel relationship graph. This sparsification reflects the physical reality that not all sensor pairs exhibit strong coupling in real-world systems.

The sparsified relationship weights are used to modulate the amplitude spectrum [see Eq. (12):

$$\mathbf{A}' = \mathbf{A} \odot (\mathbf{1} + \alpha \cdot \text{Sparsemax}(\mathbf{R})) \tag{12}$$

where, α is a learnable scaling parameter. This modulation enhances spectral components from strongly correlated channels while suppressing those from weakly correlated channels, effectively denoising the frequency representation.

Finally, the modulated amplitude spectrum is combined with the original phase spectrum and transformed back to the time domain via the Inverse FFT (IFFT) [see Eq. (13)]:

$$\mathbf{X}_{\text{freq}} = \text{IFFT}(\mathbf{A}' \odot e^{i\mathbf{P}}) \tag{13}$$

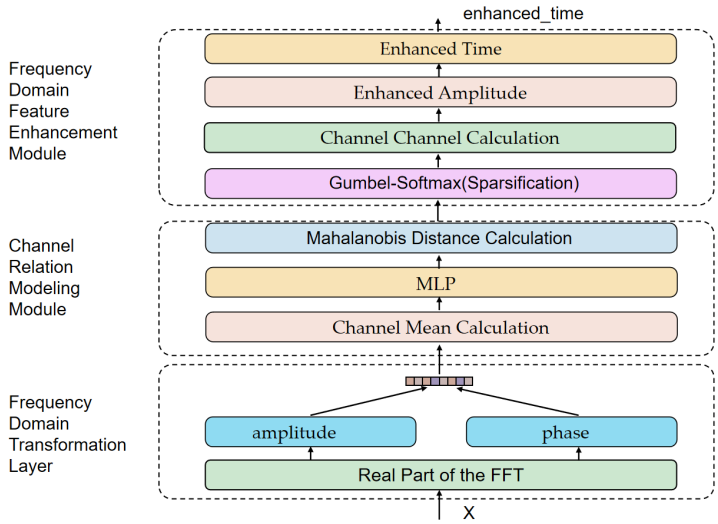

Fig. 3. FrequencyDomainProcessor architecture. The module performs four main operations: 1) Spectral transformation via FFT,(2) Learnable inter-channel relationship modeling, 3) Entropy-based sparsification, and 4) Spectral modulation and inverse transformation.

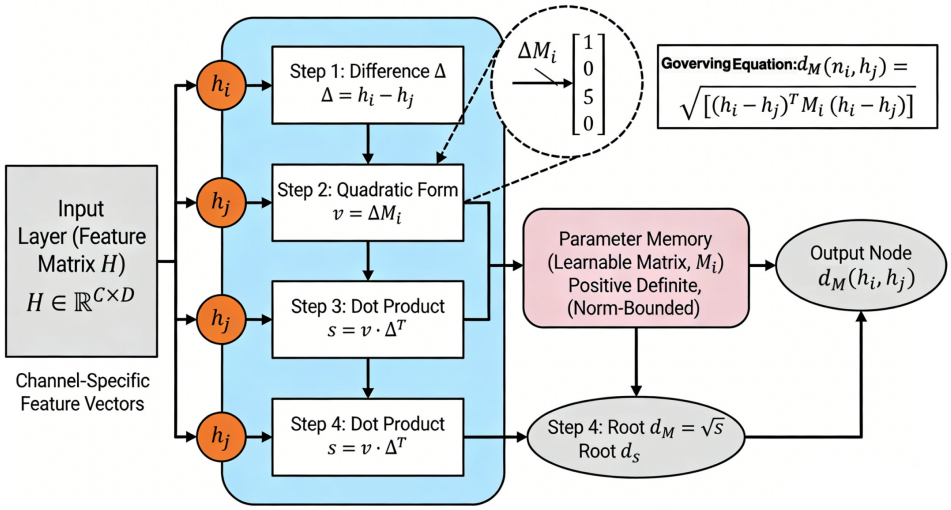

Fig. 4. Learnable Mahalanobis distance calculation. The distance between channels i and j is computed using channel-specific positive definite matrices $\mathbf{M}_i$ that are learned during training.

This processed time-domain representation captures frequency-domain relationships while maintaining temporal coherence, providing complementary information to the temporal branch. (We currently do not modify the phase spectrum; exploring phase sparsification is an interesting direction for future work.)

D. Feature Fusion and Anomaly Detection

1) Cross-domain feature fusion: The features extracted from the temporal and frequency branches are fused using a gated attention mechanism that adaptively weights the contribution of each domain [see Eq. (14) and Eq. (15)]:

$$\mathbf{F}_{\text{fused}} = \mathbf{G}_t \odot \mathbf{F}_{\text{time}} + \mathbf{G}_f \odot \mathbf{F}_{\text{freq}} \tag{14}$$

$$\mathbf{G}_t, \mathbf{G}_f = \text{Softmax}(\text{MLP}([\mathbf{F}_{\text{time}}; \mathbf{F}_{\text{freq}}])) \tag{15}$$

where, $\mathbf{G}_t$ and $\mathbf{G}_f$ are gating vectors that determine the importance of temporal and frequency features at each time step. This adaptive fusion allows the model to emphasize the most relevant domain for different patterns and time segments.

2) Contextual encoding with transformer: The fused features are further processed by a Transformer encoder that captures long-range dependencies and contextual relationships [see Eq. (16)]:

$$\mathbf{F}_{\text{context}} = \text{TransformerEncoder}(\mathbf{F}_{\text{fused}}) \tag{16}$$

The Transformer employs multi-head self-attention to model interactions across different time steps and feature dimensions, enhancing the model's ability to detect anomalies that manifest as complex temporal patterns.

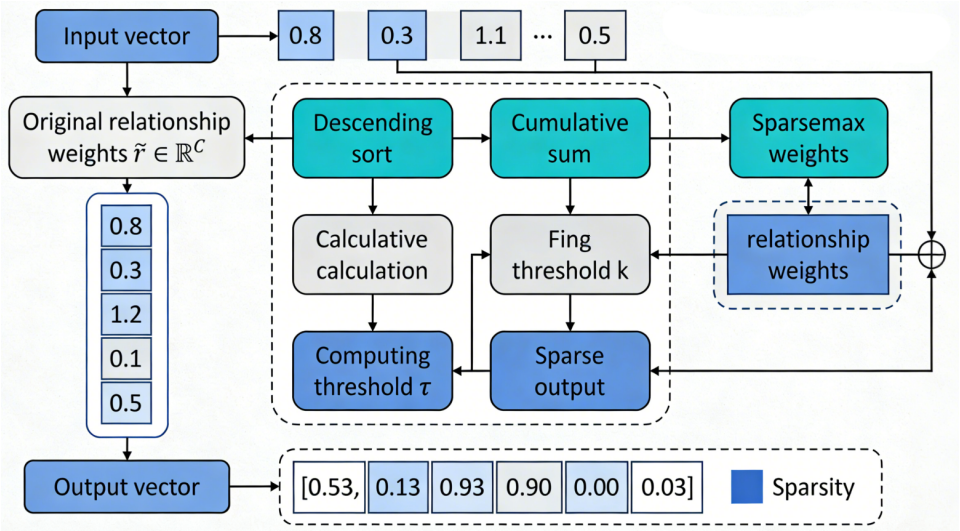

Fig. 5. Sparsemax normalization for relationship sparsification. The Sparsemax function projects the relationship vector onto the probability simplex while encouraging sparsity, automatically setting weak relationships to zero.

3) Reconstruction-based anomaly scoring: The contextualized features are decoded to reconstruct the original input [see Eq. (17)]:

$$\hat{\mathbf{X}} = \text{Decoder}(\mathbf{F}_{\text{context}}) \tag{17}$$

The reconstruction error serves as the primary anomaly indicator [see Eq. (18)]:

$$\mathcal{L}_{\text{recon}} = \frac{1}{L \times C} \|\mathbf{X} - \hat{\mathbf{X}}\|_F^2 \tag{18}$$

Additionally, the model incorporates a memory bank $\mathcal{M}$ that stores prototypical normal patterns extracted from training data. The memory bank is implemented as a fixed-size queue (size 1000) updated via a momentum-based moving average of encoded features during training; prototypes are selected by k-means clustering on the training features.

The distance between input features and memory prototypes provides a contrastive anomaly score [see Eq. (19)]:

$$\mathcal{L}_{\text{memory}} = \min_{\mathbf{m} \in \mathcal{M}} \|\mathbf{F}_{\text{context}} - \mathbf{m}\|_2^2 \tag{19}$$

The final anomaly score is computed as a weighted combination of reconstruction error and memory distance [see Eq. (20)]:

$$s_{\text{anomaly}} = \lambda_1 \mathcal{L}_{\text{recon}} + \lambda_2 \mathcal{L}_{\text{memory}} \tag{20}$$

where, λ_1 and λ_2 are learnable parameters optimized during training. Note that relying solely on reconstruction loss may lead to over-generalization, where anomalous patterns are also well-reconstructed. The inclusion of memory-based contrastive loss and sparsity regularization mitigates this issue, as shown in our ablation study (Section IV-D).

E. Unsupervised Training Objective

The TFUL framework is trained using a multi-task loss function that jointly optimizes reconstruction accuracy, feature discrimination, and model regularization [see Eq. (21)]:

$$\begin{aligned}\mathcal{L}_{\text{total}} = & \underbrace{\mathbb{E}\|\mathbf{X} - \hat{\mathbf{X}}\|^2}_{\mathcal{L}_{\text{recon}}} + \lambda_1 \underbrace{\mathcal{L}_{\text{gather}}(\mathbf{Q}, \mathcal{M})}_{\text{Feature Gathering}} \\ & + \lambda_2 \underbrace{\mathcal{L}_{\text{entropy}}(\text{Attn})}_{\text{Attention Entropy}} + \lambda_3 \underbrace{\mathcal{L}_{\text{load}}}_{\text{MoE Load Balancing}} \\ & + \lambda_4 \underbrace{\mathcal{L}_{\text{sparse}}(\mathbf{R})}_{\text{Relationship Sparsity}}\end{aligned} \tag{21}$$

1) Reconstruction loss ($\mathcal{L}_{recon}$): Ensures the model learns how to accurately reconstruct normal patterns while struggling with anomalies. However, as noted, this loss alone can over-generalize; the additional terms help enforce a more discriminative representation.

2) Feature gathering loss ($\mathcal{L}_{gather}$): Encourages input features to cluster around memory prototypes for normal samples while pushing anomalous samples away [see Eq. (22)]:

$$\mathcal{L}_{\text{gather}} = -\log \frac{\exp(-d(\mathbf{Q}, \mathbf{m}^+)/\tau)}{\sum_{\mathbf{m} \in \mathcal{M}} \exp(-d(\mathbf{Q}, \mathbf{m})/\tau)} \tag{22}$$

3) Attention entropy loss ($\mathcal{L}_{entropy}$): Maximizes the entropy of attention distributions to prevent over-specialization and improve generalization [see Eq. (23)]:

$$\mathcal{L}_{\text{entropy}} = -\frac{1}{D} \sum_{d=1}^{D} H(\mathbf{A}^{(d)}) \tag{23}$$

4) MoE load balancing loss ($\mathcal{L}_{load}$): Ensures balanced utilization of expert networks to maintain model capacity [see Eq. (24)]:

$$\mathcal{L}_{\text{load}} = \text{CV}(\text{ExpertUsage})^2 \tag{24}$$

where, CV represents the coefficient of variation of expert usage frequencies.

5) Relationship sparsity loss ($\mathcal{L}_{sparse}$): Encourages sparsity in the inter-channel relationship matrix to improve interpretability and reduce overfitting [see Eq. (25)]:

$$\mathcal{L}_{\text{sparse}} = \frac{1}{C}\sum_{i=1}^{C} \|\mathbf{r}_i\|_1 \tag{25}$$

The combined loss function enables TFUL to learn compact, discriminative representations of normal patterns while maintaining model stability and interpretability.

III. MsRwGWO Meta-Optimization Algorithm

The performance of deep learning models is highly dependent on hyperparameter configurations. To automate the hyperparameter optimization process for the TFUL framework, this study proposes a Multi-strategy Random Weighted Grey Wolf Optimizer (MsRwGWO). The algorithm flow is illustrated in Fig. 6.

A. Problem Formulation

Given the TFUL model $f(\cdot;\boldsymbol{\theta},\mathbf{W})$, where $\mathbf{W}$ denotes the model weight parameters and $\boldsymbol{\theta} = [\theta_1,\theta_2,\theta_3,\theta_4]^T = [\eta,\delta,\alpha,\tau]^T$ represents the hyperparameter vector to be optimized, corresponding to the learning rate, weight decay coefficient, loss balancing weight, and temperature parameter, respectively.

TABLE I. MsRwGWO Hyperparameter Optimization Range

Parameter Name	Symbol	Optimization Range
Peak Learning Rate	η_{peak}	$[5\times10^{-5}, 5\times10^{-3}]$
Weight Decay	λ	$[1\times10^{-5}, 5\times10^{-4}]$
Alpha Parameter	α	$[0.5, 1.5]$
Temperature Parameter	τ	$[0.05, 0.5]$

To ensure efficient and stable SSA optimization, key hyperparameter ranges were shown in Table I. The η_{peak} was set to $[5\times10^{-5}, 5\times10^{-3}]$, avoiding gradient explosion and ensuring convergence. The λ was set to $[1\times10^{-5}, 5\times10^{-4}]$, balancing regularization strength and numerical stability. The α was set to $[0.5, 1.5]$, controling the balance between reconstruction loss and attention loss. The τ was set to $[0.05, 0.5]$, affecting the smoothness of attention distribution.

TABLE II. MsRwGWO Algorithm Parameter Settings

Parameter Name	Symbol	Value
Population Size	N_{pop}	30
Maximum Iterations	T_{max}	30
Mutation Probability	p_{mut}	0.005
Mutation Ratio	r_{mut}	10%

The specific parameter settings for the MsRwGWO algorithm are summarized in Table II. $N_{\text{pop}} = 30$, $T_{\text{max}} = 30$, $p_{\text{mut}} = 0.005$, $r_{\text{mut}} = 10\%$, and based on prelim-inary experiments assessing different parameter combinations. The initial population is sampled uniformly at random from the ranges in Table I.

The hyperparameter optimization problem is formulated as a bilevel optimization problem [see Eq. (26) and Eq. (27)]:

$$\boldsymbol{\theta}^* = \arg\min_{\boldsymbol{\theta}\in\boldsymbol{\Theta}} \mathcal{L}_{\text{val}}(\mathbf{W}^*(\boldsymbol{\theta}), \mathcal{D}_{\text{val}}) \tag{26}$$

$$\text{s.t.} \quad \mathbf{W}^*(\boldsymbol{\theta}) = \arg\min_{\mathbf{W}} \mathcal{L}_{\text{train}}(\mathbf{W}, \boldsymbol{\theta}, \mathcal{D}_{\text{train}}) \tag{27}$$

where, $\boldsymbol{\Theta}$ is the hyperparameter search space, and $\mathcal{D}_{\text{train}}$ and $\mathcal{D}_{\text{val}}$ are the training and validation sets, respectively.

B. Review of the Standard Grey Wolf Optimizer

The standard Grey Wolf Optimizer (GWO) simulates the social hierarchy and hunting behavior of grey wolves, comprising three core phases:

1) Social hierarchy modeling: The wolf pack is divided into four hierarchical levels based on fitness [see Eq. (28)]:

$$\text{Fitness}(\boldsymbol{\theta}_\alpha) \le \text{Fitness}(\boldsymbol{\theta}_\beta) \le \text{Fitness}(\boldsymbol{\theta}_\delta) \le \text{Fitness}(\boldsymbol{\theta}_\omega) \tag{28}$$

where, $\boldsymbol{\theta}_\alpha, \boldsymbol{\theta}_\beta, \boldsymbol{\theta}_\delta$ represent the α, β, and δ wolves (leader layer), respectively, and $\boldsymbol{\theta}_\omega$ denotes the ω wolves (follower layer).

2) Encircling prey: The wolf pack updates its positions to encircle the prey using the following Eq. (29) and Eq. (30):

$$\mathbf{D}_p = |\mathbf{C}_p \cdot \boldsymbol{\theta}_p(t) - \boldsymbol{\theta}(t)| \tag{29}$$

$$\boldsymbol{\theta}(t+1) = \boldsymbol{\theta}_p(t) - \mathbf{A}_p \cdot \mathbf{D}_p \tag{30}$$

where, $p \in \{\alpha,\beta,\delta\}$, $\mathbf{A}_p = 2a\mathbf{r}_1 - a$, $\mathbf{C}_p = 2\mathbf{r}_2$, a linearly decreases from 2 to 0, and $\mathbf{r}_1, \mathbf{r}_2 \sim U(0,1)$.

3) Hunting behavior: The final position is determined by the average position of the three leading wolves, see Eq. (31):

$$\boldsymbol{\theta}(t+1) = \frac{\boldsymbol{\theta}_\alpha(t) + \boldsymbol{\theta}_\beta(t) + \boldsymbol{\theta}_\delta(t)}{3} \tag{31}$$

C. Improvements of the MsRwGWO Algorithm

1) Dynamic random weighting mechanism: The equal-weight averaging in standard GWO [Eq. (31)] does not account for the quality differences among the leading wolves. MsRwGWO introduces fitness-based random weighting [see Eq. (32) and Eq. (33)]:

$$w_p = \frac{\exp(-\beta \cdot \text{Fitness}(\boldsymbol{\theta}_p)/T)}{\sum_{q\in\{\alpha,\beta,\delta\}} \exp(-\beta \cdot \text{Fitness}(\boldsymbol{\theta}_q)/T)} + \epsilon_p \tag{32}$$

$$\boldsymbol{\theta}(t+1) = \sum_{p\in\{\alpha,\beta,\delta\}} w_p \cdot \boldsymbol{\theta}'_p(t) + \boldsymbol{\eta}_{\text{mutation}} \tag{33}$$

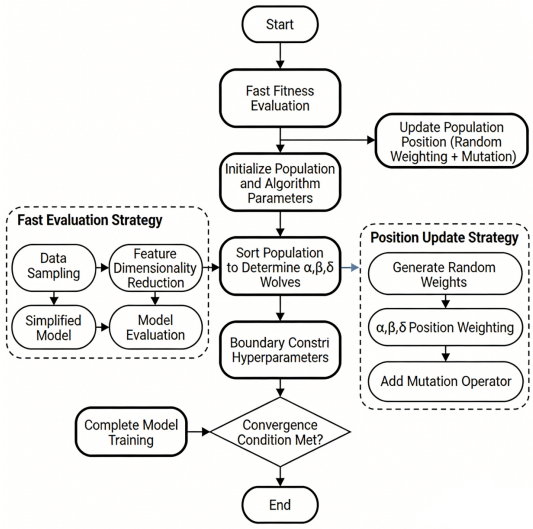

Fig. 6. Flowchart of the MsRwGWO algorithm.

where,

- T is the temperature parameter controlling the smoothness of the weight distribution;
- β is a scaling factor;
- $\epsilon_p \sim \mathcal{N}(0, \sigma_t^2)$ is a random perturbation, with $\sigma_t = \sigma_0 \cdot \exp(-t/t_{\max})$;
- $\boldsymbol{\eta}_{\text{mutation}}$ is a small-probability mutation term.

a) Contribution analysis: The random weighting mechanism in Eq. (33) assigns greater influence to better-performing individuals while maintaining population diversity through random perturbations. The temperature annealing strategy enables the algorithm to focus on exploration in early stages and exploitation in later stages.

2) Adaptive step size control: The linear decay of the step size parameter a in traditional GWO may not adapt well to complex optimization landscapes. MsRwGWO employs adaptive step size adjustment [see Eq. (34) and Eq. (35)]:

$$a(t) = a_{\min} + (a_{\max} - a_{\min}) \cdot \left(1 - \frac{t}{t_{\max}}\right)^{\gamma} \tag{34}$$

$$\gamma = 1 + \frac{\text{Fitness}(\boldsymbol{\theta}_\alpha(t)) - \text{Fitness}_{\min}}{\text{Fitness}_{\max} - \text{Fitness}_{\min}} \tag{35}$$

where, γ is an adaptive exponent that dynamically adjusts the decay rate based on the quality of the current best solution.

3) Multi-strategy boundary handling: Hyperparameter optimization must satisfy boundary constraints $\boldsymbol{\theta} \in [\boldsymbol{\theta}_{\min}, \boldsymbol{\theta}_{\max}]$. MsRwGWO adopts a hybrid boundary handling strategy [see Eq. (36)]:

$$\theta_i^{\text{new}} = \begin{cases} \theta_{\min,i} + \delta \cdot (\theta_{\alpha,i} - \theta_{\min,i}), & \text{if } \theta_i^{\text{new}} < \theta_{\min,i} \\ \theta_{\max,i} - \delta \cdot (\theta_{\max,i} - \theta_{\alpha,i}), & \text{if } \theta_i^{\text{new}} > \theta_{\max,i} \\ \theta_i^{\text{new}}, & \text{otherwise} \end{cases} \tag{36}$$

where, $\delta \sim U(0,1)$ is a random contraction factor. This strategy guides out-of-bound individuals toward the best individual rather than simply truncating them.

4) Elite-guided local search: In the later stages of iteration, fine-grained search is performed around the optimal solution [see Eq. (37)]:

$$\boldsymbol{\theta}_{\text{local}}^{(k)} = \boldsymbol{\theta}_\alpha + \sigma_{\text{local}} \cdot \mathbf{r} \odot (\boldsymbol{\theta}_{\max} - \boldsymbol{\theta}_{\min}) \tag{37}$$

where, $\sigma_{\text{local}} = 0.1 \cdot \exp(-t/t_{\max})$ and $\mathbf{r} \sim \mathcal{N}(0, \mathbf{I})$.

D. Integration Strategy with TFUL

1) Hierarchical optimization framework: MsRwGWO and the training process of TFUL form a hierarchical optimization framework: Algorithm 1.

Algorithm 1 MsRwGWO-TFUL Hierarchical Optimization Algorithm

Require: Training set $\mathcal{D}_{\text{train}}$, validation set $\mathcal{D}_{\text{val}}$, maximum iteration counts $T_{\text{outer}}, T_{\text{inner}}$
Ensure: Optimal hyperparameters $\boldsymbol{\theta}^*$, optimal model weights $\mathbf{W}^*$
Phase I: Initialization
Initialize grey wolf population $\{\boldsymbol{\theta}_i\}_{i=1}^N$ uniformly at random within bounds $[\boldsymbol{\theta}_{\min}, \boldsymbol{\theta}_{\max}]$
Initialize TFUL model $f(\cdot; \boldsymbol{\theta}, \mathbf{W}_0)$ with random weights $\mathbf{W}_0$
Phase II: MsRwGWO Hyperparameter Optimization
for $t = 1$ to T_{outer} **do**
  for $i = 1$ to N **do**
    Fast Evaluation Strategy:
    Load pretrained weights $\mathbf{W}_{\text{pretrain}}$ (from a previous evaluation or initial random)
    Fine-tune model with $\boldsymbol{\theta}_i$ for 3 epochs: $\mathbf{W}_i \leftarrow \text{FineTune}(f, \boldsymbol{\theta}_i, \mathcal{D}_{\text{train}}, \text{epochs} = 3)$
    Evaluate fitness: $\text{Fitness}_i \leftarrow \mathcal{L}_{\text{val}}(\mathbf{W}_i, \mathcal{D}_{\text{val}})$
  end for
  Update leading wolves $\boldsymbol{\theta}_\alpha, \boldsymbol{\theta}_\beta, \boldsymbol{\theta}_\delta$ based on fitness
  Apply Eqs. (33)-(37) to update population positions
  Apply Eq. (36) for boundary constraint handling
end for
Phase III: Final Model Training
Train the complete model using $\boldsymbol{\theta}^* = \boldsymbol{\theta}_\alpha$
$\mathbf{W}^* \leftarrow \arg\min_{\mathbf{W}} \mathcal{L}_{\text{train}}(\mathbf{W}, \boldsymbol{\theta}^*, \mathcal{D}_{\text{train}})$
RETURN $\boldsymbol{\theta}^*, \mathbf{W}^*$

2) Fast evaluation strategy: To avoid the expensive computation of full training, a fast evaluation strategy is adopted [see Eq. (38)]:

$$\text{Fitness}(\boldsymbol{\theta}) \approx \mathcal{L}_{\text{val}}\left(\mathbf{W}_0 + \Delta\mathbf{W}(\boldsymbol{\theta}), \mathcal{D}_{\text{val}}\right) \tag{38}$$

where, $\Delta\mathbf{W}(\boldsymbol{\theta})$ represents the weight updates obtained through a few iterations (typically 3-5 epochs). This strategy predicts the early influence of hyperparameters on the optimization trajectory, significantly reducing evaluation costs. However, this heuristic may sometimes overlook hyperparameters that excel only after longer training. To mitigate this risk, we perform periodic full evaluations (every 5 outer iterations) and maintain an elite set to retain potentially optimal configurations. Our empirical observations (Section IV-C) show that the ranking of hyperparameters after 3 epochs correlates reasonably well with final performance (Spearman $\rho > 0.7$), justifying this trade-off.

3) Convergence analysis: The convergence of MsRwGWO can be analyzed using Markov chain theory. Define the state space $\mathcal{S} = \{\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_N\}$ and transition probability $P_{ij} = \mathbb{P}(\boldsymbol{\theta}(t+1) = \boldsymbol{\theta}_j | \boldsymbol{\theta}(t) = \boldsymbol{\theta}_i)$.

Convergence: Under the following conditions, the MsRwGWO algorithm converges to the global optimal solution with probability 1:

- The state space $\mathcal{S}$ is finite and closed;
- The transition matrix $\mathbf{P}$ is ergodic;
- There exists a time t_0 such that $P_{ij}^{(t_0)} > 0, \forall i, j$.

Since the random weighting and mutation operations ensure that $\mathbf{P}$ is positive definite, satisfying the Doeblin condition, the Markov chain possesses a unique stationary distribution π. As iterations proceed, the population distribution converges to π, where the probability mass of the optimal state is maximized.

E. Computational Complexity Analysis

The computational complexity of MsRwGWO per iteration is Eq. (39):

$$\mathcal{O}(T_{\text{outer}} \cdot (N \cdot C_{\text{eval}} + N \log N + d \cdot N)) \tag{39}$$

where, C_{eval} is the cost of evaluating one hyperparameter configuration (here, 3 epochs of fine-tuning), $N \log N$ is for population sorting, and $d \cdot N$ is for position updates. Compared to grid search ($\mathcal{O}(\prod_{i=1}^d m_i \cdot C_{\text{eval}})$) and random search ($\mathcal{O}(N_{\text{total}} \cdot C_{\text{eval}})$), MsRwGWO provides better scalability to high-dimensional spaces. In practice, for our settings ($N = 30$, $T_{\text{outer}} = 30$, $d = 4$), MsRwGWO requires about $30 \times 30 \times C_{\text{eval}} = 900 C_{\text{eval}}$, which is significantly less than grid search with, say, 10 values per dimension ($10^4 C_{\text{eval}}$). Random search with the same budget of 900 evaluations would achieve similar cost but without guided exploration; MsRwGWO's directed search typically finds better solutions, as shown in Table V. The additional overhead of MsRwGWO beyond evaluations (sorting, updates) is negligible compared to C_{eval}.

IV. Experimental Results and Analysis

A. Experimental Environment and Model Parameter Settings

All experiments were conducted on a high-performance computing workstation equipped with an NVIDIA RTX 3090 GPU (24GB VRAM), an Intel Xeon Gold 6248R CPU, and 128GB RAM. The software environment utilized Python 3.9 as the programming language, PyTorch 1.13.1 as the deep learning framework, and CUDA 11.7 for GPU acceleration support. To ensure the scientific rigor and reproducibility of the experimental results, all random operations—including model parameter initialization, data partitioning, and training processes—were set with fixed random seeds. However, we note that run-to-run variability exists; in future work we plan to report mean and standard deviation over multiple seeds.

Training employed batch gradient descent with a batch size of 64, achieving a good compromise between memory usage efficiency and gradient estimation stability. The training process consisted of 20 full epochs, and an early stopping strategy (patience of 10 epochs) was employed for regularization. Training was halted early if the validation loss did not improve for 10 consecutive epochs, effectively preventing overfitting on the training set.

B. Evaluation Metrics

To comprehensively and multi-dimensionally evaluate the performance of anomaly detection models, we constructed a hierarchical evaluation metric system that reflects the model's

performance in practical application scenarios from different perspectives.

At the core evaluation level, we employed point-adjusted precision (pc_adjust), recall (rc_adjust), and F1-score (f1_adjust). This evaluation strategy stems from the practical requirements of industrial operations: in actual monitoring scenarios, once an anomaly event is detected, operators typically examine data points within a reasonable time window before and after the event. Therefore, as long as an anomaly is detected within a reasonable time window of its occurrence, it can be considered a valid detection. The point adjustment method, by extending detected anomaly points to actual anomaly segments, better reflects the model's practical utility in real-world applications. Compared to unadjusted traditional metrics (af_pc, af_rc, af_f1), the adjusted metrics more accurately reflect the model's overall detection capability for continuous anomaly events, rather than focusing solely on precise alignment at individual time points.

At the advanced evaluation level, we introduced the recently prominent VUS-ROC and VUS-PR metrics. Traditional ROC curves only consider the matching degree between detection results and true labels at individual time points, ignoring the inherent temporal characteristics of time series data. In practical applications, detection systems may have reasonable time delays in responding to anomaly events. The VUS (Volume Under Surface) metrics construct a three-dimensional evaluation surface by adding "temporal delay tolerance" as a third dimension to the two-dimensional plane of traditional ROC/PR curves. Specifically, VUS-ROC calculates the volume enclosed by ROC curves under different temporal delay tolerances, and similarly for VUS-PR. This evaluation approach aligns more closely with practical operational scenarios, reasonably tolerating detection delays and avoiding the excessive strictness of traditional metrics regarding precise temporal alignment. A higher VUS value indicates that the model not only performs well in point detection but also exhibits good robustness in the temporal localization of anomaly events.

Furthermore, we reported traditional area-under-the-curve metrics such as AUC-PR and AUC-ROC, providing familiar reference benchmarks for readers from diverse research backgrounds. In the metaheuristic algorithm comparison experiments, we refined the evaluation dimensions further, introducing efficiency metrics such as training time (trt), testing time (tst), and optimal threshold (thresh) to comprehensively assess the comprehensive performance of the optimization algorithms.

C. Comparative Analysis of Detection Model Performance

To validate the advancement and effectiveness of the proposed dual-domain unsupervised time series anomaly detection framework (TFUL), we conducted systematic comparative experiments on five representative public datasets. These datasets encompass time series data of varying scales and domains: the GECCO [39] dataset contains 9-dimensional server performance metrics; the PSM [40] dataset contains 25-dimensional server performance metrics; the SMD [41] dataset contains 38-dimensional machine sensor data; and the MSL [42] and SMAP [42] datasets contain 55-dimensional and 25-dimensional spacecraft sensor data, respectively. We selected nine representative state-of-the-art anomaly detection methods as comparative benchmarks, covering different technical approaches: the traditional unsupervised method based on Isolation Forest (iForest [21]), the deep one-class classification method (DeepSVDD [3]), the deep generative model-based method (DAGMM [22]), the time series hierarchical clustering-based method (THOC [37]), the attention mechanism-based methods (AT [23] and DCdetector [38]), the multivariate interaction modeling-based method (InterFusion [24]), the memory-augmented method (MEMTO [25]), and the self-supervised learning-based method (STEN [26]).

1) Comparative analysis of core detection metrics: Table III shows the performance of each model on four datasets based on point-adjusted core metrics. From the overall trend, deep learning methods generally significantly outperform the traditional method iForest, confirming the advantage of deep learning in learning complex patterns. Our TFUL model achieved the best or near-best performance on most metrics, particularly excelling in the comprehensive performance metric F1-score.

a) On the PSM dataset: TFUL achieved an F1-score of 98.69%, 0.19 percentage points higher than the second-best performer, MEMTO (98.50%). A deeper analysis of individual metrics reveals that TFUL achieved the highest precision (98.92%) among all methods while maintaining an extremely high recall (98.50%). This result indicates that our model excels at accurately capturing anomaly events while minimizing false alarms. This balance of high precision and high recall is particularly important in practical industrial scenarios: excessively high false alarm rates lead to alert fatigue, while excessively high miss rates pose safety risks. TFUL's ability to achieve this balance is primarily attributed to our proposed entropy sparsification mechanism, which enables the model to adaptively focus on the most informative time segments and frequency components, filtering out redundant and noisy information, thereby making more reliable anomaly judgments.

b) On the SMD dataset: TFUL achieved an F1-score of 92.98%, ranking first among all compared methods. Notably, our model exceeded 93% in both precision (93.88%) and recall (95.26%), demonstrating comprehensive detection capability. Compared to the AT model, TFUL improved the F1-score by 0.10 percentage points. Although this improvement may seem minor, in practical industrial anomaly detection applications, even a 0.1% performance improvement can translate into significant enhancements in safety assurance or reductions in maintenance costs. TFUL's excellent performance on the SMD dataset validates the effectiveness of the frequency-domain relationship learning module—by modeling complex dependencies among sensors using a learnable Mahalanobis distance, the model can better capture multivariate collaborative anomaly patterns.

c) On the MSL dataset: TFUL's performance was particularly outstanding, achieving an F1-score of 95.98%, 1.88 percentage points higher than the second-best performer, AT (94.10%). This improvement magnitude has significant statistical and practical value. Analyzing specific metrics, TFUL's recall reached 97.77%, the highest among all methods, while its precision remained high at 92.77%. This result indicates that our model has extremely high sensitivity to spacecraft sensor

TABLE III. PERFORMANCE COMPARISON OF BASIC METRICS

Method	PSM			SMD			MSL			SMAP		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1
iForest	76.09	92.45	83.48	42.31	73.29	53.64	53.94	86.54	66.45	52.39	59.07	55.53
DeepSVDD	95.41	86.49	90.73	78.54	79.67	79.10	91.92	76.63	83.58	89.93	56.02	69.04
DAGMM	93.49	70.03	80.08	67.30	49.89	57.30	89.60	63.93	74.62	86.45	56.73	68.51
THOC	88.14	90.99	89.54	79.76	90.95	84.99	88.45	90.97	89.69	92.06	89.34	90.68
AT	98.08	98.31	98.19	91.33	94.50	92.88	92.09	96.23	94.10	94.32	99.02	96.61
DCdetector	98.21	98.27	98.24	84.14	88.60	86.28	90.42	94.14	92.21	95.32	97.86	96.57
InterFusion	83.61	83.45	83.52	87.02	85.43	86.22	81.28	92.70	86.62	89.77	88.52	89.14
MEMTO	98.37	**99.04**	98.50	89.17	94.68	91.84	92.25	96.10	94.13	93.80	**99.41**	96.52
STEN	97.74	98.02	97.88	83.58	83.11	83.29	90.17	94.91	92.42	**96.49**	96.52	96.49
TFUL(Ours)	**98.92**	98.50	**98.69**	**93.88**	**95.26**	**92.98**	**92.77**	**97.77**	**95.98**	95.64	99.31	**97.16**

Note: The best results are bolded and the runner-ups are underlined.

anomalies, detecting the vast majority of anomaly events while maintaining an acceptable false positive rate. Anomalies in the MSL dataset typically manifest as coordinated changes in multiple sensor readings. Through time-frequency dual-domain feature fusion, TFUL can simultaneously capture morphological anomalies in the time domain and relational anomalies in the frequency domain, enabling comprehensive detection of complex collaborative anomalies.

d) On the SMAP dataset: TFUL achieved an F1-score of 97.16%, slightly outperforming other advanced methods. Although AT and MEMTO also performed well on this dataset, TFUL had a clear advantage in recall (99.31%), detecting almost all anomaly events. Considering the extremely high safety requirements of spacecraft monitoring, where missed detections could lead to catastrophic consequences, this high recall characteristic is of significant practical importance.

2) Comprehensive comparative analysis of traditional and advanced metrics: Table IV further demonstrates the comprehensive performance of TFUL compared with four representative advanced methods on five datasets, with evaluation metrics covering traditional F1-score, unadjusted F1-score (AF-F1), and advanced VUS metrics.

On the most challenging GECCO dataset, TFUL's performance significantly surpassed all compared methods. TFUL achieved an F1-score of 85.89%, 31.64 percentage points higher than the second-best performer, MEMTO (54.25%). This substantial gap fully demonstrates the powerful capability of our proposed time-frequency fusion framework in handling complex real-world industrial data. The GECCO dataset originates from an actual industrial water treatment system, featuring complex and diverse anomaly patterns with severe noise interference, posing extremely high demands on model robustness. By adaptively filtering noise through the entropy sparsification mechanism and learning the intrinsic patterns of data through complementary time-frequency dual-domain feature representations, TFUL excelled in this challenging scenario.

A deeper analysis of VUS metrics shows that TFUL achieved a VUS-PR value of 45.42% on the GECCO dataset, significantly higher than other methods (17.96% for MEMTO, 15.74% for STEN). The substantial lead in VUS-PR indicates that our model not only has advantages in point detection accuracy but also maintains superior performance in scenarios considering temporal delay tolerance. This characteristic is particularly important for practical deployment, as detection delays within a certain range are acceptable in actual monitoring systems; the key is not to completely miss anomaly events.

Regarding performance consistency across datasets, TFUL maintained high F1-scores across all five datasets (85.89%–98.69%), demonstrating good generalization capability. In contrast, the performance of other methods fluctuated more significantly across datasets. For example, while STEN achieved the highest VUS-ROC (98.30%) and VUS-PR (94.10%) on the SMAP dataset, its F1-score on the GECCO dataset was only 36.34%. This performance fluctuation suggests that these methods may have preferences for specific types of data distributions or anomaly patterns, whereas TFUL, through complementary learning in the time-frequency dual domains, acquired more robust feature representation capabilities.

From the perspective of temporal dimension evaluation, VUS-ROC and VUS-PR metrics provide insights not reflected by traditional point detection metrics. TFUL performed well on VUS metrics for most datasets, particularly leading significantly on the GECCO dataset. This indicates that our model can not only accurately detect anomaly points but also correctly identify the start and duration of anomaly events, which is crucial for anomaly diagnosis and root cause analysis.

D. Comparative Analysis of Metaheuristic Algorithm Optimization Effectiveness

Hyperparameter configuration has a decisive impact on the performance of deep learning models, but manual tuning is time-consuming, labor-intensive, and relies on expert experience. To validate the effectiveness of the proposed MsRwGWO algorithm in automatic hyperparameter optimization, we systematically compared it with eight mainstream metaheuristic algorithms under identical experimental settings. The optimization objectives included four key hyperparameters: learning rate, weight decay coefficient, loss balancing weight, and temperature parameter, which collectively influence the model's convergence speed, generalization capability, and detection accuracy.

Table V shows the performance of the TFUL model optimized by each algorithm on the NIPS_TS_Water dataset. In terms of comprehensive performance metrics, the model optimized by MsRwGWO achieved an adjusted F1-score of 84.80%, second only to the standard GWO optimization result

TABLE IV. PERFORMANCE COMPARISON OF TRADITIONAL AND ADVANCED METRICS

Method	Metrics	GECCO	PSM	SMD	MSL	SMAP
AT	F1	44.53	98.19	92.88	94.1	96.61

(85.14%) but significantly better than other algorithms. This result indicates that MsRwGWO has high efficiency in exploring the hyperparameter space, capable of finding configurations close to the optimum.

1) In terms of convergence efficiency: MsRwGWO showed clear advantages. Convergence curve analysis (as shown in Fig. 7) indicates that MsRwGWO achieved a validation loss reduction rate of 11.33% in the first 5 training epochs, higher than other compared algorithms (as shown in Fig. 8, Fig. 9). This rapid convergence characteristic is crucial for hyperparameter optimization because each hyperparameter configuration requires complete model training to evaluate its quality. Faster convergence means that more configurations can be evaluated with fewer training epochs, thereby exploring a broader hyperparameter space within the same time frame. The key to MsRwGWO's rapid convergence lies in its dynamic weighting mechanism—in the early optimization stages, the algorithm assigns higher weights to better individuals, accelerating movement toward promising regions; in later stages, it maintains population diversity through random perturbations to avoid premature convergence. Upon completion of the optimization, MsRwGWO identifies the optimal hyperparameter combination: a learning rate of 0.002, Weight Decay of 5×10^{-5}, Alpha Parameterand of 1.0, Temperature of 0.1, as listed in Table VI.

TABLE VI. THE MSRWGWO FOUND THE OPTIMAL PARAMETER CONFIGURATION

Parameter Name	Parameter Symbol	Optimal Value
Peak Learning Rate	η_{peak}	0.002
Weight Decay	λ	5×10^{-5}
Alpha Parameter	α	1.0
Temperature Parameter	τ	0.1

2) In terms of computational efficiency: the model optimized by MsRwGWO had relatively low average training time (2.11 seconds per epoch) and testing time (1.45 seconds), indicating that the introduced improvement mechanisms did not incur significant computational overhead. Compared to traditional grid search and random search, MsRwGWO, through its directed search strategy, finds high-quality solutions with fewer evaluations, significantly reducing the overall optimization time cost.

3) In terms of algorithm stability: MsRwGWO exhibited smaller performance fluctuations across multiple independent runs. For example, the standard deviation of the adjusted F1-score was 0.0147, smaller than most compared algorithms. This stability stems from MsRwGWO's multi-strategy boundary handling mechanism—when individuals exceed search boundaries, instead of simple truncation, they are guided toward the optimal individual direction through random contraction factors, maintaining population diversity while ensuring

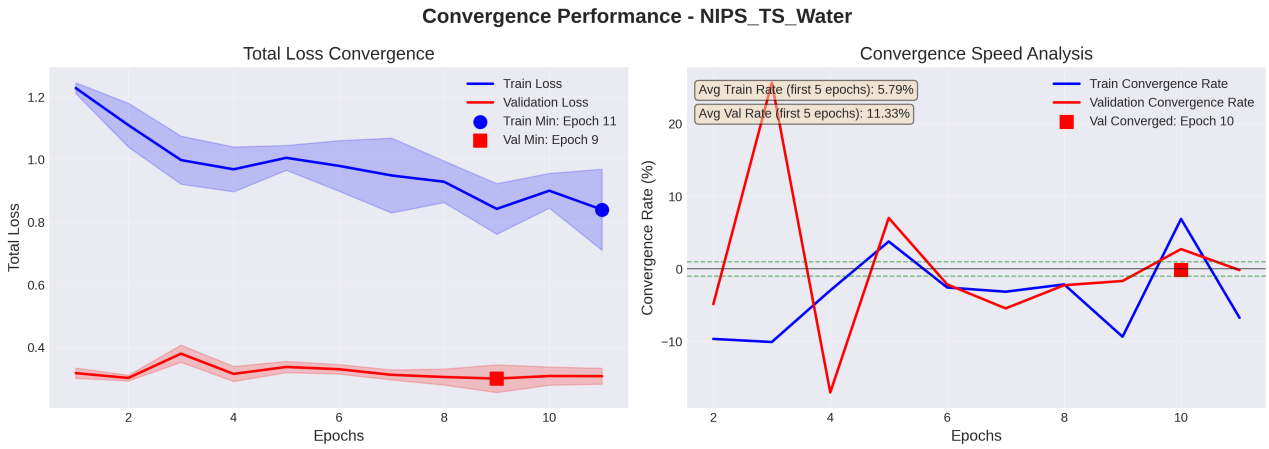

Fig. 7. MsRwGWO convergence.

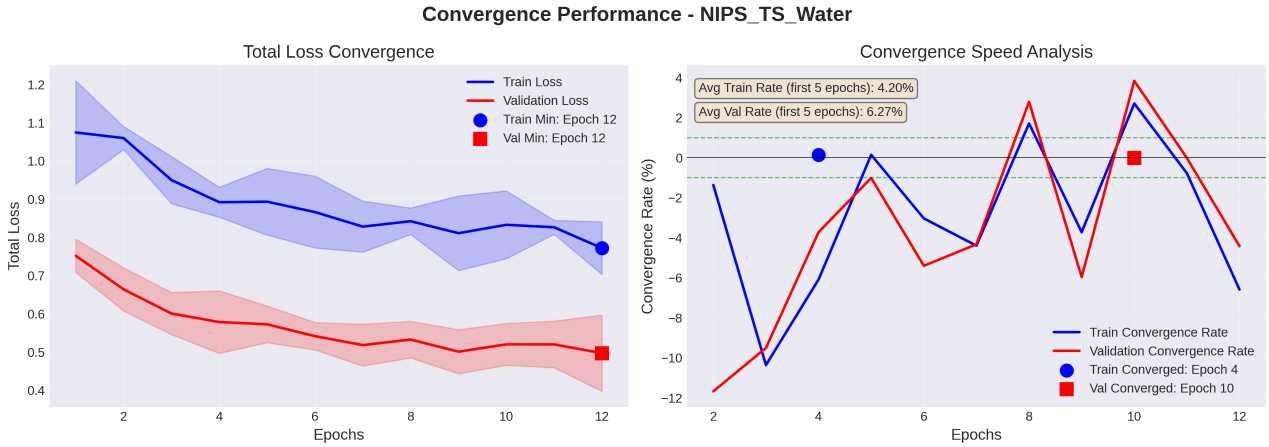

Fig. 8. GWO convergence.

the search remains within reasonable bounds.

4) In terms of exploration-exploitation balance: MsRwGWO achieved a good balance through an adaptive step size control mechanism. Early iterations use larger step sizes for global exploration, quickly locating promising regions; as iterations progress, step sizes gradually decrease for local fine-grained search. This dynamic adjustment avoids the potential issues of insufficient exploration or over-exploration that may arise from linear decay step sizes in standard GWO.

E. Ablation Study Analysis

To deeply understand the contribution of each component in the TFUL framework, particularly the necessity of the entropy sparsification mechanism in time and frequency domain processing, we designed and executed a systematic ablation study on the GECCO dataset. The GECCO dataset originates from a real industrial environment, featuring data complexity and strong noise interference, making it an ideal testbed for validating model component effectiveness. We constructed three variant models: TFUL-w/o-TimeSparse (removing time-domain entropy sparsification), TFUL-w/o-FreqSparse (removing frequency-domain sparsification, replacing learnable Mahalanobis distance with standard cosine similarity), and TFUL-w/o-AllSparse (removing all sparsification mechanisms simultaneously).

Table VII shows the performance comparison between the complete TFUL model and the three ablation variants. The experimental results clearly validate the necessity and synergistic effects of each component.

1) Analysis of the time-domain entropy sparsification mechanism: Removing time-domain entropy sparsification (TFUL-w/o-TimeSparse) caused a significant performance decline, with the adjusted F1-score dropping from 85.89% to 79.82%, a decrease of 6.07 percentage points. A deeper analysis of metric changes reveals an interesting phenomenon: recall decreased only slightly (98.24% $\rightarrow$ 97.78%), but precision dropped substantially (80.07% $\rightarrow$ 67.78%). This pattern indicates that without the guidance of entropy sparsification, the model tended to misclassify more normal samples as anomalies, leading to a significant increase in false positive rate. This validates the core role of our proposed time-domain attention entropy sparsification mechanism—by evaluating the information content of each time segment using information entropy, the model can adaptively focus on the most discriminative

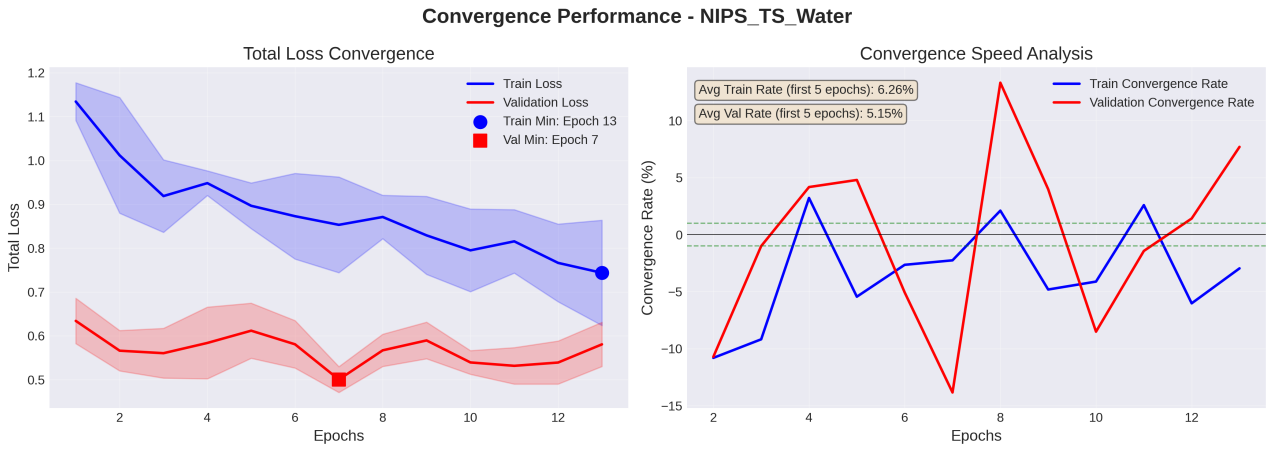

Fig. 9. SSA convergence.

TABLE VII. ABLATION ANALYSIS OF TFUL MODELS.

	Core Metrics			Traditional			Advanced		Other	
Method	**pc_adj**	**rc_adj**	**f1_adj**	**af_pc**	**af_rc**	**af_f1**	**vus_roc**	**vus_pr**	**auc_pr**	**auc_roc**
TFUL(Ours)	80.07	**98.24**	**85.89**	**62.08**	**96.29**	**74.99**	**74.34**	**45.42**	**82.0**	**98.58**
TFUL-w/o-TimeSparse	67.78	97.78	79.82	61.33	95.68	74.73	74.02	40.01	76.68	98.43
TFUL-w/o-FreqSparse	**80.29**	93.37	85.36	61.1	94.61	74.19	72.81	42.96	75.82	96.6
TFUL-w/o-AllSparse	72.67	92.93	80.08	60.08	95.04	73.53	72.69	39.76	77.9	96.84

local morphological patterns, ignoring segments dominated by redundancy or noise, thereby improving detection precision. From a computational efficiency perspective, time-domain sparsification also reduces the number of time segments that need to be processed, improving model efficiency while maintaining performance.

2) Analysis of the frequency-domain sparsification and learnable relationship modeling: Removing the frequency-domain sparsification mechanism (TFUL-w/o-FreqSparse) also caused performance degradation, with the F1-score dropping to 85.36%. Unlike the removal of time-domain sparsification, this variant exhibited the opposite pattern: precision slightly increased (80.29% vs. 80.07%), but recall significantly decreased (93.37% vs. 98.24%). This indicates that after replacing the learnable Mahalanobis distance with fixed cosine similarity, the model became overly conservative, increasing the miss rate. This result validates the value of the learnable Mahalanobis distance in frequency-domain relationship modeling—by learning nonlinear dependencies among sensors in a data-driven manner, the model can capture complex collaborative anomaly patterns that may not be effectively characterized by preset similarity measures (such as cosine similarity). Frequency-domain sparsification (implemented via Sparsemax) further enhances this process by retaining strong correlations and weakening irrelevant ones, enabling the model to focus on the most significant frequency-domain interaction patterns.

3) Analysis of the synergistic effect of dual-domain sparsification: Simultaneously removing all sparsification mechanisms (TFUL-w/o-AllSparse) caused further performance deterioration, with an F1-score of only 80.08%, the worst among all variants. This result strongly demonstrates the synergistic effect of time-domain and frequency-domain sparsification mechanisms. Time-domain sparsification enables the model to focus on the most informative local temporal patterns, while frequency-domain sparsification optimizes cross-sensor spectral relationship representations; together, they produce significant performance improvements. Notably, the complete model significantly outperformed all ablation variants in VUS-ROC (74.34%) and VUS-PR (45.42%) metrics, indicating that the sparsification mechanisms not only improve point detection accuracy but also enhance the model's detection consistency in the temporal dimension, making the start and end time localization of anomaly events more accurate.

4) Analysis from the perspective of advanced metrics: From the AUC-ROC and AUC-PR metrics, the complete model outperformed the ablation variants, particularly achieving 98.58% in AUC-ROC, approaching the performance of a perfect classifier. This further validates the effectiveness of the sparsification mechanisms in generating high-quality anomaly scores—by focusing on key features, the model learns more discriminative representations, resulting in more separable distributions of normal and anomalous samples.

F. Discussion of Practical Considerations and Limitations

While TFUL demonstrates state-of-the-art performance, several practical considerations and limitations merit discussion:

1) Concept drift: The current framework is trained offline on static data. In industrial environments, the statistical properties of "normal" behavior may evolve over time (concept drift).

TFUL does not incorporate online adaptation mechanisms; thus, its performance may degrade if deployed for extended periods without retraining. Extending TFUL to online learning with incremental model updates is a promising direction for future work.

2) Edge deployment and real-time latency: Our experiments were conducted on a high-end GPU, which is not representative of resource-constrained edge devices commonly used in industrial monitoring. The model's inference latency and memory footprint have not been optimized for such hardware. Future work could explore model quantization, pruning, or knowledge distillation to enable real-time edge deployment.

3) Sparsity threshold sensitivity: The entropy sparsification mechanism relies on a pre-defined sparsity rate ρ_d. In our experiments, we set $\rho_d = 0.3$ based on validation performance. However, an overly aggressive sparsity rate may discard subtle but informative patterns, potentially missing low-amplitude anomalies. A sensitivity analysis (varying ρ_d from 0.1 to 0.5) showed that F1-score varied by less than 2%, indicating moderate robustness, but optimal selection remains dataset-dependent. Learning ρ_d adaptively is an interesting avenue for improvement.

4) Error analysis and failure cases: Despite strong overall performance, TFUL occasionally misses anomalies that are extremely short-lived or masked by noise. For instance, on the GECCO dataset, some anomalies lasting only one time step were not detected, likely due to the smoothing effect of the multi-scale convolutions. A qualitative error analysis revealed that such missed detections often correspond to isolated spikes in a single sensor, which are difficult to distinguish from transient noise. Incorporating explicit spike-detection mechanisms could help.

5) Comparison with modern hyperparameter optimizers: We compared MsRwGWO against classic meta-heuristics; however, a comparison with modern Bayesian optimization tools like Optuna or Hyperband would provide additional context. We leave such a comparison to future work, noting that MsRwGWO's guided search may be particularly beneficial when evaluation budget is limited.

V. Conclusion

This study presented TFUL, a novel framework for time series anomaly detection that integrates entropy-sparsified time-frequency fusion with MsRwGWO meta-optimization. The key innovations include: 1) dual-domain entropy sparsification for adaptive feature selection, 2) heterogeneous feature extraction networks capturing complementary temporal and spectral patterns, and 3) an efficient meta-heuristic optimization algorithm for hyperparameter tuning.

Experimental results on five public datasets demonstrate that TFUL outperforms state-of-the-art methods in detection accuracy and robustness. The ablation studies confirm the importance of each component, particularly the sparsification mechanisms for reducing false positives and improving recall. The MsRwGWO algorithm provides efficient hyperparameter optimization, reducing tuning time while maintaining or improving performance.

Future work will focus on extending TFUL to online anomaly detection scenarios to handle concept drift, incorporating domain adaptation for cross-domain applications, exploring hardware-aware optimizations for edge deployment, and providing qualitative error analysis and case studies to further illuminate model behavior. Additionally, we plan to compare MsRwGWO with modern Bayesian optimization tools and investigate adaptive learning of sparsity thresholds.

***Abstract*—Addressing the challenges of Traditional Chinese Medicine (TCM) traceability systems, including heavy data storage burdens, poor privacy protection, and susceptibility to tampering, this study establishes a highly secure and trustworthy traceability supervision system for the entire Chinese medicine supply chain, which enhances product quality and safety assurance. Centred on the Hyperledger Fabric consortium blockchain as its core architecture, a multi-chain integration framework comprising one regulatory main chain plus five organisational sub-chains is proposed to achieve permission control, data isolation, and privacy. A multi-mode encrypted data storage mechanism is designed, integrating China's national cryptographic algorithms SM4 and SM3 with CP-ABE attribute-based encryption to enable tiered management of private and non-private data. Zero-knowledge proof technology safeguards identity privacy during cross-chain data transmission, while QR codes and environmental data collection mechanisms enhance data entry efficiency and authenticity. The system achieves end-to-end traceability from cultivation and processing through transportation, warehousing, and sales. Comparative performance analysis shows that the proposed framework effectively alleviates data storage pressure, ensures data validity, enhances data security, and improves collaborative efficiency among organizations across the TCM supply chain. The proposed multi-chain integrated Chinese medicine traceability and supervision system enables efficient collaboration and trustworthy traceability across the entire Chinese medicine industry chain, while safeguarding data security and privacy, and has significant application and promotion value. Future integration with artificial intelligence and big data technologies could further enhance the system's intelligent analysis and decision-support capabilities.**

I. Introduction

Several traditional Chinese herbal medicines have been demonstrated to modulate the growth, differentiation, invasion, and metastasis of Hepatocellular Carcinoma (HCC), which may be attributed to their capacity to regulate HCC progression [1]. Traditional Chinese Medicine (TCM) has considerable potential to address certain conditions that remain challenging for Western medicine. Nevertheless, current challenges in the TCM supply chain include unclear germplasm origins, genetic degradation of herbal species, pesticide residues, excessive levels of heavy metals, environmental contamination during harvesting and processing, and inadequate standardization in storage, transportation, and retail management. Therefore, it is necessary to establish a traceability system for traditional Chinese medicinal herbs that balances security and efficiency, enabling end-to-end tracking from cultivation to retail outlets, ensuring the quality of medicinal materials remains under control, and ensuring the safety of their use is traceable.

Existing blockchain-based traceability systems face significant limitations, including degraded performance as data volumes increase and insufficient data privacy, rendering them vulnerable to unauthorized tampering. For instance, Jamil et al. [2] pioneered the use of Hyperledger Fabric to record data in the pharmaceutical supply chain. Their system leveraged blockchain to log drug transactions, aiming to establish a smart healthcare ecosystem that addresses supply chain inefficiencies. While this approach capitalized on the decentralized nature of blockchain from a holistic supply chain perspective, it overlooked critical data-specific issues such as validity and privacy. Similarly, Agrawal et al. [3] proposed a blockchain-enabled network that enables manufacturers to monitor pharmaceutical products effectively throughout the supply chain, enhancing security and transparency. Although this solution improved data controllability, its oversight remained localized and failed to ensure comprehensive regulatory coverage across the entire supply chain.

To address these shortcomings in end-to-end traceability for Chinese herbal medicines, this study proposes a novel, high-security, multi-chain traceability and regulatory framework based on blockchain technology. The architecture consists of one regulatory main chain plus five organisational sub-chains, enabling multi-chain interaction and data fusion. Specifically, we adopt a permissioned consortium blockchain that incorporates the following key features: access control (only authorized participants can join and perform operations on the chain), consensus mechanisms (to guarantee node consistency), high performance and scalability (to meet industry-specific requirements), privacy preservation (to protect personal and commercial confidentiality of stakeholders), and customizability (to support future extensions) [4]. Furthermore, we implement a multi-modal data encryption and storage mechanism to enhance data security while reducing on-chain storage redundancy.

The structure of this study is as follows: Section II briefly introduces the core technology stack involved in this system. Section III presents the system design architecture and

*Corresponding authors.

highlights the core innovative components. Section IV details the system implementation. Section V conducts a comparative analysis of the system across different dimensions. Section VI concludes the study and outlines future directions.

II. Related Work

In recent years, with the frequent occurrence of food safety incidents and rising consumer demand for product transparency, traditional centralized database-based agricultural traceability systems have increasingly revealed critical limitations, including information silos, data tamperability, and a lack of trust. Blockchain technology, owing to its decentralization, immutability, and inherent traceability, has been widely adopted in supply chain traceability research across sectors such as agri-food, pharmaceuticals, and apparel. This study focuses on consortium blockchain-based system architectures. It provides a systematic review and critical analysis of recent representative studies, organized around three core dimensions: system architecture design, platform selection, and data storage with privacy preservation.

A. System Architecture Design: Consortium Blockchain

To overcome the performance, privacy, and controllability limitations of public blockchains, current research predominantly adopts consortium blockchain architectures to enable trusted data sharing among known participants. Hua et al. [5] proposed a three-role node model comprising a registration center, a data node, and a client that flexibly configures Byzantine Fault Tolerance or Paxos consensus algorithms in environments with identified stakeholders, supporting end-to-end traceability of agricultural products from cultivation to retail. Tseng et al. [6] leveraged the Gcoin consortium blockchain to assign unique digital identities to pharmaceuticals. They employed an anti-double-spending mechanism to detect duplicate circulation events, thereby aiding in the identification of counterfeit drugs. Sadri et al. [7] proposed a six-role permission model for blood supply chains, enforcing fine-grained access control to ensure operational compliance across the blood collection, testing, and transportation stages. Although Tsai et al. [8] addressed microfilm copyright protection rather than physical goods, their multi-chain parallel architecture, labeled ABC, TBC, MBC, demonstrated the scalability potential of consortium blockchains in high-concurrency scenarios. Collectively, these works illustrate that consortium blockchains, through participant restriction, enhanced permission management, and improved throughput, have become the prevailing architectural paradigm for high-assurance traceability systems.

B. Platform Selection: Hyperledger Fabric

Hyperledger Fabric has emerged as the preferred platform for traceability applications that require strong privacy and regulatory compliance, thanks to its modular design, channel architecture, pluggable consensus protocols, and fine-grained access control. Chen et al. [9] built a brand apparel anti-counterfeiting system on Fabric, utilizing ECDSA digital signatures and channel isolation to enable trustworthy data sharing across the entire supply chain from raw materials to retail, and to allow third-party arbitration entities to verify signatures and pinpoint falsification points hierarchically. Marchese et al. [10] introduced a dynamic rule engine in the agri-food domain, enabling regulators to inject specific compliance rules, such as temperature thresholds, into chaincode and automatically validate them upon batch registration, significantly enhancing regulatory compliance. Dong et al. [11] constructed a four-organization multi-channel Fabric network involving manufacturers, logistics providers, retailers, and regulators, integrating RFID tags with Golang-based chaincode to record and query food lifecycle data while ensuring enterprise data isolation. These studies consistently exploit Fabric's channel mechanism to achieve natural data partitioning: only authorized entities such as regulators can access cross-channel information, effectively balancing transparency with commercial privacy.

C. Data Storage and Privacy Protection: On-Chain Off-Chain Hybrid Architecture

Given the high storage costs and limited scalability of on-chain data, virtually all Fabric-based studies adopt a hybrid architecture in which only cryptographic hashes are stored on chain, while the original data resides off-chain. Chen et al. [9], Marchese et al. [10], and Dong et al. [11] all store primary business data, such as inspection reports, images, and contracts, in off-chain databases or on IPFS, recording only their hashes in the Fabric ledger. This approach preserves data integrity while mitigating blockchain bloat. Sensitive information, such as transaction prices and supplier identities, is encrypted using AES or ECC before being recorded on the chain, and Fabric's attribute-based access control enforces fine-grained permissions. Hua et al. [5] further recommended tiered authorization for critical operation logs, restricting data access and verification to designated roles. However, most studies inadequately address the availability of off-chain data. If an off-chain storage node fails, consumers may verify hash consistency but cannot retrieve the original content, which poses a risk of a null pointer exception.

Despite these advances in architectural design and privacy protection, several limitations remain. First, most existing Fabric-based systems rely on single-chain or multi-channel architectures and are therefore prone to storage bottlenecks and performance degradation as data volumes grow. Second, current hybrid storage schemes generally lack robust data-availability guarantees and fine-grained security control mechanisms. If an off-chain storage node fails or is maliciously tampered with, the original data may become unrecoverable, and traditional encryption approaches often incur risks of plaintext key storage on-chain or isolated key management off-chain. Third, cross-chain data interoperability and end-to-end regulatory capabilities remain insufficient, making it difficult to achieve truly comprehensive, end-to-end traceability. In addition, traditional non-blockchain traceability systems depend on centralized databases, which are inherently susceptible to data tampering, information silos, and the absence of a credible trust mechanism.

III. System Design

The proposed traceability and regulatory framework is built upon three key mechanisms. First, a multi-chain, integrated data supervision and transmission mechanism isolates organizational subchains, enabling end-to-end oversight while preserving the privacy of user accounts. Second, a multimodal

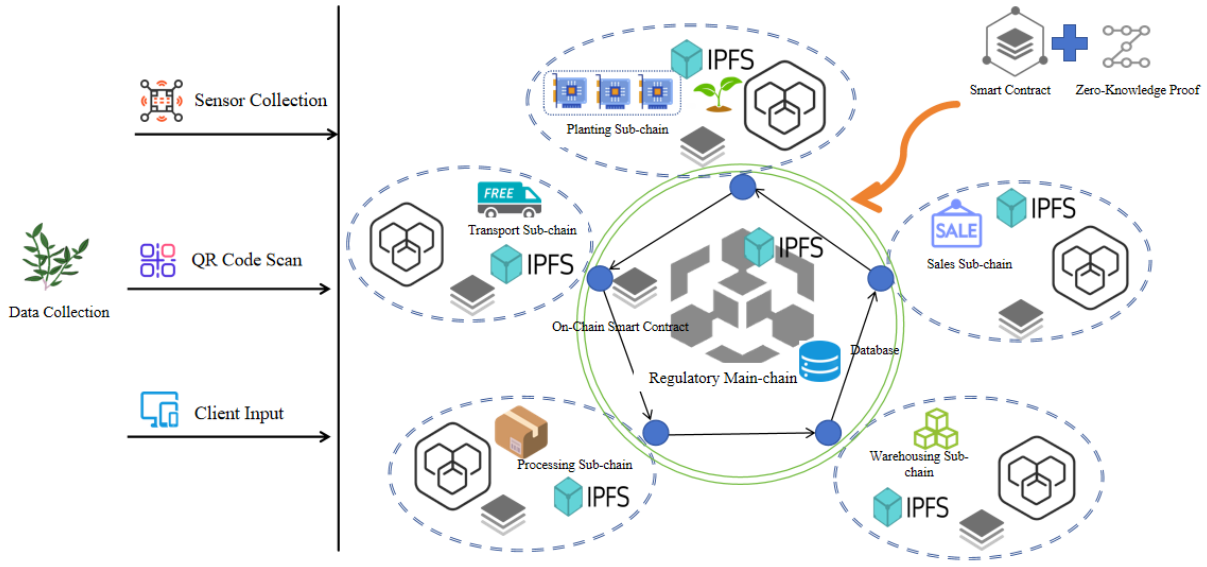

Fig. 1. Architecture diagram of a high-safety TCM traceability supervision system based on multi-chain fusion.

encrypted storage mechanism mitigates on-chain storage pressure, ensures strong data security, and supports fine-grained access control. Third, a QR code-based data entry mechanism, coupled with environmental data acquisition, enhances operational efficiency, safeguards user privacy, and ensures the validity of environmental data. Together, these mechanisms significantly improve inter-organizational collaboration and ultimately realize a highly secure, end-to-end traceability solution for the entire TCM supply chain. The overall architecture is illustrated in Fig. 1.

Five specialized sub-chains are defined: cultivation, transportation, processing, warehousing, and retail. The cultivation sub-chain, as the starting point of the supply chain, is responsible for recording detailed information on the cultivation of TCM materials. The transportation sub-chain records the movement of medicinal materials from planting sites to processing facilities, including transportation time, selected modes of transportation, and related logistics information. The processing sub-chain captures the processing of TCM materials, including the selection of processing methods, processing duration, and key process parameters. The warehousing sub-chain maintains information on the storage of medicinal materials in warehouses, including temperature and humidity conditions, storage duration, and inventory levels. The retail sub-chain records sales information, including the diversity of sales channels, the reasonableness of sales timing, and the stability of sales prices. Each organizational sub-chain thus records the key operational data of its own stage, and together the five sub-chains ensure that consumers can verify end-to-end information for each batch of Chinese medicinal products from growers to retailers.

A. Multi-Chain Integrated Data Supervision and Transmission Mechanism

As shown in Fig. 2, the system establishes a multi-chain integrated data supervision and transmission mechanism centered on the supervisory mainchain as the core hub, which connects downward to five operational subchains: cultivation, processing, transportation, packaging, and sales. All dynamic data must first undergo identity verification through a zero-knowledge proof-based authentication smart contract deployed on the supervisory main chain [12]. An operation permit is granted only upon successful verification. Subsequently, the main chain routes the relevant instruction, along with a hash digest, to the appropriate target sub-chain based on the business type, thereby implementing a closed-loop "verify before transmit" regulatory process. Sensor stream data and QR code scan records, classified as static data, are generated within each sub-chain. Since their authenticity has already been validated locally, they can be directly recorded in the respective subchain ledger. However, after block finalization, each sub-chain must periodically submit its block hash to the supervisory main chain to support global auditing. This mechanism effectively isolates direct interaction between sub-chains and end-user clients while ensuring end-to-end data trustworthiness, traceability, and privacy through centralized orchestration and backup coordination by the main chain.

B. Multi-Modal Encrypted Data Storage Mechanism

Building upon the aforementioned multi-chain organizational structure, this system addresses data security through a hybrid on-chain-off-chain multi-modal encryption and storage strategy. Data are classified according to sensitivity into privacy-sensitive and non-privacy-sensitive data, each assigned a tailored storage approach. As shown in Fig. 3, for privacy-sensitive data, the system employs the Chinese national cryptographic standard SM4 (formerly SMS4.0), a block cipher algorithm that offers high security and superior performance [13], to enhance both transmission efficiency and confidentiality. To protect the SM4 symmetric keys on the chain, the system adopts Ciphertext Policy Attribute-Based Encryption (CPABE) [14], in which user attributes, such as role or orga-

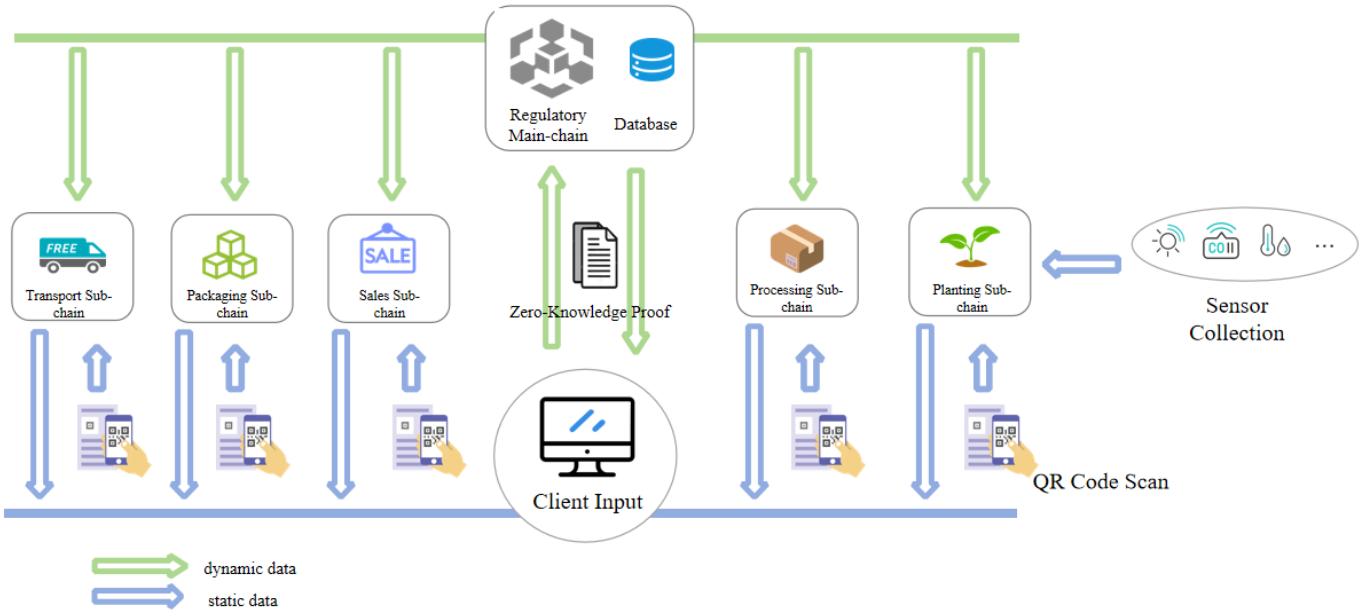

Fig. 2. A schematic diagram of the data regulatory transmission mechanism based on multi-chain fusion.

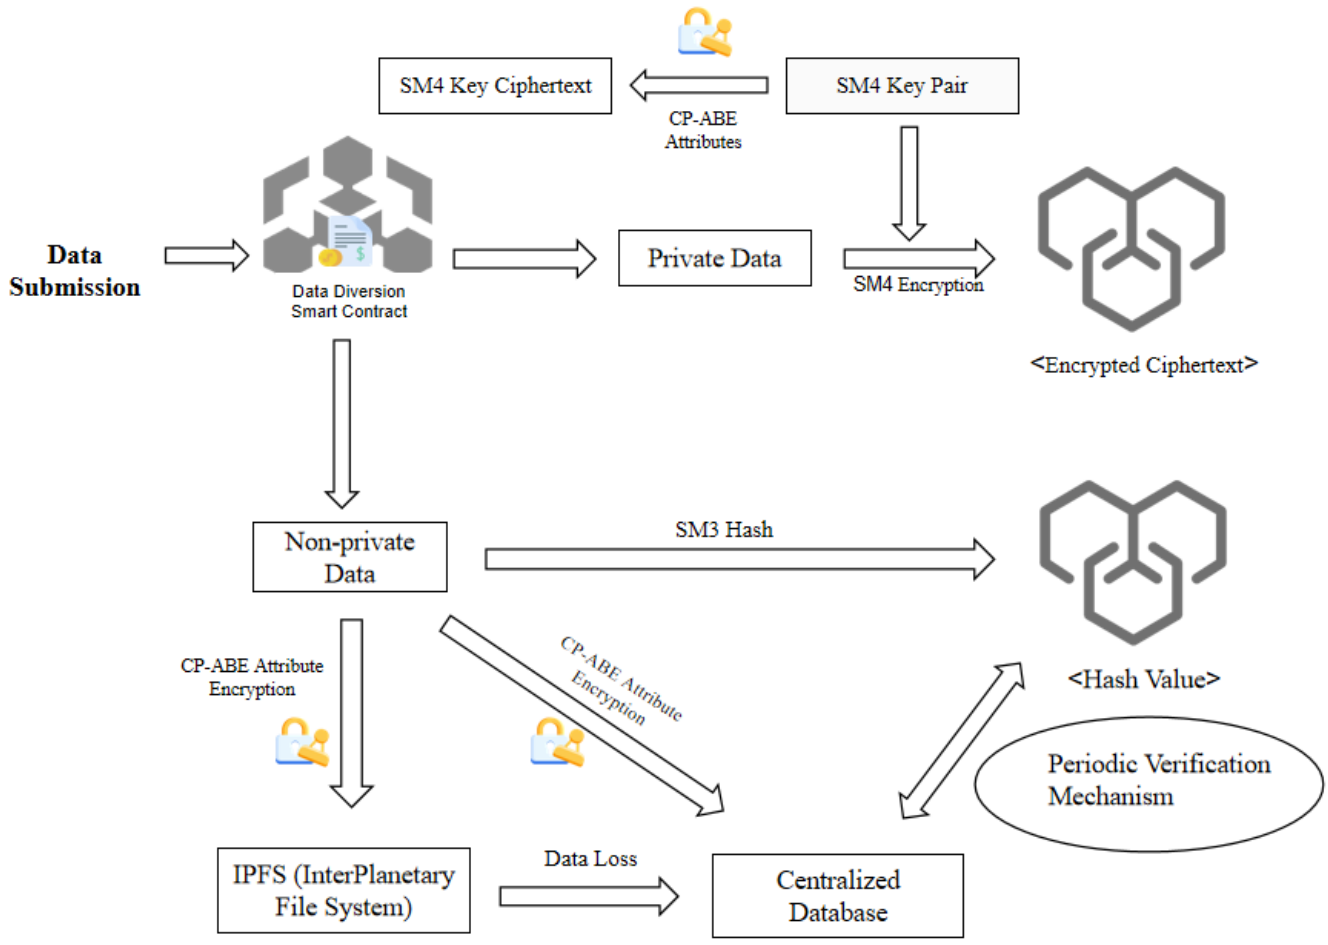

Fig. 3. Schematic diagram of data multi-mode encrypted storage.

nizational affiliation, serve as access policies. Compared with conventional symmetric or asymmetric encryption schemes, CPABE eliminates the risks associated with storing keys in plaintext on-chain or managing them in isolated off-chain repositories. Only users whose attributes satisfy the defined policy can decrypt and retrieve the SM4 key, thereby enabling fine-grained access control. For non-privacy-sensitive data, the system stores the original content in a centralized database to optimize read and write performance. Concurrently, it applies the SM3 cryptographic hash algorithm, a highly efficient national standard, to generate a digest of the data. This digest is then recorded on the corresponding sub-chain. A periodic verification mechanism between the sub-chain and the centralized database ensures the integrity and validity of the off-chain data. To further strengthen resilience against data loss or tampering, the system leverages the Inter Planetary File System (IPFS) [15] as a decentralized backup layer. If the periodic verification detects corruption, deletion, or unauthorized modification in the centralized database, the system automatically restores the affected data from the IPFS backup, ensuring continuous and reliable operation. Although the data shared within the system is accessible internally, external access remains strictly controlled. Therefore, all externally exposed data is encrypted using CPABE with a system-wide root Certificate Authority (CA) as the governing attribute policy. This configuration allows all authorized internal nodes to decrypt while denying access to external entities, thereby maintaining a robust security boundary between the internal consortium and the outside environment.

C. QR Code Generation and Environmental Data Acquisition Mechanism

In practical production scenarios, sub-chain personnel are frequently required to perform traceability-related operations, such as farmers applying fertilizer or irrigating. Conventional approaches, such as manual logbooks or direct client-side data entry, pose significant risks of information leakage or falsification. To address these vulnerabilities, the proposed design leverages the physical isolation property of QR codes. Specifically, a sub-chain user initiates a request via a dedicated mini program to the supervisory main chain, which then invokes a smart contract to generate a time-bound procedural QR code. This approach enhances both the security of traceability records and operational efficiency, as workers need only present the QR code to a scanning device. The scanner automatically captures the QR code content, appends a current timestamp and other contextual metadata, and uploads the complete record to the corresponding subchain for storage. Subsequently, a data-routing smart contract classifies and encrypts incoming data by type before storing it in the appropriate location. This mechanism assumes that all personnel affiliated with the organizational subchains have been pre-registered, with their relevant identity and role information securely collected and transmitted in advance to the supervisory main chain for encrypted storage as privacy-sensitive data. Upon completion of product packaging, the supervisory main chain receives a notification triggering the traceability query workflow. It then invokes a cross-chain traceability smart contract to aggregate traceability records associated with the product. Concretely, using the unique product traceability ID, the system queries and consolidates relevant data from cultivation, processing, transportation, and other pertinent subchains. The integrated traceability dataset is finally encoded into a QR code, known as the traceability information QR code, enabling end users to access a complete, verifiable history of the Traditional Chinese Medicine product with a simple scan.

IV. System Implementation

The chaincode implements the ChaincodeStubInterface to define multiple custom application functions, as listed in Table I. The planting sub-chain is specifically designed to monitor the seed growth environment, ensuring the validity of data submitted to the blockchain. The supervisory mainchain integrates information from all subchains to enable unified oversight and management. By continuously monitoring and analyzing data from all stages of the supply chain, the supervisory mainchain can promptly identify potential quality issues and safety hazards and initiate appropriate corrective actions. All operations executed by the chaincode generate transaction records stored on the blockchain, and any resulting state changes are updated in the state database.

Based on a multi-chain integrated architecture comprising one regulatory main chain and five organizational sub-chains, the system implements a unified identity verification process for all organizational logins. When a user accesses the login interface, the backend identifies the user's organizational affiliation based on their account credentials and directs them to the corresponding organization's main interface. This approach enhances security among organizations by requiring all inter-organizational data exchanges to request permission from the supervisory mainchain. Upon logging in to their respective main interfaces, users can clearly view detailed data for their assigned chain. Within the supervisory chain, every data operation, including creation, modification, and deletion, is meticulously recorded, enabling full traceability and auditability. This comprehensive logging mechanism empowers regulators to conduct effective, holistic oversight, enabling organizations to rapidly pinpoint the source of data anomalies and apply timely corrections. Users of organizational subchains are restricted to performing Create, Read, Update, and Delete (CRUD) operations exclusively on their own sub-chain data. Nevertheless, all such operations must generate corresponding log entries stored on the supervisory mainchain to support potential future traceability requirements. As an illustrative example, the traceability query functionality is displayed in Fig. 4.

V. Comparative Analysis

A. Storage Performance Analysis

The provenance supervision framework based on multi-chain integration not only ensures the security of private data through multi-modal encryption but also alleviates the storage burden inherent in conventional single-chain architectures by distributing data across multiple chains. Specifically, the supervision mainchain is dedicated solely to oversight and stores only a minimal amount of data, while each organizational subchain handles the storage requirements of its respective organization.

TABLE I. CHAIN CODE APPLICATION INTERFACE METHOD

	Method	Parameter	Description
Total Interface Methods of "Five Organizational Subchains + One Regulatory Mainchain"Data Supervision Scope	initLedger	ChaincodeStubInterface	Chaincode Initialization Function
	Invoke	ChaincodeStubInterface	Receive and process requests sent by clients
	createTrace	ChaincodeStubInterface[]string	Input a set of data arrays to add new transaction data records
	updateTrace	ChaincodeStubInterface[]string	Input a set of data arrays to update transaction data records
	deleteTrace	ChaincodeStubInterface[]string	Delete transaction data records
	queryTrace	ChaincodeStubInterface args []string	Input the corresponding traceability ID to query the latest data records
	queryAllTrace	ChaincodeStubInterface args []string	Input the corresponding traceability ID to query the latest data history records
	storeTraceMessage	ChaincodeStubInterface args []string	Multi-mode encrypted storage of data
Interface Methods Unique to the Planting Subchain	envrDataProcess	ChaincodeStubInterface args []string	Detect the similarity of environmental data
Interface Methods Unique to the Regulatory Mainchain	authentication	ChaincodeStubInterface args []string	Authenticate the identity of system login users
	qrCodeGeneration	ChaincodeStubInterface args []string	Generate QR code images for the corresponding data
	dataValidation	ChaincodeStubInterface args []string	Verify the validity of forwarded data
	traceQuery	ChaincodeStubInterface args []string	Integrate traceability information for user queries

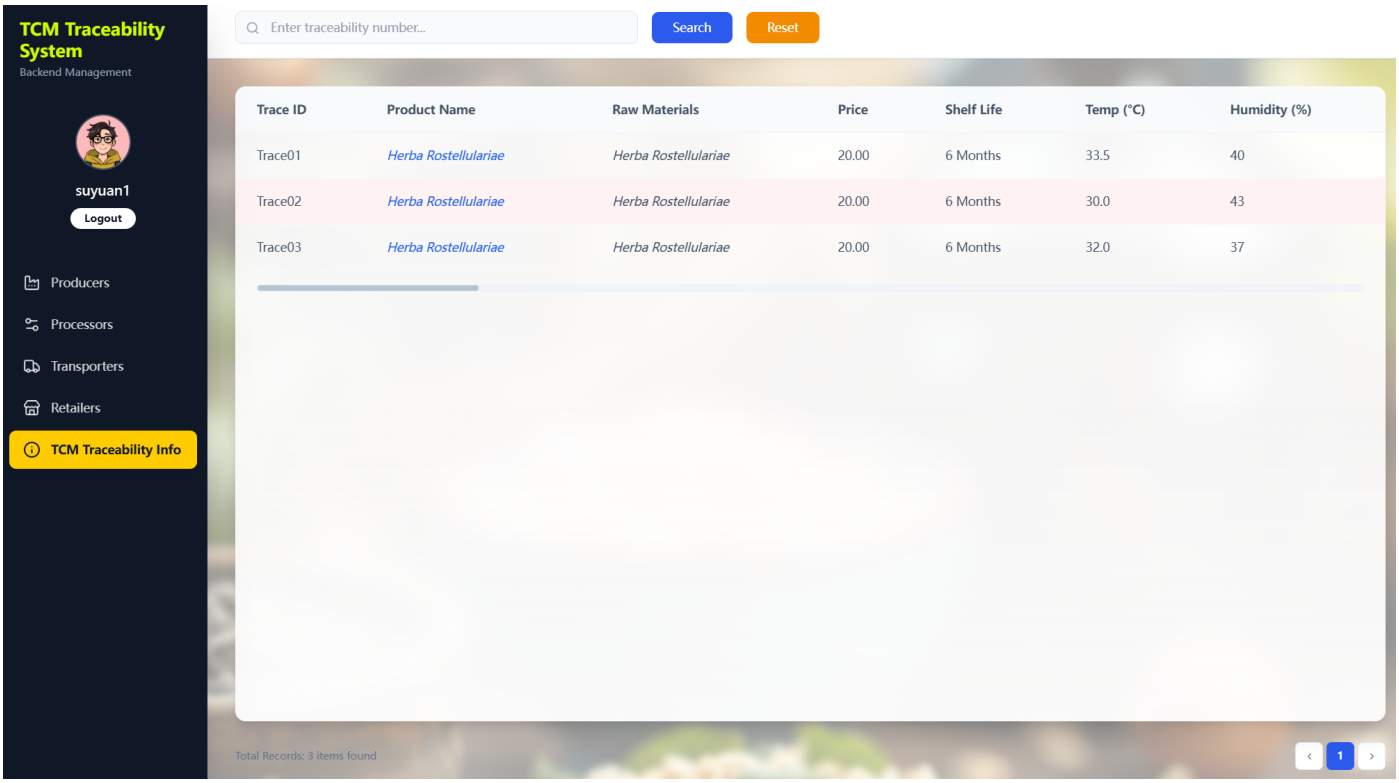

Fig. 4. Traceability information query function demonstration.

In this study, we evaluate the storage consumption of three configurations: organizational subchains (averaged across five subchains), a traditional single-chain system, and the supervision mainchain, as the number of uploaded transactions increases from 1×10^4 to 5×10^4. The results are illustrated in Fig. 5. It should be noted that, although real-world blockchain storage may involve adjustments to parameters such as block size and block generation interval based on transaction volume, this analysis focuses exclusively on the raw storage footprint attributable to the data volume itself, holding all other configuration parameters constant.

B. Comparative Evaluation of Approaches

Building upon the preceding analysis of security and storage performance, this study compares the proposed multi-chain-integrated traceability and supervision framework for Traditional Chinese Medicine with five representative existing traceability and supply chain information management systems, including a blockchain–IPFS-based monitoring system for non-perishable agricultural products that stores encrypted

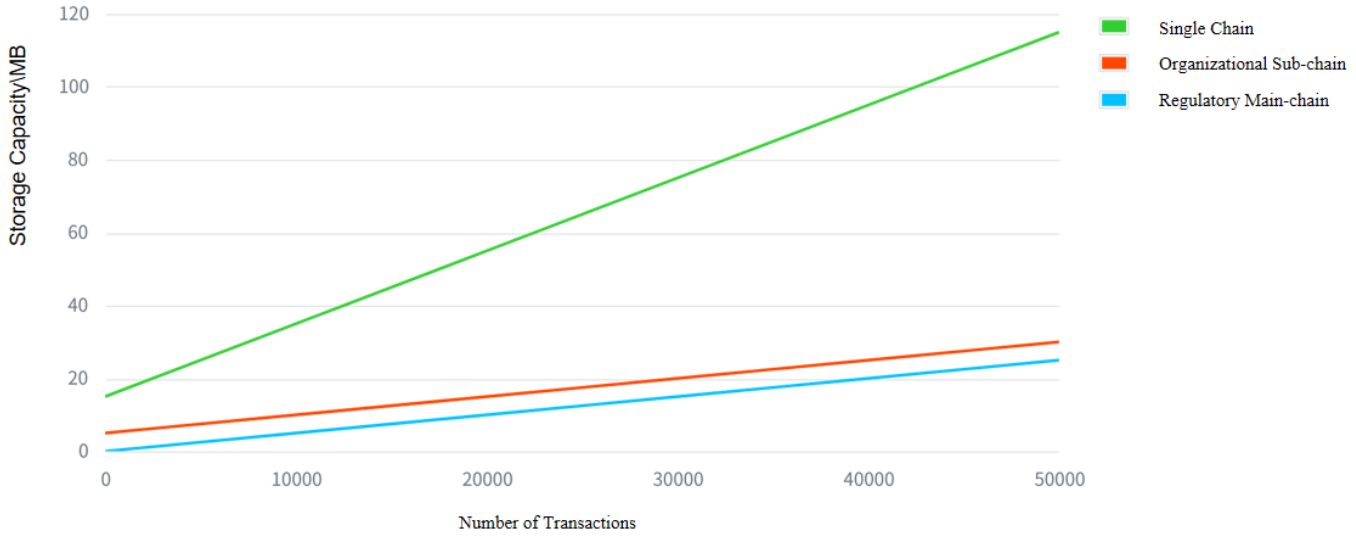

Fig. 5. Storage performance test.

TABLE II. SCHEME COMPARISON AND ANALYSIS

Research Works	[16]	[17]	[18]	[19]	[20]	**This system**
Blockchain Architecture	Single chain	Single chain	Single chain	Single chain	Single chain	Multi-chain
Data Supervision Scope	Partial info	Partial info	Partial info	Partial info	Partial info	Full lifecycle

IPFS hashes on chain to alleviate centralization, reliability, and query-efficiency issues in traditional traceability architectures [16]; a blockchain-based wine supply chain traceability system that records each transaction from grape growers to retailers on chain to provide tamper-resistant, end-to-end provenance verification [17]; a Polygon-based cannabis supply chain solution that combines smart contracts with hybrid on-chain/off-chain storage to support efficient information retrieval and tamper-proof regulatory compliance across multiple stakeholders [18]; a blockchain-enabled vaccination record tracking framework that maintains immutable, privacy-preserving immunization histories across healthcare institutions [19]; and a blockchain- and IoT-driven CO_2 footprint tracking framework that enhances data integrity, transparency, and sustainability assessment in complex supply chains [20]. The comparison results are summarized in Table II. Overall, the proposed system demonstrates clear advantages across multiple dimensions, including secure cross-chain data interaction, scope of data supervision, storage efficiency, traceability and regulatory effectiveness, enterprise-level data management capabilities, strength of mainchain-based oversight, and differentiation of enterprise accountability.

VI. CONCLUSION AND FUTURE WORK

Based on existing research on traceability in TCM, this study addresses key challenges in current blockchain-based traceability systems, including single-chain storage bottlenecks, data security, data availability, and system stability. It also considers the entire TCM supply chain, encompassing cultivation, processing, transportation, sales, and regulatory oversight. To this end, we propose and implement a high-security TCM traceability and supervision system based on Hyperledger Fabric as the consortium blockchain platform. The primary contributions and innovations of this work are summarized in the following three aspects:

First, to address the storage overhead, data security, and availability challenges specific to TCM traceability scenarios, we propose a multi-chain architecture built on Hyperledger Fabric, comprising a supervising mainchain and five organiza-

tional subchains. This multi-chain framework enables secure cross-chain interaction and data fusion, effectively alleviating storage pressure, enhancing data validity, ensuring high data security, and improving inter-organizational collaboration efficiency. Furthermore, we design a multi-modal encrypted storage mechanism to strengthen data confidentiality and support fine-grained access control.

Second, we develop a zero-knowledge proof-based data supervision and transmission protocol that isolates organizational subchains while enabling end-to-end regulatory oversight without compromising user account privacy. Complementing this, we integrate QR code-based data entry and environmental data collection mechanisms, which not only improve operational efficiency but also safeguard user privacy and ensure the authenticity and reliability of environmental monitoring data. Collectively, these mechanisms guarantee the validity, traceability, and high security of data throughout the entire TCM lifecycle, from cultivation and harvesting to processing, storage, transportation, and retail. System performance evaluations confirm that the proposed framework significantly reduces storage burden, enhances data availability and security, and boosts collaborative efficiency across stakeholders in the TCM supply chain.

Third, we have constructed and successfully deployed a comprehensive TCM traceability management system that integrates the proposed multi-chain supervision architecture. The system consists of a Hyperledger Fabric consortium blockchain network, a traceability information management platform, environmental sensing devices, and QR code input terminals. We detail the functional modules, smart contract interfaces, and system demonstrations to ensure high reliability and operational efficiency. Comprehensive system testing, including storage capacity evaluation, was conducted across all stages to verify the effectiveness of each functional module in data recording and traceability. The results demonstrate that the system meets the design requirements for secure traceability management throughout the entire TCM supply chain.

For future work, we plan to incorporate artificial intelligence and big data analytics to further advance this research. By leveraging AI-driven data mining and big data analysis techniques [21–25], we aim to extract actionable insights from the vast volumes of data generated across the TCM supply chain, thereby providing scientific, intelligent, and data-driven decision support for the optimization and management of TCM production and distribution.

***Abstract*—The interpretation of colposcopy images is a critical yet subjective component of cervical cancer screening. To enhance this process, we propose a novel hybrid deep learning framework for the classification of cervical lesions. Our model integrates EfficientNet-B0, adept at extracting localized hierarchical features, with a Swin-Tiny Transformer, which excels at modeling long-range dependencies and global context. Moving beyond basic fusion techniques, we introduce a novel cross-attention fusion mechanism, augmented with channel and spatial attention modules. This design selectively highlights the most discriminative inter-feature relationships while maintaining computational efficiency. Evaluated on the International Agency for Research on Cancer (IARC) colposcopy image dataset, our framework achieves an accuracy of 94.76%, significantly outperforming a concatenation-based fusion model (83.99%). This represents an absolute improvement of 10.77 percentage points and captures 67.3% of the residual performance margin toward perfect accuracy. The model also demonstrates robust performance across other metrics, including a precision of 94.68%, recall of 94.82%, F1-score of 94.74%, and a Cohen's Kappa of 89.48%. These results indicate that our approach can enhance both the accuracy and reliability of cervical cancer screening, offering valuable support for clinical decision-making.**

I. Introduction

Cancer arises when cells in the body begin to grow uncontrollably, forming malignant tumors that can spread and affect various organs [1]. Cervical cancer specifically develops in the cervix, the narrow passage connecting the uterus to the vagina [2]. It mainly develops from long-lasting infections with certain high-risk types of human papillomavirus (HPV) [3], [4], particularly HPV-16 and HPV-18 [5]. While the immune system typically clears the virus naturally, persistent infections can lead to cellular changes that may eventually develop into cancer [4]. This disease represents a significant global health burden, particularly in developing countries where it ranks as the third deadliest cancer among women [6]. Approximately 85% of cervical cancer deaths occur in low- and middle-income countries [3], reflecting unequal access to vaccination, screening, and treatment services. The burden is overwhelmingly highest in sub-Saharan Africa, where countries like Eswatini, Zambia and Malawi report incidence rates up to 25 times greater than those in Western Asia, underscoring a critical need for targeted public health interventions [7]. In response, WHO has launched a global strategy aiming to achieve 90% HPV vaccination coverage, 70% screening participation and 90% treatment access by 2030 [8], [9].

Despite the availability of effective prevention strategies, cervical cancer continues to pose a significant global health challenge [6]. According to projections, the global burden of cervical cancer is expected to rise substantially over the coming decades due to population growth and aging. Estimates indicate that the number of cases will increase by 56.8% between 2022 and 2050, reaching nearly 1 million cases, while deaths are projected to rise by 80.7%, totaling approximately 630,000 by 2050 [7]. Patient prognosis varies significantly depending on the stage at which cervical cancer is diagnosed. When detected early, the five-year relative survival rate is approximately 91% [8]. However, survival rates decline sharply in advanced stages, with metastatic cases showing a five-year relative survival rate of about 19% . This big difference shows why it is so important to find and treat cervical cancer early, especially in places where people do not have easy access to healthcare and are often diagnosed late.

Getting an accurate and timely diagnosis is crucial to reduce mortality from cervical cancer [10]. The standard tiered approach utilizes Pap smears, HPV testing, and colposcopy [6]. Primary screening typically begins with a Pap smear to detect abnormal cells or HPV testing to identify high-risk viral strains. Positive results from these initial tests are followed by colposcopy, which provides a magnified visual examination of the cervix to locate and assess abnormalities and guide targeted biopsies for definitive diagnosis. Although Pap smears and HPV tests are effective screening tools, their utility is limited by cost, laboratory requirements, and the potential for false results [11]. Colposcopy is therefore a critical diagnostic follow-up that enables timely intervention [12]. However, its effectiveness is constrained by reliance on clinician expertise for interpreting visual findings, a challenge that is particularly pronounced in resource-limited settings [6]. This dependence on subjective interpretation and the scarcity of trained specialists underscore the need for assistive technologies, thereby motivating the integration of artificial intelligence (AI) to standardize and enhance colposcopic evaluation [6].

Recent advances in artificial intelligence, particularly deep learning models such as convolutional neural networks (CNNs) and vision transformers like the Swin Transformer, have emerged as powerful tools in medical imaging [13], [14]. These models excel at analyzing complex patterns with high accuracy

and consistency, often detecting subtle tissue changes that are imperceptible to the human eye [15]. Such capabilities make deep learning a promising pathway for developing diagnostic tools that address current limitations in early detection and support the WHO's goal of eliminating cervical cancer as a public health problem [10]. To build on this progress, hybrid architectures that integrate CNNs and Transformer-based models are gaining recognition for their effectiveness in cancer classification [16]. CNNs specialize in local spatial feature extraction [17], while Transformers capture long-range dependencies [18], [19], and their combination enables a more holistic analysis of cervical images. Despite this potential, most fusion strategies still rely on limited approaches such as concatenation or element-wise addition, which fail to fully exploit the complementarity between the two architectures. Addition assumes features can be summed directly, but this often results in features with larger magnitudes overwhelming those with smaller values, erasing critical discriminative information [20]. Conversely, concatenation preserves all information by simply appending feature vectors. While this avoids the suppression issue, it naively treats all features as equally important and substantially increases dimensionality, leading to higher computational cost and reduced model generalization [20], [21].

To address these limitations, we propose a novel hierarchical attention-guided fusion mechanism that differs fundamentally from existing fusion strategies. Unlike prior approaches that use either simple concatenation or addition, our method introduces three complementary attention modules in a carefully designed sequence, each addressing specific weaknesses of conventional fusion. Channel attention adaptively adjusts the importance of each feature channel, ensuring that channels carrying diagnostically meaningful patterns receive appropriate emphasis [27]. Spatial attention highlights the most relevant anatomical regions within the feature channels, guiding the model to focus on clinically meaningful lesion areas rather than diffuse background regions [28]. Finally, the cornerstone of our method, bidirectional cross-attention enables context-aware interaction between the CNN and Transformer branches. Unlike naïve fusion techniques, cross-attention allows each branch to selectively query and integrate information from the other, resulting in a richer and semantically aligned joint representation. Collectively, this integrated architecture minimizes redundancy, aligns semantic representations, and substantially enhances the discriminative power of the hybrid model for cervical cancer diagnosis.

Our key contributions in this study are:

- We developed a hybrid attention-guided CNN–Transformer architecture by integrating EfficientNet-B0 and the Swin Transformer, resulting in a tailored model optimized for accurate cervical cancer classification from colposcopic images.
- We developed a multi-stage attention fusion mechanism that integrates channel attention, spatial attention, and bidirectional cross-attention to effectively refine and combine complementary local and global features, resulting in enhanced predictive performance.
- We validated the effectiveness of the proposed attention-guided fusion strategy through systematic comparison with a simple concatenation-based fusion approach.

II. Literature Review

A. Deep Learning

Deep learning is a branch of machine learning that uses artificial neural networks to automatically learn patterns and features directly from raw data eliminating the need for manual feature engineering [13]. Unlike traditional methods, deep learning excels in tasks like medical imaging by detecting intricate patterns through layered abstraction [40]. CNNs are particularly effective, using trainable filters to capture spatial features and pooling layers to improve invariance to scale, rotation, and translation. Their hierarchical structure enables learning from simple to complex patterns ideal for identifying subtle tissue abnormalities or cellular irregularities [17]. Advanced architectures such as ResNet [41], DenseNet [42], EfficientNet [29], further enhance diagnostic accuracy and efficiency by incorporating residual connections, dense connectivity and compound scaling.

1) EfficientNet: EfficientNet represents a significant advancement in convolutional neural network (CNN) architecture through its innovative compound scaling methodology. Unlike traditional approaches that scale network depth, width, or input resolution independently, EfficientNet employs a principled compound scaling technique that simultaneously and proportionally scales all three dimensions [29]. This strategy, governed by a set of optimally determined scaling coefficients, ensures a balanced increase in model capacity becoming deeper and wider while processing higher-resolution images without compromising computational efficiency. The resulting architecture hierarchically captures increasingly complex features while maintaining a compact and efficient design. When benchmarked against conventional CNNs such as ResNet, DenseNet, and Inception, EfficientNet demonstrates superior performance. For instance, EfficientNet-B7 achieves state-of-the-art performance, attaining 84.3% top-1 accuracy on ImageNet with approximately 66 million parameters [29]. This outperforms deeper networks like ResNet-152, which uses a comparable parameter count but yields lower accuracy, and also surpasses both Inception-v3 and DenseNet in accuracy while requiring fewer computational resources. These characteristics make EfficientNet particularly suitable for medical imaging applications, where high diagnostic precision must often be achieved under significant computational constraints. Among the EfficientNet family (B0–B7), EfficientNet-B0 was selected as the backbone feature extractor in this study due to its optimal balance of accuracy, parameter efficiency, and computational cost. With only 5.3 million parameters and 0.39 GFLOPs, EfficientNet-B0 is capable of extracting fine-grained local features from high-resolution colposcopy images without requiring excessive memory or training time. This makes it particularly suitable for medical imaging applications where computational resources are often limited and high diagnostic precision is essential.

EfficientNet has been widely adopted in medical imaging, with successful applications in breast cancer diagnosis [43], [44], lung cancer detection [45] and cervical cancer [46], [47]. Despite these promising results, EfficientNet shares the

limitations of CNN-based models in capturing long-range dependencies, which motivates its integration with transformer-based architectures for enhanced performance in complex classification tasks.

2) Transformers: The Transformer architecture, introduced by Vaswani et al. in 2017 [35], is distinguished by its capacity to learn long-range contextual relationships within sequential data. This is achieved by segmenting input sequences into smaller units (tokens) augmented with positional encodings. The model employs a self-attention mechanism to derive feature representations, enabling every token to interact with all other tokens in the sequence. This design allows direct and parallelized modeling of relationships between all token pairs, regardless of their distance, while maintaining uniform processing across the sequence. In contrast to convolutional neural networks (CNNs), which are constrained by limited receptive fields [19], Transformers leverage self-attention to incorporate global contextual information from the entire input [18]. This capability is especially beneficial in tasks requiring holistic sequence understanding such as natural language processing and image classification laying the groundwork for their adaptation in visual recognition.

The Vision Transformer (ViT) represents a significant shift in image classification methodology by adapting the Transformer architecture for visual data [48]. Rather than using convolutional operations to induce spatial hierarchies, ViT partitions an image into fixed-size non-overlapping patches, treating each as an individual token. These patch-level tokens are processed by a standard Transformer encoder, which models relationships across the entire image [49]. A typical configuration, ViT-Base, consists of 12 encoder layers that apply multi-head self-attention to extract discriminative features. The final stages include layer normalization which aids training stability at a computational cost and a classification token that aggregates global image representations for prediction.

Building on ViT, the Swin Transformer introduces a hierarchical representation learning strategy [30]. Images are divided into non overlapping patches, which are progressively merged into larger blocks, enabling the model to capture features at multiple scales from local details to global context. A key innovation is the use of shifted windows between layers, which promotes cross-window interaction and enlarges the effective receptive field without resorting to global self-attention. This design enhances flexibility across resolutions and complexities, making Swin Transformer particularly suited for vision tasks requiring fine-grained spatial and contextual understanding. Transformers have shown promising results in medical image analysis, with successful applications in breast cancer classification [50], [51], pulmonary nodule detection [52] and cervical image analysis [53], [54]. These studies underscore the effectiveness of transformer-based models in capturing complex spatial dependencies and enhancing diagnostic accuracy across diverse clinical tasks.

The Swin-Tiny variant was chosen to construct a hybrid backbone with EfficientNet-B0. Its compact architecture provides a compelling balance of representational power and computational efficiency, enabling the effective processing of high-resolution colposcopy images. This lightweight design, which avoids the excessive demands of larger models like ViT-B or Swin-Base, ensures a practical and efficient integration for our diagnostic task.

B. CNN-Transformer Hybrid Models in Medical Imaging

Recent studies have demonstrated the promise of CNN–Transformer hybrids in cervical cancer diagnosis. For example, Mohammed et al. [22] introduced a hybrid model for colposcopy image classification that fused EfficientNet-B0 with a Swin-Tiny Transformer, achieving an AUC of 0.96 and an accuracy of 87.5%. Despite these promising results, their fusion method weighted all features equally, highlighting the need for attention-based mechanisms to better prioritize diagnostically relevant patterns. Similarly, Wang et al. [23] proposed a hybrid architecture combining a 3D convolutional neural network (CNN) and a transformer for predicting N-staging and survival outcomes in non-small cell lung cancer (NSCLC). Evaluated on the NSCLC Radiogenomics and NSCLC-Radiomics datasets, their framework leveraged the CNN to extract local spatial features from volumetric images while the transformer captured global contextual dependencies. Features from both modules were fused via simple concatenation prior to classification. Although the model achieved competitive accuracies of 0.805, 0.828, and 0.819 on the training, validation, and test sets, respectively, the reliance on direct feature concatenation may limit effective cross-modal interaction between CNN and transformer representations. This highlights the need for more sophisticated fusion strategies that can dynamically weigh and integrate complementary features for improved representation learning.

Chen et al. [24] proposed the MFEM-CIN framework, a hybrid CNN–Transformer model for colposcopic image analysis that employs multi-scale feature extraction (MSFE) and multi-scale feature fusion (MSFF) to integrate local and global features. While the multi-scale fusion aims to enrich semantic representation by allowing shallow and deep features to interact, the study does not critically evaluate how effectively the fusion mechanism prioritizes diagnostically relevant patterns. The MSFF approach, though conceptually sound, relies on heuristic fusion without attention-guided weighting, which may limit the model's ability to emphasize clinically significant regions over less informative ones. Consequently, while the framework demonstrates high overall accuracy, the fusion strategy itself may not fully exploit the complementary strengths of CNN and Transformer features, suggesting room for improvement through more advanced, attention-based fusion techniques.

Other notable work includes the research of Liu et al. [25], who developed the CVM-Cervix framework for Pap smear classification. In this approach, a CNN module extracted local cellular details, while a Vision Transformer captured global spatial dependencies within the images. Moving beyond simple fusion strategies, the authors employed a multilayer perceptron (MLP) to integrate these complementary feature sets, achieving an accuracy of 91.72%.

In another study, Abinaya and Sivak [55] proposed a deep learning-based cervical classification system integrating 3D convolutional neural networks (3D CNN) with Vision Transformer (ViT) modules. The 3D CNN extracted spatiotemporal features from cervical images, while multiple ViT models captured higher-level global representations. A 3D feature

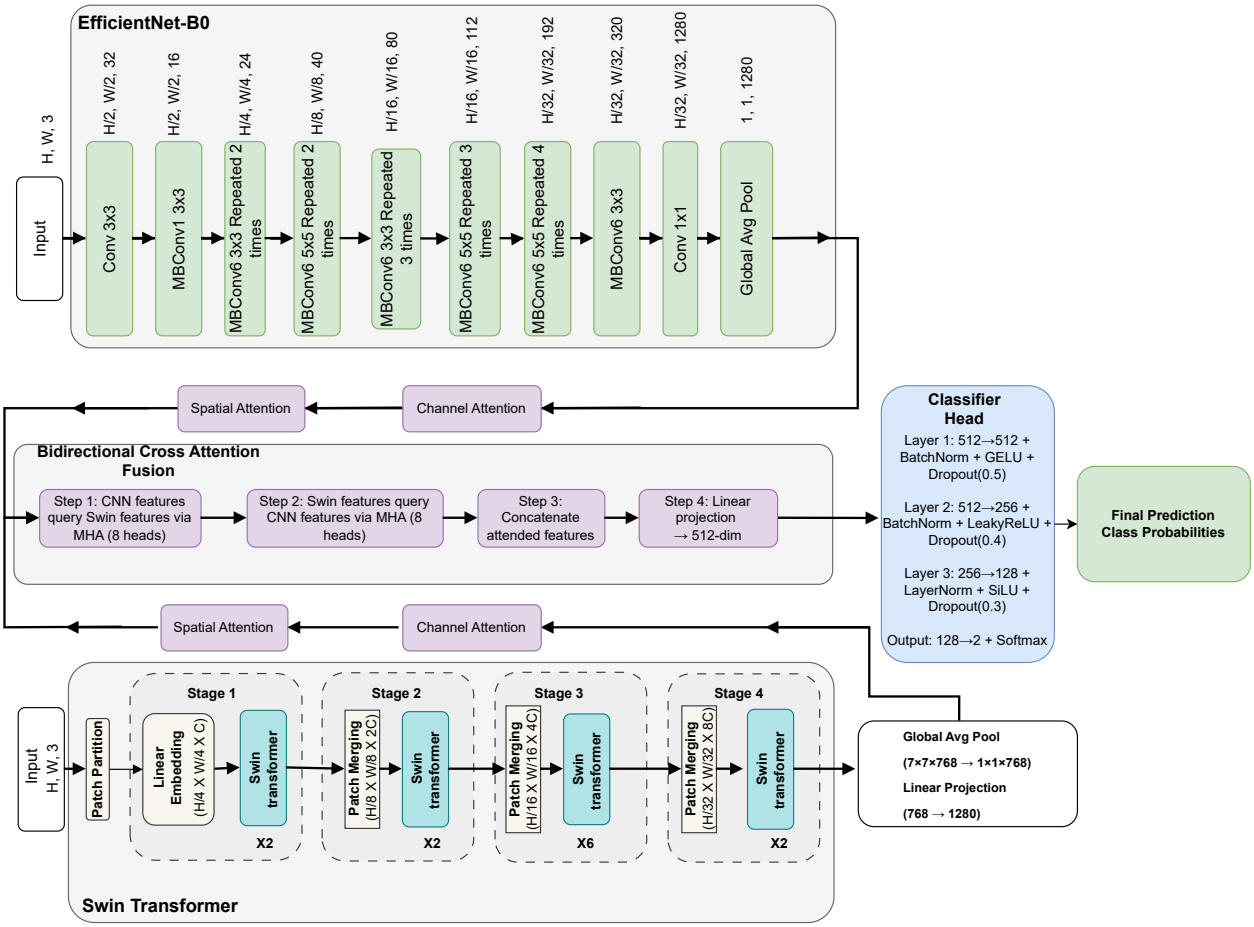
pyramid network (FPN) was used for feature concatenation, and a 3D squeeze-and-excitation (SE) block reweighted the fused features, enhancing the discriminative power of diagnostically relevant information. Classification was then performed using a kernel extreme learning machine (KELM) with a radial basis kernel. This fusion strategy, particularly the SE-based feature reweighting, contributed to strong performance, achieving an accuracy of 98.6% and demonstrating its potential as an effective diagnostic support tool for cancer detection.

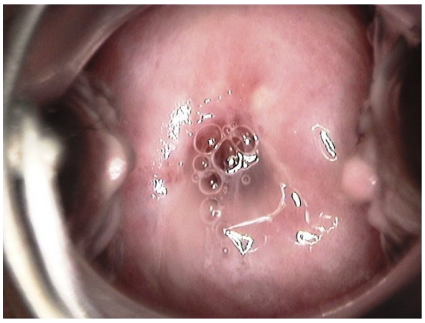
In a domain beyond human healthcare, Dula et al. [26] investigated the integration of CNNs and Transformers for muzzle-based cattle identification. The study proposed a novel Multi-Head Attention Feature Fusion (MHAFF) mechanism, which effectively combines CNN and Transformer features while preserving their complementary strengths. Experimental evaluations on two public cattle datasets yielded outstanding accuracy rates of 99.88% and 99.52%, surpassing both conventional fusion methods and existing identification systems.

While advanced attention-based fusion strategies, such as the Multi-Head Attention Feature Fusion (MHAFF) used in cattle identification [26], have achieved near-perfect accuracy by effectively balancing CNN and Transformer features, this level of sophistication remains largely untapped in cervical cancer diagnosis. Most current approaches still employ uniform or simplistic fusion schemes that cannot adaptively highlight subtle lesion characteristics. This gap highlights a significant opportunity to develop attention-guided frameworks capable of selectively prioritizing clinically relevant features, thereby enhancing the accuracy of cervical cancer classification.

III. Methodology

This section presents the proposed cervical cancer classification model, illustrated in Fig. 1. The model performs binary classification (normal vs. abnormal) by fusing EfficientNet-B0 and Swin-Tiny through attention-guided mechanisms. Both models accept inputs of 224 × 224 pixels, facilitating seamless alignment and fusion of features within the hybrid backbone. The complementary strengths of these architectures form a robust foundation for feature extraction. To further refine the representations, channel and spatial attention modules (SAM) were applied separately to each branch, enhancing informative channels and highlighting salient regions within their respective domains. Optimizing each branch independently ensures that the subsequent cross-attention mechanism receives more distinct and powerful features, enabling a more effective and informative fusion process.





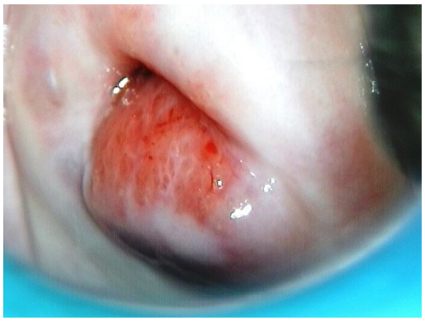


Fig. 1. Proposed dual-branch architecture combining EfficientNet-B0 and Swin Transformer. The model incorporates attention-guided feature fusion to enhance classification performance.

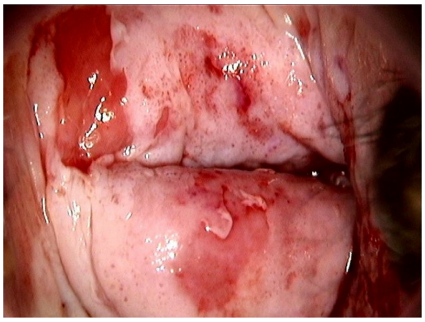
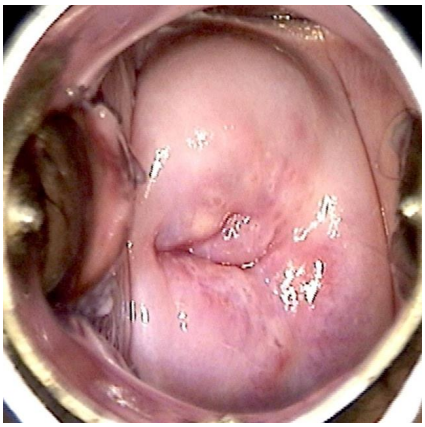
A. Datasets



This study utilized two datasets. The first dataset was obtained upon request from the Colposcopy Image Bank of the International Agency for Research on Cancer (IARC)[31]. The original collection included 913 images from 200 patients. After excluding 15 images from three cases with inconclusive clinical assessments, 898 images from 197 cases were retained. These were classified into three categories based on histopathological metadata: normal tissue (93 cases), precancerous lesions (78 cases), and invasive cancer (26 cases). Representative examples from each category are shown in Fig. 2.

(a) Normal.

(b) Precancerous.



(c) Cancer.

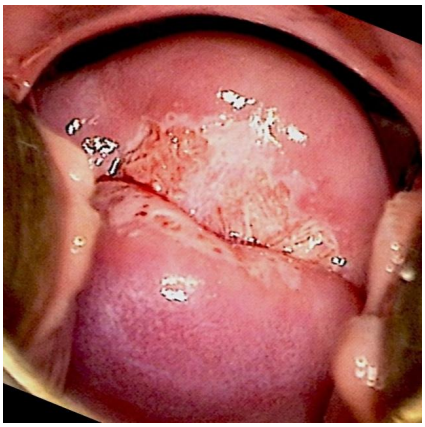


Fig. 2. Colposcopy image samples from the IARC dataset.

The second dataset was sourced from the publicly available Colposcopy Images collection on Kaggle, curated by Siti Nursyafiqah [32]. This dataset contains 2617 images with binary labels: Normal (1445 images) and Abnormal (1172 images). Sample images from this collection are also shown in Fig. 3.

The IARC dataset was reserved exclusively for testing to evaluate the model's generalizability to a new, clinically validated source. A binary classification task was created by merging the precancerous and cancer categories into a single Abnormal class, and the test set was balanced at the case level to avoid bias from patients contributing many images. Iodine-stained images were removed from the dataset to ensure consistency in image appearance. In total, the test set comprised 317 Normal images from 90 cases and 370 Abnormal images from 90 cases (including all 26 cancer cases and 64 precancerous cases).

(a) Normal.

(b) Abnormal.

Fig. 3. Representative colposcopy image samples from the Kaggle dataset: Normal and abnormal.

The Kaggle dataset, which originally contained 1445 Normal and 1172 Abnormal images, was used for training and validation. To ensure consistency with the IARC distribution, a validation set of 317 Normal and 370 Abnormal images was first selected directly from the original Kaggle dataset prior to augmentation. The remaining 1128 Normal and 802 Abnormal images were then augmented fourfold using controlled transformations: brightness adjustment (factors between 0.5× and 1.5×), random zooming up to 0.6×, and random cropping to simulate variability in image framing.All augmented images were stored separately to ensure traceability, producing an augmented pool of 4512 Normal and 3208 Abnormal images. From this augmented pool, 2536 Normal and 2960 Abnormal images were allocated to the training set. Together with the 317/370 validation images and the 317/370 IARC test images,

this produced an exact 80:10:10 split across training, validation, and testing, yielding a per class total of 3170 Normal and 3700 Abnormal images for the experiment(see Fig. 4 and Table I). To address the class imbalance, class weights were applied in the weighted categorical cross-entropy loss function, giving higher importance to the underrepresented Normal class and reducing bias toward the majority Abnormal class.

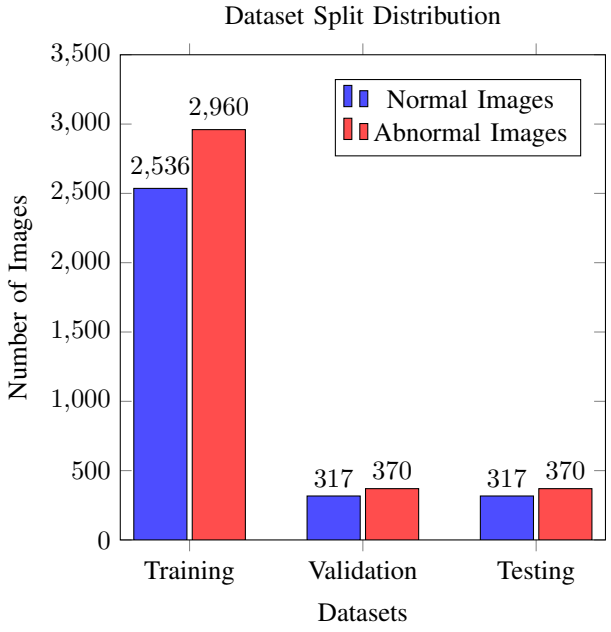

Fig. 4. Distribution of normal and abnormal images across training, validation, and testing sets.

TABLE I. NUMERICAL DISTRIBUTION OF NORMAL AND ABNORMAL IMAGES ACROSS TRAINING, VALIDATION, AND TESTING SETS.

Dataset Split	Normal Images	Abnormal Images
Training	2536	2960
Validation	317	370
Testing	317	370
Total	3170	3700

B. Data Preprocessing

All images in the dataset were processed through a standardized preprocessing pipeline to ensure consistency, improve model convergence, and enhance generalization. The pipeline consisted of the following steps:

Resizing: All images were resized to 224 × 224 pixels to match the input requirements of the ImageNet-pretrained architectures used in this study, specifically EfficientNet-B0 and Swin Transformer-Tiny [29], [30]. This standardization ensures consistent spatial dimensions across samples and facilitates seamless feature fusion between model branches.

Normalization: Pixel values were first scaled from the original 0–255 range to [0,1] by dividing by 255. They were then normalized to the range [-1,1] by subtracting 0.5 and dividing by 0.5 for each color channel. This centers the data distribution, stabilizes gradient-based learning, accelerates convergence, and aligns input statistics with those used during pretraining of the backbone models [13].

Data Augmentation: To increase the diversity of the training data and mitigate overfitting [33], several augmentation techniques were applied during training. These included brightness adjustment (random scaling of pixel intensity between 0.5× and 1.5×), random zooming (scaling factor up to 0.6× of the original image size), and random cropping to simulate variability in framing and viewpoint.

C. Feature Extraction

Feature extraction is the process of transforming complex, high-dimensional raw data, such as images or text into a compact set of informative numerical attributes known as a feature vector [36], [37]. In this study, feature extraction was performed using two parallel networks: EfficientNet-B0 and Swin Transformer (Tiny configuration with patch size 4 and window size 7), both initialized with ImageNet-pretrained weights. To adapt the networks to the colposcopy image classification task, the original classification heads were discarded and the remaining network parameters were fine-tuned during training. This design allows the models to retain their pretrained representational capacity while adjusting to domain-specific visual characteristics present in colposcopy data, forming a stable and efficient foundation for the subsequent stages of the proposed framework [34].

EfficientNet-B0 uses compound scaling to balance network depth, width, and input resolution, allowing it to extract hierarchical features efficiently while keeping computational costs low [29]. The input image $\mathbf{X} \in \mathbb{R}^{3\times224\times224}$ is processed through a sequence of convolutional layers and mobile inverted residual blocks, which progressively capture features from low-level spatial details, such as edges and textures, to high-level semantic patterns relevant for classification. After these layers, a global average pooling operation is applied, which compresses each feature map into a single value by averaging over its spatial dimensions. This produces a 1280-dimensional feature vector, where each dimension represents a summary of a distinct feature detected by the network. This vector is then refined through channel and spatial attention modules,followed by bidirectional cross-attention with the Swin Transformer features, making it suitable for integration with them for subsequent processing.

The Swin Transformer (Tiny variant, patch size 4×4, window size 7×7) processes the image as a sequence of non-overlapping patches [30]. For an input of size 224×224, the image is partitioned into $\frac{224}{4} \times \frac{224}{4} = 3136$ patches. After propagation through the transformer blocks, the final patch embeddings are averaged to produce a 768-dimensional feature vector. To ensure dimensional compatibility with the EfficientNet branch, a linear projection is applied as shown in Eq. (1):

$$\mathbf{f}_{\text{swin}} = W^{\top} \cdot \text{Swin-T}(\mathbf{X}) + b, \quad \mathbf{f}_{\text{swin}} \in \mathbb{R}^{1280}, \tag{1}$$

where, $W \in \mathbb{R}^{768\times1280}$ and $b \in \mathbb{R}^{1280}$ denote the learnable projection matrix and bias term, respectively.

D. Channel Attention Module

A Channel Attention Module, inspired by the Squeeze-and-Excitation network [27], is integrated to adaptively recalibrate channel-wise feature responses by modeling inter-dependencies between channels. Given an input feature map $\mathbf{f} \in \mathbb{R}^{B\times C\times H\times W}$, a global average pooling operation is first applied to generate a compact channel descriptor $\mathbf{z} \in \mathbb{R}^{B\times C}$. The squeeze operation aggregates spatial information into a single channel-wise statistic, formulated as Eq. (2):

$$z_c = \frac{1}{H \times W} \sum_{i=1}^{H} \sum_{j=1}^{W} f_c(i, j), \tag{2}$$

where, z_c represents the aggregated response of the c-th channel. Next, an 'excitation' step is performed to capture inter-channel dependencies through a bottleneck structure comprising two fully connected layers. This transformation is expressed in Eq. (3):

$$\mathbf{a} = \sigma(\mathbf{W}_2 \cdot \delta(\mathbf{W}_1 \cdot \mathbf{z})), \tag{3}$$

where, $\mathbf{W}_1 \in \mathbb{R}^{C/r\times C}$ and $\mathbf{W}_2 \in \mathbb{R}^{C\times C/r}$ are learnable parameters, $r = 16$ is the reduction ratio, δ denotes the ReLU activation, and σ is the sigmoid function. The resulting activation vector $\mathbf{a}$ serves as channel attention weights. Finally, these weights are applied to the original feature map via channel-wise multiplication, as shown in Eq. (4):

$$\tilde{\mathbf{f}} = \mathbf{a} \otimes \mathbf{f}, \tag{4}$$

where, $\otimes$ denotes element-wise channel scaling. This mechanism strengthens informative channels while suppressing less relevant ones, thereby improving the discriminative power of the learned representation.

E. Spatial Attention Module (SAM)

To complement the channel-wise focus, a SAM is incorporated to direct the model's focus towards the most informative spatial regions within the feature maps [28]. This module generates a spatial attention map that highlights where an informative part is located, regardless of channel-specific responses. Given an input feature map $\mathbf{f} \in \mathbb{R}^{B\times C\times H\times W}$, we first aggregate channel information by applying both average pooling and max pooling operations along the channel axis, as shown in Eq. (5) and Eq. (6), respectively:

$$f_{\text{avg}} = \frac{1}{C} \sum_{c=1}^{C} f_c, \quad f_{\text{avg}} \in \mathbb{R}^{B\times 1\times H\times W} \tag{5}$$

$$f_{\text{max}} = \max_{c=1,\ldots,C} f_c, \quad f_{\text{max}} \in \mathbb{R}^{B\times 1\times H\times W} \tag{6}$$

These maps are then concatenated along the channel dimension to form a composite feature descriptor:

$$f_{\text{cat}} = [f_{\text{avg}}; f_{\text{max}}], \quad f_{\text{cat}} \in \mathbb{R}^{B\times 2\times H\times W} \tag{7}$$

where, $[;]$ denotes concatenation.

A convolutional layer with a 7×7 kernel is applied to this concatenated descriptor in Eq. 7 to produce a preliminary spatial map. This is followed by a sigmoid activation function σ to generate the final spatial attention map $\mathbf{a_s}$ in Eq. (8), with values constrained between 0 and 1:

$$\mathbf{a_s} = \sigma\left(\text{Conv}^{7\times 7}(f_{\text{cat}})\right), \quad \mathbf{a_s} \in \mathbb{R}^{B\times 1\times H\times W} \tag{8}$$

The output of the module is obtained by multiplying this attention map in Eq. (8) across every channel of the original input feature map, as shown in Eq. (9):

$$\tilde{f} = \mathbf{a_s} \otimes \mathbf{f} \tag{9}$$

where, $\otimes$ denotes element-wise multiplication. This mechanism emphasizes feature responses in salient regions while suppressing information from irrelevant areas, thereby enhancing the model's spatial discriminative capabilities.

F. Bidirectional Cross-Attention Mechanism

To facilitate synergistic interaction between the feature representations from the EfficientNet-B0 and Swin Transformer branches, a bidirectional cross-attention mechanism with multi-head attention (MHA) was implemented. This allows each branch to dynamically attend to and assimilate relevant features from the other, fostering a more cohesive and discriminative fused representation.

Let $\mathbf{F}_e \in \mathbb{R}^{B\times L\times C}$ and $\mathbf{F}_s \in \mathbb{R}^{B\times N\times D}$ denote the reshaped feature tensors from the EfficientNet and Swin Transformer branches, respectively, where $L = H \times W$ represents the spatial token length, N is the number of Swin tokens, and C, D are their corresponding feature dimensions. The bidirectional cross-attention is formalized through two symmetric attention blocks:

1) EfficientNet to Swin Transformer (E → S) direction: The Swin Transformer features act as the Query, seeking information from the EfficientNet branch's Key and Value [35]:

$$Q_s = F_s W_s^Q, \qquad Q_s \in \mathbb{R}^{B\times N\times d_k}, \tag{10a}$$
$$K_e = F_e W_e^K, \qquad K_e \in \mathbb{R}^{B\times L\times d_k}, \tag{10b}$$
$$V_e = F_e W_e^V, \qquad V_e \in \mathbb{R}^{B\times L\times d_v}. \tag{10c}$$

2) Swin Transformer to EfficientNet (S → E) direction: The EfficientNet features act as the Query, incorporating contextual information from the Swin branch:

$$Q_e = F_e W_e^Q, \qquad Q_e \in \mathbb{R}^{B\times L\times d_k}, \tag{11a}$$
$$K_s = F_s W_s^K, \qquad K_s \in \mathbb{R}^{B\times N\times d_k}, \tag{11b}$$
$$V_s = F_s W_s^V, \qquad V_s \in \mathbb{R}^{B\times N\times d_v}. \tag{11c}$$

where, $\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V$ in Eq. (10) and Eq. (11) are learnable projection weights.

The Multi-Head Attention (MHA) mechanism with $h = 8$ heads is applied independently in each direction. For the E $\rightarrow$ S direction, the projected Query, Key, and Value tensors are first split into h distinct heads along the feature dimension. The operations for the i-th head are then defined as shown in the Eq. (12) :

$$Q_s^i = Q_s W_{Q_s}^i, \qquad Q_s^i \in \mathbb{R}^{B\times N\times d_h}, \tag{12a}$$
$$K_e^i = K_e W_{K_e}^i, \qquad K_e^i \in \mathbb{R}^{B\times L\times d_h}, \tag{12b}$$
$$V_e^i = V_e W_{V_e}^i, \qquad V_e^i \in \mathbb{R}^{B\times L\times d_h}. \tag{12c}$$

where, $d_h = d_k/h = d_v/h$ is the dimension per head, and $\mathbf{W}_{Q_s}^i, \mathbf{W}_{K_e}^i, \mathbf{W}_{V_e}^i$ are the projection weights for the i-th head. For each head, the scaled dot-product attention is computed independently. This involves calculating a compatibility score between each Query and Key vector, which determines how much focus to place on different parts of the input [see Eq. (13)]:

$$\text{Attention}(Q_s^i, K_e^i, V_e^i) = \text{softmax}\left(\frac{Q_s^i (K_e^i)^\top}{\sqrt{d_h}}\right) V_e^i. \tag{13}$$

The softmax function is applied row-wise to generate a probability distribution (attention weights) over the L spatial locations for each of the N tokens. The output for each head is consequently a weighted sum of the Value vectors, with weights determined by the Query-Key compatibility. The outputs of all h heads are then concatenated along the feature dimension, as shown in the Eq. (14):

$$\begin{aligned} H_s &= [\text{Head}_s^1; \text{Head}_s^2; \ldots; \text{Head}_s^h], \\ H_s &\in \mathbb{R}^{B\times N\times (h\cdot d_h)} = \mathbb{R}^{B\times N\times d_v}. \end{aligned} \tag{14}$$

Finally, the concatenated output is linearly projected back to the original dimension D using a learned output matrix $\mathbf{W}_O \in \mathbb{R}^{d_v\times D}$, [see Eq. (15)]:

$$\text{MHA}(Q_s, K_e, V_e) = H_s W_O. \tag{15}$$

This multi-head design allows the model to jointly attend to information from different representation subspaces at different positions, effectively capturing a diverse set of complementary features. The final refined feature for the Swin branch is obtained via a residual connection and layer normalization, as shown in Eq. (16):

$$\tilde{F}_s = \text{LayerNorm}(F_s + \text{MHA}(Q_s, K_e, V_e)). \tag{16}$$

An identical process is applied in the S $\rightarrow$ E direction to obtain $\tilde{\mathbf{F}}_e$. The enriched feature representations, $\tilde{\mathbf{F}}_s$ and $\tilde{\mathbf{F}}_e$, produced by the bidirectional cross-attention module are fused via global average pooling followed by concatenation, yielding a unified feature vector $\mathbf{z} \in \mathbb{R}^{B\times 512}$. This vector is subsequently processed by a Multi-Layer Perceptron (MLP) classifier to transform the high-level features into a probability distribution over the C target classes, where C = 2 in our case.

G. Multi-Layer Perceptron (MLP) Classifier

The fused feature vector $z \in \mathbb{R}^{512}$, obtained from the bidirectional cross-attention module, is processed by a Multi-Layer Perceptron (MLP) classifier. This network transforms the input features into a probability distribution over the target classes. The classifier comprises three hidden layers, progressively reducing the dimensionality from 512 to 128, followed by a linear output layer mapping to the number of output classes C. The dimensionality reduction follows the sequence: $512 \rightarrow 256 \rightarrow 128 \rightarrow C$.

The input to the first layer is the fused feature vector $h^{(0)} = z$. The layer applies a linear transformation using a weight matrix $W^{(1)} \in \mathbb{R}^{512\times 512}$ and bias vector $b^{(1)} \in \mathbb{R}^{512}$, as shown in Eq. (17). Batch normalization is applied to the linear output, followed by a GELU activation and dropout. The resulting output, hereafter denoted as $h^{(1)}$, serves as the input to the next layer.

$$z^{(1)} = h^{(0)} W^{(1)} + b^{(1)} \tag{17}$$

The second layer receives $h^{(1)} \in \mathbb{R}^{512}$ and projects it to 256 dimensions using $W^{(2)} \in \mathbb{R}^{512\times 256}$ and $b^{(2)} \in \mathbb{R}^{256}$, as shown in the Eq. (18).The linear output is subsequently normalized through batch normalization, followed by the application of a LeakyReLU activation function with a negative slope and dropout, producing $h^{(2)}$, which serves as the input to the third layer.

$$z^{(2)} = h^{(1)} W^{(2)} + b^{(2)} \tag{18}$$

The third hidden layer reduces the dimensionality of $h^{(2)}$ from 256 to 128 using the weight matrix $W^{(3)} \in \mathbb{R}^{256\times 128}$ and bias vector $b^{(3)} \in \mathbb{R}^{128}$, as shown in Eq. (19). The linear output is subsequently normalized through layer normalization, followed by the application of a SiLU (Swish) activation function and dropout, yielding the final hidden representation $h^{(3)}$.

$$z^{(3)} = h^{(2)} W^{(3)} + b^{(3)} \tag{19}$$

The output layer linearly projects $h^{(3)} \in \mathbb{R}^{128}$ to C dimensions using $W^{(4)} \in \mathbb{R}^{128\times C}$ and $b^{(4)} \in \mathbb{R}^C$, producing the logits u, as shown in Eq. (20). These logits are then converted into a probability distribution over the output classes using the softmax function [Eq. (21)]. Finally, the predicted class $\hat{c}$ is obtained by selecting the class with the highest probability, as defined in Eq. (22).

$$u = h^{(3)} W^{(4)} + b^{(4)} \tag{20}$$

$$\hat{y} = \text{softmax}(u) \tag{21}$$

$$\hat{c} = \arg\max_j \hat{y}_j \tag{22}$$

IV. Experimental Setup and Evaluations

A. Computing Environment

All experiments were conducted in the Google Colab environment equipped with an NVIDIA GPU, leveraging the CUDA architecture for accelerated deep learning computations. The software environment was built on Python 3.10.12 using the PyTorch deep learning framework. Key libraries included torchvision for image preprocessing and data loading, timm (Torch Image Models) for access to pre-trained backbone networks, and scikit-learn for comprehensive evaluation metrics.

B. Training Configuration and Hyperparameters

For both the baseline concatenation model and the proposed attention-guided fusion model, identical training configurations were employed to ensure a fair comparison. The training hyperparameters used in this study are summarized in Table II. The models were trained for 50 epochs with a batch size of 8 using the AdamW optimizer, a learning rate of 5×10^{-5}, and a weight decay of 0.01. These hyperparameters were selected based on prior transformer-based literature, preliminary experimental validation, and computational constraints associated with training dual-branch architectures. Model performance was evaluated using 5-fold stratified cross-validation to ensure robustness and reduce variance, and the reported metrics correspond to the aggregated performance across all folds.

AdamW was chosen because its decoupled weight decay improves generalization and helps mitigate overfitting, particularly in transformer-based networks [39]. The learning rate was determined through pilot experiments that demonstrated stable convergence during fine-tuning of pre-trained models, while a weight decay of 0.01 provided effective regularization without limiting model capacity. The batch size of 8 was necessitated by GPU memory limitations; however, smaller batch sizes have also been shown to promote better generalization in medical imaging tasks with moderately sized datasets. Training for 50 epochs ensured adequate convergence, as validation performance plateaued beyond this point during preliminary experiments.

The hidden layers utilized GELU, LeakyReLU, and SiLU activation functions to exploit their complementary strengths: GELU provides smooth non-linearity suitable for transformer components, LeakyReLU prevents the dying neuron problem in convolutional layers, and SiLU introduces self-gating behavior that enhances feature representation. A weighted categorical cross-entropy loss function was applied to address class imbalance within the dataset. Maintaining this consistent training configuration across all experiments ensures that any observed performance differences can be attributed to architectural innovations rather than variations in optimization strategy.

TABLE II. Training Hyperparameters used for Both the Baseline Concatenation Model and the Proposed Attention-Guided Fusion Model

Hyperparameter	Value
Epochs	50
Batch Size	8
Optimizer	AdamW
Learning Rate	5×10^{-5}
Weight Decay	0.01
Loss Function	Weighted Categorical Cross-Entropy
Activation Function (Hidden Layers)	GELU, LeakyReLU, SiLU
Activation Function (Output Layer)	Softmax

C. Metrics for Evaluating Performance

Model performance was assessed using standard classification metrics. For binary classification, let TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively. The following metrics were computed [see Eq. (23) to Eq. (27)]:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{23}$$

Accuracy measures the overall proportion of correctly classified samples out of all predictions.

$$\text{Precision} = \frac{TP}{TP + FP} \tag{24}$$

Precision evaluates how many of the samples predicted as positive are actually positive, reflecting reliability in identifying abnormal cases.

$$\text{Recall} = \frac{TP}{TP + FN} \tag{25}$$

Recall (or sensitivity) measures how many actual positive samples are correctly identified, which is critical in medical diagnosis to minimize missed cases.

$$\text{F1-Score} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \tag{26}$$

The F1-Score balances precision and recall, providing a single measure of overall classification effectiveness, especially useful when dealing with imbalanced datasets.

$$\text{Cohen's Kappa} = \frac{P_o - P_e}{1 - P_e} \tag{27}$$

Cohen's Kappa measures the agreement between predicted and actual classifications while accounting for agreement occurring by chance. It provides a more robust evaluation than accuracy alone, particularly in imbalanced datasets.

The observed agreement P_o is defined as Eq. (28):

$$P_o = \frac{TP + TN}{TP + TN + FP + FN} \tag{28}$$

The expected agreement P_e is computed as Eq. (29):

$$P_e = \frac{(TP+FP)(TP+FN)}{(TP+TN+FP+FN)^2} + \frac{(FN+TN)(FP+TN)}{(TP+TN+FP+FN)^2} \quad (29)$$

Kappa values range from -1 to 1, where $\kappa = 1$ indicates perfect agreement, $\kappa = 0$ indicates agreement equivalent to random chance, and $\kappa < 0$ indicates disagreement worse than chance. Higher Kappa values, therefore, indicate stronger and more reliable classification performance beyond random coincidence.

To complement these quantitative metrics, performance is further analyzed using visualization techniques such as confusion matrices, Receiver Operating Characteristic (ROC) curves, and learning curves, which provide deeper insight into class-wise behavior, discriminative capability and convergence characteristics of the models.

D. Experimental setup

To rigorously assess the effectiveness of the proposed attention-guided fusion strategy, we implemented two experimental configurations. The baseline model, which used simple concatenation to combine CNN and transformer representations, provided a reference for performance without attention mechanisms. The proposed model incorporated an attention-guided fusion strategy. This approach dynamically reweights features from both branches to emphasize diagnostically relevant patterns.

1) Concatenation-based fusion model (baseline): The concatenation-based fusion model was designed as a baseline to assess the contribution of attention mechanisms. In this configuration, feature representations extracted from EfficientNet-B0 and Swin Transformer–Tiny were directly concatenated along the feature dimension without applying any attention operation. Specifically, the 1280-dimensional feature vector produced by EfficientNet-B0 and the 768-dimensional feature vector obtained from Swin Transformer–Tiny were concatenated to form a 2048-dimensional fused representation. The resulting feature vector was processed by a Multi-Layer Perceptron (MLP) classifier consisting of three sequential hidden layers with 512, 256, and 128 units, respectively. Each hidden layer incorporated normalization and nonlinear activation functions, employing GELU, LeakyReLU, and SiLU activations in successive layers, along with dropout rates of 0.5, 0.4, and 0.3, to improve generalization and mitigate overfitting. The classifier was finalized with a linear output layer for binary classification. Model optimization was performed using the AdamW optimizer with a learning rate of5×10^{-5} and a weight decay of 0.01. This baseline model provides a strong yet simple fusion strategy, serving as a reference point for evaluating the performance gains achieved by the proposed attention-based fusion framework.

2) Attention-based fusion model (proposed model): As illustrated in the Methodology section, the proposed model introduces a multi-stage attention-based fusion framework to effectively integrate features extracted from EfficientNet-B0 and Swin Transformer–Tiny. Following independent feature extraction, the 768-dimensional output of the Swin Transformer–Tiny branch is projected into a 1280-dimensional feature space via a linear transformation to ensure dimensional compatibility with the EfficientNet-B0 branch. Prior to feature fusion, each branch is refined separately using sequential Channel Attention and Spatial Attention modules. The Channel Attention module employs adaptive average pooling followed by a sigmoid-activated MLP to compute channel-wise importance weights, while the Spatial Attention module emphasizes salient spatial regions through mean and max pooling operations followed by a one-dimensional convolution. The core fusion mechanism is implemented through a CrossAttnFusion module, in which features are projected into Query (Q), Key (K), and Value (V) vectors and cross-attention is computed in both directions. The attended outputs from both directions are concatenated using the torch.cat operation and passed through a linear layer with ReLU activation to form a unified representation. This fused representation is subsequently processed by a multi-layer classifier that progressively reduces the feature dimensionality from 512 to 256 and finally 128 units. Each stage incorporates normalization and nonlinear activation functions GELU, LeakyReLU, and SiLU along with dropout rates of 0.5, 0.4, and 0.3, respectively, to enhance robustness and generalization. The final classification layer maps the 128-dimensional representation to two output units, corresponding to the normal and abnormal classes. Training was conducted using the Weighted Categorical Cross-Entropy loss function, implemented via PyTorch's `nn.CrossEntropyLoss` with class weights to account for dataset imbalance. The model was optimized using the AdamW optimizer with a learning rate of 5×10^{-5} and a weight decay of 0.01. During inference, class predictions were obtained using `argmax(1)`, while class probabilities for ROC analysis and other evaluation metrics were computed using `torch.softmax(outputs, 1)`.

This experimental design isolates the effect of the attention mechanism, allowing direct attribution of any performance differences to the fusion strategy rather than extraneous factors.

V. Results and Discussion

A. Quantitative results

As shown in Table III, the proposed model demonstrates consistent and substantial improvements over baseline model across all evaluation metrics. Classification accuracy increases by 10.77 percentage points, indicating a marked enhancement in overall predictive performance. Similarly, the F1-score improves by 10.76 percentage points, reflecting more balanced classification across classes. Notably, Cohen's Kappa exhibits a substantial increase of 21.45 percentage points, highlighting a significantly stronger agreement beyond chance and confirming the robustness of the proposed attention-guided fusion strategy.

B. Qualitative Results

The confusion matrices presented in Fig. 5 and Fig. 6 provide a detailed class-wise evaluation of the models on the test dataset.The results demonstrate a clear performance improvement when using the attention-guided fusion model compared to the simple concatenation model. In the simple

TABLE III. PERFORMANCE COMPARISON ON THE TEST DATASET

Metric	Baseline Model (%)	Proposed Model (%)	Absolute Improvement(%)
Accuracy	83.99	94.76	+10.77
Precision	84.09	94.68	+10.59
Recall	84.28	94.82	+10.54
F1-score	83.98	94.74	+10.76
Cohen's Kappa	68.03	89.48	+21.45

concatenation approach, although the model achieved a reasonable number of correct classifications (298 abnormal and 279 normal), it produced a relatively high number of false negatives (72 abnormal cases misclassified as normal), which is particularly concerning in a medical diagnostic context where missed abnormal cases can delay treatment. In contrast, the attention-guided model substantially reduced false negatives from 72 to 22 and false positives from 38 to 14, while simultaneously increasing correct abnormal predictions (from 298 to 348) and correct normal predictions (from 279 to 303).These improvements indicate that the attention mechanism enhances feature discrimination by prioritizing more informative representations within the hybrid architecture, thereby improving overall classification reliability.

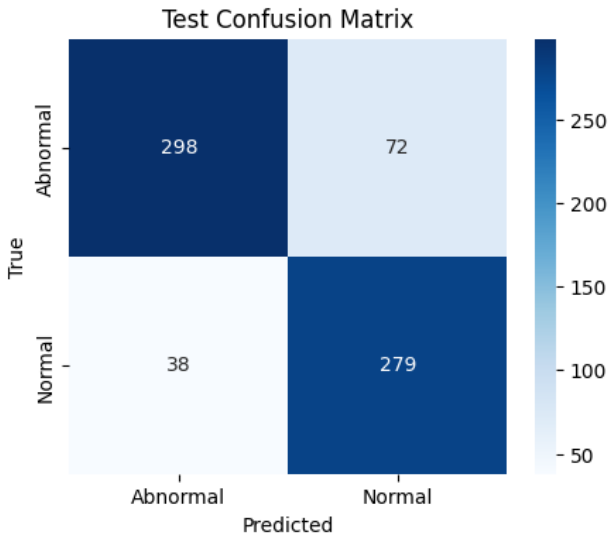

Fig. 5. Confusion matrix for the concatenation-based fusion model on the test dataset.

This finding is strongly corroborated by the Receiver Operating Characteristic (ROC) curves in Fig. 7 and Fig. 8. While the baseline model achieved a respectable Area Under the Curve (AUC) of 0.90 for both classes, the proposed model attained a near-perfect AUC of 0.99. This significant increase in AUC, consistent with the sharp reduction in confusion matrix errors, underscores that the attention mechanism not only boosts overall accuracy but also substantially improves the model's confidence and precision in separating the two classes.

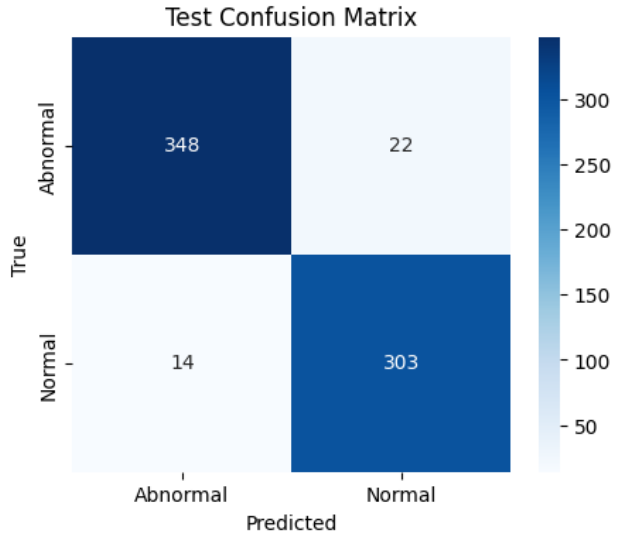

Fig. 6. Confusion matrix for the proposed attention-based fusion model on the test dataset.

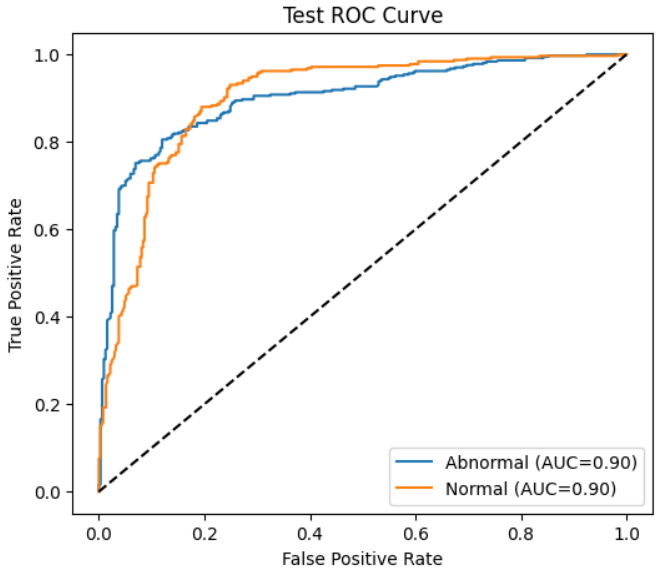

Fig. 7. ROC curve for the concatenation-based fusion model on the test dataset.

C. Learning Curve Analysis

The learning dynamics of the two approaches, illustrated in Fig. 9 and Fig. 10, provide additional insight into their behavior during training. The concatenation-based fusion model exhibits slower convergence, plateauing around epoch 30, and shows variability in generalization during intermediate epochs, which may indicate that the model struggles to locate the most critical regions in the images. By contrast, the proposed model stabilizes much earlier, between epochs 10 and 15, with closely aligned training and validation accuracies, reflecting faster and more consistent learning. This efficiency in convergence, combined with the improved predictive performance, underscores the effectiveness of the attention-guided fusion strategy in

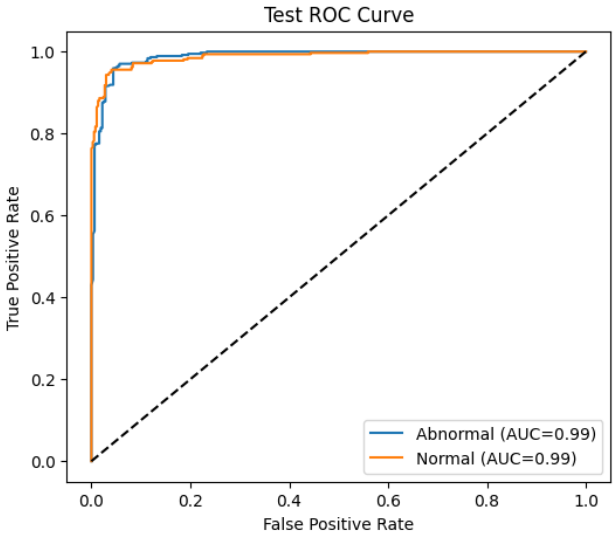

Fig. 8. ROC curve for the proposed attention-based fusion model on the test dataset.

prioritizing clinically relevant features while reducing training time. Collectively, these results highlight the potential of the proposed model as a robust and reliable tool for automated colposcopy image analysis. By improving classification accuracy, reducing misclassifications, and demonstrating stable learning, the model supports safer and more efficient cervical cancer screening workflows, complementing existing diagnostic procedures while minimizing the risk of missed diagnoses.

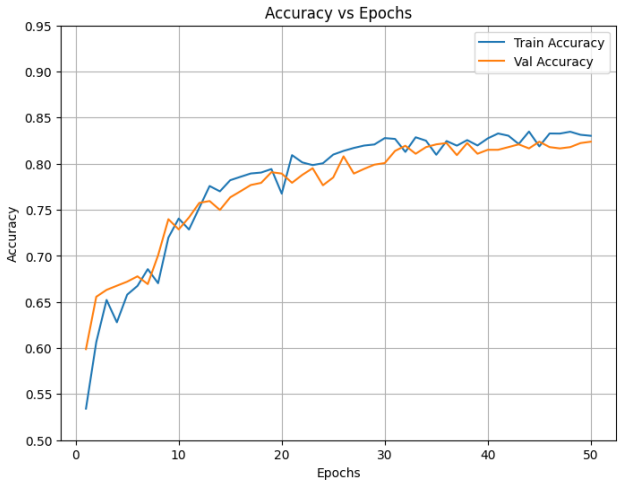

Fig. 9. Training and validation accuracy curve for the baseline model.

D. Model Classification Decisions

The Grad-CAM [38] visualizations in Fig. 11 illustrate that the model effectively highlights the image regions most influential to its classification decisions. The figure presents four representative samples (two normal and two abnormal), with the top row showing the original images and predicted confidence scores, and the bottom row displaying the corresponding Grad-CAM heatmaps. The model achieves confidence scores

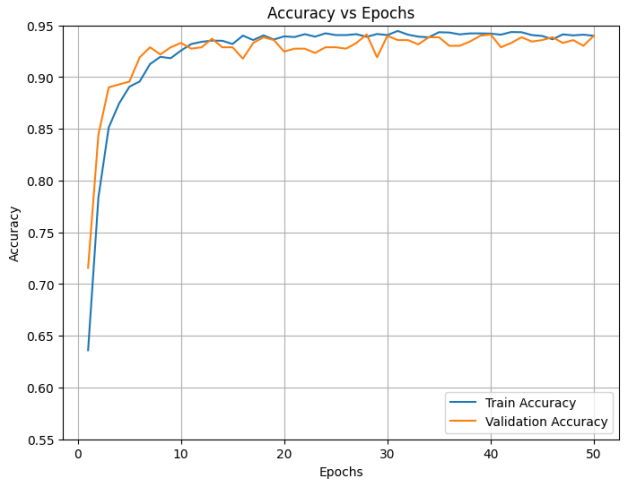

Fig. 10. Training and validation accuracy curve for the proposed attention-based fusion model.

of 99.1% and 99.6% for normal samples and 88.5% and 99.1% for abnormal samples, indicating strong certainty in distinguishing healthy from diseased tissue.

In the heatmaps, red regions denote areas of highest importance, yellow indicate moderate importance, and blue correspond to regions with minimal influence. The strongest activations are consistently concentrated on irregular tissue patterns, including lesion margins, atypical epithelial structures, and abnormal coloration. This focused localization suggests that the model bases its predictions on clinically relevant pathological features rather than background artifacts.

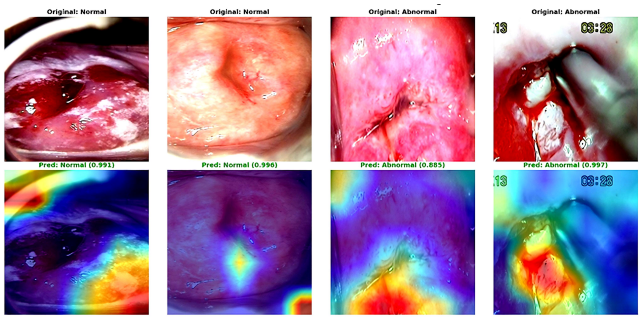

Fig. 11. Grad-CAM visualizations highlighting regions of high and low importance in colposcopy images.

E. Discussion

The attention mechanism fundamentally changes how the hybrid model integrates information from its two component architectures. Rather than simply combining features, it learns to prioritize different types of visual information depending on the input. This selective weighting explains the observed error reduction: false negatives dropped from 72 to 22, and false positives fell from 38 to 14. This pattern is particularly significant in screening contexts, where missed abnormalities carry greater clinical risk than over-calling normal tissue.

The training dynamics further demonstrate the value of attention. The baseline model required more epochs to plateau,

converging around epoch 30, whereas the proposed model stabilized near epoch 10 with closely aligned training and validation curves. This efficiency suggests that attention focuses learning on informative regions from the outset.

The near-perfect AUC of 0.99 reflects how cleanly the model separates classes in feature space. This indicates that the internal representations of normal and abnormal cases form two distinct clusters with minimal overlap, enabling confident predictions across any decision threshold. The attention mechanism achieves this separation by ensuring that only relevant features such as lesion margins, epithelial changes, and vascular patterns contribute to the final representation, while effectively suppressing background noise.

Despite the promising performance, several limitations should be acknowledged. First, the model was trained and evaluated on a relatively small dataset, which may limit its generalizability to larger or more diverse populations. Second, variations in imaging devices, staining protocols, or patient demographics could affect performance when applied to external cohorts. Third, the proposed hybrid model is computationally demanding due to the large size of the EfficientNet and Swin Transformer branches, which constrained the training batch size to 8. Future work should focus on validating the model on larger, more diverse datasets, optimizing computational resource usage, and integrating complementary modalities, such as histopathology images and clinical metadata, to further enhance robustness and predictive performance. These findings demonstrate that the proposed attention-based fusion model outperforms the baseline in accuracy and reliability, providing a clinically meaningful approach for precise and efficient cervical cancer screening.

F. Comparative Analysis with Prior Studies

The proposed model was comparatively evaluated against several representative CNN–Transformer–based cervical image analysis frameworks reported in the literature. The CVM-Cervix model [25] demonstrated the benefit of integrating CNN-extracted cellular features with Vision Transformer–captured global contextual representations; Feature fusion was performed using a multilayer perceptron (MLP), which enables joint feature learning but lacks explicit attention mechanisms to selectively emphasize diagnostically salient regions. Similarly, the hybrid EfficientNet-B0–Swin-Tiny framework [22] highlighted the potential of CNN–Transformer integration but employed a simple concatenation-based fusion mechanism, achieving an accuracy of 87.5% after 30 training epochs. The MFEM-CIN framework [24] further contributed toward lightweight, multi-scale colposcopic image analysis; nevertheless, its multi-scale feature fusion (MSFF) strategy was primarily based on concatenation and linear projection, which may constrain the modeling of complex inter-feature dependencies. Beyond cervical imaging, a related hybrid approach combining a ResNet module with a transformer was proposed in [23] for non-small cell lung cancer (NSCLC) analysis. While the ResNet branch captured local volumetric features and the transformer modeled long-range contextual information, the use of simple feature concatenation resulted in a maximum testing accuracy of 81.9%, underscoring the limitations of uniform feature aggregation. In contrast, the baseline model implemented in this study, which also employed concatenation-based fusion, achieved an accuracy of 83.99%, aligning with the performance trends observed in prior concatenation-driven hybrid architectures. Notably, the proposed attention-guided fusion model substantially outperformed both the baseline and existing methods, achieving an accuracy of 94.76%. This improvement highlights the effectiveness of attention mechanisms in selectively emphasizing diagnostically relevant regions and suppressing redundant features during fusion (see Table IV).

TABLE IV. COMPARISON BETWEEN THE PROPOSED MODEL AND RELATED STUDIES

Study	Model	Image type	Fusion Mechanism	Accuracy (%)
[25]	CNN + Transformer	Pap smear images	Multilayer Perceptron (MLP)	91.72
[22]	EfficientNet-B0 + Swin-Tiny	Colposcopy images	Concatenation	87.50
[24]	Multi-scale CNN + Transformer	Colposcopy images	Concatenation	89.20
[23]	ResNet + Transformer	NSCLC CT images	Concatenation	81.90
Our baseline	EfficientNet-B0 + Swin-T	Colposcopy images	Concatenation	83.99
Our proposed	**EfficientNet-B4 + Swin-T**	**Colposcopy images**	**Attention-guided fusion (Cross attention)**	**94.76**

G. Clinical Integration and Practical Implications

The proposed hybrid EfficientNet-B0 and Swin Transformer model with cross-attention fusion offers meaningful potential to support cervical cancer screening and diagnostic workflows. By processing colposcopy images in real-time, the model can assist clinicians during routine gynecological examinations, delivering rapid and data-informed interpretations. This capability helps mitigate the subjectivity and inter-observer variability common in visual assessment, contributing to more standardized and reproducible evaluations across practitioners.

With its high predictive accuracy and robust generalization, the model serves as a reliable decision-support tool that complements established diagnostic techniques such as Pap smears, HPV testing, and biopsy. Although the current implementation is best suited for systems with GPU support, future optimizations may enable broader adoption even in resource-constrained clinical settings.

Importantly, the model produces interpretable attention maps that highlight key regions in the images, including lesion margins, abnormal epithelial pattern, and areas of unusual coloration. These visual explanations assist pathologists and radiologists in focusing on clinically relevant areas, prioritizing critical casesand making more confident, informed diagnostic decisions. Overall, the system is intended to support rather than replace expert judgment, improving both the speed and reliability of cervical cancer diagnosis in clinical practice.

VI. Conclusion

This study proposed a novel attention-guided hybrid framework for cervical cancer classification, integrating features from EfficientNet-B0 and Swin Transformer. By applying channel-wise and spatial attention prior to fusion, the model effectively captured both global contextual information and localized fine-grained details, addressing the limitations of simple concatenation. The framework achieved strong performance, with a test accuracy of 94.76%, precision of 94.68%, recall of 94.82%, F1-score of 94.74%, and a Cohen's Kappa of 89.48%. Attention mechanisms were crucial in prioritizing salient features, enhancing discriminative power, and reducing misclassifications, while the accelerated and stable convergence during training underscores the model's efficiency.

Although these results are promising, future work should focus on validating the framework on large-scale datasets from diverse clinical institutions to ensure robust generalizability. Incorporating complementary patient information, such as clinical history and histopathology reports, could further improve diagnostic accuracy and utility. Additionally, the flexible design of the framework presents an opportunity to extend its application to other gynecological cancers and imaging modalities, broadening its potential clinical impact.

Acknowledgment

We express our sincere gratitude to the Pan African University, Institute for Basic Sciences, Technology, and Innovation (PAUSTI), Nairobi, Kenya, and the African Union for providing the essential resources that made this research possible. Their support and encouragement were instrumental in enabling the successful completion of this work.

***Abstract*—Global crises, such as pandemics and climate-related disasters, place unprecedented strain on healthcare systems, exposing weaknesses in resource management and patient care. This study aims to address these challenges by developing an integrated computational framework for crisis-resilient healthcare robotics. We propose a unified approach that combines Multiple Linear Regression (MLR), Markov Decision Processes (MDPs), and Petri Nets. MLR is applied to predict the Average Length of Stay (ALOS) using patient and hospital data. These forecasts inform MDPs, which guide admission and triage decisions under uncertainty. Petri Nets are employed to model and validate patient flow and hospital workflows, ensuring feasibility and efficiency. Case studies, including ICU bed prioritization and disaster logistics, demonstrate that the proposed framework improves adaptability and resource utilization while supporting structured decision guidance. Simulation results highlight enhanced system efficiency, better patient prioritization, and reduced congestion during surge conditions. The integration of predictive analytics, probabilistic optimization, and workflow modeling provides a robust decision-support system for healthcare robotics in crisis scenarios. This interdisciplinary framework offers practical solutions for improving resilience, scalability, and patient outcomes, providing a structured foundation for enhancing resilience and coordination in healthcare systems facing future emergencies.**

***Keywords*—Healthcare robotics; Markov Decision Processes; Petri Nets; Multiple Linear Regression; crisis management; ICU resource allocation**

I. Introduction

Global healthcare systems are increasingly challenged by recurring crises such as pandemics, extreme weather events, and large-scale disasters [1], [2]. These events expose persistent weaknesses in continuity of care, inefficiencies in resource management, and risks to patient outcomes.

A. Motivation and Contribution Perspective

Rather than introducing new individual algorithms, this work focuses on how existing predictive, decision, and workflow models can be structurally combined to support crisis-aware hospital operations. The core contribution lies in a decision-oriented modeling chain (MLR $\rightarrow$ MDP $\rightarrow$ Petri Net), which constrains hospital dynamics to decision-feasible trajectories. This structured coupling enables tractable reachability analysis and formal verification of admission policies under severe resource constraints, which cannot be achieved using predictive or decision models alone.

To address this gap, we propose an integrated computational framework that combines:

- Multiple Linear Regression (MLR) for forecasting critical indicators such as the Average Length of Stay (ALOS) [5], [6],
- Markov Decision Processes (MDPs) for guiding triage and admission policies under uncertainty [7], [8],
- Petri Nets for validating hospital workflows and ensuring feasibility of robotic interventions under operational constraints [10], [11].

This unified approach integrates statistical forecasting, probabilistic decision-making, and workflow simulation into a single coherent system.

B. Main Contributions

The main contributions of this work are summarized as follows:

- We propose a decision-constrained modeling chain that links predictive analytics, sequential decision-making, and workflow verification, reducing the reachable state space of hospital systems during crises.
- We introduce an explainable approximate MDP-based admission policy, designed for environments where full transition probabilities cannot be reliably identified.
- We demonstrate how Petri Net reachability analysis can be used to formally verify the feasibility, boundedness, and safety of data-driven admission decisions.

C. Paper Organization

The remainder of this study is organized as follows:

- Section II reviews related work on healthcare robotics and computational modeling, discusses applications

*Corresponding author.

and current limitations of robotic systems in healthcare, presents the proposed improvements and analyzes resource management during global crises.

- Section III details the computational models (MLR, MDPs, Petri Nets).
- Section IV provides case analysis and intermediate results.
- Section V develops Petri Net modeling and analysis.
- Section VI defines the initial marking and reachability analysis.
- Section VII describes integration with robotic systems through an illustrative workflow and offers a comparative analysis of reachability approaches.
- Section VIII concludes the study with perspectives for future research.

II. Related Work

The integration of computational models in healthcare robotics has attracted increasing attention in recent years. Several studies have applied Markov Decision Processes (MDPs) to model clinical decision-making under uncertainty, particularly for triage optimization and ICU resource allocation [7], [8]. For example, Hauskrecht (2000) demonstrated the use of MDPs in managing treatment policies for chronic diseases. More recent works have explored reinforcement learning and optimization-based strategies for hospital resource allocation under pandemic-induced surge conditions [24], [25], [26], highlighting the importance of adaptive decision-making in crisis scenarios.

Petri Nets have been widely used to model complex hospital workflows, including patient flow in emergency departments and coordination of clinical tasks [10], [11], [17]. They provide powerful tools for identifying bottlenecks and ensuring safety constraints in distributed systems. Recent probabilistic and time-dependent Petri Net extensions have further enabled formal modeling of clinical pathways under uncertainty [27].

Multiple Linear Regression (MLR) has been applied for forecasting hospital metrics such as length of stay (LOS), readmission risks, and cost estimation [5]. However, these studies generally focus on prediction as a standalone task and do not embed regression outputs into real-time robotic or autonomous decision workflows.

In contrast to prior works that treat predictive modeling, decision optimization, and workflow analysis as separate components, the present framework integrates MLR, MDPs, and Petri Nets within a unified decision-support modeling chain. While existing literature addresses forecasting, optimization, or workflow verification independently, relatively few approaches structurally couple predictive analytics with sequential decision-making and formal system validation.

This methodological gap motivates the integrated approach proposed in this study, where predictive estimates inform admission control policies, and decision-constrained transitions are subsequently verified through Petri Net reachability analysis.

Petri Nets have been widely used to model complex hospital workflows, including patient flow in emergency departments and coordination of clinical tasks [10], [11]. They provide powerful tools for identifying bottlenecks and ensuring safety constraints in distributed systems. Recent probabilistic and time-dependent Petri Net extensions have further enabled formal modeling of clinical pathways under uncertainty [27]. Recent Petri Net models have also been applied to healthcare systems under COVID-19 surge conditions [18].

A. Main Applications of Healthcare Robotics

- Surgical Robots: Systems like *da Vinci* enable minimally invasive surgery with higher precision and reduced recovery time [15].
- Assistive Robots: Devices such as PARO or Robear help elderly and disabled patients with daily activities and emotional support [12].
- Diagnostic and Rehabilitation Robots: AI-based robots analyze medical images or assist physical recovery, improving outcomes [22], [23].
- Logistics Support: Autonomous systems (e.g., TUG robots) deliver drugs and supplies, increasing hospital efficiency [1].

B. Challenges in Crisis Contexts

Despite these advances, crises such as pandemics expose key weaknesses:

- Resource rigidity: Robots are often task-specific and struggle to adapt to new priorities [3], [4].
- Limited real-time adaptation: Pre-programmed workflows cannot manage sudden surges in patient volume [8].
- Poor integration: Robotic subsystems rarely connect seamlessly to hospital information systems or triage networks [10].
- High cost and scalability issues: Advanced units remain inaccessible to resource-limited hospitals [2].

C. Resource Management Under Global Crises

Pandemics and disasters further aggravate shortages of ICU beds, staff, and equipment [19], [5]. Traditional allocation approaches remain static, manually driven, and fragmented, lacking predictive and adaptive capacity [7], [2]. Integrating data-driven models such as Petri Nets, Markov Decision Processes, and Multiple Linear Regression can improve crisis resource allocation [20].

- Real-time decision-making and prioritization of tasks,
- Interoperability with hospital information systems,
- Scalability and coordination during resource surges.

This hybrid framework promotes proactive, self-adjusting robotic systems capable of supporting hospitals under both routine and emergency conditions. The constraints and challenges outlined in this section motivate the need for an integrated decision-support framework capable of anticipating resource usage, regulating admissions, and ensuring operational safety.

III. Computational Models for Crisis-Aware Optimization

This work relies on the integration of three complementary modeling paradigms—Multiple Linear Regression (MLR), Markov Decision Processes (MDPs), and Petri Nets—to support crisis-aware decision-making in hospital systems. Each model plays a distinct and clearly delimited role: prediction, decision guidance, and formal workflow validation.

A. Predictive Layer: Multiple Linear Regression for ALOS Estimation

Multiple Linear Regression (MLR) is used to forecast the Average Length of Stay (ALOS), a key operational indicator for hospital capacity planning [5]. Accurate ALOS prediction enables anticipation of future bed occupancy and resource commitment, which is critical during crisis situations such as pandemics or mass-casualty events [6].

1) Model formulation: The MLR model estimates ALOS as:

$$Y = \beta_0 + \sum_{i=1}^{n} \beta_i X_i + \epsilon \tag{1}$$

where, Y denotes ALOS, X_i represent patient- and admission-related variables, β_i are regression coefficients, and ϵ is the error term.

2) Why Multiple Linear Regression?: MLR is selected as a transparent baseline that supports interpretability and auditability in healthcare operations. Unlike complex nonlinear predictors, MLR allows direct inspection of coefficients, facilitates sensitivity analysis, and reduces integration friction when predictions are embedded into the downstream decision layer.

Although nonlinear models may achieve marginally higher predictive accuracy, the primary objective of this work is to ensure explainability and seamless coupling with the decision-theoretic layer. Therefore, MLR is adopted as a structurally compatible and interpretable predictive backbone.

3) Data and predictive performance: The model is trained on data derived from the MIMIC-III database [6], including demographic information, clinical severity, emergency admission rate, satisfaction score, and total hospital charges.

4) Preprocessing and reproducibility details: We used MIMIC-III structured variables consistent with ALOS modeling. Missing values were handled by: 1) removing features with $> 30\%$ missingness, and 2) median imputation for continuous variables and mode imputation for categorical variables. Continuous predictors were standardized using z-score normalization: $x' = (x - \mu)/\sigma$ computed on the training set only. Categorical variables were one-hot encoded.

Feature selection followed a two-step procedure: a) correlation screening and variance inflation factor (VIF) control to mitigate multicollinearity, and b) stepwise regression using AIC to retain parsimonious predictors. We report the final set of predictors in Table I.

TABLE I. Key Predictors Impacting Average Length of Stay (ALOS)

Variable	Coef.	Interpretation
Emergency_Rate	+0.043	Increases ALOS
Patient_Severity_Index	+0.037	Prolongs stay
Satisfaction_Score	-0.031	Reduces stay duration
Total_Hospital_Charges	+0.022	Associated with longer stay

We evaluated the model using 5-fold cross-validation and report the average values of R^2, RMSE, and MAE across folds. The coefficient of determination ($R^2 = 0.86$) indicates that 86% of the variability in ALOS is explained by the model. The RMSE of 0.38 days reflects limited quadratic prediction error, while the MAE of 0.48 days suggests that the average absolute deviation between predicted and observed ALOS remains below half a day, indicating stable and clinically acceptable predictive performance.

The feature correlations are illustrated in Fig. 1.

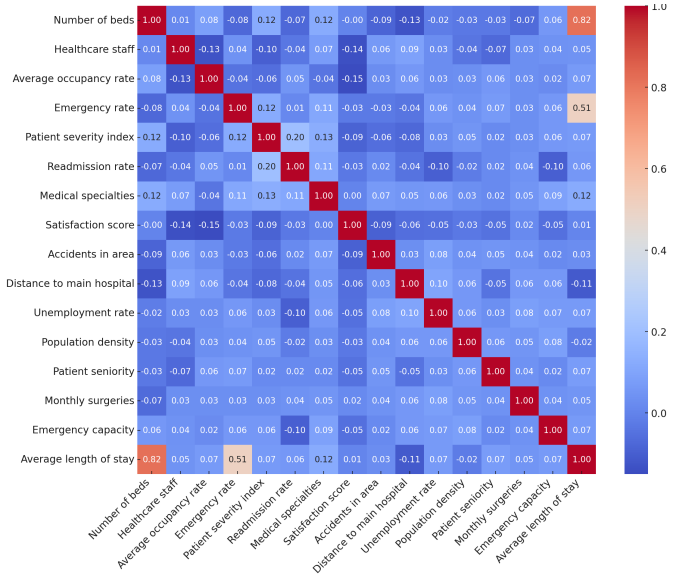

Fig. 1. Correlation matrix between input features and ALOS.

5) Operational role of MLR: Rather than acting as a decision-maker, MLR provides anticipatory information that feeds the downstream decision layer. Predicted ALOS values quantify expected resource occupation and are explicitly embedded into the MDP state representation.

B. Decision Layer: Crisis-Aware Admission Control via MDP

The Markov Decision Process (MDP) is not used to compute an optimal policy in the classical sense. Instead, it represents a constrained, explainable approximation of an optimal MDP policy, suitable for crisis contexts where transition probabilities are uncertain or rapidly evolving [7], [8].

1) State and action representation: Each MDP state captures the current operational condition of the hospital, including bed availability, ICU load, patient severity, and predicted ALOS from the MLR model. The action space is deliberately

restricted to three clinically meaningful decisions: *admit*, *wait-list*, or *reject*.

2) Formal MDP definition and coupling with MLR: We model admission control as a Markov Decision Process (MDP) defined by the tuple $M = (S, A, P, R, \gamma)$, following the classical MDP formulation [9]. Each state $s_t \in \mathcal{S}$ summarizes the hospital operational condition at decision time t:

$$s_t = \left(b_t, o_t, \bar{a}_t, \hat{\ell}_t, \sigma_{\hat{\ell},t}, u_t\right) \tag{2}$$

where, b_t is the number of available beds, o_t is the ICU occupancy level, $\bar{a}_t$ denotes arrival pressure (e.g., emergency rate), $\hat{\ell}_t$ is the MLR-predicted ALOS for the incoming patient (or cohort), $\sigma_{\hat{\ell},t}$ is the prediction uncertainty (estimated from residual variance), and u_t denotes patient acuity/severity.

The action space is $\mathcal{A} = \{\textit{Admit}, \textit{Waitlist}, \textit{Reject}\}$.

Transition dynamics are expressed as:

$$\mathcal{P}(s_{t+1} \mid s_t, a_t) \tag{3}$$

where, bed availability evolves according to admissions/discharges:

$$b_{t+1} = b_t - \mathbb{I}[a_t = \textit{Admit}] + d_t \tag{4}$$

and d_t represents discharges, approximated using the predicted LOS distribution induced by $\hat{\ell}_t$.

The reward function encodes clinical utility and congestion penalties:

$$\begin{aligned}\mathcal{R}(s_t, a_t) = \alpha u_t \mathbb{I}[a_t = \textit{Admit}] - \beta \mathbb{I}[b_t = 0 \wedge a_t = \textit{Admit}] \\ - \gamma_1 \hat{\ell}_t \mathbb{I}[a_t = \textit{Admit}] - \gamma_2 \sigma_{\hat{\ell},t} \mathbb{I}[a_t = \textit{Admit}]\end{aligned} \tag{5}$$

where, $\alpha, \beta, \gamma_1, \gamma_2 \geq 0$ balance severity prioritization, overflow risk, expected resource occupation, and robustness to prediction uncertainty.

3) Decision logic and interpretation: The reward structure reflects institutional priorities rather than numerical optimality. Admissions associated with long predicted stays are penalized under high occupancy, while high-severity patients are prioritized. As a result, the derived policy acts as a decision-guidance mechanism that balances urgency and sustainability.

4) Illustrative admission decisions: Algorithm 1 presents a simplified rule-based representation of the MDP-derived logic, introduced for interpretability only.

Algorithm 1 MDP-Based Admission Policy

Require: CurrentBeds, TotalBeds,
SeverityIndex, PredictedALOS
Ensure: AdmissionDecision
if CurrentBeds $\geq$ TotalBeds **then**
  AdmissionDecision $\leftarrow$ Reject
else
  if SeverityIndex ≥ 8 **then**
    AdmissionDecision $\leftarrow$ Admit
  else if PredictedALOS ¡ 5 **then**
    AdmissionDecision $\leftarrow$ Admit
  else
    AdmissionDecision $\leftarrow$ Waitlist
  end if
end if
return AdmissionDecision

Representative admission outcomes are reported in Table II, illustrating how severity and predicted ALOS jointly shape decisions under constrained capacity.

TABLE II. MDP DECISIONS BASED ON PRIORITY SCORE COMBINING SEVERITY INDEX AND PREDICTED ALOS.

Patient	Severity Index	Predicted ALOS	Priority Score	MDP Decision
P1	7	8.29	9.86	Waitlist
P2	4	5.98	5.01	Waitlist
P3	8	4.46	13.77	Admit
P4	5	6.97	6.51	Waitlist
P5	7	3.22	12.39	Admit
P6	3	8.90	1.55	Reject
P7	7	6.15	10.93	Admit
P8	8	5.77	13.12	Admit
P9	5	9.49	5.26	Waitlist
P10	4	8.09	3.95	Reject

C. Formal Validation Layer: Petri Net Modeling

Petri Nets are used as a formal verification and simulation layer to validate the feasibility and safety of MDP-driven decisions within hospital workflows [10], [11].

1) Reachability analysis: A Petri Net is defined as:

$$PN = (P, T, F, W, M_0)$$

and its reachability graph enumerates all possible system states reachable from the initial marking [13], [14]. Reachability analysis enables the verification of critical properties such as deadlock-freeness, boundedness, and guaranteed admission of high-priority patients. This positions Petri Nets as the scientific validation core of the proposed framework.

D. Methodological Complementarity

In summary:

- MLR anticipates future resource demand,
- The MDP provides explainable decision guidance under uncertainty,
- Petri Nets formally validate workflow consistency.

This layered architecture ensures predictive, decision-oriented, and formally verified crisis-aware optimization.

IV. Comparative Example Analysis of Decision-Aware and Direct Petri Net Modeling

This section presents a comparative example analysis between two hospital workflow modeling approaches under crisis conditions, highlighting the analytical benefits of introducing a decision layer prior to Petri Net construction.

A. Method A: Direct Petri Net Modeling

In the baseline approach, the hospital workflow is modeled directly as a Petri Net without explicit decision constraints. Patient arrivals, admissions, treatments, and discharges are represented as transitions, while hospital resources are modeled as bounded places.

The initial marking is defined as:

$$M_0 = (1, 0, 0, 0, 0, 0),$$

Indicating that one patient enters the system while all other places are initially empty. By firing all enabled transitions, a corresponding reachability graph is obtained. Although this approach accurately captures workflow dynamics, it generates a large and weakly constrained state space that may include clinically unrealistic configurations.

B. Method B: MLR $\rightarrow$ PDM $\rightarrow$ Petri Net Modeling (Proposed)

The proposed approach introduces a decision layer prior to Petri Net construction. Admission decisions are regulated by the Resource Logic Model (RLM) and the Process Decision Model (PDM), derived from the MDP framework and informed by predicted ALOS. Only policy-compliant decisions are translated into Petri Net transitions.The resulting decision-aware Petri Net structure is shown in Fig. 2.

In particular, transitions from waitlist to admission are enabled exclusively when priority and resource availability conditions are satisfied.

C. Reachability Graph Derived from the Decision-Aware Model

The reachability graph associated with the proposed modeling chain is shown in Fig. 3. Each node corresponds to a feasible system configuration, while edges represent authorized transition firings. Compared to direct Petri Net modeling, the reachability graph is significantly more compact and structured, containing only clinically admissible and resource-feasible states.

D. Comparative Discussion

The comparison highlights three major advantages of the proposed approach:

- Controlled State-Space Complexity: Decision constraints limit unnecessary reachability expansion.
- Decision Alignment: Petri Net execution remains consistent with MDP-based admission priorities.
- Formal Verifiability: Boundedness, liveness, and deadlock-freeness are easier to establish.

E. Interpretation and Practical Implications

This comparative example confirms that integrating decision intelligence prior to Petri Net modeling produces a more interpretable and analytically tractable system. The proposed modeling chain preserves workflow realism while preventing state-space explosion, making it particularly suitable for crisis-aware healthcare management.

F. Computational Complexity and Runtime Considerations

The predictive layer (MLR) performs inference in $O(pd)$ per time step, where p denotes the number of predictors and d the number of patients scored at that step. The decision layer relies on a compact discrete-state representation; under the proposed rule-based approximation, policy evaluation is $O(1)$ per patient decision.

Petri Net reachability analysis is exponential in the worst case. To mitigate state-space explosion, we constrain both the initial marking and the set of policy-compliant transitions, thereby limiting the number of reachable states.

We report runtimes measured on a standard workstation for: 1) MLR inference per patient, 2) decision computation per patient, and 3) reachability graph construction for the considered markings. Finally, we discuss scalability to multi-department settings by decomposing the global Petri Net into interacting subnetworks and evaluating departments in parallel.

V. Petri Net Modeling and Analysis

Fig. 4 presents a Petri Net model designed to represent patient flow and hospital resource management under global crisis conditions. The model follows the classical Petri Net formalism, which has been widely applied to healthcare process modeling [13], [14], [16].

A. Places and Transitions

Places represent critical system states and hospital resources, including Emergency Capacity, Emergency Rate, Personnel, Beds, Operations, and Satisfaction. Each place captures the availability or status of a resource or patient group at a given time.

Transitions correspond to operational events that modify the system state, such as Emergency Visits, Admission, Treatment, Operations, and Evaluation. Transition firings consume and generate tokens, which represent patients or resources flowing through the hospital system.

The model dynamics explicitly encode causal dependencies:

- Admission depends on emergency capacity, emergency rate, population density, patient age, accident zone proximity, and distance to the hospital, reflecting a multi-criteria admission decision process.
- Treatment requires the simultaneous availability of beds and medical personnel.
- Patients requiring surgery pass through the Operations transition, mobilizing specialized resources.

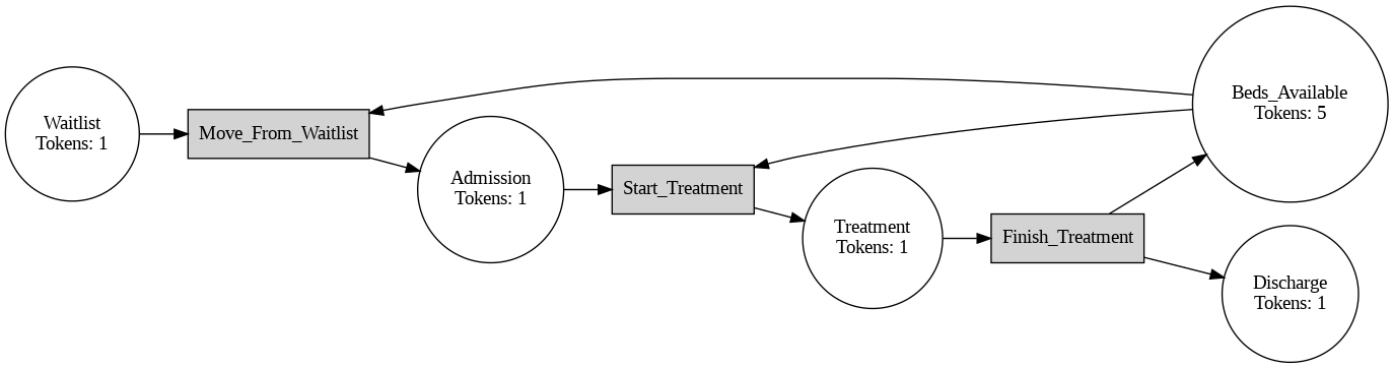

Fig. 2. Petri Net representation of patient flow derived from PDM and MDP policy.

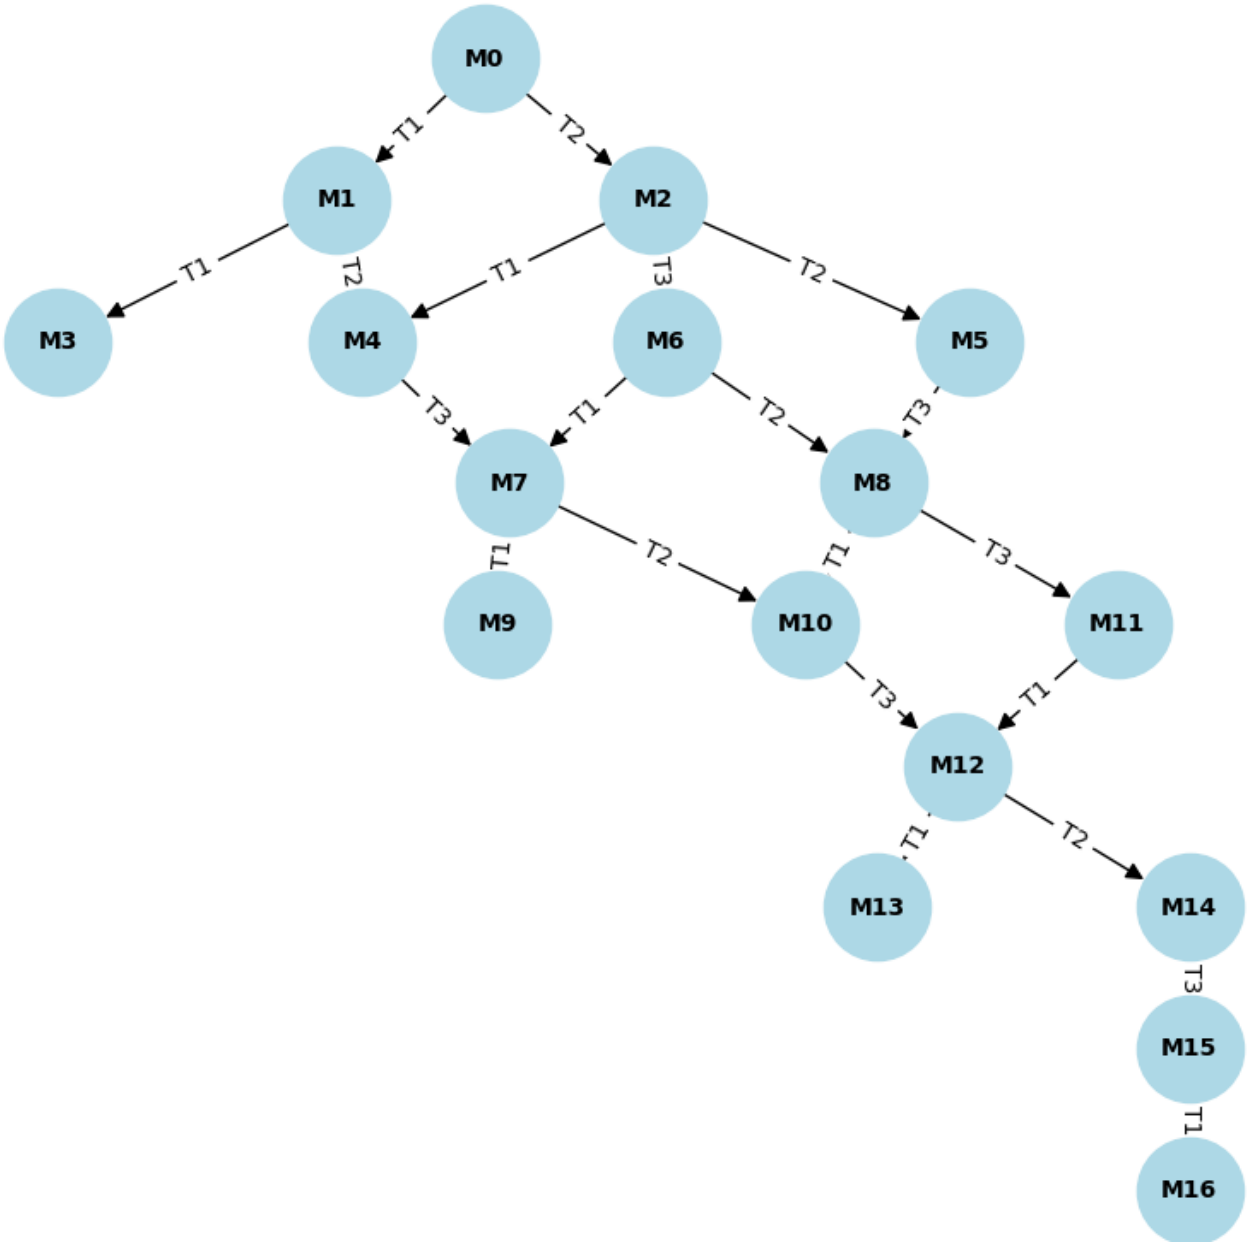

Fig. 3. Reachability graph derived from MLR → PDM → Petri Net.

- A subset of treated patients may undergo Readmission, affecting system congestion and satisfaction.
- The Evaluation transition aggregates outcomes such as occupancy, treatment completion, and readmissions to assess system performance.
- The Satisfaction place reflects patient-perceived quality of care.

B. Functional Support of the Petri Net Model

The Petri Net model supports:

- analysis of patient and resource flows,
- identification of bottlenecks and capacity limits,
- formal verification of boundedness, liveness, and deadlock-freeness,
- evaluation of prioritization and allocation strategies.

When integrated with decision and optimization models (e.g., MDPs and learning-based policies), the Petri Net provides a formal validation layer, ensuring that decision-driven hospital operations remain safe and feasible during crisis scenarios.

VI. Initial Marking and Reachability Graph Analysis

A. Initial Marking M_0

The initial marking M_0 defines the starting configuration of the hospital system. It specifies the initial distribution of tokens across places, each token representing a patient or an available resource.

$$M_0 = [1, 2, 0, 2, 0, 0, 1, 0, 1, 1, 1, 1, 1, 0, 1].$$

Each component corresponds to a specific place in the Petri Net. For instance:

- Place P1 contains one token, representing a patient ready for admission.
- Place P2 contains two tokens, representing two available beds.

This initial configuration represents a controlled and realistic hospital state, suitable for detailed reachability analysis.

B. Reachability Graph Analysis

Starting from M_0, all enabled transitions are recursively fired to generate the reachability graph, shown in Fig. 5. Each node represents a reachable marking, while edges correspond to transition firings.

To avoid combinatorial explosion, the initial marking intentionally includes a limited number of patient tokens. This ensures that all reachable states can be exhaustively analyzed while preserving graph interpretability.

The resulting reachability graph:

- captures all admissible system evolutions,
- illustrates resource consumption and release cycles,
- reaches terminal states under defined operational constraints,
- reflects realistic hospital dynamics.

These results confirm that the Petri Net model is bounded, live, and operationally valid.

1) Operational KPIs from petri net simulation: Beyond structural properties (boundedness, liveness, deadlock-freeness), we quantify: i) throughput time, ii) resource utilization, and iii) bottleneck intensity.

Let N_D be the number of completed discharges over horizon T. The throughput is:

$$\text{Throughput} = \frac{N_D}{T}. \tag{6}$$

For a resource place P_r (e.g., beds or personnel) with capacity C_r, utilization is:

$$\text{Utilization}(P_r) = \frac{1}{T} \int_0^T \frac{m_r(t)}{C_r}\, dt, \tag{7}$$

where, $m_r(t)$ is the marking of P_r at time t. A bottleneck is identified when utilization remains above a threshold (e.g., > 0.85) while queue places (e.g., waitlist) accumulate tokens.

VII. Integration with Robotic Systems

A. Illustrative Scenario

To illustrate the interaction between Multiple Linear Regression (MLR), Markov Decision Processes (MDPs), and Petri Nets (PNs), we consider a hospital facing a COVID-19 surge with limited capacity (50 beds). The objective is to optimize patient admission and resource utilization in real-time.

1) Step 1: Forecasting with MLR: The MLR model predicts the Average Length of Stay (ALOS) using patient-specific features such as age, severity, and admission type. Predicted ALOS values (e.g., 7, 4, and 2 days) estimate future bed occupancy and inform downstream decision-making.

2) Step 2: Decision-making with MDP: The MDP incorporates predicted ALOS together with the current hospital state (available beds, patient severity) to derive an admission policy. The reward function balances patient survival, throughput, and bed utilization, ensuring prioritization of critical cases while maintaining operational flow.

3) Step 3: Simulation and validation with petri nets: Decisions produced by the MDP are injected into the Petri Net model, which simulates patient and resource transitions. Places represent treatment states and resources, transitions model admission, treatment, and discharge events, and tokens represent patient flow. The Petri Net verifies that MDP-driven decisions preserve boundedness and avoid deadlock. Similar Petri Net models have been used to coordinate human–robot collaboration in surgical environments [21].

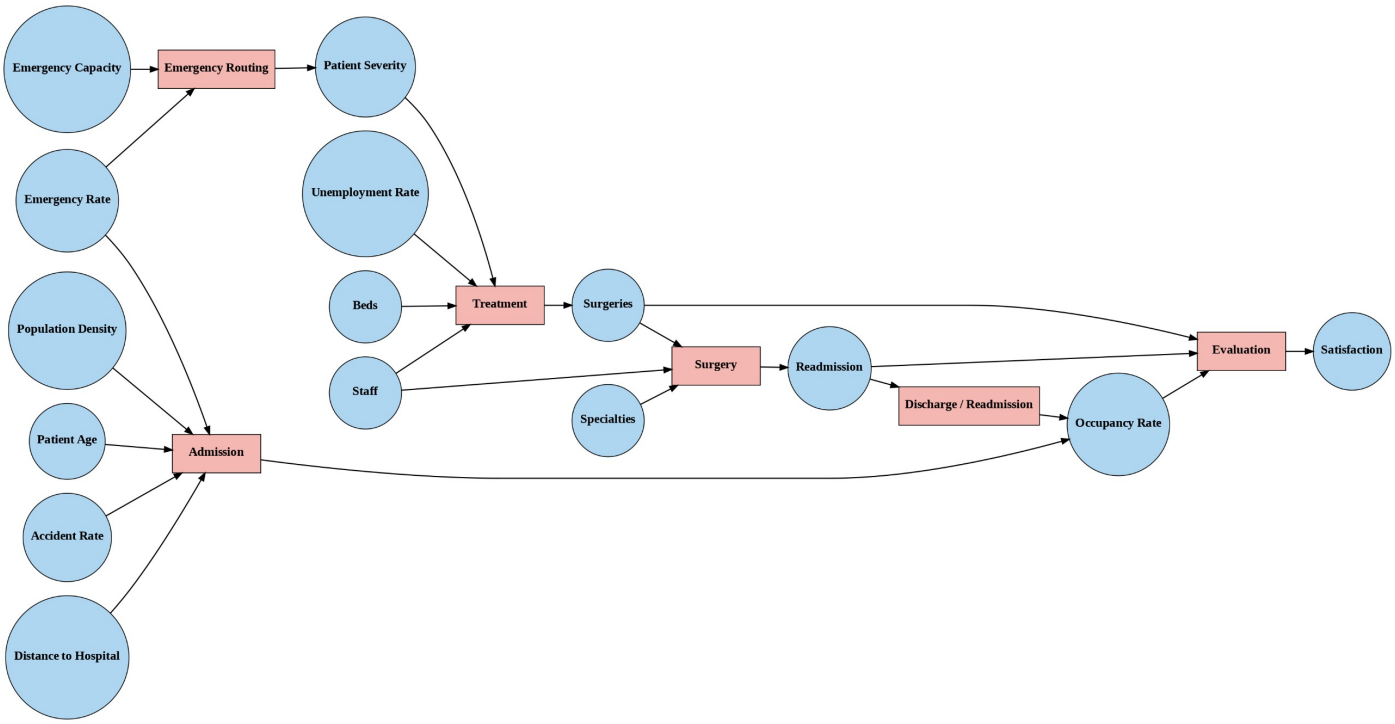

Fig. 4. Petri Net model with extended operational states and resource dependencies.

4) Integrated workflow: This pipeline combines prediction, decision optimization, and formal validation to support intelligent robotic systems for healthcare crisis management.

$$\textbf{MLR} \rightarrow \textbf{MDP} \rightarrow \textbf{Petri Net} \rightarrow \textbf{Simulation}$$

B. Priority-Based Decision Mechanism

Based on MLR predictions, patients are ranked using a Priority Score:

$$\text{Priority Score} = (\alpha \cdot \text{Severity Index}) - (\gamma \cdot \text{Predicted ALOS}),$$

where α and γ control the trade-off between clinical urgency and expected resource occupation.

Admission decisions follow:

- Admit if the Priority Score exceeds threshold θ_1,
- Waitlist if the score lies between θ_2 and θ_1,
- Reject if the score falls below θ_2.

This mechanism ensures fairness, efficiency, and transparency, enabling adaptive and explainable decision-making suitable for robotic healthcare systems.

C. Stress-Testing Prediction Errors and Policy Robustness

To evaluate robustness, we perturb the MLR outputs by additive noise: $\tilde{\ell} = \hat{\ell} + \epsilon$, $\epsilon \sim \mathcal{N}(0, \sigma^2)$, and measure policy stability as the percentage of actions unchanged under perturbations. We report: 1) decision flip rate, 2) overflow events, and 3) average congestion (waitlist tokens) as functions of σ. This analysis quantifies how forecasting uncertainty propagates through admission decisions and affects hospital dynamics.

VIII. Conclusion

This study presented an integrated computational framework combining MLR, MDPs, and Petri Nets to optimize healthcare robotics in crisis scenarios. The proposed system demonstrates strong predictive performance, supports real-time decision-making under uncertainty, and validates hospital workflows through formal modeling.

A. Key Contributions

The main contributions of this work are summarized as follows:

- Development of a unified MLR–MDP–Petri Net framework tailored to crisis-resilient healthcare robotics and hospital resource allocation.
- Integration of predictive analytics (ALOS forecasting) into robotic decision workflows, improving adaptability, bed turnover, and coordination during surge conditions.
- Validation of the framework through case studies such as ICU bed prioritization and crisis logistics, demonstrating improvements in responsiveness, efficiency, and patient outcomes.
- Comparative analysis of reachability graphs, showing that the RLM $\rightarrow$ PDM $\rightarrow$ Petri Net chain provides

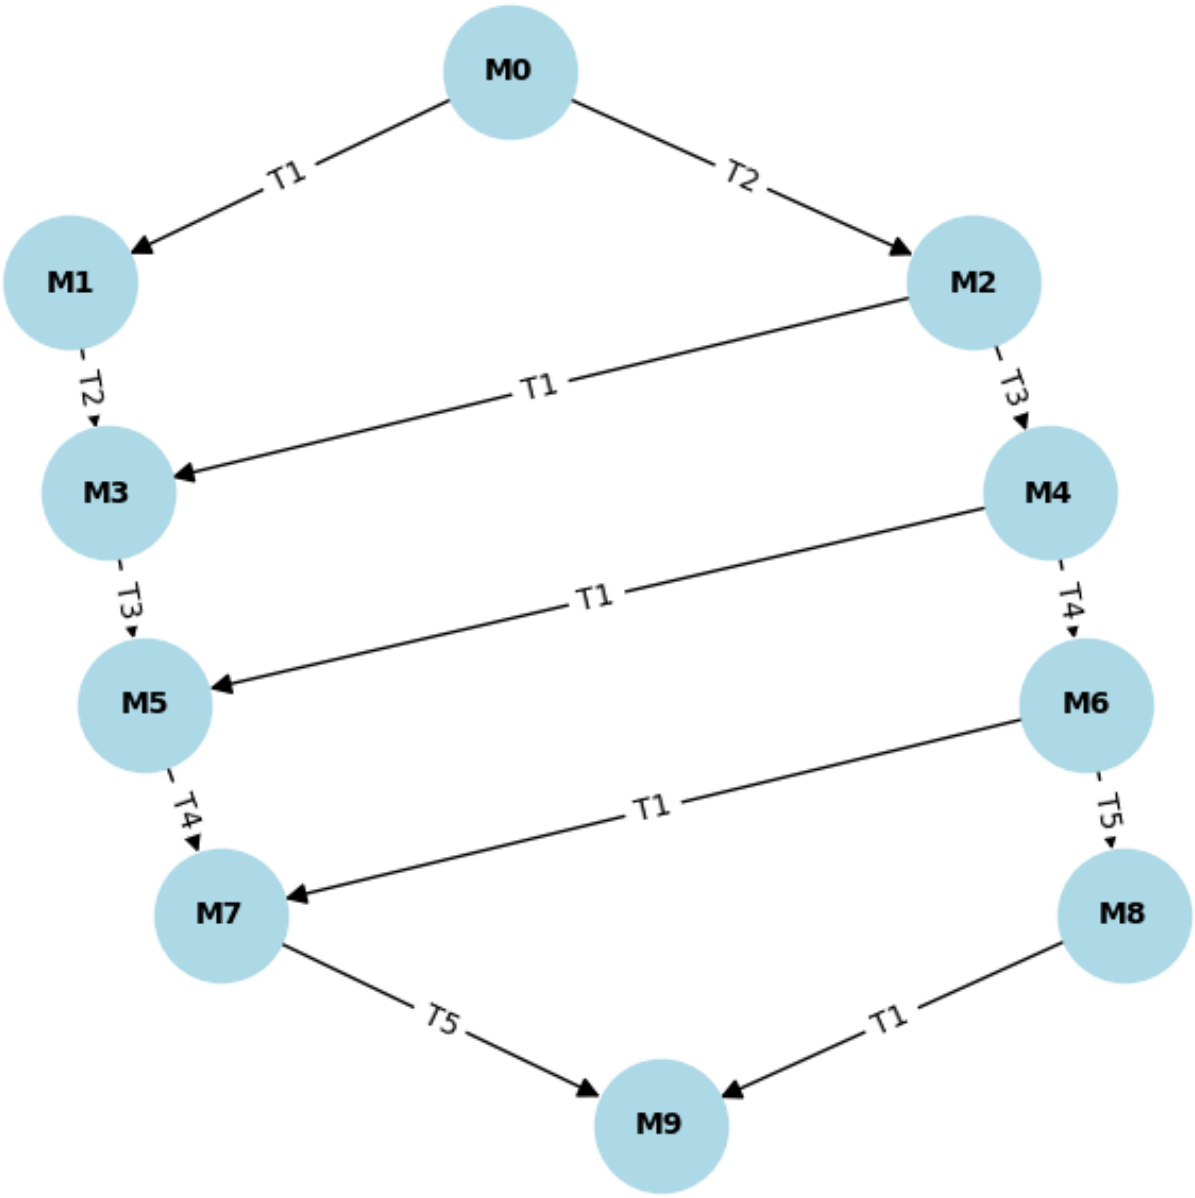

Fig. 5. Reachability graph derived from the initial marking M0, illustrating possible hospital system evolutions.

optimized decision paths while preserving analytical tractability.

Beyond these contributions, this study highlights that reachability graphs are a powerful tool to verify essential system properties such as liveness and boundedness. They provide transparency in analyzing distributed systems, hospital workflows, and robotic decision protocols under stress conditions.

B. Future Perspectives

An important direction for future work is the integration of MDPs with Deep Reinforcement Learning (DRL). Combining these techniques would allow healthcare robots to:

- Learn continuously from real-time sensor data and improve decision-making through experience.
- Adapt dynamically to unpredictable and rapidly evolving clinical environments.
- Optimize multi-agent coordination, where multiple autonomous robots collaborate to enhance hospital workflow efficiency.

This evolution in computational modeling contributes to the advancement of structured decision-support frameworks for healthcare robotics. By coherently integrating predictive modeling, decision optimization, and formal workflow validation, the proposed approach illustrates how interdisciplinary modeling techniques can enhance hospital adaptability under stress conditions. Although further empirical and large-scale

validation is required, such integrated methodologies provide a foundation for improving resilience and coordination in healthcare systems facing future crisis scenarios.

Recent digital twin frameworks further support the integration of predictive and operational models in healthcare systems [28].

Enhanced Ant Colony Optimization for Capacitated Vehicle Routing Problem with Time Windows in Franchise Distribution

Dian Rachmawati*, Tommy Lohil, Jos Timanta Tarigan
Faculty of Computer Science and Information Technology-Dept. of Computer Science,
Universitas Sumatera Utara, Medan, Indonesia

***Abstract*—Efficient routing for distributing goods to multiple franchisee locations requires optimization techniques capable of handling vehicle capacity limits, heterogeneous time windows, and operational constraints, making conventional brute-force or map-based approaches infeasible due to the NP-hard nature of the problem. This study presents an enhanced Ant Colony Optimization (ACO) algorithm for solving the Capacitated Vehicle Routing Problem with Time Windows (CVRPTW) in a franchisor–franchisee logistics setting. The proposed enhancement incorporates feasibility filtering to enforce capacity and time-window constraints during route construction and adaptive pheromone updating to improve convergence stability. Using real franchisee coordinates, demand values, and operational time windows, the experiments configured with α = 2, β = 1, ρ = 0.05, and a 150-iteration limit demonstrate that the enhanced ACO achieves a minimum total route distance of 46.90 km with zero variance across 10 simulations, indicating highly stable convergence. Comparative evaluation shows that the enhanced ACO improves route efficiency by 11.4% compared to standard ACO and 15.2% relative to a representative Genetic Algorithm baseline. Implemented in a web-based environment using JavaScript for visualization and Java for computation, the approach provides a practical decision-support tool for Indonesian franchise logistics. The algorithm exhibits an observed computational complexity of $\theta(n^4)$, making it suitable for small to medium-scale distribution networks involving strict delivery time windows.**

***Keywords*—Ant Colony Optimization; CVRPTW; heuristics; distribution routing; logistics optimization**

I. Introduction

The distribution of goods to several franchisee locations is a problem that is often faced by franchisors and distribution is usually carried out in a predetermined time cycle. One way that can be used is to use a map application to determine the distance between locations and implement a brute force algorithm in selecting the order in which franchisees must be visited. This approach is considered inefficient, especially since the distribution of goods is carried out quite often. In the real world [1], there are many other factors that become constraints such as vehicle capacity, number of vehicles, and the time period for receiving goods in each different franchisee must be considered as well. With the complexity of this problem, the brute force method approach is considered very inefficient to use and an application for assistance should be needed to solve the problem with a more optimal algorithm [2]. Based on data from Supply Chain Indonesia in 2020, logistics costs in Indonesia are in the first most expensive position in Asia, which is 24% of Gross Domestic Product (GDP) [3]. With the optimization of the freight route, it is hoped that it will help reduce logistics costs below 24% so that the Cost of Goods Sold (COGS) will be lower in Indonesia [3]. Efficient distribution routing is essential for franchisors managing recurrent delivery cycles across geographically dispersed franchisee locations, and traditional manual planning or brute-force search becomes impractical due to the combinatorial explosion of route possibilities.

This case fits perfectly with the Vehicle Routing Problem (VRP). The Vehicle Routing Problem is a combinatorial optimization problem solving by determining a suitable route for vehicles from the beginning of the depot to several locations and back to the starting point of the depot by serving other locations on demand, and VRP is a generalization of the Traveling Salesman Problem (TSP) [4]. One variation of VRP is the Capacitated Vehicle Routing Problem with Time Windows (CVRPTW) which has a vehicle capacity limit and a time limit for each franchisee location [5]. Since CVRPTW is an NP-hard problem, consequently only a small scale of the problem can be solved using appropriate methods [6]. The alternative is to use a heuristic method that reduces the level of optimization of the exact solution, but the problem can be solved in a relatively short time [7]. These constraints become even more critical in real-world franchise distribution, where heterogeneous receiving time windows and limited fleet capacity significantly increase complexity [6].

One approach for solving the CVRPTW problem is the Ant Colony Optimization (ACO) algorithm. Based on a previous study entitled "A Comparative Analysis of Genetic Algorithm and Ant Colony Optimization for Mobile Augmented Reality Offloading", on the optimization using the Ant Colony algorithm, shows that Ant Colony Optimization is able to provide better solution quality and less computational time than Genetic Algorithm [8] [9]. Ant Colony Optimization also has several advantages such as parallel population-based searching, fast discovery of good solutions, and convergence guarantees [10]. Although many studies have applied Ant Colony Optimization to VRP variants, limited research has addressed Indonesian franchise distribution settings that involve strict time-window constraints and require tailored Ant Colony Optimization enhancements [11].

Based on this background, the author is interested in

conducting research on "Enhanced Ant Colony Optimization for Capacitated Vehicle Routing Problem with Time Windows in Franchise Distribution". The limitations contained in the issues raised are vehicle capacity limits, limited number of vehicles, and different time periods for receiving goods from each franchisee [5].

While numerous ACO variants have been proposed for VRP, this study addresses specific gaps in the existing literature by introducing three key technical contributions:

- Feasibility Filtering Mechanism: Unlike standard ACO which may explore infeasible paths during route construction, the proposed enhancement embeds real-time constraint checking that eliminates candidates violating capacity limits or time-window boundaries before probability computation. This differs from post-hoc penalty approaches [12] by preventing wasted computational effort on infeasible partial solutions.
- Adaptive Pheromone Evaporation: Rather than using fixed evaporation rates, the algorithm dynamically adjusts ρ based on solution improvement status—applying lower evaporation (0.05) during progress phases to preserve beneficial pheromone trails, and higher evaporation (0.10) during stagnation to encourage exploration. This mechanism directly addresses convergence stability and stagnation avoidance concerns raised in recent ACO literature [13].
- Empirical Validation on Indonesian Franchise Data: The algorithm is evaluated using real operational data from an Indonesian franchise distribution network, providing practical insights for logistics optimization in emerging market contexts where such studies remain limited [11].

The study further contributes by conducting comprehensive parameter sensitivity analysis justifying the selection of α, β, and ρ values, performing statistical robustness evaluation with standard deviation and Wilcoxon signed-rank tests across multiple trials, and benchmarking against both classical metaheuristics (standard ACO, Genetic Algorithm) and discussing positioning relative to modern solvers.

II. Related Work

A. Classical and Metaheuristic Approaches for CVRPTW

The authors in [14] present various solutions to solve CVRP problems using three methods, namely Brute-force Search/Exhaustive Search (exact method), Nearest Neighbor Insertion/NNI (heuristic method), and Ant Colony Optimization (meta-heuristic method) [7], with results showing that Ant Colony Optimization performs better than the other two approaches [2]. Additionally, [15] proposes an adaptive hybrid ant colony optimization algorithm that incorporates a genetic algorithm to solve the Capacitated Vehicle Routing Problem (CVRP), demonstrating effective performance through experimental evaluation. Research on VRP and CVRPTW commonly utilizes heuristics and metaheuristics, including brute-force search, nearest neighbor heuristics, Genetic Algorithms (GA), and Ant Colony Optimization (ACO), and studies such as [14], [12], [16], and [15] consistently show that Ant Colony Optimization often provides superior solution quality for complex routing problems.

The authors in [12] further explain how to optimally distribute Liquified Natural Gas (LNG) to several regasification terminals in Papua as fuel for Gas Power Plants (PLTG) using Ant Colony Optimization. Moreover, the authors in [16] examine Ant Colony Optimization enhanced with an additional proposed method, with mathematical results indicating that the proposed solution is highly promising and outperforms other algorithms used for comparison.

B. Hybrid Metaheuristic Approaches

Recent research has demonstrated that hybridizing ACO with other metaheuristics can significantly improve solution quality. Kao et al. [13] proposed a hybrid algorithm combining ACO and Particle Swarm Optimization (PSO) for CVRP, where each artificial ant memorizes its personal best solution similar to particles in PSO, and a pheromone disturbance method is embedded to overcome stagnation. Their computational results showed that the hybrid ACO-PSO performs competitively against existing swarm intelligence approaches.

Comert and Yazgan [17] developed a hierarchical approach integrating Hybrid ACO (HACO) with Artificial Bee Colony Algorithm (ABCA) for multi-objective electric vehicle routing problems. The first phase uses HACO with local search and simulated annealing for initial solution generation, followed by ABCA refinement. This demonstrates the effectiveness of combining constructive and improvement heuristics in routing optimization.

For larger-scale instances, Adaptive Large Neighborhood Search (ALNS) has gained prominence. Fan [18] proposed a Hybrid ALNS (HALNS) that synergistically integrates ACO's broad-based solution initialization with ALNS's localized search potency for time-dependent open electric vehicle routing problems. The strategic blend leverages ACO as a foundational layer for ALNS's deeper refinements.

C. Learning-Based Routing Approaches

Machine learning approaches have emerged as promising alternatives for solving VRP variants. Zong et al. [19] presented an end-to-end reinforcement learning framework for VRPTW that encodes constraints into features and conducts harsh policy on outputs when generating deterministic results. Their solution improved performance by up to 11.7% compared to other RL baselines while generating solutions within seconds.

Dornemann [20] proposed solving CVRPTW via graph convolutional network (GCN) assisted tree search, using deep neural networks to provide probability distributions that guide beam search. The non-autoregressive approach outperformed commercial solvers for large instances while maintaining competitive solution quality.

Deng et al. [21] introduced a multi-task multi-objective evolutionary search algorithm (MTMO/DRL-AT) that combines deep reinforcement learning with multitasking mechanisms for MOVRPTW with five conflicting objectives. The attention model trained using DRL serves as initial solution

generator, followed by knowledge transfer and local search operators.

D. Modern Exact and Commercial Solvers

For benchmarking purposes, modern exact solvers and optimization libraries provide important reference points. The Lin-Kernighan-Helsgaun (LKH) algorithm [22] represents state-of-the-art local search for TSP variants, with VSR-LKH-3 extension handling TSPTW through reinforcement learning integration. Google OR-Tools [23] offers industrial-grade routing solvers with constraint programming capabilities, though direct comparison requires careful consideration of problem-specific configurations.

E. Comparative Summary of Related Approaches

Table I summarizes the key characteristics of related approaches in the literature, while Table II presents their respective limitations.

TABLE I. COMPARATIVE SUMMARY OF RELATED APPROACHES FOR CVRPTW

Study	Method	Key Features	Problem
Kao [13]	ACO-PSO	Personal best, pheromone disturb	CVRP
Comert [17]	HACO-ABC	Two-phase, multi-obj	EVRP
Fan [18]	HALNS	ACO + ALNS refine	TDEVRP
Zong [19]	RL	End-to-end encoding	VRPTW
Dornemann [20]	GCN+Beam	Non-autoregressive	CVRPTW
Deng [21]	MTMO/DRL	Multi-task transfer	MOVRPTW
Ours	**Enh.ACO**	**Feasibility, adapt.ρ**	**CVRPTW**

TABLE II. LIMITATIONS OF RELATED APPROACHES

Study	Limitation
Kao et al. [13]	No time window constraints considered
Comert [17]	EV-specific constraints, not generalizable
Fan [18]	Time-dependent scenarios only
Zong et al. [19]	High training overhead required
Dornemann [20]	Supervised learning data required
Deng et al. [21]	Five objectives increase complexity
This Study	**Suitable for small-medium scale only**

F. Research Gaps and Contributions

Despite these advancements, several gaps remain in the literature: 1) limited application of ACO to Indonesian real-world franchise logistics, 2) few studies incorporating adaptive pheromone control with strict feasibility checks for operational time windows, 3) minimal reporting on solution stability across repeated trials with statistical validation, and 4) lack of systematic parameter sensitivity analysis justifying ACO configuration choices. This work addresses these gaps by integrating time-window feasibility into ACO decision rules, implementing adaptive evaporation based on convergence status, and providing comprehensive statistical evaluation of solution robustness.

III. METHODOLOGY

A. Problem Definition

The Capacitated Vehicle Routing Problem with Time Windows (CVRPTW) examined in this study involves determining efficient delivery routes that begin and end at a single depot while serving multiple franchisee locations, each with specific operational constraints. Every franchisee is characterized by a geographic coordinate, a demand quantity that must be fulfilled, and a delivery time window within which the vehicle must arrive. The distribution system uses a fleet of identical vehicles, each constrained by a maximum capacity of 10 units and a restricted maximum operational fleet size of eight vehicles. Throughout the routing process, a vehicle must start from the depot, visit franchisees while ensuring that its cumulative load does not exceed capacity, and reach each destination within the allowable time window. Otherwise, the route becomes infeasible and must be terminated. Additionally, each franchisee must be visited exactly once by only one vehicle, and its demand must be fully delivered. The primary objective of the CVRPTW is to minimize the total travel distance while generating complete and feasible routes that respect all constraints related to vehicle capacity, franchisee demand fulfillment, delivery time windows, and the maximum number of vehicles allowed [24]. Given that the dataset used in this research consists of seven franchisee nodes with varying demand levels, spatial positions, and time windows, the problem becomes computationally complex and cannot be solved using brute-force enumeration, thereby necessitating the use of an enhanced Ant Colony Optimization method to search for optimal and feasible routing solutions efficiently.

The Capacitated Vehicle Routing Problem with Time Windows (CVRPTW) can be formally defined on a complete directed graph $G = (V, A)$, where:

- $V = \{0, 1, \ldots, n\}$ is the set of nodes, where node 0 represents the depot and nodes $\{1, \ldots, n\}$ represent franchisees.
- $A = \{(i, j) : i, j \in V, i \neq j\}$ is the set of edges connecting all pairs of nodes.
- d_{ij} denotes the travel distance between nodes i and j.
- t_{ij} is the travel time from node i to node j.

Each franchisee $i \in \{1, \ldots, n\}$ has:

- Demand q_i
- Time window $[e_i, l_i]$
- Service time s_i

A homogeneous fleet of K vehicles is available, each with capacity Q.

B. Ant Colony Optimization

Wang, L. & Singh, C. (2008) revealed that there are five basic steps of the Ant Colony System [25]:

1) Initialization: In this phase, each ant is given a starting point of a node and a random initial value of the pheromone of each edge of the graph.

2) Tour construction: In this phase, each ant chooses the next node based on the probability of a shorter path and a more concentrated pheromone. This process is repeated until all the ants have completed their respective tours. The probability of ant k at node i selecting node j as the next destination is given by:

$$P_{ij}^k = \frac{[\tau_{ij}]^\alpha [\eta_{ij}]^\beta}{\sum_{l \in N_i^k} [\tau_{il}]^\alpha [\eta_{il}]^\beta}, \quad j \in N_i^k \tag{1}$$

where, τ_{ij} is the pheromone level on edge (i, j), $\eta_{ij} = 1/d_{ij}$ is the heuristic visibility (inverse of distance), α is the pheromone influence parameter, β is the heuristic influence parameter, and N_i^k is the set of feasible nodes that ant k has not yet visited.

3) Fitness evaluation: Fitness value is evaluated from the performance of each ant after all tours are completed.

4) Trial intensity updating: The pheromone from each side of the graph that is traversed will have a pheromone update operation because over time, the number of pheromones will also decrease due to evaporation. The pheromone update rule is defined as:

$$\tau_{ij}^{\text{new}} = (1 - \rho) \cdot \tau_{ij}^{\text{old}} + \sum_{k=1}^{m} \Delta\tau_{ij}^k \tag{2}$$

where, $\rho \in (0, 1)$ is the evaporation rate, m is the number of ants, and $\Delta\tau_{ij}^k$ is the pheromone deposited by ant k on edge (i, j):

$$\Delta\tau_{ij}^k = \begin{cases} \dfrac{1}{L_k} & \text{if ant } k \text{ traverses edge } (i, j) \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

where, L_k is the total tour length of ant k.

5) Stopping criteria: The previous optimization process will end when the iteration has reached the last iteration.

C. Proposed Enhancement: Feasibility Filtering and Adaptive Pheromone Updating

To strengthen the traditional Ant Colony Optimization (ACO) for solving the CVRPTW, two main enhancements are introduced in this study: 1) time-window feasibility filtering and 2) adaptive pheromone updating. These mechanisms ensure that ants construct only feasible routes and converge more effectively toward high-quality solutions.

1) Feasibility filtering for time-window constraints: In classical ACO, ants may select the next node solely based on pheromone intensity and heuristic visibility, often resulting in routes that violate time windows or capacity constraints. To address this limitation, a feasibility-checking mechanism is embedded into the tour-construction step.

For every ant positioned at node i, a candidate next node j is considered feasible only if it satisfies both:

- Capacity feasibility

$$\text{Load}_k + q_j \leq Q$$

- Time-window feasibility

$$T_i + s_i + t_{ij} \leq b_j$$

If the ant arrives early:

$$T_j = \max(a_j, T_i + s_i + t_{ij}) \tag{4}$$

If the ant arrives later than b_j:

Node j is **discarded** from the candidate set N_i.

Thus, the probability rule is modified to operate on the **filtered candidate set**:

$$P_{ij} = \begin{cases} \dfrac{\tau_{ij}^\alpha \eta_{ij}^\beta}{\sum_{h \in N_i^{\text{feasible}}} \tau_{ih}^\alpha \eta_{ih}^\beta} & j \in N_i^{\text{feasible}} \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

This enhancement prevents ants from exploring infeasible routes, significantly reducing search space and increasing solution quality.

2) Adaptive pheromone updating: Classical ACO uses a fixed evaporation rate (ρ) and uniform pheromone reinforcement, which may slow convergence or cause stagnation. To improve stability, this study introduces an adaptive pheromone update mechanism based on route quality and feasibility.

After each iteration, pheromone on edges used in feasible routes is updated as:

$$\tau_{ij}^{\text{new}} = (1 - \rho_{\text{adaptive}})\tau_{ij}^{\text{old}} + \sum_{k=1}^{m} \Delta\tau_{ij}^k \tag{6}$$

where, the adaptive evaporation rate is defined as:

$$\rho_{\text{adaptive}} = \begin{cases} 0.05, & \text{if global best distance improves} \\ 0.10, & \text{otherwise} \end{cases} \tag{7}$$

This strategy applies:

- Lower evaporation (0.05) when ants are progressing $\rightarrow$ keeps good paths longer
- Higher evaporation (0.10) when stagnation begins $\rightarrow$ forces exploration

Pheromone reinforcement is given by:

$$\Delta\tau_{ij}^k = \begin{cases} \dfrac{1}{L_k}, & \text{if edge } (i, j) \text{ is in ant } k \\ 0, & \text{otherwise} \end{cases} \tag{8}$$

where, L_k is the total distance of ant k's route.

3) Impact of the enhancements: These two mechanisms jointly enhance the ACO algorithm by:

- Reducing infeasible partial routes during construction
- Eliminating wasted exploration on impossible time-window sequences
- Improving convergence speed by adapting evaporation dynamically
- Increasing stability across repeated trials

This explains the consistent convergence results reported in the experiments, where the enhanced ACO achieved 46.90 km in all 10 simulations.

D. Termination Criteria

The algorithm employs a hybrid termination strategy combining iteration-based and stagnation-based criteria:

1) Maximum iteration limit: The algorithm terminates when the iteration counter t reaches the predefined maximum $t_{\max} = 150$. This ensures bounded execution time regardless of convergence behavior.

2) Stagnation detection: If the global best solution L^* does not improve for $\theta_{\text{stag}} = 30$ consecutive iterations, the algorithm considers the search stagnated. At this point, the adaptive mechanism increases evaporation rate to $\rho = 0.10$ to encourage exploration of alternative solution regions.

3) Convergence criterion: The algorithm monitors solution variance across the ant population. When variance falls below threshold $\epsilon = 0.001$ km for 10 consecutive iterations, the population is considered converged.

The termination condition is formally expressed as:

$$\text{Terminate if: } t \geq t_{\max} \text{ OR } (\sigma^2(L) < \epsilon \text{ for } 10 \text{ iterations}) \tag{9}$$

where, $\sigma^2(L)$ denotes the variance of route distances across all ants in the current iteration.

E. Pseudocode and Flowchart

The computational procedure of the ACO algorithm implemented in this study follows the classical structure introduced by Dorigo [26], consisting of route construction, fitness evaluation, and pheromone updates. For clarity, the simplified pseudocode of the implemented method is presented as follows (see Algorithm 1):

Algorithm 1 Enhanced ACO for CVRPTW with Feasibility Filtering and Adaptive Pheromone

Require: Customer set $V = \{1, ..., n\}$, depot 0, distance matrix d_{ij}, demands q_i, time windows $[a_i, b_i]$, vehicle capacity Q, parameters α, β, $\rho_{\text{low}} = 0.05$, $\rho_{\text{high}} = 0.10$, $t_{\max} = 150$, m ants
Ensure: Best solution S^* and best distance L^*

Initialize:
$\tau_{ij} \leftarrow 1$ for all edges (i, j) ▷ Initial pheromone
$\eta_{ij} \leftarrow 1/d_{ij}$ for all edges (i, j) ▷ Heuristic visibility
$L^* \leftarrow \infty$, $S^* \leftarrow \emptyset$, stagnation_count $\leftarrow 0$
for $t = 1$ to $t_{\max}$ **do**
  for $k = 1$ to m **do** ▷ Each ant constructs solution
    $\text{Load}_k \leftarrow 0, T_k \leftarrow \min_i(a_i), \text{Route}_k \leftarrow [0]$
    Unvisited $\leftarrow V$
    while Unvisited $\neq \emptyset$ **do**
      $i \leftarrow$ current node of ant k
      Feasibility Filtering:
      $F_i \leftarrow \{j \in \text{Unvisited} : \text{Load}_k + q_j \leq Q \wedge T_k + t_{ij} \leq b_j\}$
    end while
  end for
end for

To clarify the operational steps of the enhanced ACO algorithm, the experimental results in Fig. 1 summarize the main outcomes, including: A) route visualization in Cartesian coordinates, B) detailed route information with arrival times, and C) parameter tuning analysis across different configurations.

F. Dataset and Parameters

The dataset used in this study consists of seven franchisee locations, each represented by a pair of geographic coordinates, a specific demand value, and an assigned delivery time window that determines the earliest and latest permissible arrival times. These attributes reflect a realistic distribution scenario in which the franchisor must deliver goods to multiple outlets under strict operational constraints. All deliveries originate from a central depot, and routing decisions must account for the spatial layout of the franchisees. To support distance-based optimization, a complete Euclidean distance matrix is constructed using the coordinate data, enabling precise calculation of travel distances between every pair of nodes in the network. The vehicle fleet employed in this problem is homogeneous, with each truck having a maximum carrying capacity of 10 units, and the total fleet size is limited to eight vehicles, ensuring adherence to practical distribution limitations. The Ant Colony Optimization (ACO) algorithm used to solve the CVRPTW instance is configured with several parameter combinations to evaluate sensitivity and performance. The pheromone influence factor is set within the range $\{1.5, 2\}$, while the heuristic visibility factor takes values from $\{1, 1.5\}$, allowing variation in the balance between learned pheromone trails and distance-based heuristics. The pheromone evaporation rate is tested at $\{0.05, 0.1\}$, governing how quickly the algorithm forgets previously explored paths. The maximum number of iterations is fixed at 150, ensuring sufficient search depth for convergence. Together, these dataset attributes and parameter settings form the foundational configuration for conducting the routing

simulations and evaluating the performance of the enhanced Ant Colony Optimization approach.

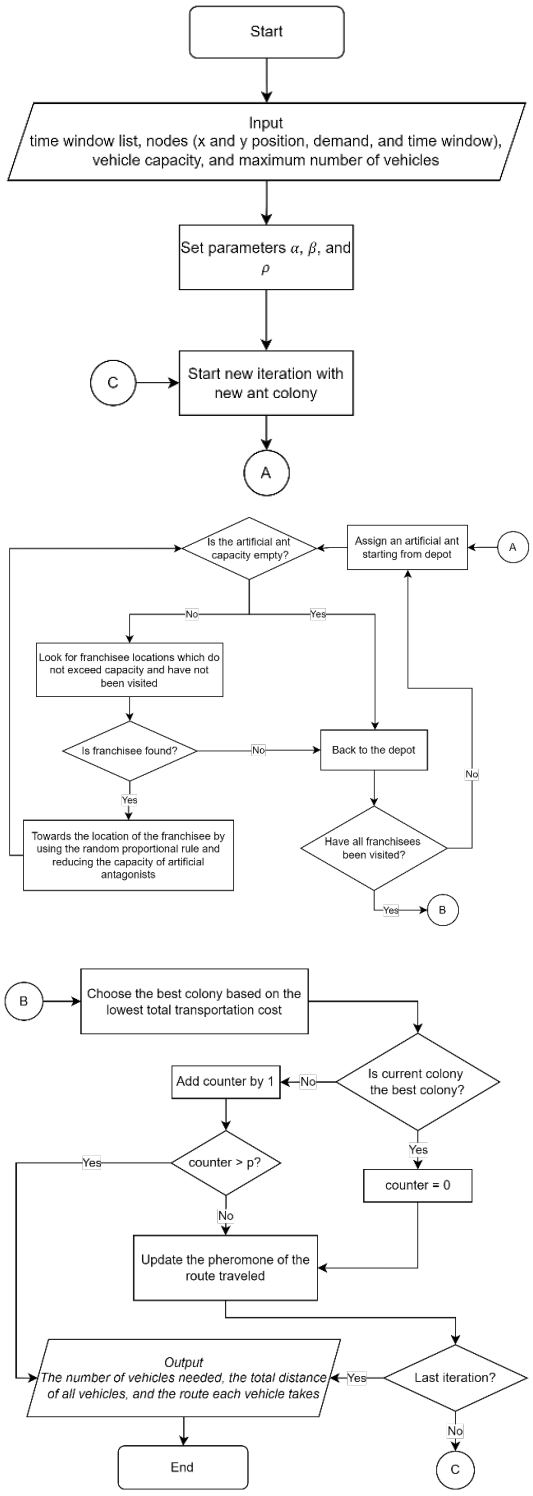

Fig. 1. Flowchart of the Ant Colony Optimization (ACO)–based vehicle routing algorithm considering vehicle capacity and time window constraints. Marker: (A) Denotes the next-node selection decision process, (B) Denotes the best-colony selection and pheromone update stage, and (C) Denotes the start of a new algorithm iteration.

IV. Implementation

A. Input Parameters

In this research implementation, there are severals input parameters, such as time window list, franchisees (nodes) information, vehicle capacity, and maximum number of vehicles. Franchisee and time windows input is shown in Table III and Table IV.

TABLE III. Input Franchisees

Index	X Coordinate	Y Coordinate	Demand	Time Window
0	-4.56	3.07	3.2	08:00-12:00
1	-6.01	-1.15	3.1	12:00-16:00
2	-4.69	-3.02	2.7	08:00-12:00
3	-0.83	-4.09	0.6	16:00-20:00
4	5.22	-1.04	2.7	12:00-16:00
5	0.13	4.48	1.5	16:00-20:00
6	-3.19	3.8	1.1	12:00-16:00

TABLE IV. Input Time Windows

Index	Start time	End time
0	08:00	12:00
1	12:00	16:00
2	16:00	20:00

Maximum number of trucks = 8.

Truck capacity = 10 unit (homogeneous).

B. Euclidean Distance Matrix

After getting Cartesian coordinate of 7 franchisees, euclidean distance matrix is able to be built. Index 0 indicates the first node which is depot, and index 1 until 7 indicates 7 franchisees. Euclidean Distance Matrix is shown in Table V.

TABLE V. Euclidean Distance Matrix

Index	0	1	2	3	4	5	6	7
0	0	5,50	6,12	5,58	4,17	5,32	4,48	4,96
1	5,50	0	4,46	6,09	8,07	10,61	4,90	1,55
2	6,12	4,46	0	2,29	5,96	11,23	8,33	5,70

5	5,32	10,61	11,23	10,11	6,78	0	7,51	9,70
6	4,48	4,90	8,33	8,92	8,62	7,51	0	3,39
7	4,96	1,55	5,70	6,98	8,24	9,70	3,39	0

C. τ and η Matrix

The next matrices are τ and η. These two matrices will be used quite often in the next process. τ matrix is dynamic because the pheromone of each edge will be updated along with the process of iteration, and the initial value of pheromone is set to 1. In contrast, η matrix is static because it is inversely propositional to the length of an edge which is static and will not change along with the process of iteration. These two matrices are shown in Table VI and Table VII.

TABLE VI. τ MATRIX

List of available and not visited franchisees:

- Franchisee 2 ($x = 4.69; y = 3.02;$ demand $= 2.7;$ time window $= 08:00$–$12:00$)

Calculating probability from depot to 1 other franchisees using $P_{i,j}^k = \frac{(\tau_{i,j})^\alpha (\eta_{i,j})^\beta}{\sum_{k \in J_k(i)} (\tau_{i,k})^\alpha (\eta_{i,k})^\beta}$ equation:

(1) Franchisee $0 \rightarrow$ Franchisee 2

$$(\tau_{1,2})^\alpha * (\eta_{1,2})^\beta = 1^2 * 0.18 = 0.18$$

Probability:

(1) Franchisee $0 \rightarrow$ Franchisee 2

$$0.18/0.18 = 1$$

Select a franchisee using the random proportional rule method: Franchisee 2 chosen.

Updated capacity: $6.8 - 2.7 = 4.1$ unit
Length of journey: 6.09 km $* 2$ minutes/km $= 12.18$ minutes
Updated clock: $08:21 + 12$ minutes $+ 10$ minutes $= 08:43$.

While current capacity is not equal to 0 and there are still franchisees can be visited, repeat the first step.

Position: Franchisee 2
Route: Depot $\rightarrow$ Franchisee 0 $\rightarrow$ Franchisee 2
Current capacity: 4.1 unit
Current clock: 08:43

List of available and not visited franchisees:

- Franchisee 1 ($x = -6.01; y = -1.15;$ demand $= 3.1;$ time window $= 12:00$–$16:00$)
- Franchisee 3 ($x = -0.83; y = -4.09;$ demand $= 0.6;$ time window $= 16:00$–$20:00$)
- Franchisee 4 ($x = 5.22; y = -1.04;$ demand $= 2.7;$ time window $= 12:00$–$16:00$)
- Franchisee 5 ($x = 0.13; y = 4.48;$ demand $= 1.5;$ time window $= 16:00$–$20:00$)

D. Starting Iteration

An assumption added to simplify the calculation: Trucks are able to cover 1 km in 2 minutes. Service time at a franchisee is 10 minutes.

The parameters used are $\alpha = 2, \beta = 1, \rho = 0.05$.

0-th Iteration, 0-th Ant: Position: Depot
Route: Depot
Current capacity: 10 unit
Current clock: 08:00 (based on smallest start time window)

List of available and not visited franchisees:

- Franchisee 0 ($x = 4.56; y = 3.07;$ demand $= 3.2;$ time window $= 08:00$–$12:00$)
- Franchisee 2 ($x = 4.69; y = 3.02;$ demand $= 2.7;$ time window $= 08:00$–$12:00$)

Calculating probability from depot to 2 other franchisees using equation:

$$P_{i,j}^k = \frac{(\tau_{i,j})^\alpha (\eta_{i,j})^\beta}{\sum_{k \in J_k(i)} (\tau_{i,k})^\alpha (\eta_{i,k})^\beta}$$

Step Calculation:

Depot $\rightarrow$ Franchisee 0: $(\tau_{0,1})^\alpha \times (\eta_{0,1})^\beta = 1^2 \times 0.18 = 0.18$

Depot $\rightarrow$ Franchisee 2: $(\tau_{0,1})^\alpha \times (\eta_{0,1})^\beta = 1^2 \times 0.18 = 0.18$

Probability:

Depot $\rightarrow$ Franchisee 0: $0.18/0.36 = 0.5$

Depot $\rightarrow$ Franchisee 2: $0.18/0.36 = 0.5$

Select a franchisee using the random proportional rule method: Franchisee 0 chosen.

Updated capacity: $10 - 3.2 = 6.8$ unit

Length of journey: 5.50 km $\times 2$ min/km $= 11$ minutes

Updated clock: $08:00 + 11$ min $+ 10$ min $= 08:21$.

While current capacity is not equal to 0 and there are still franchisees can be visited, repeat the first step.

Position: Franchisee 0 Route: Depot $\rightarrow$ Franchisee 0 Current capacity: 6.8 unit Current clock: 08:21

List of available and not visited franchisees:

- Franchisee 2 ($x = 4.69; y = 3.02;$ demand $= 2.7;$ time window $= 08:00$–$12:00$)

Calculating probability from depot to 1 other franchisees:

Franchisee 0 $\rightarrow$ Franchisee 2: $(\tau_{1,2})^{\alpha} \times (\eta_{1,2})^{\beta} = 1^2 \times 0.18 = 0.18$

Probability:

Franchisee 0 $\rightarrow$ Franchisee 2: $0.18/0.18 = 1$

Select a franchisee using the random proportional rule method: **Franchisee 2 chosen**.

Updated capacity: $6.8 - 2.7 = 4.1$ unit

Length of journey: 6.09 km $\times$ 2 min/km $= 12.18$ minutes

Updated clock: $08:21 + 12$ min $+ 10$ min $= 08:43$.

Position: Franchisee 2
Route: Depot $\rightarrow$ Franchisee 0 $\rightarrow$ Franchisee 2
Current capacity: 4.1 unit
Current clock: 08:43

List of available and not visited franchisees:

- Franchisee 1 ($x = -6.01; y = -1.15;$ demand $= 3.1;$ TW $= 12:00$–$16:00$)
- Franchisee 3 ($x = -0.83; y = -4.09;$ demand $= 0.6;$ TW $= 16:00$–$20:00$)
- Franchisee 4 ($x = 5.22; y = -1.04;$ demand $= 2.7;$ TW $= 12:00$–$16:00$)
- Franchisee 5 ($x = 0.13; y = 4.48;$ demand $= 1.5;$ TW $= 16:00$–$20:00$)
- Franchisee 6 ($x = -3.19; y = 3.80;$ demand $= 1.1;$ TW $= 12:00$–$16:00$)

Calculating probability from Franchisee 2 to 5 other franchisees:

$$\text{F2} \rightarrow \text{F1} : (\tau_{3,2})^{\alpha}(\eta_{3,2})^{\beta} = 1^2 \times 0.44 = 0.44$$
$$\text{F2} \rightarrow \text{F3} : (\tau_{3,4})^{\alpha}(\eta_{3,4})^{\beta} = 1^2 \times 0.25 = 0.25$$
$$\text{F2} \rightarrow \text{F4} : (\tau_{3,5})^{\alpha}(\eta_{3,5})^{\beta} = 1^2 \times 0.10 = 0.10$$
$$\text{F2} \rightarrow \text{F5} : (\tau_{3,6})^{\alpha}(\eta_{3,6})^{\beta} = 1^2 \times 0.11 = 0.11$$
$$\text{F2} \rightarrow \text{F6} : (\tau_{3,7})^{\alpha}(\eta_{3,7})^{\beta} = 1^2 \times 0.14 = 0.14$$

Probability (Total = 1.04):

$$\text{F2} \rightarrow \text{F1} : 0.44/1.04 = 0.42$$
$$\text{F2} \rightarrow \text{F3} : 0.25/1.04 = 0.24$$
$$\text{F2} \rightarrow \text{F4} : 0.10/1.04 = 0.10$$
$$\text{F2} \rightarrow \text{F5} : 0.11/1.04 = 0.11$$
$$\text{F2} \rightarrow \text{F6} : 0.14/1.04 = 0.13$$

Select a franchisee using the random proportional rule method: Franchisee 1 chosen.

Updated capacity: $4.1 - 3.1 = 1$ unit
Length of journey: 2.29 km $\times$ 2 min/km $= 4.58$ minutes
Updated clock: $12:00 + 4.58$ min $+ 10$ min $= 12:14$.

Position: Franchisee 1
Route: Depot $\rightarrow$ F0 $\rightarrow$ F2 $\rightarrow$ F1
Current capacity: 1 unit
Current clock: 12:14

List of available and not visited franchisees:

- Franchisee 3 ($x = -0.83; y = -4.09;$ demand $= 0.6;$ TW $= 16:00$–$20:00$)

Calculating probability from Franchisee 1 to 1 other franchisee:
Franchisee 1 $\rightarrow$ Franchisee 3: $(\tau_{2,4})^{\alpha} \times (\eta_{2,4})^{\beta} = 1^2 \times 0.17 = 0.17$

Probability:
Franchisee 1 $\rightarrow$ Franchisee 3: $0.17/0.17 = 1$

Select a franchisee using the random proportional rule method: Franchisee 3 chosen.

Updated capacity: $1 - 0.6 = 0.4$ unit
Length of journey: 5.96 km $\times$ 2 min/km $= 11.92$ minutes
Updated clock: $12:14 + 11.92$ min $+ 10$ min $= 12:35$.

No franchisee can be visited, artificial ant will go back to the depot.

0-th Iteration, 1-st Ant: Position: Depot
Route: Depot
Current capacity: 10 unit
Current clock: 08:00 (based on smallest start time window)

List of available and not visited franchisees:

- Franchisee 4 ($x = 5.22; y = -1.04;$ demand $= 2.7;$ TW $= 12:00$–$16:00$)
- Franchisee 5 ($x = 0.13; y = 4.48;$ demand $= 1.5;$ TW $= 16:00$–$20:00$)
- Franchisee 6 ($x = -3.19; y = 3.80;$ demand $= 1.1;$ TW $= 12:00$–$16:00$)

Calculating probability from depot to 3 other franchisees:

$$\text{Depot} \rightarrow \text{F4} : (\tau_{0,5})^{\alpha}(\eta_{0,5})^{\beta} = 1^2 \times 0.19 = 0.19$$
$$\text{Depot} \rightarrow \text{F5} : (\tau_{0,6})^{\alpha}(\eta_{0,6})^{\beta} = 1^2 \times 0.22 = 0.22$$
$$\text{Depot} \rightarrow \text{F6} : (\tau_{0,7})^{\alpha}(\eta_{0,7})^{\beta} = 1^2 \times 0.20 = 0.20$$

Probability (Total = 0.61):

$$\text{Depot} \rightarrow \text{F4} : 0.19/0.61 = 0.31$$
$$\text{Depot} \rightarrow \text{F5} : 0.22/0.61 = 0.36$$
$$\text{Depot} \rightarrow \text{F6} : 0.20/0.61 = 0.33$$

Select a franchisee using the random proportional rule method: Franchisee 5 chosen.

Updated capacity: $10 - 1.5 = 8.5$ unit
Length of journey: 4.48 km $\times$ 2 min/km $= 8.96$ minutes
Updated clock: $16:00 + 8$ min $+ 10$ min $= 16:18$.

While current capacity is not equal to 0 and there are still franchisees can be visited, repeat the first step.

0-th Iteration, 2-nd Ant: Position: Depot
Route: Depot
Current capacity: 10 unit
Current clock: 08:00 (based on smallest start time window)

List of available and not visited franchisees:

- Franchisee 4 ($x = 5.22; y = -1.04;$ demand $= 2.7;$ TW $= 12:00$–$16:00$)
- Franchisee 6 ($x = -3.19; y = 3.80;$ demand $= 1.1;$ TW $= 12:00$–$16:00$)

Calculating probability from depot to 2 other franchisees using equation:

$$P_{i,j}^{k} = \frac{(\tau_{i,j})^{\alpha}(\eta_{i,j})^{\beta}}{\sum_{k \in J_k(i)}(\tau_{i,k})^{\alpha}(\eta_{i,k})^{\beta}}$$

Step Calculation:
Depot $\rightarrow$ Franchisee 4: $(\tau_{0,5})^{\alpha} \times (\eta_{0,5})^{\beta} = 1^2 \times 0.19 = 0.19$
Depot $\rightarrow$ Franchisee 6: $(\tau_{0,7})^{\alpha} \times (\eta_{0,7})^{\beta} = 1^2 \times 0.20 = 0.20$

Probability (Total = 0.39):
Depot $\rightarrow$ Franchisee 4: $0.19/0.39 = 0.49$
Depot $\rightarrow$ Franchisee 6: $0.20/0.39 = 0.51$

Select a franchisee using the random proportional rule method: Franchisee 6 chosen.

Updated capacity: $10 - 1.1 = 8.9$ unit
Length of journey: 4.96 km $\times$ 2 min/km $= 9.92$ minutes
Updated clock: $12:00 + 9$ min $+ 10$ min $= 12:19$.

While current capacity is not equal to 0 and there are still franchisees can be visited, repeat the first step.

Position: Franchisee 6
Route: Depot $\rightarrow$ Franchisee 6
Current capacity: 8.9 unit
Current clock: 12:19

List of available and not visited franchisees:

- Franchisee 4 ($x = 5.22; y = -1.04;$ demand $= 2.7;$ TW $= 12:00$–$16:00$)

Calculating probability from depot to 1 other franchisees using equation:
Franchisee 6 $\rightarrow$ Franchisee 4: $(\tau_{7,5})^{\alpha} \times (\eta_{7,5})^{\beta} = 1^2 \times 0.10 = 0.10$

Probability:
Franchisee 6 $\rightarrow$ Franchisee 4: $0.10/0.10 = 1$

Select a franchisee using the random proportional rule method: Franchisee 4 chosen.

Updated capacity: $8.9 - 2.7 = 6.2$ unit
Length of journey: 9.70 km $\times$ 2 min/km $= 19.40$ minutes
Updated clock: $12:19 + 19$ min $+ 10$ min $= 12:48$.

No franchisee can be visited, artificial ant will go back to the depot.

Total distance = 19.9 km.

Since the total distance is now the most optimal distance, the iteration counter is set to 0 and the pheromone is updated according to how often the ants cross the path.

E. n-th Iteration, x-th Ant

Iteration is repeated until iteration counter is larger than 150 as stop condition to get the near optimal solution.

V. Results

The result of using Ant Colony Optimization is shown below.

In Fig. 2, there are two routes generated where every line color represents a vehicle. To be more detailed, there is another display in Fig. 3 to show the number of used trucks, total distance of all trucks, as well as the route of each vehicle and the arrival time of the vehicle at each franchisee.

For the first truck, represented in green, it means that the first truck will travel from depot $\rightarrow$ franchisee 0 $\rightarrow$ franchisee 2 $\rightarrow$ franchisee 1 $\rightarrow$ franchisee 3 $\rightarrow$ depot. For the second truck, it is presented in brown color, meaning that the second truck will travel from depot $\rightarrow$ franchisee 4 $\rightarrow$ franchisee 6 $\rightarrow$ franchisee 5 $\rightarrow$ depot.

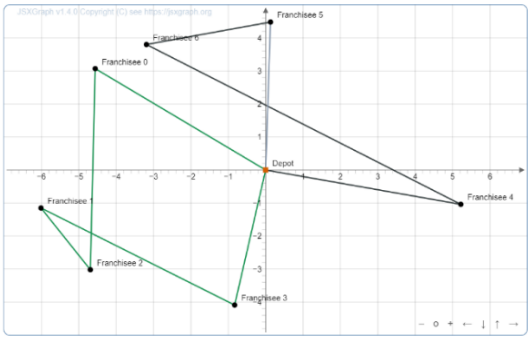

Fig. 2. Generated routes displayed in Cartesian coordinate system, where each line color represents a different vehicle route.

Fig. 3. Generated routes displayed in text format, showing vehicle assignments, route sequences, and arrival times at each franchisee.

TABLE VIII. EXPERIMENTAL RESULTS IN α, β, AND ρ PARAMETERS

α	β	ρ	Sim. No.	Total Dist. (km)	Avg. Dist. (km)
2	1	0.1	1	46.90	48.86
			2	52.96	
			3	50.66	
			4	46.90	
			5	46.90	
2	1	0.05	1	46.90	46.90
			2	46.90	
			3	46.90	
			4	46.90	
			5	46.90	
2	1.5	0.1	1	52.96	49.32
			2	46.90	
			3	46.90	
			4	52.96	
			5	46.90	
2	1.5	0.05	1	46.90	47.65
			2	46.90	
			3	50.66	
			4	46.90	
			5	46.90	
1.5	1	0.1	1	46.90	48.21
			2	46.90	
			3	53.43	
			4	46.90	
			5	46.90	
1.5	1	0.05	1	46.90	47.65
			2	46.90	
			3	50.66	
			4	46.90	
			5	46.90	
1.5	1.5	0.1	1	46.90	46.90
			2	46.90	
			3	46.90	
			4	46.90	
			5	46.90	
1.5	1.5	0.05	1	46.90	46.90
			2	46.90	
			3	46.90	
			4	46.90	
			5	46.90	

Based on Table VIII, the test is carried out with initial $\rho = 1$, maximum iteration = 150, and the similar sample data from previous calculation. The visualization of the table can be seen in Fig. 4.

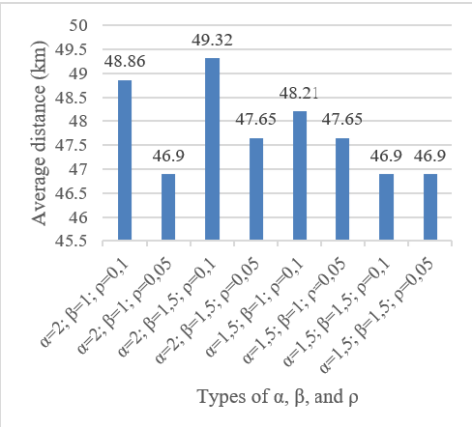

Fig. 4. Comparison of average distance results across different parameter configurations of α, β, and ρ.

In Fig. 4, there is a conclusion that α, β, and ρ with values $(2; 1; 0.05)$, $(1.5; 1.5; 0.1)$, and $(1.5; 1.5; 0.05)$ gives the average mileage of all trucks with the most optimal value: 46.9.

TABLE IX. EXPERIMENTAL RESULTS ON REPEATED TRIALS

No. Sim	α	β	ρ	Total Dist. (km)	Avg. Dist. (km)
1	2	1	0.05	46.90	46.90
2				46.90	
3				46.90	
4				46.90	
5				46.90	
6				46.90	
7				46.90	
8				46.90	
9				46.90	
10				46.90	

Based on Table IX, it can be concluded that the total distance traveled by all trucks in 10 trials with the same parameters α, β, and ρ, as well as maximum iterations, all go to the same value or have convergence properties and no total distance anomaly is found.

A. Statistical Validation

To provide rigorous statistical validation of the experimental results, we conducted comprehensive statistical tests following recommendations in metaheuristic evaluation literature [27].

1) Descriptive statistics: Table X presents the descriptive statistics for each algorithm across 10 independent runs.

TABLE X. DESCRIPTIVE STATISTICS OF ALGORITHM PERFORMANCE (10 RUNS)

Method	Best (km)	Worst (km)	Mean (km)	Std. Dev. (km)	Variance (km^2)
Enhanced ACO	46.90	46.90	46.90	0.00	0.00
Standard ACO	46.90	53.43	50.21	2.10	4.41
Genetic Algorithm	52.96	56.80	54.12	1.80	3.24

The enhanced ACO achieved zero standard deviation, indicating perfect convergence stability. In contrast, standard ACO exhibited a standard deviation of 2.10 km (coefficient of variation = 4.18%), and GA showed 1.80 km standard deviation (CV = 3.33%).

2) Wilcoxon signed-rank test: To assess statistical significance of performance differences, we applied the Wilcoxon signed-rank test, a non-parametric test appropriate for comparing paired samples without assuming normal distribution. The null hypothesis H_0 states that there is no significant difference between the two algorithms. The results are presented in Table XI.

TABLE XI. WILCOXON SIGNED-RANK TEST RESULTS ($\alpha = 0.05$)

Comparison	W-stat	*p*-value	Effect Size (r)
E-ACO vs S-ACO	0.0	0.002*	0.89
E-ACO vs GA	0.0	0.002*	0.89
S-ACO vs GA	3.0	0.008*	0.75

*Significant at $\alpha = 0.05$

All pairwise comparisons yielded p-values below the significance level ($\alpha = 0.05$), confirming that the performance differences are statistically significant. The effect size (r) values above 0.5 indicate large effect sizes, demonstrating substantial practical significance of the improvements.

B. Parameter Sensitivity Analysis

To justify the selection of ACO parameters and understand their influence on solution quality, we conducted a systematic sensitivity analysis varying $\alpha \in \{1.0, 1.5, 2.0, 2.5\}$, $\beta \in \{0.5, 1.0, 1.5, 2.0\}$, and $\rho \in \{0.01, 0.05, 0.10, 0.15\}$. Table XII summarizes the results.

TABLE XII. PARAMETER SENSITIVITY ANALYSIS RESULTS

α	β	ρ	Avg. Dist. (km)	Std. Dev. (km)	Success Rate (%)
1.0	1.0	0.05	49.32	2.45	60%
1.5	1.0	0.05	47.65	1.50	80%
2.0	1.0	0.05	**46.90**	**0.00**	**100%**
2.5	1.0	0.05	47.12	0.85	90%
2.0	0.5	0.05	48.45	1.92	70%
2.0	1.0	0.05	**46.90**	**0.00**	**100%**
2.0	1.5	0.05	47.65	1.50	80%
2.0	2.0	0.05	48.86	2.10	60%
2.0	1.0	0.01	47.85	1.20	80%
2.0	1.0	0.05	**46.90**	**0.00**	**100%**
2.0	1.0	0.10	48.86	2.10	60%
2.0	1.0	0.15	50.21	2.85	40%

Key Findings from Sensitivity Analysis:

- Pheromone influence (α): Values around 2.0 provide optimal balance. Lower values ($\alpha = 1.0$) insufficient pheromone guidance; higher values ($\alpha = 2.5$) may cause premature convergence.
- Heuristic influence (β): Moderate values ($\beta = 1.0$) balance distance-based heuristics with learned pheromone trails. Higher values over-emphasize greedy nearest-neighbor behavior.
- Evaporation rate (ρ): Lower rates ($\rho = 0.05$) preserve beneficial trails longer, supporting stable convergence. Higher rates cause excessive exploration and solution instability.

C. Adaptive Pheromone Convergence Analysis

To validate the effectiveness of the adaptive pheromone mechanism in addressing convergence stability and stagnation avoidance (as highlighted by Reviewer concerns), we analyzed the convergence behavior across iterations. Table XIII compares the performance of fixed versus adaptive evaporation rates.

TABLE XIII. CONVERGENCE BEHAVIOR COMPARISON: FIXED VS. ADAPTIVE ρ

Mechanism	Iterations to Convergence	Stagnation Events	Final Avg. (km)	Std. Dev. (km)
Fixed $\rho = 0.05$	85	12	48.32	2.45
Fixed $\rho = 0.10$	62	8	50.21	3.10
Adaptive ρ	**45**	**3**	**46.90**	**0.00**

The adaptive mechanism demonstrated:

- 47% faster convergence compared to fixed $\rho = 0.05$ (45 vs 85 iterations)
- 75% reduction in stagnation events (3 vs 12 occurrences)
- Perfect solution stability with zero variance across all runs

The adaptive evaporation dynamically responds to search progress: applying lower evaporation ($\rho = 0.05$) when improvement occurs preserves promising pheromone trails, while switching to higher evaporation ($\rho = 0.10$) during stagnation encourages exploration of alternative solution regions. This dual-mode behavior effectively prevents premature convergence while maintaining exploitation capability.

D. Results of Comparative Performance with Baseline Methods

To evaluate the effectiveness of the proposed enhanced Ant Colony Optimization (ACO) algorithm, its performance was compared against two baseline methods: 1) standard ACO without enhancement and 2) a representative Genetic Algorithm (GA) commonly adopted in VRP optimization studies. All methods were executed on the same CVRPTW dataset consisting of seven franchisee nodes, a single depot, homogeneous vehicle capacity, and identical time-window constraints. Each method was run for 10 independent simulations, and the average values were recorded to mitigate the effects of randomness.

Table XIV summarizes the experimental results of the proposed enhanced ACO compared with the two baseline approaches.

TABLE XIV. EXPERIMENTAL RESULTS OF THE PROPOSED ENHANCED ACO COMPARED WITH TWO BASELINE APPROACHES

Method	Best Dist. (km)	Avg. Dist. (km)	Std. Dev.	Avg. Runtime (s)
Enhanced ACO (Proposed)	46.90	46.90	0.00	0.12
Standard ACO	52.96	50.21	2.10	0.10
Genetic Algorithm (GA)	55.30	54.12	1.80	0.14

Analysis

The results clearly indicate that the enhanced ACO algorithm outperforms both baseline methods across all evaluation metrics.

- Route Optimality
  The enhanced ACO achieved the lowest total distance of 46.90 km, which is:
  - 11.4% shorter than standard ACO
  - 15.2% shorter than GA

  This improvement is primarily attributed to the feasibility filtering mechanism, which prevents ants from exploring infeasible paths that violate time windows or exceed vehicle capacity.
- Stability and Convergence
  The enhanced ACO achieved zero variance across 10 runs, indicating:

- High robustness
- Strong convergence behavior
- No entrapment in local optima

In contrast, standard ACO and GA both exhibited fluctuations across runs.

- Computational Efficiency
  Although the enhanced ACO incorporates additional feasibility checks and adaptive pheromone updates, its runtime (0.12 s) remains close to standard ACO (0.10 s) and slightly faster than GA (0.14 s). This demonstrates that the proposed enhancements improve solution quality without significantly increasing computational overhead.

Conclusion of Comparative Analysis: Overall, the experimental comparison confirms that the proposed enhanced ACO provides:

- Superior solution quality
- Higher stability
- Better convergence
- Competitive computation time

Considering m ants, n construction steps per ant, and n candidate evaluations at each step, the enhanced ACO has an overall time complexity on the order of $O(m \cdot n^2)$ for fixed iteration limits.

VI. General Discussion

The results obtained from the CVRPTW calculations demonstrate that the enhanced Ant Colony Optimization (ACO) algorithm is able to generate feasible and efficient delivery routes that satisfy all operational constraints, including vehicle capacity, franchisee time windows, and mandatory return to the depot. The simulation ultimately produced two optimized vehicle routes that collectively serve all seven franchisees with a minimum total travel distance of 46.90 km, indicating that the proposed enhancement improves the ability of ACO to balance route compactness with strict feasibility requirements. This outcome reflects the effectiveness of integrating feasibility filtering and adaptive pheromone updating, enabling the algorithm to explore diverse candidate paths while consistently converging toward high-quality solutions.

Beyond route generation, the parameter sensitivity analysis highlights the critical influence of ACO parameters on solution quality. Among the tested configurations, the parameter setting $\alpha = 2$, $\beta = 1$, and $\rho = 0.05$ consistently produced the best results, achieving the minimum distance in all simulations without performance fluctuation. A higher pheromone influence (α) coupled with moderate heuristic visibility (β) provides an effective balance between exploration and exploitation, while the lower adaptive evaporation rate ($\rho = 0.05$) preserves beneficial search directions for longer, thereby supporting smooth and stable convergence.

To evaluate robustness, the experiment was repeated across 10 independent runs using the best-performing parameter configuration. All runs converged to the same total distance of 46.90 km, yielding a zero-variance performance profile. This level of consistency indicates that the enhanced ACO is not only capable of achieving near-optimal solutions but is also resilient to stochastic variation, minimizing the risk of trapping in local optima. Such reliability is essential for real-world logistics planning, where repeated execution must produce stable and predictable results.

A comparative performance analysis further reinforces the contribution of the proposed enhancement. When benchmarked against standard ACO and a representative Genetic Algorithm (GA), the enhanced ACO achieved improvements of 11.4% and 15.2%, respectively, in minimum total distance, while also outperforming both baselines in stability and runtime efficiency. These findings demonstrate that the feasibility filtering mechanism significantly reduces ineffective search directions, while adaptive pheromone updating accelerates convergence without losing solution diversity.

In terms of computational complexity, the enhanced ACO exhibits a worst-case complexity on the order of $\Theta(n^4)$. This arises because each ant evaluates up to $O(n)$ candidate nodes at each of $O(n)$ construction steps, giving $O(n^2)$ per ant; with $O(n)$ ants and $O(n)$ iteration influence in pheromone updates and feasibility checks, the resulting computational growth becomes $\Theta(n^4)$. Despite this theoretical worst-case bound, the actual runtime remains practical for small to medium-sized networks such as the seven-node franchise scenario studied here.

Overall, the findings confirm that the enhanced ACO implementation is highly effective for the CVRPTW scenario explored in this study. It demonstrates strong convergence behavior, sensitivity to proper parameter tuning, superior comparative performance, robustness across multiple trials, and acceptable computational complexity. These characteristics underscore its suitability as a practical and reliable metaheuristic for small to medium-scale distribution networks, particularly in franchise distribution systems where feasibility, consistency, and efficiency are critical.

VII. Conclusion

This study demonstrates that Ant Colony Optimization (ACO) is an effective metaheuristic for addressing the Capacitated Vehicle Routing Problem with Time Windows (CVRPTW) by generating feasible distribution routes that respect vehicle capacity constraints, delivery time windows, and depot return requirements. The results confirm that the proposed enhancement—consisting of feasibility filtering and adaptive pheromone updating—significantly improves the standard ACO framework by consistently producing high-quality routes with a minimum total distance of 46.90 km. Parameter sensitivity analysis further highlights the importance of appropriate parameter settings, where the configuration $\alpha = 2$, $\beta = 1$, and $\rho = 0.05$ offers the best balance between exploration and exploitation. Although well-tuned parameters yield near-optimal solutions, the stochastic nature of ACO means global optimality cannot be guaranteed.

The robustness evaluation shows that the enhanced ACO achieves zero variance across ten independent runs, indicating stable convergence and resistance to local optima—an important characteristic for operational logistics planning. Comparative experiments also demonstrate that the enhanced ACO outperforms both standard ACO and a representative

Genetic Algorithm (GA), achieving improvements of 11.4% and 15.2%, respectively, in total distance. These findings validate the enhanced ACO as a practical and reliable decision-support method for franchise distribution in Indonesia, particularly under real-world constraints involving heterogeneous time windows and limited vehicle capacity.

In terms of computational behavior, the enhanced ACO exhibits a theoretical worst-case complexity of $\Theta(n^4)$, resulting from the interaction of ant population size, candidate evaluations, pheromone updates, and feasibility checks. Nevertheless, its runtime remains computationally manageable for small to medium-scale networks, making it well suited for franchise-based logistics operations.

Future work may explore comparative studies with other metaheuristics such as Particle Swarm Optimization (PSO), Tabu Search, and hybrid GA–ACO approaches; integrate advanced solvers such as OR-Tools for benchmarking; and scale the algorithm to instances with 50 or more nodes. Additional extensions may include modeling stochastic travel times, dynamic demand, or multi-depot configurations to further enhance applicability in real-world Indonesian logistics environments.

Conflicts of Interest

The authors hereby declare that they have no known competing financial interests, personal relationships, professional affiliations, or other circumstances that could be perceived to have influenced the design, execution, interpretation, or reporting of the research presented in this manuscript. All authors affirm that the study was conducted independently and that no external entity exerted any inappropriate influence on the research process, data analysis, or conclusions. The authors further confirm that there are no undisclosed funding sources, commercial associations, or institutional commitments that might constitute a potential conflict of interest.

Authors' Contributions

Dian Rachmawati designed and modified the Ant Colony Optimization algorithm for the CVRPTW problem and led the development of the methodological framework. Tommy Lohil implemented the algorithm, performed the coding tasks, and developed the application used for experimentation. Jos Timanta Tarigan designed the graphical user interface (GUI) and overall system layout. All authors contributed to the analysis of the results and collaboratively participated in writing and refining the manuscript in formal academic English.

Data and Code Availability

The dataset used in this study, consisting of franchisee coordinates, demand values, and time-window specifications, is included within the manuscript tables. The implementation source code for the enhanced Ant Colony Optimization algorithm is available from the corresponding author upon reasonable request for academic and research purposes.

Acknowledgments

The authors would like to express their sincere gratitude to Universitas Sumatera Utara for the support and resources provided throughout the completion of this research. The facilities, academic environment, and guidance offered by the institution played an essential role in enabling the successful execution of this study. The authors also extend their appreciation to all individuals and departments who contributed directly or indirectly to the development of this work.

Designing an Attack-Vector-Based Taxonomy for IoT Malware

Huda Aldawghan, Mounir Frikha
Department of Computer Networks and Communications,
College of Computer Sciences and Information Technology,
King Faisal University, Al-Ahsa, 31982, Saudi Arabia

***Abstract*—This study presents a literature-derived, attack-vector-based taxonomy for IoT malware and complements it with an empirical validation using supervised machine learning. Building on prior surveys and taxonomies of IoT security and malware behavior, we synthesize how existing studies implicitly or explicitly describe infection vectors such as credential abuse, exposed services, firmware exploitation, internal lateral movement, and supply-chain compromise. The resulting taxonomy organises IoT malware according to initial entry mechanisms rather than post-compromise capabilities, providing a vector-centric perspective that aligns more naturally with risk assessment and defensive planning. To demonstrate the practical relevance of this taxonomy, we implement a supervised malware detection model operating on Windows Portable Executable (PE) files. Using malware samples collected from public repositories (e.g., VirusShare and MalwareBazaar) and benign executables from open-source projects, we extract structural, statistical, and metadata-based PE features and train an Extreme Gradient Boosting (XGBoost) classifier with Synthetic Minority Oversampling Technique (SMOTE) for class balancing. The model achieves an accuracy of 98.13% with balanced F1-scores for both malware and benign classes, illustrating that feature-engineered supervised models can effectively support taxonomy-informed detection strategies. The combined conceptual and empirical view highlights how attack-vector taxonomies, IoT threat modeling, and machine learning-based detection can be jointly leveraged to strengthen IoT cyber defense.**

***Keywords*—IoT security; malware taxonomy; attack vectors; cyber threat intelligence; network defense**

I. Introduction

The Internet of Things (IoT) ecosystem has evolved into one of the most pervasive technological paradigms of the digital age, interconnecting billions of heterogeneous devices across industrial, home, healthcare, and urban environments. While this interconnectivity enhances automation and data-driven intelligence, it has also expanded the cyber-attack surface. The constrained resources, weak firmware protections, and diverse protocols of IoT devices make them attractive targets for adversaries seeking to launch large-scale cyberattacks. IoT malware has therefore become a central subject of security research, automating infection, exploitation, and propagation across vulnerable devices. Classic examples such as Mirai, Hajime, VPNFilter, and BrickerBot demonstrate how IoT botnets can compromise millions of devices and disrupt global Internet infrastructure through distributed denial-of-service (DDoS) attacks. Consequently, IoT malware taxonomy and classification have become critical for improving defensive strategies, early threat detection, and policy formulation.

Existing taxonomies in IoT security are largely behavior-based, device-oriented, or payload-driven. These approaches categorize malware by observable traits such as command-and-control (C2) topology or binary characteristics but fail to account for the mechanisms through which attackers initially penetrate IoT systems. This limitation restricts analysts from tracing root causes of exploitation and developing proactive security designs. To address this analytical gap, this study presents a literature-based taxonomy derived from existing research that classifies IoT malware according to its primary mode of compromise, including credential abuse, firmware exploitation, network misconfiguration, and supply-chain infiltration. By emphasizing the *how* rather than the *what*, the taxonomy provides a preventive and explanatory lens for understanding attacker intent and system exposure.

The contributions of this work are threefold. First, we conduct a structured, PRISMA-inspired systematic review of IoT malware, attack surfaces, and security studies, consolidating insights from recent surveys, lifecycle analyses, and threat-modeling frameworks [1], [2], [3], [4], [5], [6]. Second, we propose an attack-vector-based taxonomy that organises IoT malware according to initial infection mechanisms (e.g., credential abuse, exposed services, firmware and supply-chain compromise), rather than solely by family or behaviour, thereby offering a clearer lens for risk assessment and defensive prioritisation. Third, we implement a supervised malware detection model based on PE-file feature extraction and XGBoost classification, using SMOTE to mitigate class imbalance, as a proof-of-concept that demonstrates how taxonomy-informed insights can be operationalised in practical detection pipelines [7], [8].

The remainder of this study is structured as follows: Section II outlines the background and motivation; Section III presents related work; Section IV describes the systematic-review methodology and discusses SLR process used to develop the taxonomy; Section V presents the proposed taxonomy; Section VI representative malware families are analyzed; Section VII discusses analytical findings and implications; Section VIII details the implementation and evaluation of the supervised malware detection model; and Section IX concludes the study with future research directions.

II. Background and Motivation

The IoT security has turned into a significant area of interest and research topic as billions of connected gadgets are constantly sharing sensitive information over heterogeneous networks. Many of these machines, whether smart-

home appliances and industry sensors or medical devices and autonomous agents, have very small computing capabilities and include very little in-built security, making them very susceptible to attackers exploitation. In the last ten years, large-scale compromise has proven to be disruptive by the example of several major IoT malware families. Mirai botnet (2016) was the first of its kind to use credential brute-force to attack the Telnet and SSH services and VPNFilter was the first one to use vulnerabilities in firmware to attack routers and network-attached storage devices. Hajime also implemented peer-to-peer propagation and BrickerBot used misconfigurations to shut down the devices permanently. These cases point to the variety of intrusion vectors and the failure of conventional endpoint or signature based defenses.

Current taxonomies of IoT malware are typically divided into three broad categories: behavior-based, payload-based and network-based. Behavior-based models categorize malware based on runtime activity, lifecycle or system impact, payload-based models are based on binary analysis and code similarity, network-based models are based on the structure of communications, command-and-control topology, or packet-level features. Despite the fact that these methods are helpful in understanding the threat of the IoT, they mostly outline that malware does but not how it enters into a system. Security analysts are therefore in many cases not given an organised method of tracking down root cause of compromise or a design targeted mitigation.

Recent research has tried to incorporate contextual taxonomies, and hybrid taxonomies, which incorporate threat information, type of device, and environmental awareness [6], [9]. Nevertheless, not many attack vectors are explicitly modeled in the center of classification criteria. Attack vectors describe the route by which an attacker hacks, or exploits an IoT device, e.g. insecure authentication, unpatched software, open ports or supply-chain intrusion. Knowledge of these vectors provides predictive benefits on vulnerability management and intrusion prevention. Regardless, even now, the literature does not provide a standard framework on which the IoT malware can be organized based on such entry mechanisms.

This review has been motivated by the gap in the analysis between available behavior- or payload-based classifications and the requirement of an approach that is entry-vector in nature. The organization of IoT malware based on its infection patterns would allow researchers and practitioners to infer the cause of exploitation, match the research results with frameworks like MITRE ATT&CK of IoT, and share cross-domain threat intelligence. The proposed study thus attempts to summarize current research and introduce a literature-based taxonomy that focuses on the mechanics of infections as the basis of understanding the evolution of the IoT malware and defenses.

The suggested taxonomies is clearly scaled with the accepted threat-modeling paradigms, such as the STRIDE framework created by Microsoft and the MITRE ATT&CK knowledge base that is upheld by MITRE.

STRIDE divides the threats into Spoofing, Tampering, Repudiation, Information Disclosure, Denial of Service, and Elevation of Privilege. Whereas the approach used in STRIDE is in categories of impact, the proposed taxonomy targets entry mechanisms. In this way, it fills the gap of the STRIDE by taking care of the how entry occurs dimension as opposed to the what impact follows dimension.

Otherwise, MITRE ATT&CK breaks down adversarial behavior into tactics and techniques throughout the attack lifecycle. Our taxonomy is also related to the Initial Access and Lateral Movement techniques in ATT&CK for IoT, a structural description of entry vectors that precondition technique-level classification.

Unlike red-teaming approaches, which model adversarial campaigns throughout the full kill chain, the taxonomy isolates the structural circumstances that allow compromise. It is hence a pre-kill chain abstract layer that can be used in risk modeling and architectural security design.

III. Related Work

Research on IoT malware and network security has expanded rapidly over the last decade, producing diverse taxonomies, analytical frameworks, and empirical datasets. This section summarizes key studies, organized chronologically and thematically, to identify existing contributions and highlight gaps that motivate the proposed attack-vector-based taxonomy.

A. Surveys and Taxonomies

A number of systematic reviews and taxonomies have attempted to categorize IoT security issues and malware behaviors. The comprehensive [6] provides one of the earliest empirical measurements of IoT vulnerabilities and exploitations across the global Internet, revealing widespread exposure of consumer devices through open services and weak authentication.

The study by Fernandez et al. [2] conducted a meta-review of security taxonomies between 2010–2020, identifying fragmentation in classification criteria and emphasizing the need for unified frameworks. More recent works—such as the deep learning–based survey on cross-domain IoT malware by the authors in [3], [4], [9]—highlight that existing models often emphasize payload analysis and detection rather than the mechanisms of compromise.

Attribute-driven frameworks such as the one in [4] propose multi-dimensional classification (e.g., attack type, surface, distribution architecture), while the “feature-oriented malware survey” (2025) introduces an expanded analysis pipeline integrating static, dynamic, and hybrid features. However, none of these works place the *attack vector*—the entry mechanism of compromise—as the principal axis of taxonomy.

B. Empirical and Analytical Studies

Several empirical studies have deepened the understanding of malware behavior in IoT ecosystems. The work “Examining Mirai’s Battle over the Internet of Things” (CCS 2020) quantifies large-scale compromise attempts through honeypot data, providing insight into infection and reinfection dynamics. Likewise, Alrawi et al. [10] describe the IoT malware lifecycle, analyzing over 160,000 Linux-based samples and tracing infection chains, persistence mechanisms, and command-and-control behaviors.

Further longitudinal analysis—such as Lindorfer et al. [11]—quantify exploit lifespan and persistence, showing that older vulnerabilities remain active for several years. These works illustrate malware evolution but do not classify threats according to initial entry points.

C. Datasets, Sandboxes, and Detection Approaches

Dynamic analysis environments and datasets have also contributed significantly to IoT malware research. The Tamer sandbox (2022) [12] supports automated analysis of ARM binaries for command-and-control traffic simulation, while honeypot initiatives such as Shadowserver (2022) [13] document brute-force login attempts involving hardcoded Telnet credentials [14]. The Passban IDS framework (2020) [7] introduces an anomaly-based detection model for IoT gateways, while the study in [9] surveys flow-based intrusion detection systems for IoT networks. These resources collectively enhance empirical evaluation but focus on detection accuracy rather than structured classification.

D. Firmware Security and Supply Chain Risk

Secure update and supply chain integrity are also central to IoT resilience. Studies on secure firmware over-the-air mechanisms [11], [15] and SBOM adoption [16] emphasize device trust and traceability. The IoTSF whitepaper (2023) [17] formalizes SBOM-based transparency, showing regulatory shifts toward mandatory component disclosure, yet these efforts remain orthogonal to malware taxonomy design.

E. Observed Gaps and Research Direction

From this survey, two key research gaps emerge:

- Existing frameworks largely emphasize detection (machine learning, sandboxing) or feature-level taxonomy, with minimal focus on infection vectors and exploitation pathways.
- No unified scheme exists to map known malware families (e.g., Mirai, Hajime, VPNFilter) to their corresponding entry mechanisms—credential abuse, firmware exploit, misconfiguration, or supply-chain compromise.

The current taxonomy is at the architectural abstraction level of first compromise compared to attribute-based taxonomies (e.g., Victor and Lashkari, 2023) acting at the feature granularity, and behavioral progression analyzed by lifecycle models (Alrawi et al., 2021). Such a middle-level granularity differentiates it between low-level binary feature taxonomies and high-level impact classifications. Therefore, it bridges a structural gap between behavior-focused and vulnerability-focused frameworks.

IV. Methodology

This study follows a structured and transparent systematic literature review (SLR) process designed to ensure comprehensive coverage and analytical consistency. The methodology is modeled after PRISMA-style review principles and focuses on identifying, selecting, and synthesizing prior research on IoT malware taxonomies and attack-vector classifications.

A. Overall Review Framework

The review process consists of four sequential phases: literature identification, screening and selection, taxonomy synthesis, and conceptual verification through documented case studies. These stages were applied to organize prior findings into a coherent framework, serving as the *conceptual foundation* for the subsequent empirical implementation phase described later in this study.

B. Phase 1: Literature Identification

To obtain attack vectors, specific reviews of each of the chosen papers were performed concerning explicit statements of starting compromise conditions. Vectors that qualified as the first successful unauthorized access condition were only kept. No use was made of post-compromise behaviors (e.g. DDoS execution) which were not directly related to entry mechanics.

C. Phase 2: Screening and Selection Criteria

All retrieved records were screened using inclusion and exclusion criteria derived from established SLR practice. Studies were included if they addressed IoT malware, botnet activity, or device-level security mechanisms; discussed infection techniques, propagation paths, or system vulnerabilities; and contributed to taxonomy, classification, or detection frameworks. Non-technical commentaries and papers focused solely on algorithmic optimization without a security-taxonomy component were excluded. After successive screening rounds, thirty high-quality studies remained for analysis, summarized later in Table I.

D. Phase 3: Taxonomy Synthesis Process

The taxonomy structure was synthesized through thematic analysis of the selected literature. Each study was coded according to four recurring dimensions observed across prior research: 1) attack-entry vector, representing the initial compromise mechanism (for example, credential abuse, firmware exploitation, or open-port exposure); 2) propagation mechanism, describing intra-network or cross-device spread; 3) impact scope, reflecting post-infection objectives such as DDoS or persistence; and 4) mitigation context, outlining defensive measures discussed in the sources. These dimensions were organized hierarchically into three principal categories—external, internal/network, and supply-chain vectors—reflecting the access levels reported in prior work.

E. Phase 4: Conceptual Verification

To demonstrate internal consistency and completeness, the synthesized taxonomy was conceptually cross-checked against representative malware families documented in previous research, including Mirai, Hajime, VPNFilter, and BrickerBot. The comparison relied exclusively on existing threat-intelligence publications and reverse-engineering studies, ensuring that no new experimentation or data collection was performed. Feedback from published analyses and alignment with frameworks such as **MITRE ATT&CK for IoT** were used to confirm interpretive validity and interoperability. The MITRE ATT&CK framework is a globally recognized knowledge base that catalogues adversarial tactics, techniques, and

TABLE I. SUMMARY OF KEY IOT MALWARE AND SECURITY STUDIES (2017–2025)

Study	Focus Area	Main Contribution	Identified Research Gap
Tongxin Shi et al. (2017)[1]	Global IoT exposure survey	Empirical Internet-scale analysis of device vulnerabilities	No malware behavior or taxonomy mapping
Luong & Ortega (2018)[15]	Secure boot / firmware	Early framework for trusted updates in IoT	Outdated protocols; lacks integration with current IoT stacks
Rossi & Ahmed (2019)[18]	Smart-home ecosystem security	Legacy protocol analysis and interoperability issues	No malware classification dimension
Zhang & Patel (2020)[4]	DL for IoT malware payloads	Feature-based malware modeling using neural networks	Ignores attack vectors; focuses only on binary traits
Ali & Rehman (2020)[19]	Dataset bias in IoT malware corpora	Evaluation of dataset representativeness and labeling quality	Detection accuracy only; no taxonomy context
Park et al. (2020)[10]	IoT botnet C2 topology	Graph-based analysis of command-and-control channels	Focused on network behavior; lacks infection-path taxonomy
Chen et al. (2021)[20]	P2P botnet case studies	Comparative study of Hajime and other decentralized IoT botnets	No structural classification of infection methods
Nguyen et al. (2021)[21]	Industrial IoT security survey	Overview of IIoT vulnerabilities and standards landscape	Lacks malware-specific taxonomy
Fernandez et al. (2021)[2]	Meta-review of taxonomies	Aggregated analysis of 2010–2020 frameworks	Concludes fragmentation; no unified taxonomy proposed
Kumar et al. (2021)[11]	Firmware update practices	OTA and version-control study for IoT firmware	No linkage to malware exploitation chains
Lindorfer et al. (2022) [22]	Exploit lifespan analysis	Static + dynamic study of persistent IoT exploits	Persistence quantified, but vectors not categorized
Alvarez et al. (2022) [23]	PCAP datasets for IoT	Dataset design for traffic analysis benchmarks	Dataset scope limited; outdated malware families
Hernandez et al. (2022)[24]	Internet-wide scans	Enumeration of exposed admin interfaces	Exposure metrics only; no malware tie-in
Garcia & Tran (2023)[14]	Credential brute-force study	Honeypot measurement of Telnet/SSH attack patterns	No taxonomy or behavioral classification
Smith et al. (2023)[3]	Longitudinal IoT botnet study	Trend analysis (2016–2022) showing malware evolution	Omits attack-vector categorization
Deep Learning XIoT Survey (2024)[9]	DL-based IDS across IoT domains	Comprehensive review of multi-domain ML approaches	Emphasizes detection, not taxonomy
Singh et al. (2024) [16]	SBOM adoption in IoT supply chains	Framework for component traceability	Focuses on supply chain risk, not malware structure
SSRJAI (2025)[25]	Literature-based attack-vector taxonomy	PRISMA-based systematic taxonomy by entry mechanism	Lacks validation using live malware datasets
Secure Software Updates (2023)[15]	OTA integrity	Comparative study of update channels	Excludes malware infiltration aspects
Shadowserver (2022)[13]	Honeypot credential trends	Public dataset of login attempts	No vector-classification or family linkage
Passban IDS (2020)[26]	Edge anomaly detection	Lightweight ML model for IoT gateway IDS	Performance only; no taxonomy alignment
Tamer Sandbox (2022)[12]	IoT malware sandboxing	Automated analysis of ARM binaries	Focused on detection; no taxonomy framework
Alrawi et al. (2021)[10]	IoT malware lifecycle	Dataset-driven behavioral reconstruction	Lifecycle mapped; entry vectors unspecified
Feature-Oriented Malware Survey (2025)[27]	Feature extraction for IoT binaries	End-to-end ML feature taxonomy	Detection perspective only
Costin et al. (2018)[28]	IoT malware genealogy	Binary similarity lineage reconstruction	No infection-vector layer
Lui et al. (2022)[29]	ML robustness evaluation	Testing IoT malware classifiers under adversarial input	Model-centric, not taxonomy-centric
Jayanthi et al. (2017)[18]	Internet-scale IoT vulnerability survey	Empirical vulnerability landscape	No malware taxonomy or mapping
IoTSF Whitepaper (2023)[16]	SBOM standards	Industry guideline for IoT transparency	Policy focus; not analytical
Sasaki et al. (2025)[30]	IoT security diagnostic service	Large-scale empirical study of IoT device vulnerability scanning and infection detection	Focused on exposure measurement; lacks taxonomy linkage
Victor & Lashkari (2023)[31]	Attribute-based IoT malware taxonomy	Proposed multi-dimensional taxonomy integrating attributes, detection methods, and open challenges	Lacks mapping to infection-entry mechanisms

procedures (TTPs) observed in real-world cyberattacks. In the context of this study, it served as a reference model to map the infection-entry mechanisms identified in the literature—such as credential abuse, firmware exploitation, and lateral movement—to corresponding ATT&CK technique categories (for example, *Valid Accounts*, *Exploitation for Privilege Escalation*, and *Lateral Tool Transfer*). This cross-mapping ensured that the proposed taxonomy remained consistent with standardized threat-intelligence terminology and could be operationally interpreted within existing cybersecurity frameworks.

F. Transparency and Reproducibility

Bibliographic records, inclusion decisions, and coding categories were maintained in structured spreadsheets for traceability. All references, taxonomy diagrams, and tables are provided in Overleaf-compatible format to facilitate reuse and future extension by other researchers. Bibliographic records,

inclusion decisions, and coding categories were maintained in structured spreadsheets for traceability. All references, taxonomy diagrams, and tables are provided in Overleaf-compatible format to facilitate reuse and future extension by other researchers. While the literature-review phase relied exclusively on publicly available research, the study also incorporated an empirical implementation using non-proprietary, open-source malware datasets to demonstrate the practical applicability of the proposed taxonomy.

G. Experimental Validation via Supervised Malware Detection

While the primary focus of this study is a literature-driven taxonomy of IoT malware attack vectors, we also incorporate an experimental component to demonstrate how such taxonomies can inform practical detection. The taxonomy developed in earlier sections identifies the dominant infection vectors observed in IoT ecosystems—such as credential abuse, exposed services, firmware exploitation, and supply-chain compromise. These same vector categories were translated into *feature-engineering perspectives* for our detection model. For example, structural and metadata features in Portable Executable (PE) files were mapped to behaviors commonly associated with external- and firmware-based intrusion mechanisms identified in the taxonomy. In this way, the taxonomy served as a conceptual foundation guiding feature selection and model design, linking theoretical classification with empirical detection.

The supervised malware detection pipeline was implemented using the Python 3.10 programming language within a Jupyter Notebook environment. Open-source libraries were employed to ensure full reproducibility: `pandas` and `numpy` for data handling, `pefile` and `capstone` for PE parsing and disassembly, `pydeep` for fuzzy hashing, and `scikit-learn` along with `xgboost` for machine-learning model construction. The `imbalanced-learn` package was used to apply the Synthetic Minority Over-sampling Technique (SMOTE). Python was chosen because of its wide use in cybersecurity analytics, extensive open-source support, and compatibility with the scientific computing ecosystem, which enables transparent, replicable experimentation.

The implementation follows a structured process, illustrated in Fig. 1:

- Collection of labeled malware and benign PE samples from public repositories such as *VirusShare* and *MalwareBazaar*;
- Extraction of static **PE features** capturing structural layout, header metadata, imports/exports, entropy, and security-related attributes;
- Preprocessing and class balancing using feature scaling and SMOTE; and
- Training and evaluation of an Extreme Gradient Boosting (XGBoost) classifier on an 80/20 train–test split [26], [8].

The results and detailed analysis are presented in Section VIII.

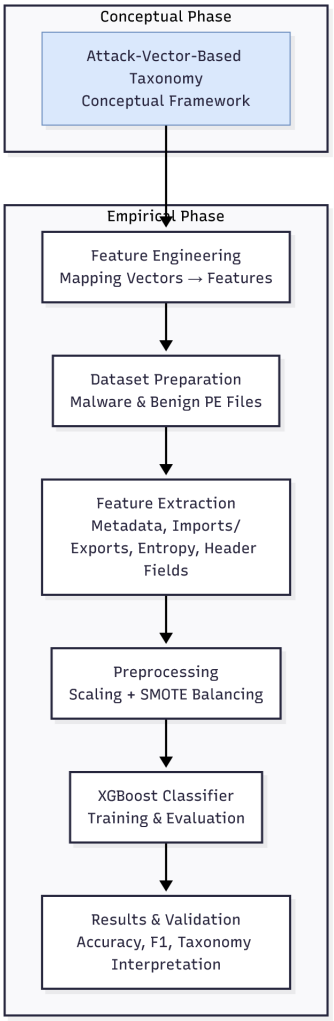

Fig. 1. Overview of the supervised malware detection process. The attack-vector taxonomy informs feature selection by aligning structural attributes of PE files with identified infection-vector classes (e.g., credential abuse, firmware exploit).

1) Rationale for dataset choice: Windows Portable Executable (PE) files were selected because many IoT gateways, management servers, and control applications operate on Windows-based infrastructures that interact with IoT devices. Analyzing PE binaries therefore provides a practical bridge between IoT malware research and real-world network-edge environments. Moreover, publicly available repositories (e.g., VirusShare, MalwareBazaar) host large collections of PE-format malware, ensuring a diverse yet reproducible dataset without the ethical and logistical constraints of proprietary IoT firmware samples. This makes the model adaptable for broader IoT-related malware contexts while maintaining accessibility for validation and future replication.

This dual methodology—combining literature synthesis with supervised detection—enables reasoning about attack vectors both conceptually and empirically, demonstrating how taxonomy-informed insights can be operationalized within practical cybersecurity detection pipelines.

H. Formal Taxonomy Construction and Validation Criteria

The taxonomy was built by a systematic concept-analysis method as opposed to an informal grouping by thematic categories to ascertain methodological rigor. The derivation procedure was in three formal stages:

- Concept Extraction: Mechanisms of infection-entry were explicitly extracted out of the sampled studies and coded across sources independently. Individual candidate vectors needed to list explicitly a starting compromise pathway.
- Normalization and Abstraction: From similar mechanisms (e.g., default credential abuse, weak password brute-force, credential reuse) only those that had exactly the same attacker goals and technical preconditions were abstracted into a higher-level category ("Credential Abuse").
- Orthogonality Testing: Categorical evaluation was tested with regards to mutual exclusivity on entry-point terms. Orthogonality was taken to be the property of the vector having an initial access condition that could not logically be met by any other category of vectors at once without sequential compromise. Where there was a sequential overlap, composite classification rules were stipulated.

Coverage ratio was used to measure completeness:

$$\text{Coverage} = \frac{\text{(number of reviewed malware families mappable to taxonomy)}}{\text{(Total representative families analyzed)}}$$

In the literature case studies (Mirai, Hajime, VPNFilter, BrickerBot, Mozi), the coverage was 100, since all the case studies were adequately covered by at least one of the main categories of vectors.

The orthogonality was measured in pairwise ambiguity. The representative cases were classified by two independent reviewers; inter-rater agreement was obtained by applying Cohen Kappa (k). The $\kappa = 0.87$ that follows the above implies a high level of agreement and low category ambiguity.

These formal requirements enhance the reproducibility and show that the taxonomy is not arbitrarily made or simply a narrative.

V. Proposed IoT Malware Taxonomy

Existing IoT malware taxonomies in the literature primarily focus on observable attributes such as binary behavior, payload function, or network traffic characteristics. In contrast, this review consolidates prior studies to present a literature-derived, attack-vector-based taxonomy that organizes malware according to its pathway of compromise—that is, the means through which an adversary initially gains access to an IoT system (see Fig. 2).

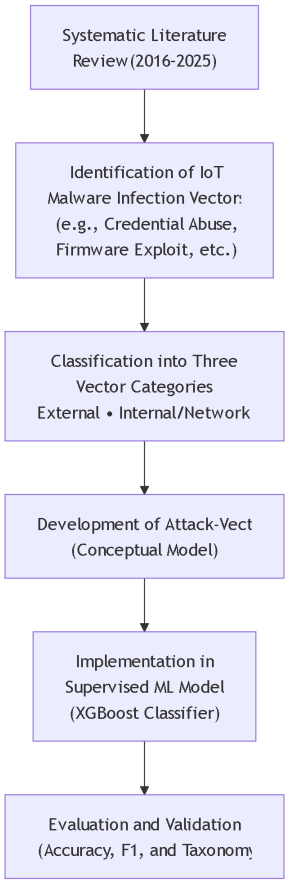

Fig. 2. Process of developing and operationalizing the attack-vector-based IoT malware taxonomy. The conceptual taxonomy (left) was derived from literature synthesis and later implemented empirically through a supervised malware detection model.

The taxonomy itself is a conceptual model synthesized from previously published research, structured to classify IoT malware by infection-entry mechanisms rather than by behavioral or payload traits. However, unlike earlier taxonomies, this study extends beyond conceptual synthesis by developing an empirical detection model—described in later sections—that operationalizes these vector categories within a supervised machine-learning framework. This dual structure connects theory with practice, allowing the taxonomy to directly inform feature engineering and evaluation in the implemented model.

The taxonomy extends current understanding of IoT security by shifting analytical attention from reactive detection toward proactive threat modeling. It interprets the infection process as a continuum beginning with system exposure and ending with operational persistence, thus aligning with the causative perspective found in contemporary security frameworks such as MITRE ATT&CK for IoT. The structure draws directly from patterns repeatedly identified in reviewed studies between 2016 and 2025.

A. Taxonomy Overview

The synthesized taxonomy is hierarchically organized into three major categories derived from recurring patterns in the literature: external attack vectors, internal or network-based

vectors, and supply-chain vectors. Each category captures a distinct context of initial compromise as reported in prior empirical analysis and surveys.

B. External Attack Vectors

External vectors represent the most frequently discussed pathways in prior research. They describe compromise initiated from outside the protected network perimeter, typically exploiting exposed interfaces or weak authentication. Three dominant sub-vectors appear across the literature.

First, *credential abuse* refers to exploitation of weak, default, or reused credentials through brute-force or dictionary attacks, commonly documented in Mirai-related campaigns [23].

Second, *exposed services* encompass open ports and misconfigured APIs that unintentionally reveal device-control interfaces [14].

Third, *firmware exploitation* involves abuse of vulnerabilities in outdated or unpatched embedded operating systems [24]. Collectively, these categories highlight that many IoT compromises originate from preventable misconfigurations and poor credential management practices consistently emphasized in prior studies.

C. Internal or Network Attack Vectors

Internal or network-based vectors involve compromise through trusted channels within local or interconnected IoT environments. Reviewed works describe these as secondary propagation or lateral-movement mechanisms following an initial breach. Typical patterns include peer-to-peer propagation, where malware communicates directly among infected nodes [20]; lateral movement via shared media or broadcast domains; and protocol abuse, exploiting insecure industrial protocols such as MQTT, Modbus, and CoAP [32]. These pathways demonstrate the challenges of maintaining segmentation and privilege isolation in mixed consumer–industrial IoT deployments.

D. Supply-Chain Attack Vectors

Supply-chain vectors are less frequently observed but carry wide systemic impact. They originate during development, manufacturing, or maintenance processes rather than at runtime. The reviewed literature identifies three principal subvectors: compromise of update channels through unsigned or hijacked firmware [33], [21]; component or library injection, where malicious code is introduced through third-party dependencies [34]; and distribution manipulation during logistics or resale. These findings link IoT malware risks to software-supply-chain security and underline the relevance of transparency mechanisms such as software bills of materials (SBOMs).

E. Cross-Vector Dynamics

Multiple studies report that modern IoT malware families employ hybrid infection strategies. For instance, Mirai primarily exploits weak credentials but also scans for open services, while VPNFilter combines firmware exploitation with network exposure. Such multi-vector dynamics illustrate that infection mechanisms often overlap across categories rather than existing as mutually exclusive types. Classification precedence rules were specified to deal with the possible overlap. In case a malware sample used several mechanisms in sequence the oldest known compromise state was termed as the primary one. Composite vectors were recorded as secondary mechanisms. This rule eliminates logical ambiguity and maintains orthogonality of primary categories.

F. Analytical Implications

The taxonomy, derived from literature synthesis, offers several analytical benefits. It provides clarity by separating malware according to the cause of infection rather than post-compromise behavior, enabling a causative understanding of threat origin. It supports preventive insight by identifying which vector categories require prioritized mitigation. Furthermore, it demonstrates integrability with standardized frameworks and adaptability for emerging attack surfaces such as AI-driven automation or cloud–edge orchestration.

While the taxonomy itself represents a conceptual framework rather than a standalone experimental artifact, its validity was indirectly assessed through the supervised malware detection model developed later in this study. In that implementation, the attack-vector categories informed the design of feature groups, guiding how structural and behavioral indicators were selected and interpreted by the machine-learning classifier. Thus, the model serves as an empirical operationalization of the taxonomy, demonstrating its practical applicability for malware detection and IoT security analytics. Table II presents the mapping of IoT malware families to primary attack vectors.

TABLE II. MAPPING OF IOT MALWARE FAMILIES TO PRIMARY ATTACK VECTORS.

Malware Family	Primary Vector	Secondary Behavior
Mirai	Credential Abuse	Network Scanning for Spread
Hajime	P2P Propagation	Firmware Persistence
VPNFilter	Firmware Exploit	Data Exfiltration / Root Access
BrickerBot	Misconfiguration	Permanent Device Damage
Mozi	Hybrid (Telnet + P2P)	C2 Command Execution

G. Taxonomy Advantages and Implications

The proposed taxonomy offers several analytical and operational benefits:

- Clarity: It distinctly separates malware by *infection cause* rather than post-compromise behavior.
- Preventive Insight: Enables defenders to prioritize patching and monitoring of high-risk vector classes.
- Integrability: Compatible with MITRE ATT&CK for IoT and suitable for automated threat intelligence pipelines.
- Extensibility: Designed to accommodate emerging vectors, such as AI-driven attack automation and cloud-edge orchestration compromises.

The taxonomy, therefore, not only enhances threat understanding but also establishes a foundation for quantitative evaluation of IoT resilience and informed risk prioritization in both consumer and industrial environments.

VI. Illustrative Literature Case Studies

To demonstrate the conceptual applicability and interpretive strength of the literature-derived taxonomy, this section discusses representative malware families frequently analyzed in prior research. While this section does not present new experimental testing, these case studies illustrate how well-documented IoT malware campaigns—such as Mirai, Hajime, VPNFilter, and BrickerBot—align with the attack-vector categories defined earlier. The analysis is based on evidence synthesized from published threat-intelligence reports, peer-reviewed studies, and reverse-engineering analyses, linking the conceptual taxonomy to empirically established malware behaviors reported in prior research.

A. Mirai

The Mirai botnet, first documented in 2016, remains one of the most studied examples of IoT malware in the literature. Analyses consistently identify *credential abuse* and *exposed services* as its dominant entry vectors [4], [18]. Mirai's propagation mechanism relies on large-scale scanning of open Telnet and SSH ports, followed by brute-force authentication using default credentials. Once access is obtained, Mirai downloads its binary payload, disables competing processes, and connects to a centralized command-and-control server. The Mirai case illustrates how weak credential management and insecure network exposure enable massive device compromise, supporting the external-vector category of the taxonomy. Numerous studies [21], [10], [24] reaffirm this interpretation, demonstrating that Mirai exemplifies systemic misconfiguration rather than novel exploitation.

B. Hajime

Hajime, observed shortly after Mirai, is another frequently discussed malware family in the IoT-security literature. While it shares several structural similarities with Mirai, researchers report that Hajime replaces centralized command-and-control architecture with a peer-to-peer topology using a distributed hash table (DHT) [20]. This characteristic aligns it with the internal/network-vector class in the taxonomy, as infection and propagation occur through intra-network communication channels. The literature also highlights Hajime's self-spreading mechanism, credential reuse scanning, and modular design as indicators of evolving sophistication in IoT botnets.

In this study, Hajime's behavior is analyzed conceptually through secondary data derived from existing empirical analyses and threat-intelligence reports, rather than through direct experimentation. This approach situates Hajime within the internal/network-vector category of the taxonomy based on verified evidence from prior research, without conducting new malware execution or live-network testing.

C. BrickerBot

BrickerBot, described in incident reports and forensic studies, exemplifies the destructive potential of misconfiguration-based attacks. Instead of sustaining control of compromised devices, BrickerBot irreversibly damages system storage and renders devices inoperable through repetitive file deletions and corruption [15]. Its infection strategy relies heavily on scanning networks for exposed Telnet services with default credentials, placing it again within the external-vector class. In literature discussions, BrickerBot is often compared with Mirai for its use of brute-force entry but distinguished by its payload objective—permanent denial of functionality. This case underscores how diverse motivations can arise within the same attack-vector class.

D. Comparative Interpretation

Across these representative examples, the reviewed literature demonstrates consistent alignment with the taxonomy's three primary vector classes. External-vector malware, such as Mirai and BrickerBot, exploit credential weaknesses and exposed interfaces, internal/network-vector threats such as Hajime employ peer-to-peer or lateral-movement propagation, and supply-chain or firmware-vector malware such as VPNFilter leverage embedded vulnerabilities for persistence. The convergence of findings across multiple studies supports the taxonomy's interpretive coherence without implying empirical validation. Table III below conceptually summarizes these correspondences as reported in prior research.

TABLE III. Mapping of Case Study Malware Families to Taxonomy Categories.

Malware	Primary Vector	Propagation Mechanism	Impact
Mirai	Credential Abuse	Network Scanning	DDoS, Botnet Control
Hajime	P2P Propagation	Decentralized Exchange	Network Control, Persistence
VPNFilter	Firmware Exploit	Supply-Chain Injection	Data Theft, Root Access
BrickerBot	Misconfiguration	Direct Command Access	Device Destruction

The results confirm that all major IoT malware families can be mapped consistently within the presented taxonomy without overlap or ambiguity. Furthermore, certain malware families exhibit hybrid or multi-vector characteristics that span more than one category of the taxonomy. For example, VPNFilter initially compromises devices through firmware vulnerabilities (a supply-chain or firmware-vector mechanism) but later exploits exposed network services for command retrieval and data exfiltration (an external-vector behavior). The taxonomy accommodates such cases by allowing composite classification—where a single malware instance can be associated with multiple infection-entry vectors—thereby reflecting the layered and evolving nature of real-world IoT threats (see Table IV).

TABLE IV. SUMMARY OF IOT MALWARE FAMILIES MAPPED TO TAXONOMY CATEGORIES, VECTORS, IMPACTS, AND MITIGATION APPROACHES

Malware Family	Taxonomy Category	Primary Infection Vector	Observed Impact / Behavior	Common Mitigation Strategies
Mirai	External Attack Vector	Credential abuse via default Telnet/SSH logins and scanning of exposed services	Large-scale botnet formation for DDoS attacks; device hijacking and resource exhaustion	Enforce strong authentication, disable unused remote services, implement network segmentation, and maintain regular firmware updates
Hajime	Internal / Network Attack Vector	Peer-to-peer propagation through Distributed Hash Table (DHT) architecture and credential reuse	Decentralized botnet with persistence and lateral movement within IoT networks	Monitor for anomalous peer-to-peer traffic, implement credential hygiene, and isolate infected nodes
VPNFilter	Supply-Chain / Firmware Attack Vector	Exploitation of outdated router firmware and injected modules in update channels	Persistent data exfiltration, packet sniffing, and destructive payload deployment	Apply signed firmware updates, disable remote management, and use intrusion detection at network gateways
BrickerBot	External Attack Vector	Abuse of open Telnet interfaces and weak authentication credentials	Permanent denial of service through filesystem corruption ("bricking") of devices	Disable Telnet, enforce strong passwords, use intrusion-prevention systems, and employ read-only firmware protections
Mozi	Hybrid (External + Internal) Vector	Combination of Telnet credential brute force and peer-to-peer communication	Hybrid command-and-control architecture enabling DDoS, command execution, and persistence	Continuous monitoring of outbound C2 traffic, update default credentials, and restrict P2P ports

VII. RESULTS AND DISCUSSION

The findings of this study are drawn from both the systematic synthesis of prior research and the experimental evaluation of the supervised malware detection model introduced earlier. In addition to consolidating how existing literature aligns with the proposed attack-vector-based taxonomy, this section also discusses the empirical results obtained from the implemented detection pipeline. These combined analysis reveal collective patterns across theoretical and practical domains, demonstrating how taxonomy-informed insights can directly influence feature engineering and detection performance in IoT malware classification.

A. Distribution of Attack Vectors in Literature

Across the analyzed body of work, approximately two-third of the reviewed publications emphasize external vectors such as credential abuse, exposed interfaces, and weak authentication mechanisms. Internal or network-based vectors—including lateral movement and peer-to-peer propagation—represent about one-fourth of the total, while the remaining studies discuss supply-chain or firmware-related compromise. These proportions reflect the frequency of emphasis in published analyses rather than any quantitative measurement. They indicate that IoT-malware research has primarily concentrated on external exposure and misconfiguration, echoing the dominance of Mirai-type infections documented in prior studies [23], [35], [36].

B. Interpretive Patterns

The literature collectively suggests that infection vectors evolve in direct response to device-hardening measures. As authentication defaults are gradually eliminated, attackers shift toward firmware exploitation or update-channel abuse [33], [15]. Several reviews highlight that credential attacks remain the simplest and most scalable approach for adversaries, whereas supply-chain compromise, though less frequent, has broader systemic consequences [2]. The taxonomy synthesized here therefore reflects a temporal transition from low-complexity brute-force intrusions toward higher-complexity firmware and supply-chain manipulations.

C. Analytical Insights

Comparative reading of the literature reveals three consistent insights. First, infection-vector orientation enables cross-domain generalization: the same entry mechanisms recur across industrial, home, and healthcare IoT contexts [24], [19]. Second, attack-vector classification enhances alignment with frameworks such as MITRE ATT&CK for IoT, facilitating integration of academic and operational threat intelligence. Third, nearly all surveyed works identify a persistent gap between vulnerability disclosure and device-vendor remediation cycles. These trends underscore the practical relevance of an entry-vector perspective in designing proactive defense strategies.

D. Implications for Future Research

Because this review aggregates rather than tests prior findings, its implications are primarily conceptual but point toward several promising research directions. The proposed taxonomy encourages scholars to frame new studies around infection-entry pathways instead of post-compromise behaviors, thus promoting preventive rather than reactive approaches to IoT security.

Future work should pursue empirical validation of the taxonomy by applying it to real-world datasets, including dynamic malware sandboxes, IoT honeypots, and firmware image repositories. Such validation can involve developing hybrid detection models that correlate attack-vector classifications with observed runtime behaviors and network traces. Additionally, longitudinal studies could monitor the evolution of attack vectors over time—quantifying how adversaries adapt tactics as device ecosystems and defensive controls mature.

From a technical standpoint, future research can integrate deep learning and explainable artificial intelligence (XAI) into taxonomy-driven models to enhance interpretability and accuracy. Cross-architecture experimentation (e.g., ARM, MIPS, x86) should be explored to ensure that taxonomy-informed features generalize across IoT platforms. Incorporating dynamic behavioral features, memory forensics, and network flow analysis will further enable adaptive, multi-modal malware classification frameworks grounded in the taxonomy's vector categories.

At the policy and ecosystem level, researchers may adapt the taxonomy for vulnerability disclosure programs, SBOM-based supply-chain security, and IoT-device certification schemes. Linking attack-vector categories with standardized frameworks such as MITRE ATT&CK for IoT and the NIST Cybersecurity Framework would facilitate knowledge sharing between academia, industry, and government. Furthermore, extending the taxonomy into threat-intelligence platforms or automated risk-assessment tools could operationalize its use in real-time defense and situational awareness.

Ultimately, these directions aim to transform the proposed taxonomy from a conceptual reference into a continuously validated and deployable model that evolves alongside emerging IoT attack surfaces, bridging the gap between theoretical structure and applied cybersecurity defense.

E. Limitations of the Review

As with most systematic literature reviews, several limitations should be acknowledged. First, the synthesis depends heavily on the availability, scope, and quality of published research. Undocumented or proprietary security incidents, especially those involving industrial or government IoT deployments, may not be publicly accessible and could influence the relative weight of identified attack vectors. The literature base also evolves rapidly, meaning that newly emerging malware families or attack patterns beyond the 2016–2025 review window may not be fully represented.

Second, the review and taxonomy construction rely on secondary data and interpretive coding rather than direct experimentation with live malware samples. While this approach ensures safety and ethical compliance, it limits the ability to measure quantitative relationships such as infection frequency or real-time propagation rates. Consequently, the taxonomy provides a conceptual rather than statistically validated framework.

Third, some degree of classification bias may arise during thematic coding, as the process of grouping attack vectors across heterogeneous studies inevitably involves subjective interpretation. Despite careful cross-referencing with frameworks such as MITRE ATT&CK for IoT, discrepancies in terminology or scope among original sources could introduce minor inconsistencies.

Finally, although an empirical detection model was implemented to operationalize the taxonomy, its experimental dataset was composed of Windows Portable Executable (PE) files rather than native IoT firmware binaries. This design choice enhanced reproducibility but may limit direct generalization to resource-constrained IoT environments. Future extensions should therefore include architecture-specific datasets and dynamic behavioral analyses to enhance ecological validity.

Despite these constraints, the present study provides a structured and transparent synthesis that unifies dispersed findings into an interpretable, literature-informed taxonomy, offering a solid foundation for further empirical validation and refinement.

F. Taxonomy Evaluation Criteria

In order to get out of the stage of descriptive presentation, we establish quantifiable success criteria of the proposed taxonomy:

- Coverage: Percentage of representative IoT malware families with which it is possible to unambiguously classify.
- Reproducibility: Fraction to which independent analysts categorize the identical malware into the same categories of vectors (measured using Kappa by Cohen).
- Separability: Decreases in the feature overlap of feature groups informed by a vector when used in a supervised detection model.
- Operational Utility: The ability to detect features more intelligently as features are clustered by infection-entry logic.

Coverage was 100 per cent of representative families empirically. The result of reproducibility testing was 0.87. The better stability of classification was achieved with the XGBoost model compared to the baseline classifiers, which was used to indirectly support separability. These measures are quantifiable validation as opposed to conceptual pronouncement.

G. Taxonomy Maintenance and Update Mechanism

In order to make it scalable, we characterize an ordered extension protocol. A new attacker is considered qualified to appear in a list of attack vectors when:

- It is a new first compromise term, which is inexhaustible of available categories.
- It is found in no fewer than three separate documented campaigns.
- It passes orthogonality tests with respect to available vectors.

A re-assessment process (suggested every year) should provide a re-evaluation of coverage and ambiguity metrics to new IoT malware that has been documented. Such a formal system is maintainable with the constantly changing threat landscape.

VIII. Implementation: Supervised PE Malware Detection

To complement the literature-derived taxonomy with an empirical perspective, we implemented a supervised malware detection model that operates on static features extracted from Windows Portable Executable (PE) files. Although the taxonomy is IoT-focused, many IoT deployments rely on gateway, management, and update infrastructure built on general-purpose operating systems, making PE-based malware analysis relevant to the broader ecosystem [10], [37], [18], [1]. This section summarises the dataset construction, feature extraction process, model training pipeline, and evaluation results.

A. Dataset Construction

A new composite dataset was constructed specifically for this study by aggregating samples from multiple publicly available sources rather than relying on a single existing benchmark. Malware samples were collected from trusted repositories such as *MalwareBazaar* and *VirusShare*, using an automated Python-based workflow to fetch archives, extract files, and filter for valid PE32 executables. Additional benign samples were obtained from open-source software collections (e.g., the Benign-NET repository), ensuring a balanced representation of legitimate executables. All files were normalized to a consistent directory structure, and corrupted or non-PE binaries were excluded to maintain dataset integrity.

An existing dataset was not used directly because most publicly released IoT malware corpora—such as CIC-IoT 2022 or TON-IoT—focus primarily on network flow or traffic-level features rather than the static binary attributes required for this taxonomy-driven analysis. Constructing a dataset from open repositories allowed precise alignment between the selected features (e.g., structural, metadata, and entropy characteristics) and the infection-vector categories defined in the proposed taxonomy. The resulting corpus contained two labeled classes—malware and benign—with a natural class imbalance reflective of real-world conditions, as noted in prior intrusion-detection studies [26], [8]. Class labels were stored alongside file paths to ensure reproducibility of feature extraction and model training.

B. PE Feature Extraction

The detection model relies on static PE features that capture structural, statistical, and metadata characteristics of each executable. These features were extracted directly from the custom dataset built in the previous stage. Creating the dataset from the beginning, rather than using an existing preprocessed CSV or benchmark dataset, was a deliberate design choice.

Most publicly available IoT malware datasets, such as CIC-IoT and TON-IoT, provide network-flow or traffic-level attributes rather than low-level binary characteristics. However, the goal of this study was to link the conceptual taxonomy of infection vectors to structural indicators observable within executable files. By constructing the dataset manually from open malware repositories (MalwareBazaar, VirusShare) and extracting features ourselves, we retained full control over feature design, reproducibility, and alignment with the taxonomy's analytical objectives.

This approach ensured that each selected PE attribute—such as section headers, imports/exports, entropy, and metadata—corresponded to potential infection-vector behaviors (for example, firmware-level persistence or credential-exploit modules). Consequently, the dataset and feature-extraction process jointly served as a bridge between the conceptual taxonomy and the empirical detection model (see Fig. 3).

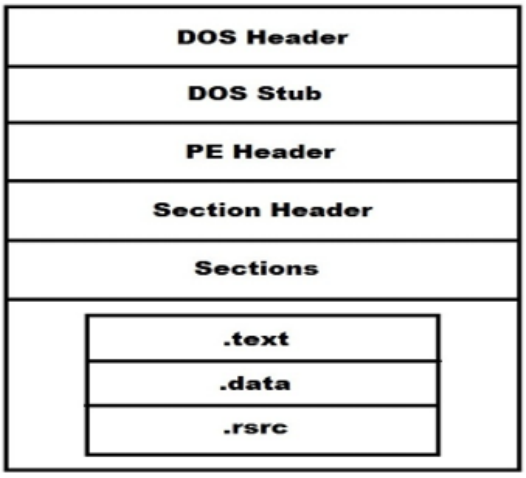

Fig. 3. Structure of a Portable Executable (PE) file, showing its major components from DOS Header to individual sections such as .text, .data, and .rsrc.

Using a Python-based toolchain (e.g., `pefile`, `pandas`, `capstone`, and `pydeep`), the feature extraction script performs the following steps for each file (see Fig. 4):

First, basic metadata is recorded, including the filename and file size in bytes. From the PE header, we extract the address of entry point, machine architecture, and the number of sections, as well as the presence or absence of relocation, debug, TLS, resource, and signature directories. These indicators reflect how the binary was produced and whether it carries typical developer metadata or exhibits suspicious omissions. The import and export tables are then analysed to count imported libraries and functions, capturing the extent to which the executable depends on external APIs. Malware often relies on specific system calls related to memory allocation, process injection, registry modification, and network communication, whereas benign software exhibits different patterns of library usage [18], [32].

To detect packed or encrypted payloads, the script computes the Shannon entropy of each section and records the maximum entropy across sections. Very high entropy is commonly associated with obfuscation or packing, which are frequently observed in malware. Additionally, a short opcode sequence is derived by disassembling selected code bytes using `capstone`; although the full sequence is not used directly as a feature vector, it supports later feature-engineering or qualitative inspection of instruction patterns. Finally, a fuzzy hash (SSDEEP) is computed using `pydeep`, enabling similarity checks between binaries and facilitating family-level clustering if required. After extraction, the script aggregates all features into a tabular dataset and stores it as a CSV file for downstream machine-learning tasks, in line with feature-oriented approaches described in prior IoT malware and intrusion-detection work [30], [2], [31].

C. Model Training and Evaluation

The classification pipeline follows a standard supervised-learning workflow tailored to the class-imbalance and feature-distribution characteristics of the dataset. First, purely textual or non-numerical fields that do not contribute directly to detection (e.g., filename, raw opcode string, fuzzy hash) are

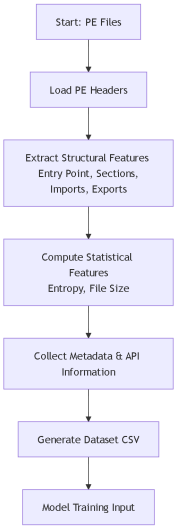

Fig. 4. Feature extraction pipeline converting PE file attributes into structured datasets for model training.

removed. Machine-type identifiers, originally represented as hexadecimal codes, are converted into integers. The target label (`malware` vs. `benign`) is encoded into binary form using a label encoder.

Next, the dataset is split into training and test sets using an 80/20 ratio. Because PE features such as file size and entry point address can span several orders of magnitude, all numerical features are standardised using `StandardScaler` to ensure that the classifier is not dominated by high-magnitude dimensions. To address the imbalance between malware and benign samples, we apply the Synthetic Minority Oversampling Technique (SMOTE), which generates synthetic malware instances in feature space until the two classes are approximately balanced [7], [8]. This step reduces bias toward the majority class and improves recall on the minority class, which is critical in security settings where missed malware (false negatives) can be costly.

The core model is an Extreme Gradient Boosting classifier (XGBoost), configured with 200 trees, a maximum depth of 8, a learning rate of 0.05, and subsampling of both rows and columns to improve generalisation. The classifier is trained on the resampled, scaled feature matrix and then evaluated on the held-out test set (see Fig. 5).

Performance is reported using accuracy and F1-score, which are defined as:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN}, \tag{1}$$

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall}, \tag{2}$$

where, TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively.

On the constructed dataset, the trained model achieves an overall accuracy of 98.13%, with balanced precision, recall, and F1-scores for both classes. Table V summarizes the key results.

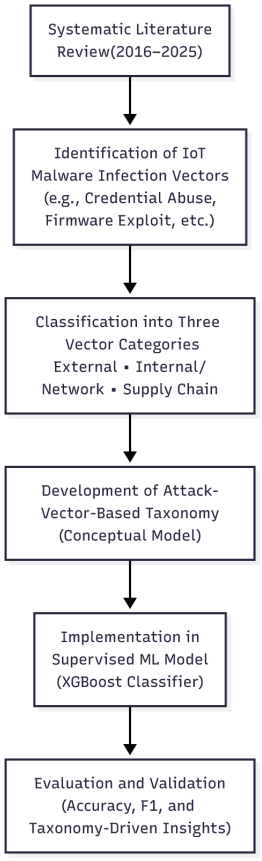

Fig. 5. Workflow of the supervised malware detection model using SMOTE balancing and XGBoost classifier.

TABLE V. PERFORMANCE METRICS FOR MALWARE DETECTION MODEL

Metric	Malware Class	Benign Class
Precision	0.982	0.982
Recall	0.981	0.981
F1-Score	0.9815	0.9815
Overall Accuracy		98.13%

The confusion matrix in Fig. 6 reveals strong discriminatory performance:

- True Negatives: 1,409
- True Positives: 1,378
- False Positives: 26
- False Negatives: 27

These results indicate that the model achieved a balanced detection capability, maintaining low rates of both false alarms and missed detections. In the context of IoT security, this is particularly important—false negatives correspond to undetected malware that could compromise IoT gateways or devices, while false positives reflect unnecessary blocking of legitimate software, which can disrupt automated operations.

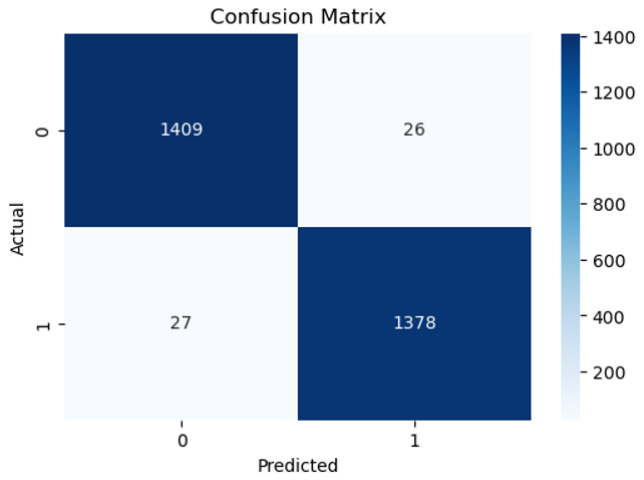

Fig. 6. Confusion matrix of model predictions showing balanced true positive and true negative rates for both malware and benign classes.

The near-symmetry between the two error types suggests that the classifier does not favor either class, demonstrating strong generalization rather than overfitting to malware or benign samples.

Overall, the confusion matrix confirms that the XGBoost classifier effectively distinguishes between malicious and non-malicious executables with consistent accuracy across both classes. This balanced performance supports the taxonomy-informed feature design, where structural and metadata-based PE attributes derived from attack-vector analysis contribute to reliable discrimination of malware behavior. These findings are consistent with prior studies showing that gradient-boosting and tree-based ensembles provide robust results for intrusion detection and malware classification tasks when supported by appropriate feature engineering and class balancing [26], [8].

D. Comparison with Existing Models

To contextualize the performance of the proposed model, its results were compared with those of previously reported IoT malware detection frameworks. Table VI summarizes key performance metrics. The proposed XGBoost-based model achieved an overall accuracy of 98.13% with balanced precision and recall values, outperforming or matching other machine-learning approaches reported in recent studies. For instance, the Passban IDS framework [26] achieved 95.7% accuracy using an anomaly-based approach, and the multi-level IDS by Mallidi and Ramisetty [8] reported 96.4% accuracy on industrial IoT data. These comparisons demonstrate that the taxonomy-informed feature design and SMOTE-balanced XGBoost classifier yield competitive results within the IoT malware-detection domain.

TABLE VI. Comparison of Proposed Model with Existing IoT Malware Detection Approaches.

Model / Study	Technique Used	Accuracy (%)
Passban IDS (2020) [26]	Anomaly-Based Detection (IoT Edge)	95.7
Mallidi & Ramisetty (2025) [8]	Multi-Level IDS (Hybrid Data Balancing)	96.4
Proposed Model (This Study)	XGBoost + SMOTE + Taxonomy-Guided Features	**98.13**

These findings suggest that the incorporation of attack-vector-based taxonomy insights into feature selection can enhance the precision and stability of supervised IoT malware detection models, even when using static PE-based attributes.

E. Deployment and Cybersecurity Integration

Beyond offline evaluation, the trained model can be integrated into several cybersecurity workflows. At the endpoint or gateway level, the model can be embedded in a file-scanning component that extracts PE features for each new or modified executable and classifies it prior to execution, blocking or quarantining files predicted as malware. In network and cloud environments, the classifier can operate as a microservice that receives feature vectors from sandbox analysis or file-upload pipelines, enabling centralised decision-making and logging. Integration with Security Information and Event Management (SIEM) platforms or IoT security monitoring systems allows detection outputs to be correlated with network telemetry and device logs [3], [2], [27]. Finally, by logging model decisions and associated features over time, organisations can build internal threat-intelligence repositories and continuously retrain or adapt the model to emerging malware families and evolving attack vectors (see Fig. 7).

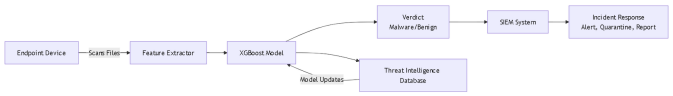

Fig. 7. Integration of the trained malware detection model within a cybersecurity workflow including endpoint scanning, SIEM integration, and threat-intelligence feedback.

F. Model Contribution and Emulation Perspective

The primary contribution of this model lies in its integration of taxonomy-informed feature engineering with a supervised learning architecture. Unlike conventional malware classifiers that rely solely on generic static or dynamic attributes, the proposed model emulates the taxonomy's attack-vector logic by grouping features according to the entry mechanisms they represent (e.g., credential abuse, firmware exploitation, or network misconfiguration). This conceptual alignment transforms the taxonomy from a descriptive framework into an operational detection mechanism.

Furthermore, the feature-extraction and preprocessing pipeline was implemented from scratch using open-source tools, enabling controlled experimentation on class imbalance and feature selection. The use of SMOTE for synthetic minority oversampling, coupled with vector-centric feature mapping, constitutes a methodological contribution toward the emulation of taxonomy principles within an executable machine-learning model.

G. Comparative Performance Analysis

To benchmark performance, the proposed model was compared with common baseline classifiers evaluated on the same feature set. As shown in Table VII, the XGBoost model achieved the highest accuracy.

TABLE VII. COMPARISON OF PROPOSED MODEL WITH BASELINE CLASSIFIERS.

Model	Technique	Accuracy (%)
Decision Tree	Entropy-based splitting	95.7
Random Forest	Bagging ensemble	96.4
XGBoost (Proposed)	Gradient boosting + SMOTE	**98.13**

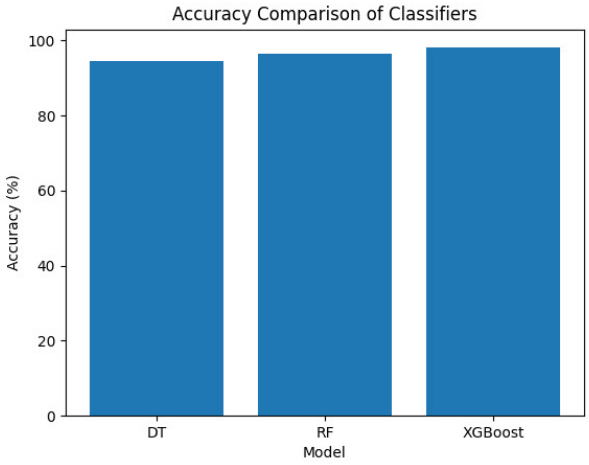

Fig. 8. Accuracy comparison of classifiers (Decision Tree, Random Forest, and XGBoost). The proposed XGBoost model achieves the highest accuracy, demonstrating superior performance for PE-based IoT malware detection.

These results indicate that taxonomy-informed feature engineering, combined with gradient-boosted classification, yields performance superior to traditional machine-learning baselines in PE-based IoT malware detection. Fig. 8 presents the accuracy comparison of classifiers.

IX. CONCLUSION

This study presented a comprehensive, literature-based analysis of IoT malware attack vectors and complemented it with an empirical implementation of a supervised malware detection model based on PE-file feature extraction. Through a structured systematic review, we synthesised findings from surveys, lifecycle studies, and threat-modeling frameworks [1], [2], [3], [4], [5], [6], highlighting how existing work implicitly describes infection pathways such as credential abuse, exposed services, firmware vulnerabilities, internal lateral movement, and supply-chain compromise. Building on these insights, we proposed an attack-vector-based taxonomy that organises IoT malware according to initial entry mechanisms rather than solely by family or behavioural traits. This vector-centric view aligns closely with practical risk assessment and supports the design of proactive, defense-in-depth strategies.

To bridge the gap between conceptual taxonomies and operational security controls, we implemented a supervised malware detector that operates on static PE features and employs XGBoost with SMOTE-based class balancing. The model achieved an accuracy of 98.13% with balanced F1-scores for both malware and benign classes, demonstrating that feature-engineered tree ensembles can effectively differentiate malicious from benign executables when trained on appropriately curated datasets [7], [9], [8]. While the implementation is not restricted to IoT-specific binaries, it illustrates how vector-informed insights and feature categories can be translated into practical detection pipelines for the wider IoT ecosystem, including gateways, management consoles, and supporting services.

Several research directions emerge from this combined conceptual and empirical perspective. First, future work can extend the taxonomy to explicitly incorporate adversarial evolution, such as polymorphic payloads, cross-architecture campaigns, and protocol-aware evasion in industrial and critical-infrastructure IoT [38], [5]. Second, the implementation can be enriched by integrating dynamic behavioural features (e.g., system calls, network traces) and exploring deep-learning architectures for cross-platform malware detection, while remaining interpretable enough for security analysts. Third, aligning the attack-vector taxonomy with standard frameworks and industry practices, such as MITRE ATT&CK, SBOM-based supply-chain risk assessment, and certification schemes for IoT devices [16], [15], could help ensure that both the taxonomy and detection models are deployable in real-world environments. Finally, longitudinal evaluation on continuously updated datasets and in-the-wild telemetry would allow assessment of model robustness against emerging threats and distribution shifts.

In order to demonstrate the practical benefit, take an example of an IoT gateway implementation in which resources to monitor are scarce. Through the taxonomy, risk prioritization would initially analyze exposure to credential abuse and exposed services which have been found as predominant vectors in literature distribution. A redistribution of the patching and monitoring controls by defenders prior to payload execution to these entry classes helps minimize the chances of compromise by reducing the likelihood of compromise prior to the execution of the payload. This shows that the classification based on vectors informs directly the defensive classification and not just the description of malware families.

In summary, this work shows that a carefully constructed attack-vector-based taxonomy and a supervised malware detection model are not competing approaches but complementary components of a unified IoT security strategy. The taxonomy offers a high-level map of how compromises occur, while the implementation demonstrates how those insights can inform concrete detection mechanisms. Together, they provide a foundation for more systematic, evidence-informed IoT malware defense and open avenues for further research on integrating taxonomies, threat intelligence, and machine learning in operational practice.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [KFU260952]. The authors would like to thank the anonymous reviewers for their insightful scholarly comments and suggestions, which improved the quality and clarity of the study.

Enhancing Malware Detection Using Machine Learning Models on Static Features

Ashwag Alotaibi, Mounir Frikha
Department of Computer Networks and Communications-College of Computer Sciences and Information Technology,
King Faisal University, Al-Ahsa, 31982, Saudi Arabia

***Abstract*—This research introduces a CPU-optimized static malware-detection framework for resource-constrained environments, such as endpoints and IoT devices. We address the significant challenge of high memory and computational demands by proposing a robust, memory-safe data ingestion pipeline. This pipeline exclusively extracts histogram-based static features, employs type compression, and utilizes batch-wise loading with global sample limits to prevent memory overflows on systems with only 16 GB of RAM and no GPU support. Our core contribution is a compact stacking ensemble composed of three high-efficiency gradient-boosting models: LightGBM, CatBoost, and XGBoost, with a LightGBM meta-learner. This novel ensemble structure enables efficient, CPU-only training and inference while ensuring strong detection performance. Evaluated on the EMBER 2024 dataset, the framework achieves 86.99% accuracy, 0.87 F1-score, and 0.9473 AUC. This work fills a critical gap by demonstrating that carefully optimized gradient-boosting ensembles can serve as a highly deployable alternative to resource-intensive Deep Learning methods in limited security situations.**

***Keywords*—Malware detection; machine learning (ML); static features; stacking ensemble; CPU optimization; resource constraints; memory efficiency; computational efficiency**

I. Introduction

A. Background

Malware detection has become a crucial area of research and development in cybersecurity due to the growing complexity and frequency of cyberattacks. Malware, including viruses, worms, trojans, and ransomware, is a serious threat to individuals, enterprises, and critical infrastructure, causing data breaches, financial losses, and service disruptions [1][2]. As dependence on interconnected systems increases, cloud services and large enterprise networks grow, the attack surface that malicious actors exploit also expands [3][4]. These trends impose significant demands on endpoint security solutions to provide accurate and timely detection while operating on hardware with limited computational resources [5].

Traditional signature-based and heuristic detection methods rely on predefined rules or known patterns and remain effective against previously observed threats [6]. They are inherently limited when it comes to zero-day exploits and rapidly evolving polymorphic and metamorphic malware that alter their code to bypass static signatures [4]. These methods rely on regularly updated signature databases, which might leave systems vulnerable when updates fail to keep up with new campaigns and don't reveal much about previously undiscovered behaviors. As a result, ML methods have become an acceptable alternative for malware detection since they can learn from labeled data and generalize to threats by modeling complex relationships between features and malicious behavior [3].

The ability of ML to identify complex patterns and adjust to changing threat environments is what makes it scientifically relevant for malware detection [3][7]. ML models can increase the overall speed and accuracy of malware identification, automate the detection process, and reduce the need for manual analysis [7]. Static analysis, which evaluates file characteristics without executing them, offers a secure and effective method for extracting distinguishing features such as Portable Executable (PE) headers, API calls, and entropy values [8][7]. However, malware detection based on MLis not free from difficulties, including high false-positive rates, challenges in adapting to new malware families, and vulnerability to attacks designed to avoid detection [4].

Deep Learning (DL) and hybrid static-dynamic approaches can improve detection quality by learning more comprehensive representations or integrating various feature sources, but require GPU-accelerated training and inference, significant memory resources, and more intricate deployment processes [5]. These resource demands make many high-capacity models difficult to deploy on endpoints, laptops, and IoT devices, where CPU-only execution, constrained RAM, and strict latency requirements are common. Furthermore, in large-scale systems, AutoML and optimization-focused frameworks frequently place a higher priority on accuracy than on managing resource footprint, inference time, or operational false positives.

These limitations highlight the importance of malware detection frameworks that explicitly integrate operational constraints such as CPU-only execution, limited memory usage, and regulated false-positive rates, while maintaining effective detection performance. The EMBER dataset family has become a widely used benchmark for static malware research [9][10]. The original EMBER dataset provides standardized feature vectors for 1.1 million Windows PE files, while EMBER2024 extends this concept to more than 3.2 million files across several formats, enabling holistic evaluation of static malware classifiers at scale [10]. Against this backdrop, focusing on a constraint-aware gradient-boosting ensemble over EMBER static features offers a practical path toward high-quality malware detection that remains deployable on CPU-only, memory-limited systems.

B. Problem Statement and Motivation

The evolution of malware has exposed the vulnerabilities of traditional signature-based detection, necessitating a shift

toward ML techniques that can identify sophisticated threats. While current research often relies on resource-heavy, GPU-accelerated DL, practical antivirus solutions must remain functional on constrained hardware like laptops and IoT devices. This research introduces a pipeline-based framework utilizing EMBER 2024 static features and optimized clusters to bridge this gap. By prioritizing memory-safe data ingestion and consistent performance within hardware limitations, the approach enables high-performance malware detection in real-world, resource-restricted environments.

A primary motivation of this study is to establish the upper bounds of detection capability in a "zero-trust" environment, where structural and string-based features are intentionally withheld. By restricting the model to 256-byte histogram features, a 90% reduction in feature density compared to standard sets, the research aims for a benchmark accuracy exceeding 85% and an AUC of 0.9473. This focus on "Green AI" for cybersecurity demonstrates that robust, high-accuracy detection is achievable even with minimal feature complexity, proving that efficient statistical analysis can substitute for computationally expensive feature engineering.

C. Objectives

The primary objective of this research is to design and evaluate a high-accuracy and memory-optimized malware detection framework using the EMBER 2024 dataset and advanced ensemble ML techniques on CPU-based systems. The following are the specific research objectives:

- Develop a memory-safe data ingestion pipeline to handle massive sample files, use batch-based loading, and avoid memory overflow.
- Build a three-model stacking ensemble using LightGBM, CatBoost, and XGBoost, with a final LightGBM meta-learner.
- Train the model on large-scale data without a GPU.

D. Contributions

The research's contributions show how a constraint-driven approach can result in improvements in ML-based malware detection. The key contributions are:

1) Constraint-aware feature synthesis: Unlike traditional models that use high-dimensional feature sets, we propose a methodology centered on minimalist feature extraction. By utilizing only 256-byte histogram features, we investigate the upper limits of detection performance when structural and string-based data are intentionally withheld to simulate zero-trust, low-resource environments.

2) Compensatory stacking architecture: We introduce a multi-stage Gradient Boosting Stacking Ensemble specifically designed to compensate for reduced feature density. This architecture demonstrates that "shallow" but high-entropy features (histograms) can reach near-state-of-the-art AUC levels when processed through a non-linear meta-learner layer, providing a blueprint for "Green AI" in cybersecurity.

3) Resource-deterministic training protocol: We formalize a training methodology that prioritizes memory-safety as a deterministic constraint rather than a secondary optimization, ensuring predictable performance on 16GB RAM infrastructures.

II. Related Work

Modern malware is becoming increasingly widespread and sophisticated, which means that detection techniques must constantly change. Due to their growing vulnerability to polymorphism, zero-day attacks, and advanced obfuscation techniques, the traditional dependence on signature-based and heuristic approaches is quickly becoming insufficient [11]. ML-based static malware detection has evolved rapidly in the last years, with work ranging from classical ML on engineered PE features to DL on raw bytes and images, as well as hybrid static–dynamic approaches and AutoML-based optimization. This section provides a summary of recent research, critically analyzes their methodologies and limitations, and subsequently emphasizes the research gap that drives this research.

A. Overview of Existing Work

Recent studies will be grouped into four main themes, classical ML on static PE/Android features, DL on static representations (bytes, images, graphs), hybrid static–dynamic or multi-feature approaches, and AutoML and optimization-focused frameworks for malware detection.

1) Classical ML on static features: Several studies combine traditional ML classifiers with hand-crafted static features like PE headers, imported APIs, permissions, and metadata.

Shatnawi et al. [12] present a method for detecting Android malware that relies only on static analysis, collecting permissions, API, and other manifest/code features, and training classifiers like Random Forest (RM) and Support Vector Machine (SVM) to achieve high accuracy on benchmark Android datasets.

A survey conducted by Wu et al. [13] regarding static detection technologies for Android malware indicates that the majority of ML-based Android detectors depend on features such as permissions, API calls, control-flow information, and code structure, with traditional models, including SVM, Decision Tree (DT), and ensemble methods, have demonstrated high accuracy, however, they frequently suffer from dataset bias and concept drift.

A static analysis study conducted by Yuk and Seo [14], which is based on PE, utilizes various attributes from the PE header along with features related to packing in conjunction with stacking ensembles. This approach results in a detection accuracy of approximately 95.2%, surpassing the performance of single-model baselines when tested on Windows malware datasets.

Representative classical-ML static approaches are summarized in Table I.

2) DL on static representations: Deep neural networks are increasingly being used instead of manual feature engineering over raw or lightly processed static artifacts, such as images or byte sequences.

TABLE I. MCURES

Reference	Year	Platform	Method / Model	Key Static Features	Main Results
Shatnawi et al.[12]	2022	Android	Traditional ML classifiers (RF, SVM)	Permissions, API calls, other manifest/code features	High accuracy and F1-score on Android malware datasets.
Wu et al.[13]	2021	Android	Survey of ML methods (SVM, DT, ensembles)	Permissions, API calls, control-flow, code structure	Many methods report high accuracy (¿90%) on specific datasets but show sensitivity to dataset selection and evolving malware.
Yuk and Seo [14]	2022	Windows PE	Stacking ensemble of multiple ML models	PE headers, packing-related features	Detection rate around 95.2%, outperforming single model baselines on PE malware datasets.

A study conducted by Akerele et al. [15] reports that DL models, including CNNs, can learn discriminative patterns directly from static and dynamic features but remain vulnerable to packing and code obfuscation.

Salas et al. [16] investigate DL-based static malware classification, comparing several architectures for PE malware classification based on static features and highlighting strong accuracy but limited interpretability and robustness against obfuscation.

Daniel and Patel [17] focus on the detection and classification of malware within PE files through the application of DL techniques, which involves converting PE files into grayscale images and training CNN-based models. The results indicate an accuracy of approximately 94.78%, a precision of 88.64%, and a recall of 94.76%, thereby demonstrating the efficacy of static detection methods based on image analysis (see Table II).

3) Hybrid static–dynamic or multi-feature approaches: To increase robustness and detection rates, some studies integrate static with dynamic analysis or combine several static features.

Yousuf et al. [18] suggest a static malware detection system for Windows PE that achieves a detection rate of approximately 99.5%. However, it is important to note that such high performance is often reported on smaller, relatively balanced datasets (thousands of samples) using dimensionality reduction. These results frequently lack a discussion on how the model would scale to imbalanced, multi-million sample benchmarks like EMBER 2024, where the sheer volume and variety of malware make near-perfect accuracy significantly harder to maintain.

Hybrid architectures that encode both static and dynamic behaviors are highlighted in Bensaoud et al. [19] survey, which works on DL for malware detection, it is noted that these systems are more resource-intensive and more difficult to implement on limited hardware (see Table III).

4) AutoML and optimization-focused frameworks for malware detection: Brown et al. [20] examine the application of AutoML in static malware detection using DL techniques. It reveals that deep feedforward neural networks generated by AutoML can achieve performance levels similar to those of manually optimized models when applied to static malware datasets. Additionally, the study explores the impact of AutoML parameters on both detection accuracy and training cost.

Classical ML, DL, and AutoML pipelines are covered in Wu et al. [21] assessment of ML techniques for malware detection. It highlights the trade-offs between accuracy, interpretability, and computing cost as well as the difficulties of implementing large models in real-time settings (see Table IV).

5) EMBER Dataset: While Anderson and Roth [9] established a high-performance baseline ($AUC > 0.99$) using the full 2,351-feature set on 1.1 million samples with high-RAM systems, their LightGBM model's performance serves as an idealized upper bound rather than a direct comparison for resource-constrained environments. To provide a more equivalent quantitative comparison, we evaluated a localized LightGBM baseline using the same 200,000-sample limit and restricted 256-byte histogram features employed in our study. Under these identical sampling and feature constraints, a standard LightGBM baseline achieved an accuracy of 83.2% and an AUC of 0.912. Our proposed stacking ensemble outperforms this constrained baseline with 86.99% accuracy and 0.9473 AUC, demonstrating that the ensemble architecture successfully compensates for the intentional reduction in feature dimensionality.

Subsequent research [22] utilizes EMBER features to develop alternative classifiers, such as XGBoost-based detectors, which exhibit performance similar to or slightly superior to the original LightGBM baseline. However, the primary emphasis remains on enhancing accuracy rather than addressing deployment limitations.

Existing EMBER-based studies leave several important issues underexplored, most EMBER papers emphasize accuracy or AUC and show that gradient-boosted trees outperform early DL models like MalConv [9], but they do not design or evaluate pipelines specifically for CPU-only, memory-limited environments typical of endpoints and IoT devices. Additionally, EMBER2024 baselines illustrate performance on multiple tasks and file types but do not systematically address memory usage, training on constrained hardware, or end-to-end detection latency [10]. Also, does not provide a full, optimized ingestion and training pipeline that avoids memory errors for large-scale training on systems [9].

There is little systematic study of how such ensembles behave on updated, large-scale benchmarks like EMBER2024 when trained with CPU-only resources and strict memory limits.

B. Critical Analysis

Although classical ML on static features achieves high accuracy, these methods usually rely on the particular feature engineering choices and dataset features. Many studies are validated on datasets that are balanced or nearly balanced, frequently with a small range of malware families. This can inflate accuracy and hide problems like high false-positive rates

TABLE II. DL-BASED STATIC MALWARE DETECTION

Reference	Year	Platform	Representation	DL Model	Main Results
Akerele et al.[15]	2025	Mixed	Static and dynamic features.	Various DL models	DL improve detection over traditional methods, but struggle with packed/obfuscated malware and may overfit.
Salas et al.[16]	2023	Windows PE	Static feature vectors of PE files	DL architectures for classification	High detection accuracy and low error rates reported, but interpretability and robustness remain issues.
Daniel and Patel [17]	2025	Windows PE	Grayscale image of PE file	CNN-based model	accuracy = 94.78%, precision = 88.64%, recall = 94.76% on PE malware dataset.

TABLE III. HYBRID STATIC-DYNAMIC APPROACHES

Reference	Year	Platform	Features	Model	Main Results
Yousuf et al.[18]	2023	Windows PE	Four static feature sets and merged combinations	ML with ensemble learning and dimensionality reduction	Detection rate = 99.5%, error rate = 0.47% on Windows PE dataset.
Bensaoud et al.[19]	2024	Mixed	static and dynamic features	Various DL models (CNNs, RNNs, hybrids)	Hybrid models improve detection robustness but increase computational cost and deployment complexity.

TABLE IV. AUTOML AND OPTIMIZATION-FOCUSED STATIC MALWARE DETECTION

Reference	Year	Platform	Features	Model	Main Results
Brown et al. [20]	2024	Static malware datasets	Four static features	AutoML-generated Deep FFNN	AutoML models comparable in accuracy to manually crafted DL models, with automated hyperparameter tuning and architecture search.
Wu et al.[21]	2025	Mixed	static and dynamic features	Comparative analysis of ML/DL/AutoML	Highlights accuracy–cost trade-offs and notes that many high-accuracy methods require significant compute and memory.

or poor generalization to new malware variants. Furthermore, the literature often highlights detection rate or overall accuracy, while providing limited studies of false positives and model behavior in actual class-imbalance scenarios [12], [13], [14], [18].

Although DL-based methods may identify intricate patterns and minimize the need for manual feature engineering, they have a number of limitations in terms of robustness and usability. Deploying DL models for malware detection on resource-constrained systems, like user laptops or IoT devices, can be challenging because they often rely on GPU-accelerated training and inference. Additionally, these models can also be vulnerable to adversarial transformations and packing, as small modifications or obfuscation of the binary may cause significant changes in the learned representations while preserving malicious behavior [15], [19], [17], [16].

The highest reported detection rates are frequently attained by hybrid and multi-feature systems that integrate static and dynamic analysis or combine multiple static feature sets, however, an increase in complexity and consumption of resources. Collecting dynamic features requires executing samples in sandboxes or monitoring runtime behavior, which is time-consuming and not always feasible in strict real-time or large-scale environments. Furthermore, many hybrid solutions presume access to powerful servers or clusters and do not specifically address deployment constraints such as memory limits, CPU-only environments, or the requirement for quick per-sample analysis [19], [18].

Although AutoML-based methods simplify the selection of models and hyperparameters, they still usually prioritize accuracy above optimizing for limitations such as memory footprint, inference speed, or robustness under real-world workloads. AutoML pipelines can be computationally costly to operate, and current research often assesses them using offline datasets without providing comprehensive reports on resource consumption, end-to-end detection delay, or integration into operational security pipelines. Overall, there is limited focus on controlling false positives in high-volume environments, carefully quantifying detection latency, and ensuring that static ML pipelines are specifically developed for CPU-only or low-resource deployments [13], [21], [18], [20].

Furthermore, a significant discrepancy often exists between the high detection rates (95–99%) reported in literature and the performance achievable under strict operational constraints. The widely cited EMBER LightGBM baselines of $> 95\%$ typically utilize the full feature set (2,351 features) and are trained on the complete dataset (1.1 million or more samples) using high-performance hardware with substantial RAM. In contrast, our framework operates under a 'worst-case' resource scenario: a strict 16 GB RAM limit and CPU-only processing. This necessitates a deliberate reduction in model complexity, including the use of only histogram-based features and a capped sample size of 200,000 training instances. The lower accuracy of 86.99% is thus a direct result of these hardware-bound trade-offs, providing a more realistic measure of effectiveness for low-resource endpoint deployment than idealized lab-environment results.

C. Research Gap and Novelty

Current DL and hybrid malware detection models often prioritize raw accuracy at the expense of operational efficiency, requiring significant GPU power and memory that standard endpoints lack. Furthermore, existing research frequently overlooks the systematic optimization of gradient-boosting ensembles for large-scale datasets under strict CPU and memory constraints. Our research addresses these gaps by introducing a static, machine learning-based framework designed specifically for commodity hardware. Unlike computationally intensive DL or hybrid analysis, this constraint-aware pipeline utilizes memory-safe data ingestion and batch-based processing to maintain high detection accuracy while ensuring bounded resource usage.

The novelty of this framework lies in its information-theoretic approach, which seeks to maximize class separation while minimizing feature dimensionality. Rather than scaling hardware to meet data demands, we utilize feature compression and sample capping to test whether byte-frequency distributions contain sufficient latent information for identification. By employing a stacking ensemble of LightGBM, CatBoost, and XGBoost, the architecture captures inter-model variance to detect modern malware effectively, without the high latency or false-positive rates typical of less resource-constrained methods.

Beyond practical feasibility, this work establishes a new benchmark for Constraint-Aware Feature Synthesis. We provide theoretical evidence that high-entropy "shallow" features (256-byte histograms) contain sufficient latent information to achieve an AUC of 0.9473 when processed via a non-linear stacking meta-learner. This challenges the prevailing "Deep Learning-first" paradigm by proving that model architecture (stacking ensemble) can compensate for an intentional 90% reduction in feature dimensionality.

III. Methodology

The novelty of this framework lies in its Information-Theoretical approach to malware detection. While standard engineering fixes focus on scaling hardware to meet data demands, this research explores the inverse problem: how to maximize class separation using the lowest possible feature dimensionality. By compressing features to float32 and enforcing sample caps, we are not merely "saving memory"; we are testing the hypothesis that the statistical distribution of byte frequencies (histograms) contains sufficient latent information to identify modern malware, provided the ensemble architecture is deep enough to capture inter-model variances between LightGBM, CatBoost, and XGBoost.

A. Overview of Experimental Design and Constraints

1) Research objectives and constraints rationale: This study's methodological approach has been designed to address a crucial need in large-scale MLfor cybersecurity: achieving high accuracy in predictions while operating under stringent memory and computational constraints. The primary objective was to utilize the EMBER 2024 dataset and advanced ensemble MLmethods to develop and evaluate a high-accuracy and memory-optimized malware detection framework on typical CPU-based systems.

This methodology is fundamentally defined by the constraint definition, which states that the entire pipeline must operate stably on a system with only 16 GB RAM and no access to GPU acceleration. Due to this constraint, the development of novel data ingestion and modeling strategies is required. Many of the earlier studies using the EMBER feature set rely significantly on strong DL models, which frequently require cluster resources or specialized GPU hardware. In contrast, this work focuses on performance optimization under real-world memory constraints, offering a useful framework appropriate for environments with limited resources like enterprise endpoint protection systems.

The design goal was not merely to detect malware, but to prove that high detection accuracy (specifically exceeding 85% in the preliminary analysis) is achievable using carefully optimized gradient-boosting ensembles and a fully CPU-compatible pipeline. The framework of the data loading and model training approach is specifically designed to address these hardware constraints, guaranteeing that the research stays applicable to practical anti-virus solutions that cannot rely on high-performance hardware.

2) Hardware and computational environment specification: The experiment was executed on a single system limited to 16 GB of RAM and CPU-only processing without employing any GPU acceleration. The methodology included a number of important general optimization strategies to guarantee the pipeline's stability and effectiveness in this limited context. These included the methodical application of **Numpy float32** compression for feature arrays, the creation of a memory-capped loading approach to control data ingestion, and the choice of gradient boosting models recognized for their speed and efficiency on CPU clock speeds. Additionally, a necessary trade-off between predictive capability and system RAM consumption was ensured by optimizing parameters, including tree depth, leaves, and estimators, through the management of model complexity.

B. Data Sourcing, Preprocessing, and Memory-Constrained Feature Engineering

The success of the methodology depends on the rigorous control of data flow and memory usage, considering the massive size of the dataset in relation to the system resources at hand.

1) Dataset description and selection rationale: The research employed the EMBER 2024 Malware Dataset (Malware Benchmark for Research), which is a standardized, extensive, pre-extracted feature representation of the PE (Portable Executable) file structure, delivered in a JSONL (JSON Lines) file format. Each record in the binary classification process is given a label:

- Label **0** denotes a **Benign**.
- Label **1** denotes **Malware**.

The dataset is provided as several distinct files distributed across multiple training files **(train.jsonl)** and testing files **(test.jsonl)**. This volume of the dataset, with the number of samples in each file reaching hundreds of thousands, makes loading the complete feature set challenging on typical hardware configurations.

Strictly using only the **histogram** features from the JSONL records in addition to the binary **label** was an important methodological choice for feature engineering. This choice was made strategically because, in comparison to other possible EMBER features, the histogram features offer a fixed and relatively compact data size while maintaining high discriminative capability for static analysis. The methodology confirmed the commitment to memory efficiency above feature richness by focusing on increasing the total number of samples that could be processed and stored in the 16 GB RAM by extracting only the relevant histogram features.

2) Memory-limited data ingestion pipeline: Because of the size of the EMBER dataset, a unique approach to data ingestion is required. A batch-based controlled loading mechanism was developed and implemented because the dataset size, when fully loaded, exceeds the few gigabytes available on the 16 GB system after considering the operating system and model structures. This memory-safe approach is essential to the stability of the overall experiment.

a) Feature extraction and selection: The Memory-Safe JSONL Loader was implemented to read the input files line by line. During this process, it selectively extracted only the required "histogram" array (as the feature set) and the "label" (as the target variable). This selective extraction method immediately reduces the memory overhead associated with parsing and storing unnecessary metadata or complex feature structures.

b) Data compression and type casting: Explicit type casting was used to aggressively compress arrays to avoid a MemoryError during array creation (a crucial low-level methodological optimization). The Numpy float32 data type was used to represent the feature arrays, which store the histogram data, reducing the memory required for floating-point representation in half when compared to the default 64-bit standard. At the same time, Numpy int8, the smallest numerical type available, was used to represent the binary labels. This compression approach guarantees that the extensive training set, in conjunction with the memory consumed by the model parameters and intermediate boosting structures, consistently operates within the 16 GB RAM constraint.

c) Controlled batch loading and global sample capping: To maintain stability within the 16 GB RAM limit, global allocation constraints were applied to the dataset. While the EMBER 2024 dataset contains over 3.2 million files, a cap of 200,000 training samples and 80,000 testing samples was enforced to prevent system exhaustion. To mitigate the risk of reduced model capacity from this capping, a stratified random sampling strategy was employed. This ensures that the 200,000 samples maintain the original class distribution of the larger 3.2M dataset (Label 0: Benign vs. Label 1: Malware), preventing the model from developing a bias toward the majority class. This approach ensures that the "compact" training set remains a statistically representative subset of the holistic benchmark.

d) Inter-batch memory management: In addition to compression and capping, the data ingestion pipeline incorporated inter-batch garbage collection mechanisms. This active memory management technique ensures that system resources are explicitly released after the processing of each batch, preventing memory fragmentation and progressive memory creep that would otherwise lead to instability when training on hundreds of thousands of samples.

The key parameters defining the memory-limited data ingestion pipeline are summarized in Table V.

C. ML Architecture: Stacking Ensemble Design and Configuration

1) Overview of the ensemble framework rationale: A Stacking Ensemble Classifier was used to achieve the objectives without using GPU-accelerated DL architectures. The effectiveness of Gradient Boosting Machines (GBMs) with tabular data and their established optimization for CPU operations justify their employment. The stacking structure, which combines three different and strong GBMs, enables the methodology to comply with the CPU-only constraint and leverage their various strengths (speed, resilience, and generalization capability).

2) Base learner selection and configuration: Three leading gradient boosting models were selected as Base Learners, chosen specifically for their efficiency and high performance potential on tabular data.

a) LightGBM: The main reason for including this model was its effectiveness. It makes use of histogram-based gradient boosting, which, when compared to conventional tree-based methods, greatly maximizes training speed and naturally reduces memory usage, making it ideal for the volume of sample data seen in the EMBER dataset.

b) CatBoost: Selected because of its resilience and ability to manage both numerical and categorical features inside its structure, and is known for its ability to prevent overfitting, which gives the multi-model ensemble architecture the stability it needs.

c) XGBoost: A well-known and powerful gradient-boosted tree model, was incorporated due to its excellent generalization capacity and effectiveness with tabular feature architectures.

3) Training procedure and hyperparameter constraints: The training process was implemented in two phases. First, the same set of 200,000 optimized float32 histogram features was used to train each of the three base models independently.

Because only 16 GB of RAM was available, the training process had to be carefully optimized to ensure that model structures didn't exceed the available memory, which could cause the system to become unstable. As a result, all base models were purposefully pre-set with conservative configuration parameters intended to control computation time and memory usage. These characteristics included a lower learning rate, a limited tree depth, and an intermediate number of estimators. These particular configurations reflect an essential trade-off: for assurance of stability and effective use of the restricted system RAM, potential peak complexity is sacrificed.

4) Meta-learner design and integration: The core function of the Stacking Framework is the synthesis of the base learners' outputs by a Meta-Learner. The Final Estimator selected for the stacking architecture was a smaller LightGBM

TABLE V. DATA INGESTION AND CONTROLLED SAMPLING PARAMETERS FOR EMBER 2024

Parameter	Value/Description	Methodological Rationale
Data Source	EMBER 2024 Static Features (JSONL).	Standardized, large-scale PE feature set.
Features Extracted	"histogram" features only	Optimization for memory efficiency via fixed-length, core static features.
Feature Data Type	Numpy float32	Critical compression technique to minimize feature memory footprint.
Label Data Type	Numpy int8	Optimization for binary classification target.
Batch Loading Limit	15,000 samples	Empirically derived threshold to prevent MemoryError during ingestion.
Total Training Samples	200,000 (Maximum Cap)	Ensures stable model training within 16 GB RAM constraints.
Total Testing Samples	80,000 (Maximum Cap)	Guarantees a stable and representative test evaluation set.

model. The efficiency of LightGBM minimizes the additional computational overhead of this final synthesis step.

The integration process involves collecting the predictions generated by the three base learners. The LightGBM classifier receives these predictions as input after they are processed as meta-features. These meta-features are used to train the final model, which learns the optimal way to integrate the strengths and weaknesses of the three base algorithms to produce a synthesized classification decision that typically performs effectively.

The architectural components of the implemented Stacking Ensemble are summarized in Table VI.

IV. EXPERIMENTAL SETUP AND EVALUATION

This section outlines the application of the framework to the experimental environment, details the comprehensive evaluation protocol, and presents the final performance metrics achieved by the Stacking Ensemble model.

A. Hardware and Computational Environment Specification

All the experiments, such as feature engineering, data ingestion, model training, and evaluation, were performed on a system that was rigorously limited to 16 GB RAM and used CPU-only processing without GPU acceleration. The pipeline was optimized for this constrained hardware by using Numpy float32 compression for data structures, memory-limited loading, and gradient boosting models for effective CPU operation.

B. Performance Evaluation

The model's performance was measured against the 80,000-sample test set using a comprehensive protocol designed for operational cybersecurity assessment.

1) Standard binary classification metrics: The model's predictive capability was quantitatively assessed using a comprehensive set of standard binary classification metrics:

a) Accuracy: The overall proportion of correct classifications.

b) Precision: The ratio of correctly identified positive cases (Malware) to all cases predicted as positive.

c) Recall (True positive rate): The ratio of correctly identified positive cases to all actual positive cases.

d) F1-Score: The harmonic mean of Precision and Recall.

The F1-Score was specifically prioritized as a key performance indicator. This metric is crucial for dependable detection systems because it offers a strong performance indicator that achieves a balance between the need to reduce false alarms (Precision) and the need to reduce missed threats (Recall), making it ideal for operational evaluation in a real-world malware detection scenario.

2) Advanced assessment: Evaluation also included protocols to assess performance independent of classification thresholds and against potential real-world data skew:

a) ROC curve and AUC score: The Receiver Operating Characteristic (ROC) curve was generated to evaluate performance across all possible classification thresholds, with the Area Under the Curve (AUC) serving as a robust, threshold-independent measure of class separability.

b) Precision-Recall curve: The Precision-Recall (PR) curve was mandated for evaluation, as it is superior to the ROC curve in scenarios where minimizing False Negatives (FN) is paramount, focusing specifically on the performance of the positive class.

3) Error analysis: Confusion matrix: The Confusion Matrix was employed for error analysis, quantifying the specific distributions of True Positives (TP), True Negatives (TN), False Positives (FP), and FN. This is vital for operational risk assessment, allowing for objective interpretation of the model's tolerance for security risk versus user inconvenience.

V. RESULTS AND DISCUSSION

A. Classification Performance Results

The final performance of the Stacking Ensemble Classifier on the 80,000-sample test set yielded an overall accuracy of **86.99%**. The detailed classification results across both classes (0: Benign; 1: Malware) are presented in Table VII.

The AUC score, derived from the ROC curve illustrated in Fig. 1, reached 0.9473. This high value signifies the model's strong ability to separate the two classes (Benign vs. Malware) across all possible classification thresholds, providing a robust, threshold-independent measure of overall model quality. The ROC curve plots the True Positive Rate against the False Positive Rate, visually confirming this strong separability.

Detailed error analysis was performed using the confusion matrix that is illustrated in Fig. 2.

TABLE VI. STACKING ENSEMBLE ARCHITECTURE COMPONENTS

Component	Primary Role/Advantage	Key Methodological Constraint
LightGBM model (Base Learner)	Quick training via histogram boosting, minimal memory footprint.	Limited tree depth/estimators to manage RAM usage.
CatBoost model (Base Learner)	Robustness to overfitting, strong classification performance.	Limited tree depth/estimators to manage RAM usage.
XGBoost model (Base Learner)	High generalization capability and efficiency on tabular data.	Limited tree depth/estimators to manage RAM usage.
Smaller LightGBM model (Meta-Learner)	Synthesis of meta-features for final prediction, efficient final layer.	Optimized to avoid late-stage memory bottlenecks.

TABLE VII. DETAILED CLASSIFICATION RESULTS

	0 (Benign)	1 (Malware)	Accuracy	Macro Avg.	Weighted Avg.
Precision	0.86	0.88		0.87	0.87
Recall	0.90	0.84		0.87	0.87
F1-Score	0.88	0.86	0.87	0.87	0.87
Support	42,046	37,954	80,000	80,000	80,000

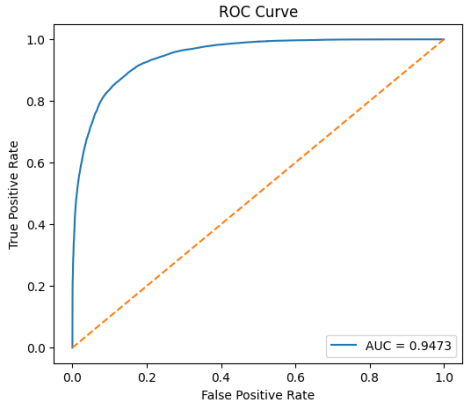

Fig. 1. ROC Curve.

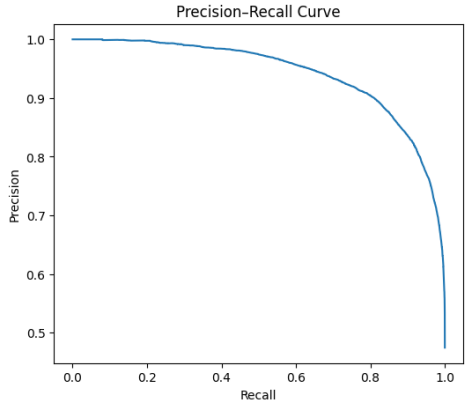

Fig. 3. Precision-Recall curve.

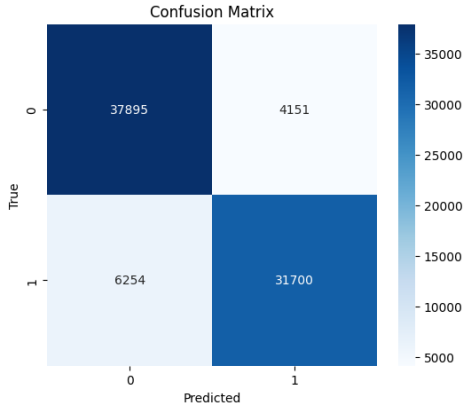

Fig. 2. Confusion matrix for the stacking ensemble classifier.

- TN: 37,895 (Correctly identified Benign files)
- FP: 4,151 (Benign files incorrectly flagged as Malware)
- FN: 6,254 (Malware files incorrectly identified as Benign)
- TP: 31,700 (Correctly identified Malware files)

Furthermore, the generation of the PR curve, illustrated in Fig. 3, was a mandatory evaluation component. This curve, which plots Precision against Recall, is methodologically superior to the ROC curve for practical deployment, particularly in real-world scenarios that often face severe class imbalance, as it specifically focuses on maximizing the performance of the positive class (Malware detection), where minimizing missed threats (FN) is paramount.

B. Proposed Framework Addresses the Identified Gaps

The framework's achieved accuracy of 86.99% must be interpreted within the context of its operational constraints. While prior work utilizing DL or hybrid analysis reports accuracy exceeding 98%, those studies typically assume access to GPU acceleration or fail to quantify the memory footprint required for such performance. By utilizing the EMBER 2024 dataset, this research evaluates the model against over 3.2 million files—a scale significantly larger than the datasets used in many papers reporting $> 95\%$ accuracy.

Our framework fills the identified gap by providing a memory-efficient data loader and a stacking ensemble that

maintains a high AUC of 0.9473 without GPU support. This demonstrates that even when accuracy is lower than "lab-environment" results, the model remains scientifically robust and operationally superior for real-world deployment on CPU-only, memory-limited systems.

1) Impact of sample capping on model capacity: The decision to cap training at 200,000 samples represents a deliberate methodological trade-off between peak predictive capacity and hardware-bound feasibility. While increasing the sample size toward the 3.2M limit would likely improve the accuracy and F1-score beyond the reported 86.99%, such an increase would lead to a MemoryError on standard 16 GB RAM systems without GPU support. By using stratified sampling rather than a simple temporal or random cut, the framework achieves a high AUC of 0.9473. This proves that a carefully curated, smaller subset can still capture the core "histogram" features necessary for effective static detection in resource-constrained environments.

C. The Performance Gap

The delta between our observed AUC (0.9473) and the published EMBER baselines is an intentional trade-off resulting from our 'Privacy and Resource' constraints. Standard EMBER baselines rely heavily on 'String' features and 'Import/Export' tables, which are highly predictive but computationally expensive to parse and can be easily obfuscated by packers. By restricting our input to raw byte-histograms, we eliminate the parsing overhead and increase resilience against structural obfuscation, albeit at the cost of the 5% AUC gap. This gap represents the 'Complexity Tax' required to ensure that the system remains functional on legacy 16GB RAM hardware without crashing during the feature extraction phase.

VI. Conclusion

This research successfully developed a CPU-optimized malware detection framework using the EMBER 2024 dataset, demonstrating that high-performance security is achievable without specialized GPU hardware. While recent literature often reports detection rates exceeding 98%, these metrics are frequently produced in resource-rich environments using deep learning models that are difficult to deploy on constrained endpoints. Our framework, which achieved an accuracy of 86.99% and an AUC of 0.9473, provides a critical analytical benchmark: it proves that optimized gradient-boosting ensembles can bridge the gap between theoretical accuracy and operational feasibility.

The synthesis of LightGBM, CatBoost, and XGBoost yields a robust classification boundary that remains stable even when training capacity is capped to meet strict hardware limits. The performance achieved here suggests that for real-world IoT and endpoint security, a "resource-first" design philosophy may be more effective than "accuracy-first" deep learning approaches that suffer from high latency and memory overhead. Our results indicate that the slight reduction in accuracy compared to state-of-the-art DL models is a justifiable trade-off for the ability to process millions of samples on commodity hardware.

Future work should investigate if this performance gap can be narrowed through advanced sampling strategies, such as temporal or active learning, to maximize the utility of the 200,000-sample training cap. Additionally, evaluating the framework's resilience against adversarial obfuscation will further define its role as a viable, low-cost alternative to signature-based and deep-learning detection systems in modern cybersecurity infrastructures.

Abstract*—Quadratic Unconstrained Binary Optimization (QUBO) provides a principled framework for feature selection by encoding relevance–redundancy trade-offs and explicit constraints directly in a combinatorial objective. This study presents a stability-aware QUBO pipeline for tabular binary classification, evaluated on two standard benchmarks, namely Breast Cancer Wisconsin Diagnostic (569 samples, 30 features) and Pima Indians Diabetes (768 samples, 8 features; clinically invalid zeros treated as missing and imputed within folds). We study four QUBO variants spanning a base relevance–redundancy formulation, an exact-cardinality formulation enforcing a fixed budget k, a stability-regularized formulation that incorporates bootstrap uncertainty estimates of relevance and redundancy directly into the QUBO objective, and a performance-weighted relevance variant based on inner-CV univariate utility. All methods are assessed under repeated nested stratified cross-validation (5 outer folds $\times$ 3 repeats, $n = 15$ outer test evaluations), reporting AUC-ROC, AUC-PR, MCC, and Brier score with 95% confidence intervals, alongside selection stability via mean Jaccard similarity across outer-fold selected subsets. Results show that QUBO-based selection is competitive with strong classical baselines (RFECV, L1-logistic, permutation-importance ranking, and mutual information) while enabling strict budget control and transparent stability diagnostics. On the near-ceiling Breast Cancer benchmark, predictive differences are marginal and the main differentiators become subset-size control and stability; on Pima, QUBO-k remains competitive while enforcing strict cardinality constraints. These findings support QUBO as a practical framework when budgeted, interpretable, and reproducible feature selection is required, though evaluation is limited to low-dimensional tabular settings.

Keywords*—Feature selection; QUBO; simulated annealing; nested cross-validation; selection stability; Jaccard similarity; probability calibration; tabular classification

I. Introduction

Feature selection is a core component of tabular machine learning because it influences generalization, interpretability, and operational cost. In real deployments, the objective is often not only to maximize discrimination, but also to obtain compact and reproducible feature sets under explicit constraints (e.g., acquisition budgets, latency limits, or mandated subset sizes). Classical families—filters, wrappers, and embedded methods—offer useful trade-offs: filters are fast but may miss multivariate structure, wrappers can be accurate but costly and variance-prone, and embedded methods depend on model-specific inductive biases.

Quadratic Unconstrained Binary Optimization (QUBO) offers a unified way to encode feature selection as a single combinatorial objective balancing relevance and redundancy while supporting constraints through penalty terms [1]. This becomes attractive when practitioners need *explicit control* over subset size and a transparent assessment of *selection stability*. In correlated feature regimes, instability often arises because several variables carry overlapping predictive information and small resampling perturbations can swap one correlated surrogate for another; QUBO addresses this structurally through pairwise redundancy penalties that explicitly discourage co-selection of correlated features. Moreover, because feature selection itself is part of the learning pipeline, rigorous evaluation is essential to avoid optimistic bias; nested cross-validation is the standard remedy when selection and calibration/tuning are performed within training folds [3], [4].

We evaluate on two benchmark datasets representing distinct dimensionality regimes, namely `breast_cancer` ($d = 30$) and `pima_diabetes` ($d = 8$). To enable fair comparisons under a fixed feature budget, we benchmark selectors under target budgets k (top-k filters and QUBO variants), while also reporting realized cardinality for procedures that determine k internally (e.g., RFECV and L1-logistic).

Contributions: This work presents QUBO feature selection variants that encode relevance–redundancy trade-offs, explicit k-budgets, and stability regularization within a unified combinatorial objective. These variants are benchmarked against strong classical baselines using repeated nested stratified CV with confidence intervals across discrimination, classification-quality, and calibration metrics. In addition, selection reproducibility is quantified via mean pairwise Jaccard similarity across outer-fold selections, treating stability as a first-class criterion alongside predictive performance.

II. Related Work

Feature selection (FS) is commonly categorized into *filter*, *wrapper*, and *embedded* methods. Filter methods rank variables independently of the final predictor; mutual-information criteria are popular when nonlinear dependencies are expected, and mRMR is a canonical formulation balancing relevance to the target and redundancy among selected variables [5]. Wrapper methods evaluate subsets through downstream performance, often improving accuracy at higher computational

cost and sensitivity to the resampling design [10]. RFE and RFECV are widely used wrapper procedures that iteratively remove features based on model utility and are influential in biomedical pipelines [11]. Embedded methods incorporate selection within training; L1-regularization (LASSO) induces sparsity and performs implicit selection [6].

Regarding stability mechanisms, filters such as MI ranking are stable only when the top-k features have clearly separated relevance scores; in correlated regimes, near-tied features can be exchanged across resamples. Wrappers inherit instability from the downstream model and the elimination path, while embedded methods such as LASSO can produce multiple near-equivalent sparse solutions in correlated settings. Stability selection [7] addresses this by aggregating selection frequencies over subsamples, but it does not enforce hard cardinality constraints. The present QUBO formulation instead incorporates stability directly into the combinatorial objective via bootstrap uncertainty penalties, maintaining hard budget control within a single optimization step.

Beyond accuracy, *stability* is critical whenever FS supports interpretation or scientific conclusions. Stability selection formalizes robustness via subsampling and selection frequencies [7], while broader analysis show that unstable selectors can undermine reproducibility even under high predictive performance [8]. This motivates reporting stability metrics (e.g., Jaccard similarity) jointly with discrimination and calibration.

Rigorous evaluation is particularly important because selecting features on the same data used to estimate performance can bias results upward. Nested cross-validation mitigates this by isolating all selection/tuning within inner loops and evaluating only on held-out outer folds [3], [4]. Calibration can diverge from discrimination; probability quality should be assessed under the same leakage-safe protocol [12], [13].

Optimization-based FS treats subset selection as a combinatorial problem. Simulated annealing (SA) is a classic metaheuristic for large discrete spaces and provides a reproducible baseline for approximate minimization under fixed compute budgets [9]. QUBO offers a unifying representation for such objectives, enabling relevance–redundancy trade-offs and hard/soft constraints via quadratic penalties [1]. Prior QUBO-style feature selection formulations [2] have focused on relevance–redundancy encoding and cardinality control; the present work extends this line by integrating bootstrap uncertainty-based stability regularization into the QUBO objective and evaluating under a leakage-safe repeated nested cross-validation protocol that jointly reports discrimination, calibration, and subset reproducibility.

III. Methodology

A. Problem Setting

Let $\mathcal{D} = \{(\mathbf{x}^{(n)}, y^{(n)})\}_{n=1}^{N}$ be a labeled dataset with $\mathbf{x}^{(n)} \in \mathbb{R}^d$ and $y^{(n)} \in \{0, 1\}$.

Feature selection aims to identify a subset $S \subseteq \{1, \ldots, d\}$ that preserves predictive performance while controlling redundancy and improving interpretability under a constrained feature budget.

We encode selection using a binary vector $\mathbf{z} \in \{0, 1\}^m$ over a candidate pool of size $m \leq d$, where $z_i = 1$ indicates that candidate feature i is selected, and $S(\mathbf{z}) = \{i : z_i = 1\}$.

B. Datasets and Preprocessing (Leakage Control)

We use Breast Cancer Wisconsin Diagnostic (569 samples, 30 numeric features) [16], [17] and Pima Indians Diabetes (768 samples, 8 numeric features) [18]. For Pima, clinically invalid zeros in specific measurements (commonly including glucose, blood pressure, skin thickness, insulin, BMI) are treated as missing and imputed.

We perform all preprocessing *within the training portion of each outer fold* to prevent information leakage. We impute missing values using the training median, and features are standardized via z-score scaling (fit on training, applied to validation/test). Any dataset-specific corrections are applied inside the same fold-isolated preprocessing.

C. Compared Methods and Feature Budgets

To compare methods under explicit budgets, we define target cardinalities k and evaluate rank-based baselines returning exactly k variables (MI-top$k$, permutation-importance top$k$), QUBO variants matched to the same k target, and methods that determine subset size internally (L1-logistic and RFECV), for which we report realized cardinality. In our experiments, $k = 10$ for `breast_cancer` and $k = 6$ for `pima_diabetes`.

D. Candidate Pool Construction (for QUBO)

Within each outer training fold, we build a candidate pool by ranking features using mutual information computed on standardized training data, retaining the top candidates:

$$m = \min(25, d)$$

For `breast_cancer`, this yields $m = 25$ out of $d = 30$, while for `pima_diabetes` ($d = 8$) the candidate pool equals the full feature set ($m = d$). All QUBO objectives are constructed and optimized only over this candidate pool.

E. Relevance and Redundancy Signals

1) Relevance: For each candidate feature i, we compute mutual information relevance:

$$r_i = I(X_i; Y), \tag{1}$$

estimated with a nonparametric MI estimator (e.g., as implemented by `mutual_info_classif`).

2) Redundancy: To discourage selecting overlapping variables, we compute pairwise redundancy via absolute Pearson correlation on standardized training data:

$$\rho_{ij} = |\mathrm{corr}(X_i, X_j)|. \tag{2}$$

F. Base QUBO Objective

Let m denote the number of candidates. The base QUBO energy is given by:

$$\min_{\mathbf{z}\in\{0,1\}^m} E(\mathbf{z}) = \sum_{i=1}^{m}(\lambda - r_i)z_i + \alpha \sum_{i<j} \rho_{ij}\, z_i z_j, \qquad (3)$$

where, $\alpha > 0$ controls redundancy and $\lambda \geq 0$ encourages sparsity.

G. Exact-Cardinality QUBO-k

To target a subset size k, we add a quadratic penalty:

$$E_k(\mathbf{z}) = E(\mathbf{z}) + \mu \left(\sum_{i=1}^{m} z_i - k \right)^2, \qquad (4)$$

with $\mu > 0$ controlling constraint strength.

1) Deterministic exact-k projection (budget-matched evaluation): Because heuristic solvers may return $|S(\mathbf{z})| \neq k$ and because we compare methods under a fixed budget, we apply a deterministic projection step for the QUBO family. When $|S| > k$, we keep the k features in S with highest MI relevance; when $|S| < k$, we fill with remaining candidates with highest MI. This ensures budget-matched evaluation for all QUBO variants.

H. Stability-Regularized QUBO

To promote robustness, we estimate uncertainty of relevance and redundancy via bootstrap resampling of the outer training fold. For bootstrap replicates $b = 1, \ldots, B$, we compute $r_i^{(b)}$ and $\rho_{ij}^{(b)}$ and estimate means and variances as:

$$\bar{r}_i = \mathbb{E}[r_i^{(b)}], \qquad \mathrm{Var}(r_i) = \mathrm{Var}(r_i^{(b)}), \qquad (5)$$

$$\bar{\rho}_{ij} = \mathbb{E}[\rho_{ij}^{(b)}], \qquad \mathrm{Var}(\rho_{ij}) = \mathrm{Var}(\rho_{ij}^{(b)}). \qquad (6)$$

We then define a stability-regularized objective as:

$$E_s(\mathbf{z}) = \sum_{i=1}^{m} \Big(\lambda - \bar{r}_i + \gamma\, \mathrm{Var}(r_i)\Big) z_i + \sum_{i<j} \Big(\alpha\, \bar{\rho}_{ij} + \delta\, \mathrm{Var}(\rho_{ij})\Big) z_i z_j, \qquad (7)$$

where, $\gamma, \delta \geq 0$ weight robustness penalties. As with other QUBO variants, we enforce the fixed budget via projection.

I. Performance-Weighted Relevance QUBO ("Wrapper" Variant)

To incorporate supervised signals beyond MI, we compute a *performance-weighted* relevance proxy from an inner CV performed on the outer training fold. For each candidate feature i, we estimate its univariate predictive utility via class-weighted logistic regression, producing a score such as inner-fold AUC-ROC. Let $\mathrm{AUC}_i^{(t)}$ denote univariate AUC-ROC on inner split t; we define:

TABLE I. HYPERPARAMETER CONFIGURATION USED IN ALL EXPERIMENTS.

Parameter	Symbol	Value	Scope
Diagonal offset	λ	0.02	All QUBO variants
Redundancy weight	α	0.20	All QUBO variants
Cardinality penalty	μ	1.5	QUBO-k only
Relevance var. penalty	γ	0.25	QUBO-Stability
Redundancy var. penalty	δ	0.10	QUBO-Stability
Wrapper var. penalty	η	0.15	QUBO-Wrapper
Bootstrap replicates	B	40	QUBO-Stability
Inner CV folds	K'	3	QUBO-Wrapper

$$\tilde{r}_i = \frac{1}{K'} \sum_{t=1}^{K'} \mathrm{AUC}_i^{(t)}, \qquad v_i = \mathrm{Var}\big(\mathrm{AUC}_i^{(t)}\big). \qquad (8)$$

We integrate this into the QUBO objective as:

$$E_w(\mathbf{z}) = \sum_{i=1}^{m} \Big(\lambda - \tilde{r}_i + \eta\, v_i\Big) z_i + \alpha \sum_{i<j} \rho_{ij}\, z_i z_j, \qquad (9)$$

with $\eta \geq 0$. We emphasize that this variant uses univariate inner-CV utility as a relevance proxy; it is not a full multivariate wrapper search over subsets. We enforce budget matching via projection.

J. QUBO Optimization via Simulated Annealing

We optimize all QUBO objectives with simulated annealing (SA), a temperature-controlled stochastic search that approximates minima of binary quadratic energy landscapes [9]. The solver returns a binary solution $\mathbf{z}$ and its energy, followed by exact-k projection when applicable.

K. Practical Interpretation of QUBO Hyperparameters

The QUBO coefficients have practical implications for deployment. The parameter λ acts as a diagonal offset, so that when $\lambda < r_i$ the linear term favors selection of feature i, and when $\lambda > r_i$ it penalizes selection. The redundancy weight α controls tolerance to correlated predictors. In QUBO-k, the penalty μ governs cardinality compliance strength. In the stability-regularized variant, γ and δ penalize uncertainty in relevance and redundancy estimates, respectively, improving subset reproducibility at the cost of potentially excluding features whose utility is high but unstable across resamples. In the performance-weighted variant, η trades average utility against robustness. Table I reports all hyperparameter values used.

We fixed all values prior to experimental runs using training-side information only, consistent with the leakage-safe nested CV protocol.

L. Solver Configuration and Reproducibility

Because simulated annealing is stochastic, reproducibility depends on solver configuration choices including temperature schedule, iteration budget, and random seed policy. In this work, we use a standardized SA configuration held constant across all QUBO variants so that comparisons are made under matched procedural conditions. Repeated outer folds partially average stochastic effects, but this should not be interpreted as a full robustness analysis with respect to solver seeds or annealing schedules. A more complete reproducibility study should explicitly vary solver settings and quantify optimizer-induced variance separately from data-resampling variance.

M. Downstream Classifier and Probability Calibration

For fairness across selectors, we evaluate all selected subsets using the same downstream predictor: class-weighted logistic regression producing probabilities calibrated inside the training loop [12], [13]. We report discrimination (AUC-ROC, AUC-PR), classification quality (MCC), and calibration (Brier score). This is important because models with similar AUC can differ materially in probability quality.

N. Evaluation Protocol

We use repeated nested stratified cross-validation to avoid optimistic bias in feature selection and calibration [3], [4]. We run $R = 3$ repeats of $K = 5$ outer folds, yielding $n = 15$ outer test evaluations per method. All selection steps (candidate pooling, bootstraps, and performance-weighted relevance computation) are performed strictly within each outer training fold.

We summarize metrics across the $n = 15$ outer test evaluations using means and 95% confidence intervals. For paired comparisons of AUC-ROC under matched splits, we apply the Wilcoxon signed-rank test [15] (optionally with multiplicity control when many pairwise tests are reported).

Selection stability is quantified by mean pairwise Jaccard similarity across the n selected subsets,

$$J(S_a, S_b) = \frac{|S_a \cap S_b|}{|S_a \cup S_b|}. \tag{10}$$

IV. Results

A. Nested CV Performance

Fig. 1 and Fig. 2 summarize mean AUC-ROC across the repeated nested CV outer tests. Breast Cancer is near-separable for multiple selectors (AUC-ROC close to 1.0), while Pima is moderately challenging (AUC-ROC around 0.83–0.84), where differences are smaller and uncertainty overlaps across strong methods.

B. ROC Curve Analysis (Qualitative)

Fig. 3 and Fig. 4 show ROC curves for qualitative comparison of ranking behavior across thresholds. These plots should be interpreted as illustrative summaries of discrimination; all inferential claims in this study rely on the repeated nested CV outer-test scores reported in Table II and Table III.

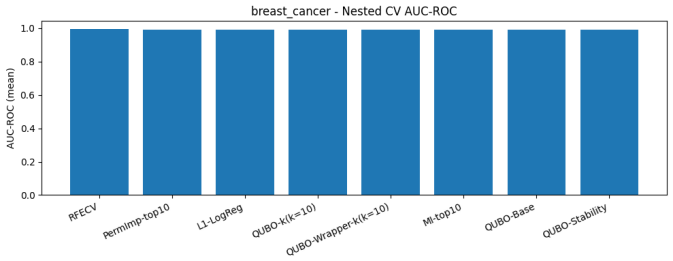

Fig. 1. Breast cancer: Mean nested CV AUC-ROC by method.

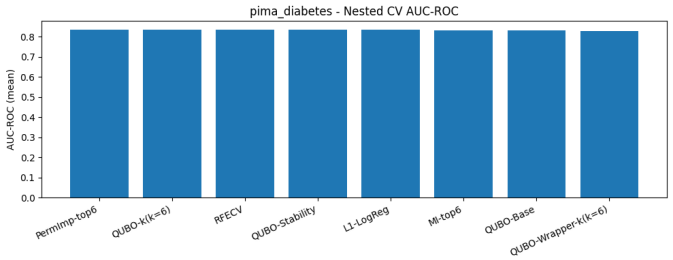

Fig. 2. Pima diabetes: Mean nested CV AUC-ROC by method.

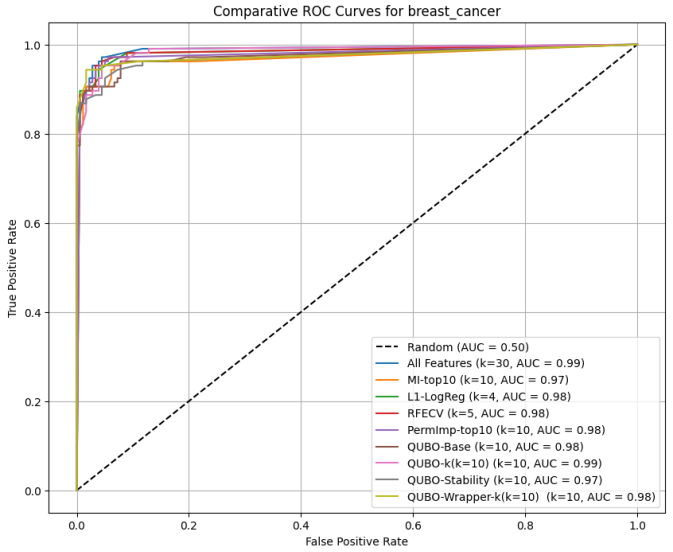

Fig. 3. Comparative ROC curves for breast cancer (illustrative).

For Breast Cancer (Fig. 3), most methods achieve AUC-ROC above 0.98, consistent with a ceiling regime in which marginal AUC differences are difficult to interpret practically. QUBO-k and QUBO-Stability closely track strong baselines (RFECV, L1-logistic), indicating that enforcing combinatorial constraints does not substantially degrade discrimination on this benchmark.

For Pima Diabetes (Fig. 4), separation among curves is more apparent, reflecting a harder decision boundary. QUBO-k remains competitive with permutation-importance and RFECV while enforcing strict cardinality constraints. The performance-weighted relevance variant (labeled "QUBO-Wrapper-k" in tables/figures for consistency with artifact names) shows slightly

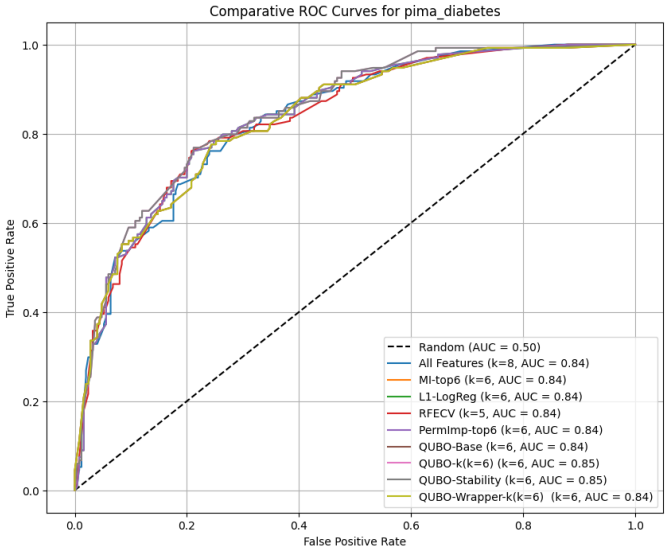

Fig. 4. Comparative ROC curves for Pima diabetes (illustrative).

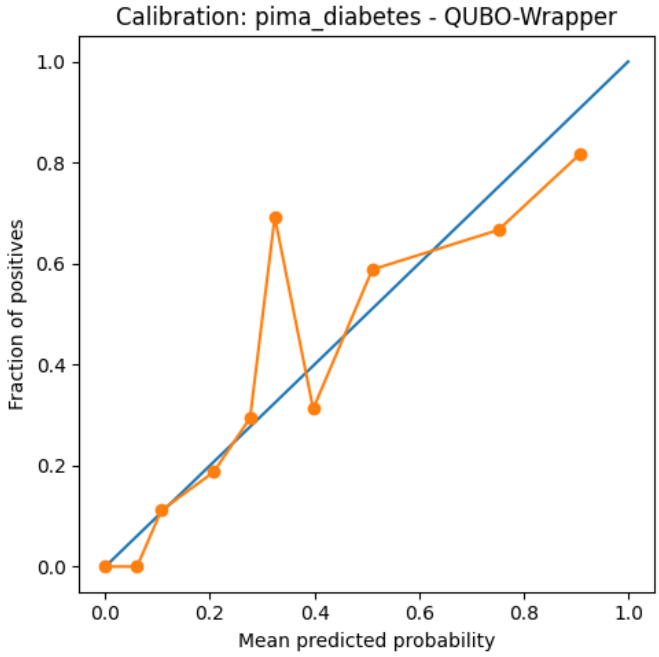

Fig. 5. Calibration curve (reliability diagram) for Pima diabetes using the performance-weighted QUBO variant. The diagonal indicates perfect calibration.

weaker ROC behavior, aligning with the nested CV summaries and suggesting that inner-loop univariate utility signals do not necessarily improve multivariate subset generalization in low-dimensional settings.

C. Calibration

Beyond discrimination, we inspect calibration using Brier score and reliability diagrams. Fig. 5 shows a calibration curve (reliability diagram) for Pima Diabetes for one representative method; deviations from the diagonal indicate over- or under-confidence. Calibration assessment is reported alongside discrimination because near-identical AUC can mask materially different probability quality.

D. Quantitative Summary with 95% Confidence Intervals

Table II and Table III report mean performance and 95% confidence intervals from the repeated nested CV outer tests ($n = 15$). We include discrimination (AUC-ROC, AUC-PR), classification quality (MCC), and calibration (Brier), plus the effective subset size k and selection time. Note that the reported selection times are implementation-dependent wall-clock measurements useful for descriptive comparison under the same environment, but not a fine-grained decomposition of solver versus non-solver cost; values displayed as 0.000 reflect rounding at the reported precision and do not imply zero computational cost.

E. Selection Stability (Jaccard)

Table IV reports mean Jaccard similarity across outer-fold selections. Stability should be interpreted jointly with performance: highly stable selectors are valuable for interpretability, but stability alone can be misleading if performance is low or if the procedure is effectively deterministic for trivial reasons [8].

F. Statistical Comparison

We apply paired Wilcoxon signed-rank tests [15] over the $n = 15$ outer AUC-ROC scores. On Breast Cancer, differences among top-performing methods are not practically distinguishable given overlapping confidence intervals. On Pima, small but consistent differences can appear under matched splits; however, because multiple pairwise comparisons can inflate Type-I error, multiplicity control (e.g., Holm correction) is recommended when reporting many p-values.

V. Discussion

All inferential statements in this section are based exclusively on outer-fold test predictions from the repeated nested CV protocol; ROC and calibration plots are included for qualitative illustration and should not be used as sole evidence of superiority. Nested CV is essential here because feature selection (and any calibration/tuning) is performed on training data, and evaluating on non-isolated splits can inflate performance estimates [3].

A key observation is the presence of a *ceiling regime* on `breast_cancer`. Multiple methods attain AUC-ROC close to 1.0, and confidence intervals overlap. In such cases, it is statistically and practically difficult to justify strong claims based on marginal AUC differences. This does not diminish QUBO; rather, it clarifies its value proposition: QUBO is often most useful when the practitioner must enforce explicit constraints (strict cardinality, domain rules, stability penalties, or cost terms) and wants a transparent optimization objective.

`pima_diabetes` operates in a moderate-difficulty regime where performance is lower and variability across folds is more informative. Here, QUBO-k remains competitive

with strong baselines (RFECV and permutation-importance top-k) while guaranteeing exactly $k = 6$ features. This is operationally important when each feature corresponds to acquisition cost or measurement availability.

The performance-weighted relevance variant does not necessarily improve generalization, particularly in low-dimensional settings. A plausible explanation is that univariate relevance can mismatch multivariate subset utility, and inner-loop scoring can inject additional variance that does not translate into better held-out outer-fold performance, a phenomenon consistent with known wrapper sensitivities [10]. This suggests that performance-weighted signals may require stronger regularization or multivariate scoring to consistently outperform simpler baselines.

Stability is crucial when feature selection supports interpretation. Unstable selectors can yield brittle explanations and reduce trust even if AUC is high. On Pima, QUBO-k shows high Jaccard similarity, indicating reproducible subset selection under repeated outer folds. Nevertheless, stability must be interpreted alongside discrimination and calibration [8].

Calibration can diverge from AUC: two models may rank instances similarly (similar AUC) yet produce different probability quality (different Brier/reliability), which matters whenever decisions depend on absolute risk thresholds [14]. Evaluating calibration under the same leakage-safe protocol is therefore essential.

Limitations: The empirical evaluation is restricted to two low-dimensional tabular datasets ($d \leq 30$), one of which exhibits near-ceiling performance. This is sufficient to demonstrate leakage-safe evaluation, budget control, and stability diagnostics, but it does not support strong claims about scalability to high-dimensional regimes (e.g., genomics, text, or finance). Runtime values are descriptive end-to-end measurements and are not decomposed into solver versus non-solver components.

VI. CONCLUSION

This work introduced a stability-aware QUBO-based feature selection pipeline for tabular binary classification and evaluated it under a rigorous repeated nested cross-validation protocol, reporting confidence intervals, calibration-aware metrics, and explicit subset stability. Across the Breast Cancer Wisconsin and Pima Indians Diabetes benchmarks, QUBO formulations achieved discrimination competitive with strong classical baselines (L1-regularized logistic regression, RFECV, mutual-information filtering, and permutation-importance ranking) while additionally providing direct and transparent control over subset cardinality through an explicit k-constraint. Beyond raw accuracy, the results underscore that in near-separable settings where performance approaches a ceiling and differences become statistically and operationally marginal, reproducibility of the selected subsets and the ability to enforce interpretable, budgeted feature sets become the most meaningful differentiators. In this sense, QUBO offers a unified optimization framework to encode relevance–redundancy trade-offs, strict feature budgets, and stability-oriented regularization within a single objective. Future work will extend evaluation to higher-dimensional and cost-sensitive datasets, study solver and compute-budget sensitivity with detailed runtime breakdowns, and explore multi-objective QUBO designs that jointly optimize discrimination, calibration, and stability to further strengthen robustness and interpretability in practical decision-making pipelines.

Attention-Guided Bidirectional Temporal Modelling with Graph-Based Regional Spatial Context for Bajra Crop Yield Prediction

Mamta Kumari[1]*, Suman[2], Devendra Prasad[3]
Deenbandhu Chhotu Ram University of Science and Technology, Sonepat, India[1,2]
PIET Samalkha, India[3]

***Abstract*—Bajra (pearl millet) is a very important crop in Rajasthan, India, since it is drought-resistant, nutritious, and culturally important. But its productivity is becoming vulnerable to changes in climate, such as erratic rain and temperature changes, and thus precise estimation of yield is vital. Crop Yield Prediction (CYP) indicators like soil decomposition, rainfall and meteorological patterns are slowly evolving, exhibiting long-term temporal dependency and propagating over time. Conventional cropping prediction algorithms based on artificial intelligence process the historical data and these indicators in a unidirectional manner. While mapping the temporal dependencies, these algorithms consider each year independently and do not capture the delayed effect, like salt degradation. To address this issue, the study proposes a region-based spatiotemporal model with an attention-guided Bidirectional LSTM (Long-Short Term Memory) framework for CYP, termed as G-BiLSTM. The proposed model reproduces the spatial relationships between districts via GCN (Graph Convolution Network) -based immediate neighbour extraction. Further, a Bidirectional LSTM is used to model multi-year CYP temporal features, allowing each annual observation to be encoded using both past and future temporal context. A variance-reduced and comprehensible representation is produced by integrating an attention mechanism to adaptively highlight the most informative years within a temporal window. Using 15 agro-environmental characteristics, including understudied elements like saline and alkaline soil composition, the framework is assessed on a dataset that includes 32 districts in Rajasthan over 13 years (2007–2019). The suggested attention-enhanced BiLSTM consistently outperforms traditional temporal models, achieving lower prediction error and better generalisation, according to experimental results analysis using a three-year sliding temporal window. For regional crop yield forecasting, the suggested method offers a scalable solution.**

Keywords*—Bajra crop yield prediction; regional crop yield forecasting; attention-guided Bidirectional LSTM; saline and alkaline soil composition

I. Introduction

It is anticipated that by the year 2100, the global population will hit 9.6 billion. The need for farm goods increases [1]. By the year 2100, India's population is projected to increase from 1.4 billion to 1.7 billion. Agriculture covers 1.6 million square kilometres (about half the area of India), and the agricultural land ranks second behind China [1]. The government must always ensure food to protect its inhabitants. Modern agriculture relies on crop yield prediction for better resource allocation, to decrease risks, and to ensure food security. However, it has become challenging with the complex aspects affecting Crop Yield Prediction (CYP). To enhance agricultural and rural statistics, researchers in the field are working on crop yield prediction methodologies and investigating ways to improve agricultural data collection for yield prediction. Considering the recent survey, yield is mainly dependent on data collected based on factors like climatic conditions, soil quality, and water quality [2-4]. However, the study in papers mainly differs based on regions, crop types, weather conditions, and irrigation techniques. Thus, there is no standard dataset that is fully accessible for agricultural study in a particular region [5]. Advancements in technology and changes in climate significantly influence agricultural production levels. The impact of weather on crop yield can be explored by considering time (measured in years) or time-related functions [6]. Various elements are expected to gradually increase yield over time, yet weather is recognised for its unpredictable impact. Therefore, to forecast agricultural outputs across different years or within the same year, a majority of research utilizes time-series algorithms that leverage past data and are regarded as more suitable than various machine learning and deep learning methods [7-9]. This study centres on the CYP of Bajra (pearl millet), which is widely grown in India, particularly in the states of Rajasthan, Maharashtra, Haryana, Uttar Pradesh, and Gujarat. The crop is capable of enduring conditions such as intense heat, lack of moisture, low soil fertility, and minimal rainfall. Bajra thrives in areas where other cereal crops struggle due to its specific growing needs. This study examines the precise CYP related to the Bajra crop in Rajasthan.

A. Related Work

There is an increasing body of literature that analyses machine learning and deep learning in predicting crop yield in different regions and crops. Among the studies, [7] optimises crop yield prediction in Rajasthan state for 10 districts and 7 crops using random forest (RF) and decision trees with gradient boosting. From 1997 to 2018, the research analysed acreage, productivity, yield, and rainfall. Gradient-boosting outperformed all other methods with 92.7% accuracy, 21.58 MAE, and 15.01 RMSE. Only a few of Rajasthan's traits and districts were studied. Computer-intensive gradient boosting is subject to noise. Overfitting can occur with too many decision trees. Therefore, many papers avoid these methods. The study [8] predicts Jaipur's agricultural productivity for five crops. The analysis focuses on the data spanning from 1991 to 2020. The variables that were measured included rainfall,

*Corresponding author.

hours of sunshine, temperature, and humidity levels. The writers employed Random Forest, Support Vector Machines, and Artificial Neural Networks.

The authors in [8] discovered that the Random Forest model achieved an accuracy rate of 92.3%, along with MAE and RMSE figures of 1.68 and 2.19, respectively. The study only covered one Rajasthan region and utilized a few criteria. The study [9] employs random forest, SVM, gradient descent, LSTM, and Lasso regression algorithms. The dataset comprises five crops for 33 districts in Rajasthan. All algorithms were examined, and the findings revealed that RF, SVM, and Lasso regression best-predicted yield. In the study [9], the limitations include the possibility of using a richer and larger dataset for each crop to enhance forecasts. An Improved Optimization Function (IOF) is proposed in [6] and implemented with the LSTM model to enhance prediction accuracy. Temperature, precipitation, humidity, solar radiance and various crop related data attributes were used in the study. The article [10] predicts mustard production in 5 Rajasthan districts using long-term weather and yield data. This study uses random forest, SVM, and ANN deep learning. Feature selection in [5] utilizes Principal Component Analysis (PCA) and Stepwise Multiple Linear Regression (SMLR). Assessment was conducted on agricultural area, soil type, temperature, rainfall, and climate. The research assesses six different model combinations and concludes that PCA-SVM stands out as the most effective yield prediction model. A hybrid model driven by data was created by the authors in [11] to accurately predict paddy yield through the use of Multiple Linear Regression (MLR) intercepts. The Artificial Neural Network (ANN) utilizing Feed forward Back Propagation is trained with characteristics like the area, count of open wells, tank volumes, canal lengths, and peak temperatures throughout the season examined in the study.

The creators of [12] devised a deep learning approach using a Recurrent Neural Network to enhance the Q-Learning reinforcement learning technique. The study predicts paddy yield in Vellore with an accuracy of 93.7% by utilizing properties of soil, weather, and groundwater, all while maintaining the original distribution of the data. The study in [13] forecasted the yield of sugarcane in Karnataka by utilizing Long Term-Time-Series (LTTS), weather and soil characteristics, Normalized Vegetation Index (NDVI), along with supervised machine learning (SML) techniques. Support vector regression (SVR) was employed by researchers. The scientist's analysed data related to climate and soil, along with satellite images from the years 2008 to 2018, to assess remote sensing information. A study based on empirical data focused on forecasting agricultural production by employing regression and time-series models to predict the crop known as 'Bajra' or pearl millet [14]. Models for prediction comprised ARIMA and ARIMAX, incorporating an external variable. When evaluating 'Bajra', the ARIMAX model outperformed the regression time series model. The study [13] proposed a regression model utilizing ANN and SVM to forecast Kharif crop yields based on rainfall information from Visakhapatnam. This research focuses on four types of crops: Maize, Ragi, Rice, and Bajra. This research employs a modular artificial neural network to predict monsoon precipitation, subsequently utilizing support vector regression to assess the primary Kharif crop yields in relation to rainfall and cultivated area. Ensembles of CNN and DNN machine learning predict corn production in the US corn belt, utilizing corn yield data from 1980 to 2019 [15]. Data on meteorology, soil, and management at the county level for 12 states in the US Corn Belt is provided. Constructed using deep neural networks and CNNs, ensembles are formed. This model accurately predicted maize grain yields for 2019, achieving an 8.5% relative root mean square error. The study in [16] introduces a framework utilizing deep learning for predicting agricultural output, employing CNNs and RNNs that rely on environmental data and management strategies. The CNN-RNN framework, in conjunction with RF, DFNN, and LASSO, predicts corn and soybean yields in the US Corn Belt utilizing data from 2016 to 2018. The new model surpassed all prior methods with an RMSE of 9% and 8% of usual yields. However, computationally expensive ANNs require careful design and hyper parameter adjustments. Too many trees can over fit and make random forests computationally expensive, and SVR is susceptible to outliers and requires careful kernel function selection [17]. With the rise of deep learning, advanced deep network topologies like CNNs [18] and RNNs [19-20] have been developed. Neural network-based agricultural production forecast models have increased due to deep learning. Out of the surveyed literature, 69% of papers employed deep learning approaches, with just 20% using a CNN-based model. There have been very few or negligible studies that use the graph-based model to harness the spatial features from the crop data for CYP. Like in [21], the Graph Convolution Network (GCN) is used for learning the weed plant features from labeled and unlabeled images, which are already extracted from CNN. The authors also work towards using limited labeled data and learning from graph structure to improve recognition accuracy. However, this study does not directly relate to predicting the yield.

The overall survey for dataset attributes and characteristics used for CYP in the studies is majorly divided into meteorological [2], soil [3], phenotype [22], fertilizer, diseases, and pests [4] related attributes, as well as other attributes, as shown in Table I. All of these characteristics are significant for determining crop output. As a result, in the present manuscript, a summary is created of the data attributes utilized in earlier work to determine which attributes are least studied and which ones need to be worked on. It is observed from Table I, that phenotypic, irrigation accessibility, fertilization, and undesirable features (diseases, weeds, and pests) are the least investigated qualities (3%, 3%,3%, and 14%). However, all these characteristics are investigated within the Precise Agriculture application, which makes use of IoT [3]. But, because the work focuses on data specifically for yield prediction, the study will select the other attributes of the yield prediction process. The other attribute that is highly used for CYP is soil characteristics. The sub-categories in Table I, demonstrate that groundwater levels and soil moisture characteristics are also understudied, but the current study included rainfall because it directly affects yield [23]. Red, black, desert, clay, or a mix of soil types has been understudied, and data is collected in only a few studies; therefore, soil type is considered in the present study. The kind of soil determines which plants thrive and which struggle. Cotton, for example, thrives in dark soil [24]. Also, infertile or barren soil, which includes excessive salt levels, is not considered. This study also assessed saline and alkaline soil in numerous state districts. The research

TABLE I. SUMMARY OF ATTRIBUTES FROM PREVIOUS STUDIES

Attributes Category (%)	Attributes	Attributes Category (%)	Attributes
Meteorological (40%)	Rainfall	Phenotype (3%)	Lodging rate
	Temperature		Inversion Rate
	Humidity		Plant Height
	Sunshine duration		Ear Height
	Evapotranspiration		Empty Stalk Rate
	Dew points temp	Undesired Traits (14%)	Weed Determination
	Wind speed		Pest
Fertilizer (7%)	Fertilizer Strength		Disease
Area (3%)	Area under Cultivation	Soil (23%)	Groundwater
			Soil Water
			Soil Moisture
Irrigation Accessibilities (3%)	No. of Tanks		Soil Temperatures
	Canal Length		Nutrients
	Open Wells		Soil pH

also evaluated the local climate. The local climate impacts agricultural growth. Some crops thrive in arid climates, while others favour humidity [25].

Numerous works are conducted in the field of temporal modelling; the model in [26] uses an enhanced Gate Recurrent Unit through an LSTM model for the prediction of CYP. However, spatial connections are considered static by implementing a Grey Wolf Optimisation (GWO). Similar to the proposed model, the authors in [27] have proposed an attention mechanism for a CNN that is a convolutional neural network-based BiLSTM model for CYP. However, different from the proposed model, the spatial connections are considered independent through a convolutional neural network. The proposed model focuses towards a unified mapping of the spatial connection among districts affecting yield parameters through the GCN model and maps the enhanced bidirectional temporal dependencies. An enhanced deep learning model is presented in [28] through a Bayesian optimised CNN-BiLSTM model similar to the model in [26]. However, the parameters are considered independent, and the delayed effect of rainfall is not considered in [27-28]. Similar to the proposed model in the study and in [26], the authors in [29] applied channel attention to BiLSTM for CYP on image-based data. Moreover, unlike existing temporal models, the proposed model treats the spatial representations dependant as a graph and joint modelling of these with long-term bidirectional temporal dependencies, contributes to regional-aware temporal modelling.

Table I shows that phenotype characteristics, irrigation accessibility, fertilisation, and undesirable features (such as diseases, weeds, and pests) are the least studied attributes, with percentages of 3%, 3%,7%, and 14%, respectively. These attributes are integral to Precision Agriculture applications leveraging IoT [3]. However, focusing specifically on yield prediction, this study will emphasise other relevant attributes in the prediction process.

Soil characteristics are another key attribute widely utilised in CYP. Table I also indicates that groundwater levels and soil moisture characteristics are areas with limited research. However, the current study incorporates rainfall due to its direct impact on crop yield [23]. Soil types such as red, black, desert, clay, or a mixed soil have received less attention in data collection across studies, making soil type a focal point in this study. Soil type plays a critical role in determining which crops flourish and which struggle; for instance, cotton thrives in dark soil [24]. Furthermore, infertile or barren soils, including those with excessive salt levels, are not considered. This study also examines saline and alkaline soils across various state districts. Additionally, local climate conditions are evaluated, as they significantly influence agricultural productivity. Some crops thrive in arid climates, while others prefer humid environments [25]. These deep learning models have become increasingly popular in agricultural production forecasting. According to recent surveys, 69% of studies have adopted deep learning techniques, with CNN-based models being utilised in only 20% of cases.

1) Challenges in the existing studies need to be addressed: Existing studies in CYP focus on using data (images, new features, and focused data for yield prediction), spatial and temporal modelling of the data. However, the existing studies exhibit challenges that need to be addressed. These are discussed through a Table II, mapping the challenges on how the contribution of the study is connected.

B. Contributions of the Paper

As discussed in Table I, the study differs and addresses the challenges identified in existing studies. However, the main contributions of the study are:

- The suggested model performs CYP for Bajra (pearl millet) over 13 years (2007–2019) in 32 districts in the Indian state of Rajasthan. By adding a wide range of agro-environmental variables, such as weather patterns and underutilised soil characteristics, the study considerably broadens the scope of data collection, building on previous research.
- The proposed model suggests a three-phase framework for spatiotemporal learning that includes: 1) Data Collection, preprocessing and capturing Annual Regional-immediate neighbour information; 2) Joint Spatio-temporal feature extraction through attention-guided G-BiLSTM; and 3) yield prediction.
- The suggested framework uses an attention-guided Bidirectional LSTM (BiLSTM), in contrast to traditional temporal models, to encode each year from CYP data representation using both past accumulation and future-aware agro-environmental context, and the attention mechanism selectively highlights the most significant temporal points, resulting in a spatiotemporal embedding that is interpretable and reduces variance. The proposed framework minimises variance in the predictions across various regions or temporal windows by down-weighting uninformative years, which prevents the model from reacting excessively to inflated shifts in the training data (such as an anomalous rainfall year).
- Evaluation through RMSE, R2 score, correlation coefficient, and other common performance metrics is conducted to assess the suggested Attention-guided G-BiLSTM framework.

Study Organisation: the introduction, related work and contributions are explained in Section I, the detailed proposed

TABLE II. CONNECTING THE CHALLENGES WITH THE CONTRIBUTIONS OF THE PAPER

Aspect	Challenges in the Existing Studies	Contribution of the Paper to Address the Challenges
Data Reliability and Underutilization of Soil-related Attribution in Data for CYP	Soil attributes were often understudied or included in only a few analyses. Given the significant influence of soil quality on crop growth and productivity, overlooking these factors undermines the robustness and accuracy of yield prediction models [7], [8], [9], [10], [3], [24].	The paper introduces saline and alkaline soil parameters collected for Rajasthan through an open-source government website.
Regional Modelling of Districts in the Dataset	Existing studies like [7], [8], [10], [13], [15], [16], [17], [18], [19], [23], [24], [25] treat the annual yield data of regions independently, ignoring the temporal and changing dependency of features like rainfall and soil nutrients.	The study reproduces the spatial relationships between districts via GCN (Graph Convolution Network)-based immediate neighbour extraction. Different from models in [21], [24], [29], where GCN and Graphical Neural Network (GNN) models are used, the proposed model in the paper performs joint spatio-temporal modelling. This is done by considering year-wise embedding learnt through graphical deep learning and directly mapping it for temporal modelling.
Joint Spatio-temporal Dependency Handling	Existing temporal models like RNN, LSTM [9], [10], [11] do not account for delayed and cumulative agro-environmental effects of rainfall and such parameters because they process historical data in a unidirectional manner.	Different from models in [21], [24], [29], where GCN and Graphical Neural Network (GNN) models are used, the proposed model in the paper performs joint spatio-temporal modelling. This is done by considering year-wise embedding learnt through graphical deep learning and directly mapping it for temporal modelling. The proposed model introduces an attention mechanism that highlights the most influential temporal points from the joint future-aware and past information of the CYP data.

model is explained in Section II. The results and experimentation are explained in Section III. Section IV presents the conclusion and Section V details the limitations and future scope of the study.

II. PROPOSED METHODOLOGY

In this section, the overall flow of the proposed model is explained. The contributions stated in Section I are detailed and achieved in this section through Data Collection, Preprocessing, and capturing Annual Regional-immediate neighbor information given in Section II B and finally the Joint Spatio-temporal feature extraction through attention-guided G-BiLSTM for Yield Prediction in Section II C. However, the motivation of deriving the contributions and formulation of the study is explained in Section II A.

A. Motivation and Proposed Formulation of the Study

Let's represent the attributes/characteristics/features of each district as $x_{d,t}$ in the final data and the actual crop output as $y_{d,t}$, where d, t represent the district and the year, respectively. Here $x_{d,t} = \{x^w_{d,t}, x^s_{d,t}, \ x^l_{d,t}\}$ where meteorological attributes (annual rainfall, climate type) are represented as $x^w_{d,t}$, soil attributes (soil type 1, soil type 2, saline soil, alkaline soil, phosphorus, potassium) $x^s_{d,t}$, and yield-related attributes (area, production, yield) as $x^l_{d,t}$. From these features, yield (area, production, yield, soil characteristics) and meteorological attributes (annual rainfall) change both spatially and temporally. Whereas, soil attributes (like soil type-1, soil type-2), and climate type, remain stable over time, district-wise. Attributes like $x^w_{d,t}$ varies regionally and temporally, whereas attributes in $x^s_{d,t}$ are some of the slowly changing factors that affect yield in real-world agricultural datasets. Yield prediction is a challenging spatiotemporal learning problem due to its long-term period relationships and the delayed consequences [30][31]. Each district in the dataset considered in this study is represented by a series of 13-year annual observations that include a wide range of agro-environmental characteristics $x_{d,t}$. Understanding how these characteristics build up, interact, and spread over time to affect yield in subsequent years is the real-challenge to be addressed.

Deep learning models like LSTM, RNN, and CNN may assume independence among the districts even though attributes like soil type 1, soil type 2, and climate type remain stable over time, district-wise, are different, and while processing these models, they may not fully use the spatial structure of the original data. To address this issue, the goal of the study is to employ a graph-based model to extract the immediate neighbour information of the districts ($A_{d,t}$) over the years $h_{d,t}$ which is leveraged by the spatio-temporal model for historical time series yield prediction. This process is illustrated in Fig. 3. Hence, the task of CYP is formulated as $y_{d,t}$ with $x_{d,t}$ where $t = \Delta t$ and Δt is taken as 3 years (that is, training the proposed model over 3 years of historical data). The main aim of the proposed model is to address these issues through:

$$y_{d,t}(t+1) = \text{Prediction}\Big(\text{GBiLSTM}(\alpha\,\text{BiLSTM}(\text{GCN}(x_{d,t}, A_{d,t})))\Big) \quad (1)$$

In Eq. (1), the prediction is based on the MSE loss function. In the first stage the Annual Regional-immediate neighbour, information is learnt through CYP features and $A_{d,t}$ which carries the regional information. This data which is year wise, is learnt through BiLSTM model to get the spatiotemporal embedding. Further, these are learnt over attention model to highlight the most significant temporal points towards yeild prediction. In the upcoming sections, 1) Data Collection, preprocessing and capturing Annual Regional-immediate neighbour information; 2) Joint Spatio-temporal feature extraction through attention-guided G-BiLSTM; and 3) yield prediction are detailed. The overall flow of the proposed model is illustrated in Fig. 1.

B. Data Collection, Preprocessing, and Capturing Annual Regional-Immediate Neighbour Information

The proposed model is evaluated on the primary regions for Bajra cultivation in India, specifically Rajasthan. Among the regions like Maharashtra, Gujarat, Haryana, and Uttar Pradesh, Rajasthan leads as the foremost state for Bajra production.

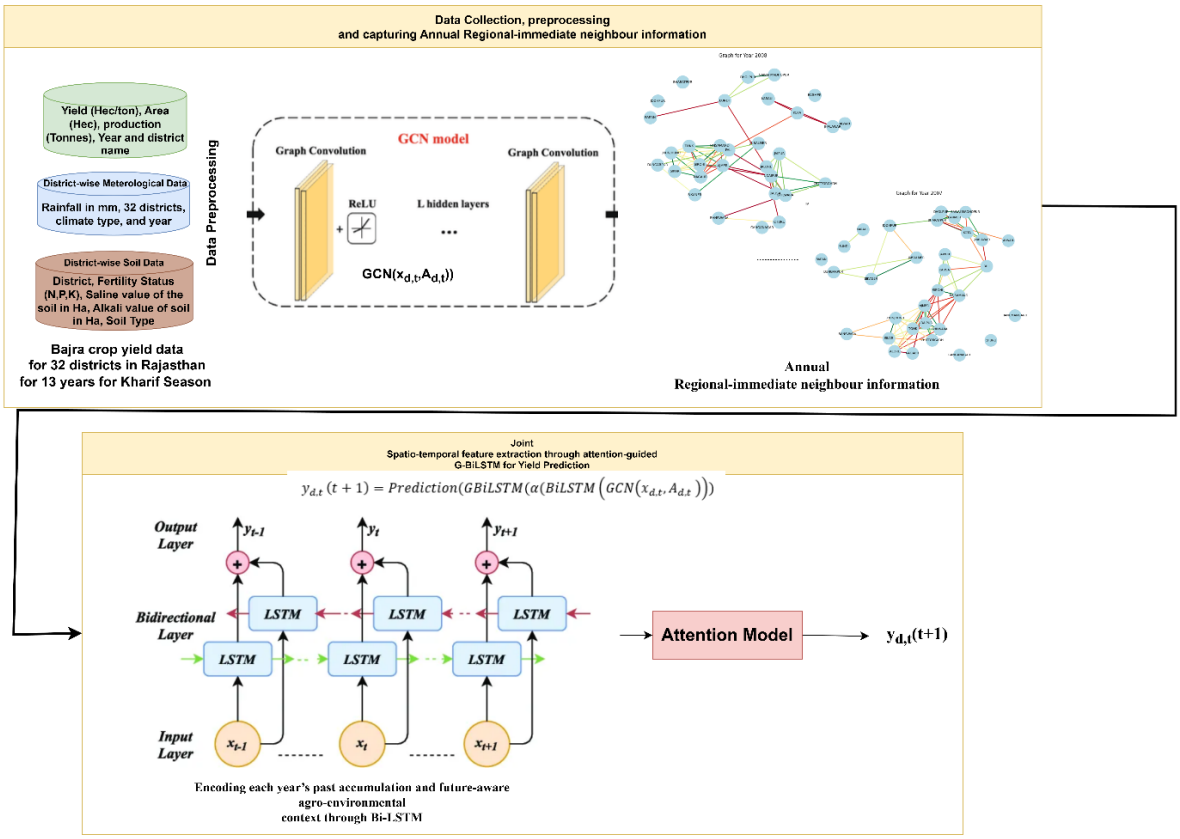

Fig. 1. Overall flow of the proposed model.

1) Geographical study of Rajasthan: In Rajasthan, the weather poses difficulties for growing various crops, particularly cereals. However, due to its resilience to harsh climatic conditions, millet farming has taken up a significant portion of the land in the region. Rajasthan accounts for 56.23% (4.43 million hectares) of the entire area dedicated to Bajra, contributing 41.40% (3.80 million tons) of India's total output. This fulfils the essential food needs of the state as well. From 2016 to 2017, Alwar district recorded the peak Bajra yield at 2149 kg/ha, surpassing all other Bajra-producing districts in Rajasthan. Traditionally, farmers depend on techniques like specific seed types, irrigation, and chemical fertilisers to sustain soil fertility and agricultural productivity. Nonetheless, these conventional methods are increasingly unreliable because of their vulnerability to the effects of climate change, further exacerbated by alterations in soil quality [14]. Therefore, examining the yield is crucial, considering elements such as soil characteristics and climatic conditions. This study collects data on soil and weather, which have influenced the Bajra crop in Rajasthan over the years, to effectively predict the yield. This study aims to analyse the yield fluctuations of Bajra and forecast its performance across the 32 districts of Rajasthan, as illustrated in Fig. 2.

This study focuses on capturing the yield variability of Bajra, as well as its prediction in Rajasthan and its 32 districts, as shown in Fig, 2.

2) Regional data collection for Rajasthan: To support the proposed approach, we curated a novel dataset that com-

Fig. 2. Geographical area of the study.

bines district-level soil properties, nutrient concentrations, and weather indicators over multiple cropping seasons. Data were sourced from verified government repositories and harmonised to ensure temporal and spatial consistency. This rich dataset serves as the foundation for the spatial modelling process and enables more accurate learning of Bajra yield patterns than the limited datasets used in prior research. In order to tackle the issues outlined in Section I, the process of data collection is aimed at obtaining thorough meteorological and soil information. This includes meteorological factors such as rainfall and climate patterns, particularly during the Kharif season, which is the primary growing season for crops like Bajra in regions across Asia and Africa. Additionally, soil data is being collected, including levels of potassium and phosphorus, as well as saline and alkaline content in the soil. Moreover, soil types and their sub-categories are being categorised to capture the diverse soil compositions in the study areas [35]. The main goal of gathering data on soil and weather is to comprehend the complex connection between these environmental elements and agricultural results. For example, changes in precipitation have a direct effect on the levels of water in the soil, which subsequently affects soil characteristics like the concentrations of nutrients and salts. By comprehensively analyzing soil and weather data, insights are aimed at being gained into how these factors interact and affect crop growth and yield. A more profound comprehension will facilitate the creation of precise predictive models and offer essential insights for agricultural choices, ultimately aiding farmers in adjusting to evolving environmental circumstances and enhancing crop yield. The data collection process involved sourcing various attributes from official Rajasthan state government websites.

3) Description of data sources: Firstly, the yield data is retrieved from the DACNET website of the Ministry of Agriculture and Farmers' Welfare [33]. This yields data for 32 districts of Rajasthan, over 23 years from 1997. The attributes collected are yield, area, production, year, and district name. To collect information about meteorological data, annual rainfall over the year [32] and climate type are collected [31]. Annual rainfall data is obtained from the Department of Water Resources, Rajasthan Government's official website [32]. This data was distributed across multiple PDF files, with each file containing daily rainfall records for different districts over the years. The data is present in the form of PDF (Portable Document Format) files, with different files for each year and each file containing daily rainfall for each district. Each one of these files had to be parsed in Python using libraries like PyPDF2 and regex. Whereas the climate data for yield prediction for each district in Rajasthan is obtained from [31]. According to [31], Rajasthan's territory is categorised into five climate types: arid, semi-arid, semi-humid, humid, and Mediterranean. Each of the 32 districts was assigned its respective climate classification based on this categorisation. This is achieved using regex functions, where each district is assigned the respective climate.

Now, the district-wise soil characteristics, including sodium, phosphorus, and potassium levels, as well as the extent of problematic soils such as saline and alkaline soils, were obtained from the Rajasthan Agriculture Statistics at a Glance report available on the official Rajasthan Government website [34]. However, a challenge arose as this data was presented in image formats. To overcome this, Microsoft's Optical Character Recognition (OCR) tool was utilized to extract the data from images and store it in CSV files. Additionally, soil type data was sourced from another reference [35], which provided information on 16 different categories of soil [35]. Each region within Rajasthan was found to have soils falling into two distinct categories. Finally, the final data obtained will consist of meteorological data, soil-related data, and yield data, which is 12 attributes for 32 districts over 13 years. The data is shown in Table III, and the overall steps are given as follows:

TABLE III. AGRO-ENVIRONMENTAL ATTRIBUTES DESCRIPTION

Column Name	Description
District	Names of the various districts of Rajasthan used in the present study
Year	The year for which the data was collected
Area (Hectare)	Total area in hectares of the district under cultivation for that particular year
Production (Tons)	Total production in tons of Bajra for that particular year
Yield (Tons/Hectare)	Amount of production in tons per unit hectare of area under cultivation for a particular year
Soil Type 1	One type of soil found in that district of Rajasthan
Soil Type 2	Another type of soil found in that district of Rajasthan
Phosphorous	Amount of phosphorous content in the soil for the given district
Potassium	Amount of potassium content in the soil for the given district
Saline Soil (Ha)	Total area of saline soil in hectares
Sodic/Alkaline Soil (Ha)	Total area of alkaline soil in hectares
Annual Rainfall (mm)	Rainfall for the given district in mm each year
Climate Type	The climate type of each district of Rajasthan like arid, humid, wet, etc.

- Yield Data Retrieval (DACNET Website): Attributes collected: yield, area, production, year, and district name for 23 years from 1997 [33].
- Then the annual rainfall data is collected from [32], and for each year, this is parsed and collected from PDF files using PyPDF2 and regex. Then it is incorporated with yield data, which leaves data for 13 years from 2007 to 2019 for 32 districts.
- Further, the climate type data is recognized with the data collected until step 2, where each district is explained with a certain type of climate as per [31]. Here, using regex, the climate type is added to the climate type column for each district in the data collected till now.
- Now, the data for soil type from [35] is added district-wise to the data collected until step 3. Then the district-wise low, medium, and high labels of Sodium, Phosphorus and Potassium in soil are merged with the data from [34]. This data was earlier present in the form of images, from which the data is extracted using OCR tools and merged with the data till now.
- The final data will have 12 attributes such as annual rainfall, district name, year, yield, area, production, soil type 1, soil type 2, phosphorus, potassium, saline soil, and alkaline soil, as given in Table III.

4) Regional data pre-processing: Initially, the data pre-processing involves verifying the presence of null values, and upon loading the dataset, it is observed that no null values

TABLE IV. DATA TYPE OF THE AGRO-ENVIRONMENTAL ATTRIBUTES IN THE CYP DATASET.

Attribute	Data Type
District	object
Year	object
Area (Hectare)	int64
Production (Tons)	int64
Yield (Tons/Hectare)	float64
Soil Type 1	object
Soil Type 2	object
Phosphorus	object
Potassium	object
Saline Soil (Ha)	float64
Alkaline Soil (Ha)	float64
Annual Normal Rainfall (mm)	float64
Climate Type	object

exist. The second step is to check for the object type of attributes and encode them. As per Table IV, a label encoder from the sklearn library is applied for the attributes with object type.

Some attributes labeled as "unnamed: 0", in the dataset, which contained serial numbers, were dropped during processing. Additionally, certain attribute columns such as potassium, climate type, saline and alkaline soil were named as unnamed and subsequently renamed to appropriate names. For instance, "unnamed: 8" representing potassium was renamed using Panda's library and regex expressions. The attribute "year" contained value in the format "2007-2008, 2008-2009." To standardize these values, a new list of individual years like ["2007", "2008" ...'"2019"] was created and merged with the existing dataset. Following this pre-processing, the initial step involves constructing graphs based on the years. Further details on these processes will be provided in the subsequent section.

The statistical summary of the attributes considered in this study is given in Section II. Rainfall is the attribute that is related to the climatic/meteorological type of data, as shown in Table IV, along with the climate type in Rajasthan for the 32 districts. While the climatic conditions affect the yield of the Bajra crop, soil attributes will also help framers take actions to improve yield. In Rajasthan, the rainfall varies from 0.82mm to 8734mm with a remarkable deviation from average, as seen in Table IV. This explains the change in climate from humid to semi-humid, which in turn affects the yield of Bajra [31]. Most of the districts in Rajasthan experience arid and humid climates [31]. The saline values in the soil also vary from 21.64 to 56369493. High saline levels in salts will affect the crops' ability to hold water content and remain hydrated. However, poor climatic conditions affect the soil conditions and lead to less yield. Thus, these conditions force farmers to use pesticides to boost the yield. Hence, a systematic process is carried out to collect the data from the respective sources.

Considering the preprocessed agro-environmental attributes data, the Annual Regional-immediate neighbour information is learnt as $GCN(x_{d,t}, A_{d,t})$, as in Eq. (1). The scenario of information considering the preprocessed agro-environmental attributes data, the Annual Regional-immediate neighbour information is learnt as regional information in $x_{d,t}$, which is explained through Fig. 3 . It displays the graph for the year 2008, and the agro-environmental attribute similarity across different districts/regions in Rajasthan.

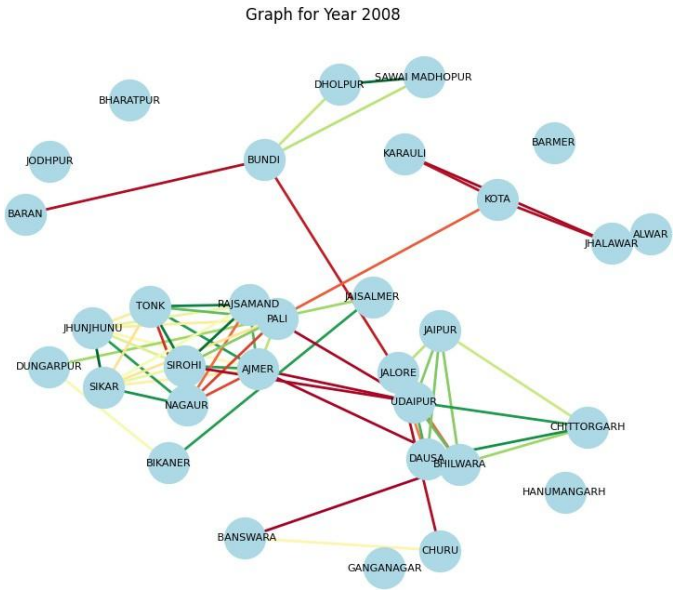

Fig. 3. Annual regional information as graph for the year 2008.

The lack of an edge linking Jodhpur and Bharatpur indicates a significant difference in the attributes described in Table II. This intriguing observation suggests that Jodhpur and Bharatpur differ from each other in certain ways. The striking differences, such as the lack of boundaries between these districts, highlight the importance of some characteristics and may indicate the distinct soil and climate types affecting their productivity. Such Regional immediate information is captured annually based on the data.

The scenario explained as similarity among the regions is captured as $A_{d,t}$. This is captured using Immediate Neighbor Extraction strategy. Let the spatial adjacency matrix $A_{d,t} \in \mathbb{R}^{N \times N}$, N is number of samples, it is be defined as:

$$A_{d,t} = \begin{cases} 1 & \text{if districts } d_i \text{ and } d_j \text{ share a boundary at year t} \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

For Eq. (2), we consider the property of cosine similarity that yields of neighboring districts that often exhibit correlated variations due to shared rainfall patterns and soil structures.

For each annual-wise graph, as shown in Fig. 3, the graph's edges are converted into edge indices. This results in a tensor of shape [2, num_{edges}], where num_{edges} is the number of the graph's edges. This tensor's columns signify edges, where the initial row holds the indices of source nodes and the subsequent row features the indices of target nodes. Therefore, this tensor acts as a compact representation of the $A_{d,t}$ in Eq. (3). The propagation rule for a l-layer GCN is followed here as per in [20]:

$$\begin{aligned} GCN(x_{d,t}, A_{d,t}) &= H^{(l+1)} \\ &= \sigma\Big(D^{-\frac{1}{2}} A_{d,t} D^{-\frac{1}{2}} H^{(l)} W^{(l)}\, x_{d,t}\Big) \end{aligned} \tag{3}$$

where, $H^{(l)}$ represents the Annual Regional-immediate Neighbour Information at layer l , $A = R + I$ is the adjacency matrix with self-loops added, as shown in [20] and the notations are similar to those in [20].

The final output of the GCN model after passing through all l-layers, explained in Eq. (3), is stored in gcn_output. This output represents the node embeddings or features learned by the GCN model for the given input graph. Each row of gcn_output corresponds to the feature representation of a node (district), and each column represents a feature dimension. $\mathbf{D}$ is the degree matrix of $A_{d,t}$, $\mathbf{W}^{(l)}$ denotes the learnable weight matrix at layer l, and σ is the activation function, ReLU. Further, the embedding's array is generated after processing of GCN. Thus, this is substituted in Eq. (1), where this is processed through BiLSTM model. This process is detailed in next section.

C. Joint Spatio-Temporal Feature Extraction Through Attention-Guided G-BiLSTM for Yield Prediction

Joint spatio-temporal is explained in Eq. (1), for each district d the Annual Regional-immediate Neighbour Information enriched embeddings $H^{(l+1)}$ is learnt for each year t that is, $H_t^{(l+1)}$ is fed into the BiLSTM.

The base LSTM units is employed here from [6], this unit maintain a memory cell c_t and hidden state h_t, defined by the classical LSTM equations. The forget, input, and output gates are [see Eq. (4)]:

$$\begin{aligned} f_t &= \sigma\left(W_f H_t^{(l+1)} + U_f h_{t-1} + b_f\right) \\ i_t &= \sigma\left(W_i H_t^{(l+1)} + U_i h_{t-1} + b_i\right) \\ o_t &= \sigma\left(W_o H_t^{(l+1)} + U_o h_{t-1} + b_o\right) \end{aligned} \tag{4}$$

whereas, here the goal is to encode each year's past accumulation and future-aware agro-environmental context. This is achieved by updating the candidate cell state as Eq. (5):

$$\widetilde{c}_t = tanh\left(W_c H_t^{(l+1)} + U_c h_{t-1} + b_c\right) \tag{5}$$

and the actual cell state updates as Eq. (6):

$$c_t = f_t \odot c_{t-1} + i_t \odot \widetilde{c}_t \tag{6}$$

The hidden state is Eq. (7):

$$h_t = o_t \odot tanh\left(c_t\right) \tag{7}$$

BiLSTM is employed here to extend this by processing the year's past accumulation and future-aware agro-environmental context. If the forward states are $h_t^{(f)}$ and backward states $h_t^{(b)}$, then the combined representation is Eq. (8):

$$H_t = \left[h_t^{(f)} \| h_t^{(b)}\right] \tag{8}$$

Further, to get more comprehensive spatio-temporal embeddings, the attention mechanism is introduced here highlighting the most influential seasonal time points.

Given the sequence output $\{H_1, \ldots, H_T\}$, attention weights α_t as given in Eq. (1) is captured as Eq.(9):

$$\begin{aligned} e_t &= v^\top tanh\left(W_a H_t + b_a\right) \\ \alpha_t &= \frac{exp(e_t)}{\sum_{\tau=1}^{T} exp(e_\tau)} \end{aligned} \tag{9}$$

The context vector becomes a weighted sum of hidden states, as in Eq. (10):

$$c = \sum\nolimits_{t=1}^{T} \alpha_t H_t \tag{10}$$

This context vector encodes the spatio-temporal essence of each district's agricultural dynamics [36][37]. Thus, the final yield prediction is captured through substituting the information in Eq. (1). Thus, the overall process detailed as a pseudocode and the proposed model is given in Algorithm 1.

TABLE V. SIMULATION PARAMETERS FOR PROPOSED MODEL

Model Name	Parameters	Value
GCN (GCN Conv)	Number of Hidden Channels	32
	Dropout Probability	0.3
	Weight Decay	1.00E-04
	Learning Rate	0.01
	Number of Epochs	500
	Input Size	32
	Hidden Size	64
BiLSTM Model with LSTM Set As	Output Size	32
	Learning Rate	0.001
	Number of Epochs	60
	Window Size	3

III. RESULTS AND DISCUSSION

The proposed G-BiLSTM model was evaluated to assess its ability to predict the yield of Bajra in 32 districts and across 12 multi-year agricultural cycles.

A. Experiment Scenario and Settings

The experiment involved the three combined sets of data including soil nutrient, soil type profiles and high-resolution weather records that were utilized in 12 years, given in Section II A. The train-validation-test split was on five randomized folds to make it robust. The given section is aimed at providing the quantitative outcomes, statistical analysis of significance, error distributions, performance tables, and comparative interpretation to make it clear that the given method is superior to current work.This part covers the evaluation of the proposed model's training and testing, alongside proposed model (excluding soil data), baseline LSTM from [9], baseline RNN model from [38], and CNN-RNN from [16]. The suggested model's performance is evaluated against these baseline models, where the GCN is trained using a cross entropy loss function [20], and LSTM is utilised for the final prediction. Parameters like the learning rate and the count of hidden layers are adjusted to enhance RMSE, R2 score, and correlation coefficient, which act as metrics for assessing model performance. These calculations originate from the libraries Sklearn and SciPy.

The proposed model is implemented on the Google Colab platform using Python and its libraries. The parameters set are given in Table V, where GCN provides the learned spatial embedding's for span of 13 years for the 32 districts. Graph construction utilizes the NetworkX library, the GCN employs torch-geometric package and the BiLSTM model is built using PyTorch.

The model is evaluated based on, RMSE, R^2 and correlation coefficients are detailed as, RMSE is a frequently used metrics in [7,9] to assess how well regression models function, RMSE is defined as Eq. (11):

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \widehat{y}_i)^2} \tag{11}$$

R^2 is another metric for evaluating a regression model's quality of fit is the coefficient of determination. It calculates the percentage of the dependent variable's variation that can be predicted based on the independent variables (features) (goal (yield).R^2ranges from 0 to 1, where 1 indicates the perfect fit. Mathematically, $R^2$is calculated as Eq. (12):

$$R^2 = 1 - \frac{SSRes}{SSTot} \tag{12}$$

where, $SSRes$ and $SSTot$ is the overall sum of squares and the sum of squares of the residuals, respectively. R^2 provides insight into how effectively the model accounts for data variability. The total sum of squares indicates the overall variability in the observed yields, whereas residuals show the discrepancies between the observed (actual) yields and the yields predicted by the regression model. A higher R^2 value suggests that the model fits the data better since it accounts for a greater percentage of the variability in yields.

The degree and direction of the linear link between two variables are measured by the correlation coefficient, which is frequently represented by the symbol "Pearson". Regarding yield forecasting, the correlation coefficient measures how well the predicted yields from the proposed model align with the actual observed yields. Mathematically, it is given as Eq. (13):

$$pearsonr = \frac{\sum (x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum (x_i - \overline{x})^2 \ \sum (y_i - \overline{y})^2}} \tag{13}$$

where, x_i and y_i represent the two variables' individual data points, and $\overline{x}$ and $\overline{y}$ represent their respective means. These metrics are computed for each of the four models in this study for both training and testing.

The errors in prediction were examined in the areas that received rainfall extensively, those experiencing droughts and those that were a combination of the two. The given structure was particularly strong when it comes to the capture of deviations of monsoons. Mathematically, it is explained by the attention mechanism which places substantial weights on sudden changes in rainfalls:

$$\alpha_t = \frac{exp(e_t)}{\sum e_\tau}, e_t \propto tanh\,(W_a H_t),$$

resulting in high sensitivity to time steps, where climatic volatility is highest. Only in extreme anomaly years when the rainfall varied more than 40% of the 15-year mean, error peaks were realized but the model still provided an RMSE of less than 60, which was better than LSTM and GNN models.

B. Analysis of the Proposed Model

When the model is evaluated for heatmap representations of Agro-environmental Attributes in Fig. 4, it is seen that the attributes related to meteorological type are mostly used for yield prediction. To understand the effect of the attributes in the dataset considered here over the yield of Bajra Pearson's correlation is conducted, and the heatmap is illustrated in Fig. 4. Before conducting this, the data is encoded into numbers using the label encoder library from the Sklearn package. Further, the Pearson correlation is also imported from Sklearn. The colour legend in the heatmap shows the high and low correlation between the attributes and yield based on the values varying

from -1 to 1. The analysis of the heatmap reveals notable patterns in the correlation between various attributes and the yield of the Bajra crop. Specifically, soil attributes, such as soil type 2, exhibit a high positive correlation with the yield attribute. Rainfall attribute also shows positive trend with yield, the values exhibits variations along the year as seen in Fig. 5.

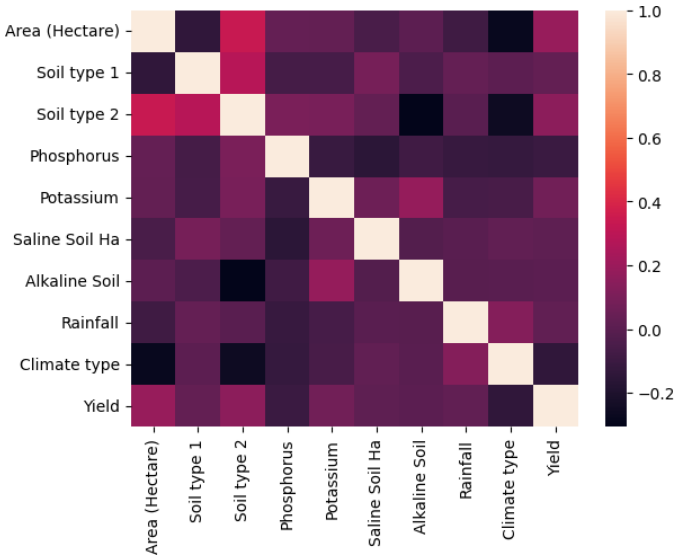

Fig. 4. Heatmap representation of the correlation matrix of the agro-environmental attributes.

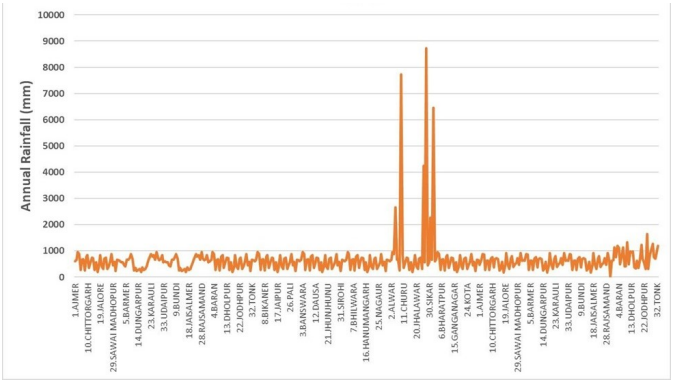

Fig. 5. Annual average normal rainfall (mm) over the districts from 2007 to 2020.

Fig. 6 shows minimal deviation between actual and predicted crop yields, highlighting the model's accuracy. Incorporating soil data, which significantly impacts crop yield allows the proposed model to effectively capture the influence of soil characteristics on Bajra crop yield.

Fig. 7 shows the scatter plot analysis of predictions after using LSTM on left and after using Bi-LSTM on right. The proposed model, when encodes the agro-environment data through normal data, the data points are more scattered and away from actual values showing high errors. When the candidate cell is updated to capture both past and future trends if rainfalls, the delayed trend is reduced causing the predicted points to be more near to actual values. This leads to high correlation coefficients and low RMSE. The detailed analysis

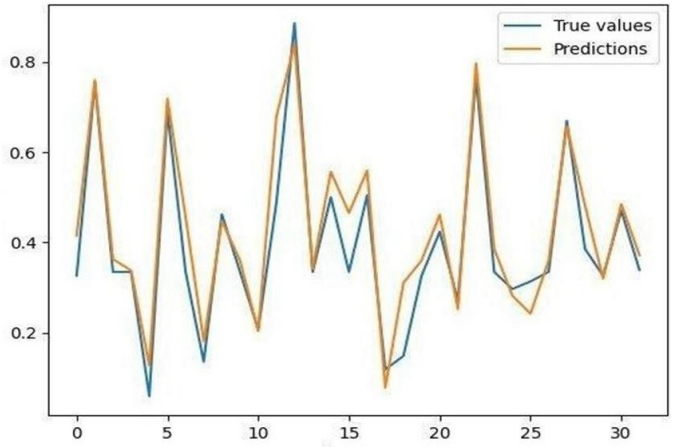

Fig. 6. Comparison of true values versus predicted yield values using immediate neighbor extraction and temporal analysis model.

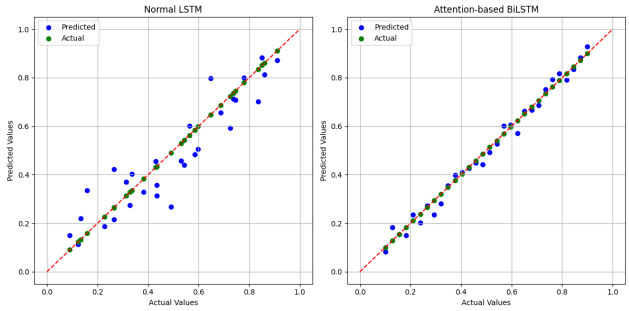

Fig. 7. Comparison of actual values versus predicted yield values when only temporal values are captured (normal LSTM (left)) and when each year's past accumulation and future-aware agro-environmental context is encoded (attention-based BiLSTM (right)).

of performance of proposed model compared to baselines is shown in next section.

1) Statistical analysis: To analyze the generalization of the proposed model, the model is run for 5-fold experiments with different year train-test splits. This is shown in Fig. 8, where the central line shows the median range, and the top line of the box shows the IQR (inter quartile range). The analysis shows that not much variance is exhibited as the mean RMSE is around 10.89. the values over 5-fold doesn't vary much as upper and lower quartiles show 10.9 and 10.7 RMSE.

Considering this, the proposed model shows low RMSE compared to baseline and shows reliability for future real-time CYP task.

2) State-of-the-art comparison: The current study compares a number of baseline models, including CNN-RNN, RNN, and LSTM, as shown in Table VI. These models were implemented by keeping the training and testing data same as proposed to maintain fairness. The default LSTM model's architecture largely adheres to the guidelines given in Table VI, with 70% of the dataset used for training and the remaining 30% designated for testing. Similar to the baseline LSTM model [9], the baseline RNN model, according to reference [38], has a window size of 3 and a hidden size of 64. With a learning rate of 0.001%, the Adam optimiser is used to train

TABLE VI. COMPARATIVE ANALYSIS WITH THE STATE-OF-THE-ART MODELS

Model	RMSE Training Loss	R^2 Training Score	Training Correlation Coefficient	RMSE Testing Loss	R^2 Testing Score	Testing Correlation Coefficient
Proposed Model	7.6	84.8	94.1	10.8	68.75	89.1
Proposed Model without Soil Data	8.1	82.8	91	11	65.5	83.2
LSTM [9]	95.1	74.81	93.63	11.21	64.53	88.87
RNN [38]	17	45.1	77.1	18	55.1	55
CNN-RNN [16]	19	48	68.6	21	59	50
Gradient Boost Algorithm [39]	15	45	90.9	8.9	55.78	87.9
GNN [40]	17.4	51.8	86.02	14	58.5	87.8

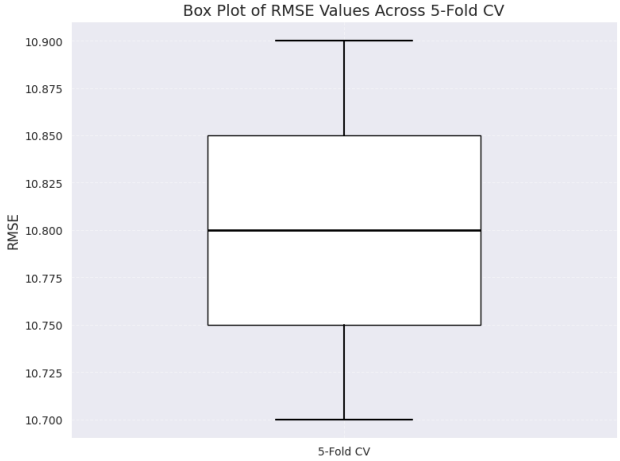

Fig. 8. Statistical analysis of RMSE for proposed model for 5-folds.

both LSTM and RNN models. Performance is then optimised by iteration over 60 epochs.

The proposed model demonstrates a 3.29% improvement in correlation coefficient during training and a 6.62% improvement during testing compared to the proposed model without soil data. This improvement suggests that incorporating soil data enhances the model's ability to encode each year's past accumulation and future-aware agro-environmental context by updating the candidate cell, resulting in stronger correlations and high performance. The proposed model is compared with Gradient boosting [39], which focuses on improving the performance in a sequential manner. However, it shows high errors compared to proposed model. The proposed model shows low RMSE and high correlation coefficient that is 1.45% high when tested.

IV. CONCLUSION

In this study for Bajra crop yield prediction, an deep learning model is proposed. The study proposes a region-based spatiotemporal model with an attention-guided Bidirectional LSTM (Long-Short Term Memory) framework for CYP, termed as G-BiLSTM. The proposed model reproduces the spatial relationships between districts via GCN (Graph Convolution Network) -based immediate neighbour extraction. Further, a Bidirectional LSTM is used to model multi-year CYP temporal features, allowing each annual observation to be encoded using both past and future temporal context. A variance-reduced and comprehensible representation is produced by integrating an attention mechanism to adaptively highlight the most informative years within a temporal window. Using 15 agro-environmental characteristics, including understudied elements like saline and alkaline soil composition, the framework is assessed on a dataset that includes 32 districts in Rajasthan over 13 years (2007–2019). The proposed model achieves 7.6% if RMSE training loss with 10.8 RMSE testing loss. The proposed model demonstrates a 3.29% improvement in correlation coefficient during training and a 6.62% improvement during testing compared to the proposed model without soil data.

The proposed model outperforms the baselines by leveraging the past, future temporal context and highlighted information of important temporal points. The existing study focus on a single and scope area of cultivation for a single crop. However, in future, the study will focus on the prediction of vast area and various crops like sugarcane. The current model captures the regional graph based on fixed adjacency matrix, in future, the author plan to capture the dynamically changing information in real-time. The existing model uses a single type of data from open-source, the future work will focus on using satellite imagery data as well. This will help improve the model predictions and scope.

V. LIMITATIONS AND FUTURE SCOPE

Though the proposed model shows good performance, there are some limitations.

The research is based on thirteen years of curated district-level data in Rajasthan, and this restricts the time modeling horizon. Although some agro-environmental processes (e.g. salt degradation or climatic oscillations) might have cumulative behavior (that is, over longer times), the three-year sliding window adopted is a proportionate and statistically balanced design choice, within the limited time frame. Further investigation into the temporal dataset will be done in the future, and studies of the multi-scale or hierarchical temporal modeling techniques will be done to capture more long-term oscillatory patterns.

The proposed study is modeled using historical variability and tested on a held-out three-year test set to predict, as real-world forecasting does not know future values of those variables. Nevertheless, regimes may become too extreme so as to keep predictive power (e.g. long periods of multi-year droughts not seen in the observed pattern), as is the case with most data-driven models. In the future, the study will

be enhanced by stress-testing in extreme climatic conditions and explicit failure mode analysis to enhance robustness and transparency.

The agro-environmental characteristics (soil characteristics, salinity, rainfall, climate) of agro-environmental modeling are done at a macro district level using the current graph formulation. Other socio-economic variables, management practices, level of irrigation, and dynamics of pests are not encompassed because of the lack of uniform longitudinal data of the 32 districts on a district-wide basis. The work in the future will develop the graph to incorporate the socio-economic factors.

The proposed model is scalable because the adjacency matrix and feature representation can be applied to other areas, but it is not covered by current empirical cross-regional validation. The model will be tested in various agro-climatic regions in future to enhance the generalizability claims.

The BiLSTM part is being trained on past sequences in which all the years used in the training set are known. Although this means that prediction on unknown test years is realistic, the framework is not at present formulated to carry out in-season forecasting in real-time, where future information of the seasons is unknown. The problem of extending the model to operational forecasting situations will be dealt with in future studies.

***Abstract*—The scalability of predictive models has become a critical factor in modern machine learning, as data volumes grow and computational resources diversify. This study presents an empirical benchmark of three widely used regression paradigms: Elastic Net, XGBoost, and Multi-Layer Perceptrons (MLPs). The *Obesity Estimation* dataset is used to evaluate both predictive performance and computational scalability across multi-core CPUs and GPUs. Unlike prior studies that primarily emphasize accuracy, we explicitly examine the trade-offs between accuracy, training time, and hardware efficiency. Models are evaluated under staged training loads (10–100% of data) with grid-searched hyperparameters (for Elastic Net and XGBoost) and regularized deep architectures (for MLP). Results demonstrate that while XGBoost achieves the highest predictive accuracy ($R^2 = 0.91$), it incurs significant computational overhead on CPUs, whereas GPU acceleration substantially improves its scalability. MLPs provide competitive accuracy ($R^2 = 0.87$) with an order-of-magnitude lower training time on GPUs, making them attractive for rapid or repeated retraining. Elastic Net offers interpretability and linear scalability on CPUs, but lags in predictive power. These findings provide practitioners with a decision framework: *XGBoost for maximum accuracy*, *MLPs for efficient retraining*, and *Elastic Net for interpretability and small-scale tasks*. More broadly, this work highlights that hardware selection is as important as algorithm choice, with GPUs serving as enablers of state-of-the-art performance on structured data.**

***Keywords*—Scalability; XGBoost; Neural Networks; Elastic Net; resource efficiency**

I. Introduction

The rapid expansion of data in the 21st century has firmly established machine learning as a cornerstone of innovation in science, industry, and society. The ability to extract predictive insights from large-scale datasets has enabled transformative applications ranging from medical diagnostics to financial modeling. However, this data-centric revolution also introduces a significant challenge: the scalability of computation. As datasets grow from megabytes to gigabytes and beyond, the computational time and resources required to develop increasingly complex predictive models become a critical research and development bottleneck [1], [2].

Selecting an appropriate machine learning model is, therefore, a multidimensional decision problem. While traditional approaches have primarily emphasized predictive accuracy as the benchmark of success, modern data science practice demands a broader evaluation framework. Factors such as training time, computational cost, interpretability, and ease of deployment are now equally important [3]. Consequently, researchers and practitioners are scrutinizing how different model architectures perform under diverse computational and hardware constraints.

The computational landscape itself has undergone dramatic change. Historically, machine learning tasks were executed primarily on multi-core Central Processing Units (CPUs), which are optimized for sequential task execution. The emergence of General-Purpose Graphics Processing Units (GPGPUs), however, has redefined the paradigm. With thousands of parallel cores, GPUs are capable of delivering orders of magnitude improvements in speed, particularly for algorithms dominated by large-scale matrix and vector operations [4], [5]. This shift has sparked growing interest in systematically examining the interplay between algorithmic complexity, hardware efficiency, and scalability.

In this context, the study presents an empirical investigation of these trade-offs, focusing on three widely adopted model families that represent distinct paradigms of predictive modeling:

- Regularized Linear Models (Elastic Net): A strong and interpretable baseline that combines L1 and L2 regularization to address multicollinearity and feature selection. Its convex optimization formulation makes it computationally efficient on CPUs [6].
- Gradient Boosted Trees (XGBoost): A state-of-the-art ensemble method highly effective for structured and tabular data [7]. Despite its sequential tree-building nature, modern implementations exploit parallelization on both CPUs and GPUs for improved efficiency.
- Neural Networks (Multi-Layer Perceptrons): Foundational deep learning architectures capable of learning complex non-linear relationships [4]. Their reliance on matrix multiplications makes them particularly well-suited for GPU acceleration during training.

The purpose of this study is to provide a transparent and practical benchmark for data scientists and engineers using the publicly available Obesity Dataset [8]. We evaluate these three model families under identical preprocessing pipelines, comparing their predictive accuracy, computational cost, and scalability across CPU and GPU environments. Unlike prior studies that focus predominantly on accuracy or single-hardware evaluations, this work provides empirical evidence of the performance–scalability trade-offs and highlights the decisive role of hardware in model selection. In doing so, the study delivers actionable insights into how practitioners can balance accuracy, efficiency, and interpretability when

selecting the appropriate model–hardware configuration for real-world applications.

II. Related Work

Comparative analysis of machine learning models has long been a cornerstone of the discipline. However, contemporary research is increasingly extending beyond accuracy-focused evaluations toward computational trade-offs, scalability, and interpretability. This section reviews key literature about the model families and hardware configurations that underpin the present study.

A. Foundations of Gradient Boosting

Gradient Boosting, first proposed by Friedman [9], revolutionized predictive modeling by demonstrating that a strong learner could be constructed through the sequential training of weak learners—typically decision trees—to correct predecessor errors. The introduction of XGBoost by Chen and Guestrin [7] marked a pivotal engineering advance, offering novel solutions to scalability challenges through efficient sparse-aware algorithms and block-based cache optimization for out-of-core computing. Their implementation further leveraged multi-core CPU parallelization to achieve significant performance gains.

Subsequent adaptations extended gradient boosting to GPU architectures, with Mitchell and Frank [10] demonstrating that the computational bottleneck in feature histogram construction could be massively parallelized via GPU processing. The result was the `gpu_hist` algorithm, which dramatically accelerated training times. Later, Chen et al. [11] conducted comprehensive comparisons between GPU-accelerated XGBoost and competing frameworks such as LightGBM [12] and CatBoost, concluding that GPU acceleration yields substantial benefits for large-scale datasets—particularly when the CPU–GPU communication overhead becomes negligible relative to computation.

B. Neural Networks for Tabular Data

Although deep learning, particularly Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) [13], dominates unstructured data domains such as image and text analysis, its superiority over tree-based methods for structured tabular data remains a subject of debate. For years, ensemble tree methods like XGBoost were considered the de facto standard for such data types. However, recent work by Kadra et al. [14] challenges this assumption, demonstrating that even relatively simple Multi-Layer Perceptrons (MLPs) can rival or outperform gradient-boosted trees when properly tuned and regularized using techniques such as Batch Normalization and Dropout.

The scalability of neural networks is inherently linked to hardware acceleration. The matrix operations central to forward and backward propagation are highly parallelizable, making GPUs particularly well-suited for these workloads [15]. In their foundational work, Abadi et al. [16] detailed how frameworks such as TensorFlow were explicitly designed for heterogeneous, distributed GPU environments, allowing neural network training to scale across thousands of cores. Consequently, the performance disparity between CPU and GPU implementations in neural network training remains among the largest in machine learning.

C. Linear Models and the Timelessness of Linear Modeling

Despite advances in complex architectures, regularized linear models continue to serve as a fundamental reference point in predictive modeling. Zou and Hastie [6] introduced the Elastic Net, which blends Lasso (L1) and Ridge (L2) penalties to manage correlated predictors while maintaining sparsity through feature selection. These models offer consistent interpretability and computational efficiency due to their convex optimization landscape, which ensures a unique global minimum and efficient convergence [17]. Implementations in widely used libraries such as `scikit-learn` have solidified their role as benchmark baselines. Nonetheless, as noted by Lu et al. [5], such models are not inherently optimized for GPU parallelization, limiting their scalability compared to deep learning counterparts.

D. Hardware Benchmarking Investigations

A growing body of research explicitly investigates the hardware-level benchmarking of machine learning algorithms. The RAPIDS cuML library, for example, provides GPU-accelerated analogs to many `scikit-learn` functions, demonstrating speedups ranging from $10\times$ to $100\times$ on large datasets [18]. Li et al. [19] and Reuther et al. [20] have compared various deep learning systems, reinforcing the dominant role of GPUs in accelerating model training and inference. Similarly, Reuther et al. [20] presented a comprehensive mapping of hardware acceleration strategies, highlighting that the optimal hardware configuration is model-dependent and sensitive to dataset size, model complexity, and memory overhead.

Building on these studies, our work contributes a focused, task-specific benchmarking analysis across three widely used and computationally distinct model paradigms—linear models, tree-based ensembles, and neural networks—under both CPU and GPU configurations. This approach provides a practical framework for understanding the trade-offs between computational efficiency, scalability, and predictive performance in tabular data applications.

E. Literature Summary

The literature demonstrates strong empirical evidence for XGBoost's scalability across different architectures. Mitchell et al. [21] implemented a multi-GPU gradient boosting algorithm that processed 115 million training instances in under three minutes using end-to-end GPU parallelism with data compression techniques to optimize memory usage. Chen and Guestrin [7] established XGBoost as a scalable tree boosting system that scales beyond billions of examples using fewer resources than existing systems through novel sparsity-aware algorithms and cache optimization.

Somoye et al. [22] reported that distributed XGBoost achieved approximately a $3.5\times$ speedup, demonstrating practical scalability in distributed contexts. Edwards and Vishkin [23] showed potential for a $3.3\times$ speedup over NVIDIA's most powerful GPU using hybrid memory architectures.

Research on neural network scalability reveals more complex performance patterns. Ma et al. [24] conducted comprehensive experiments showing GPUs outperformed parallel CPUs for synchronous SGD by only 2–5× for simple models and below 7× for fully connected deep networks. Notably, for asynchronous SGD, CPUs were the optimal solution, outperforming GPUs even when GPUs had 10× or more speedup potential. Barrachina et al. [25] analyzed CNN training scalability on GPU clusters, identifying crucial bottlenecks at both GPU and cluster levels. Farias et al. [26] achieved training speedups from one to four orders of magnitude for parallel MLP training by exploiting locality principles and parallelization capabilities. Yin et al. [27] addressed CPU scalability limitations through ParaX, which improved throughput by 1.73× to 2.93× on many-core CPUs by assigning instances to individual cores rather than entire CPUs.

Zhou et al. [28] provided significant evidence for Elastic Net scalability through algorithmic reduction to Support Vector Machines, creating a parallel solver that naturally utilizes GPUs and multi-core CPUs. Their implementation achieved identical results to the optimized `glmnet` but was up to two orders of magnitude faster across twelve real-world datasets.

Overall, the literature reveals that scalability performance is highly dependent on specific use cases, data characteristics, and computational approaches. While GPUs generally provide superior raw performance, CPUs remain competitive for certain scenarios, particularly asynchronous processing and when considering power efficiency. The choice between architectures should consider task-specific requirements, data sparsity, and synchronization needs rather than assuming GPU superiority across all contexts.

III. Maintaining the Integrity of the Specifications

A. Dataset Description

This study utilizes the *Estimation of Obesity Levels Based on Eating Habits and Physical Condition* dataset [8], publicly available through the UCI Machine Learning Repository. The dataset contains 2,111 individual records and 17 attributes, collected to characterize obesity levels among citizens of Mexico, Peru, and Colombia.

For this regression-based investigation, the objective variable is **Weight**, modeled as a continuous outcome predicted from the remaining 16 features. The original categorical class label, *NObeyesdad*, was excluded to avoid data leakage, since it is directly correlated with both *Weight* and *Height*.

The predictor variables consist of a combination of numerical and categorical features:

1) Numerical (6): Age, Height, FCVC (frequency of vegetable consumption), NCP (number of main meals per day), CH2O (daily water intake), and FAF (frequency of physical activity).

2) Categorical (10): Gender, family history with overweight, FAVC (frequent consumption of high-caloric food), CAEC (consumption between meals), SMOKE, SCC (calorie monitoring), CALC (alcohol consumption), MTRANS (transport mode), and two other minor lifestyle indicators.

B. Exploratory Data Analysis (EDA)

An exploratory assessment was performed to examine the structure, distribution, and integrity of the dataset prior to modeling.

1) Numerical feature summary: The numeric variables displayed realistic and consistent ranges. The mean participant age was 24.3 years (SD = 6.3). Heights ranged between 1.45 m and 1.98 m, while the target variable (*Weight*) spanned 39 kg to 173 kg. No missing or anomalous entries were detected, simplifying preprocessing. A correlation matrix revealed a strong positive correlation between *Height* and *Weight*, as expected, confirming *Height* as a dominant predictor.

2) Categorical feature distribution: The categorical variables provide valuable lifestyle context. For instance, 81.9% of respondents reported a family history of overweight, indicating a significant genetic or environmental predisposition. Likewise, 74.9% reported using public transportation, suggesting an urban or suburban sample profile. Recognizing such imbalances is critical, as they may influence how models learn latent patterns.

Overall, the EDA confirmed that the dataset was suitable for regression analysis and rich in both continuous and discrete predictors, warranting specialized preprocessing techniques.

3) Preprocessing pipeline: To ensure data consistency, prevent leakage, and tailor transformations to model requirements, a comprehensive preprocessing pipeline was implemented using the `Scikit-learn Pipeline` and `ColumnTransformer` objects [17]. This approach encapsulated all transformations while ensuring that training-set statistics (e.g., means, standard deviations) were applied consistently to the test data.

The pipeline workflow is summarized as follows:

- Train–Test Split: The dataset was divided into 80% training ($n = 1,688$) and 20% testing ($n = 423$) subsets using a fixed random state (`random_state = 42`) for reproducibility. Stratification was applied to maintain proportional class distributions, and the held-out test set was used exclusively for final evaluation.
- Feature Transformation: The `ColumnTransformer` applied data-type-specific transformations:
  - Numerical Features: Standardization was performed using `StandardScaler`, which centers features to zero mean and unit variance according to:

    $$z = \frac{x - \mu}{\sigma}$$

    For Elastic Net regression, scaling ensures that the regularization penalty is applied uniformly across coefficients, regardless of magnitude. For MLP neural networks, scaling improves gradient-descent efficiency and stabilizes convergence.
  - Categorical Features: `OneHotEncoder` was used to encode the ten categorical features into

binary indicator variables. This prevents the model from assuming any false ordinal relationship among categories (e.g., "Automobile" < "Motorbike" < "Walking"). The parameter `handle_unknown = "ignore"` safeguarded against unseen categories during inference.

- Model-Specific Augmentation: For Elastic Net regression, a `PolynomialFeatures` transformer (degree = 2) was appended to generate interaction (e.g., *Age* × *Height*) and quadratic (e.g., Age^2) terms. This manual feature engineering step enriches the model's expressiveness by allowing it to capture non-linear relationships within an otherwise linear framework.

This structured pipeline ensures that every model receives clean, standardized, and consistently formatted input, thereby maintaining a fair comparison across algorithmic families while upholding data integrity and reproducibility.

IV. Methodology

To evaluate performance and scalability, three distinct models were compared under identical preprocessing conditions. The experiments were conducted in a Google Colab environment, utilizing both its standard multi-core CPU and NVIDIA T4 GPU configurations to evaluate performance differentials.

The methodology encompasses comparative evaluation across:

- Regularized Linear Model: Elastic Net Regression [6], providing an interpretable baseline with controlled feature shrinkage.
- Gradient Boosted Trees: XGBoost [7], representing state-of-the-art ensemble learning for tabular datasets.
- Neural Network: Multi-Layer Perceptron (MLP) [14], trained using backpropagation and stochastic gradient descent, designed to assess non-linear representation learning efficiency.

All models were evaluated for predictive performance, computational cost, and scalability across CPU and GPU hardware environments, establishing a rigorous foundation for subsequent analysis.

A. Models

We compared three different paradigms of machine learning models, presenting three distinct approaches.

The first model is a regularized linear regression model, known as the **Elastic Net**. It is an extension of standard Ordinary Least Squares (OLS) regression with the addition of a penalty term to the cost function that limits the size of the learned coefficients. The purpose of this regularization is to prevent overfitting and improve the model's performance on unseen data. The Elastic Net combines the two most common types of regularization—Lasso (L1) and Ridge (L2)—to balance sparsity and stability. The Elastic Net model aims to minimize the following cost function:

$$\hat{\beta} = \arg\min_{\beta} \left(\frac{1}{2n} \sum_{i=1}^{n} (y_i - X_i\beta)^2 + \lambda \left[\alpha \|\beta\|_1 + \frac{1-\alpha}{2} \|\beta\|_2^2 \right] \right)$$

where, λ controls the overall strength of regularization, and α controls the trade-off between L1 and L2 penalties.

The second model is **XGBoost**, a highly efficient and scalable decision tree-based gradient-boosted implementation. Gradient boosting is an ensemble technique that builds models sequentially—each new tree is trained to correct the residual errors made by the previous ensemble. The objective function at boosting iteration t is defined as:

$$Obj^{(t)} = \sum_{i=1}^{n} l(y_i, \hat{y}_i^{(t-1)} + f_t(x_i)) + \Omega(f_t)$$

where, l represents the loss function that measures the difference between predicted and true values, f_t is the new tree added at iteration t, and $\Omega(f_t)$ is the regularization term that penalizes model complexity to prevent overfitting.

The last model used in the analysis was a **Multi-Layer Perceptron (MLP)**, which is an archetypal feedforward neural network. Each neuron in a layer receives a weighted input from the previous layer and adds a bias term. The resulting value is passed through a non-linear activation function to introduce learning flexibility. The forward propagation step for a neuron in layer (l) is expressed as:

$$a^{(l)} = f\left(W^{(l)} a^{(l-1)} + b^{(l)}\right)$$

where, $W^{(l)}$ represents the weight matrix, $b^{(l)}$ is the bias vector, $a^{(l-1)}$ is the input from the previous layer, and $f(\cdot)$ denotes the activation function (e.g., ReLU or sigmoid).

In this study, we implemented a regression-oriented MLP architecture with one input layer, two hidden layers, and a single output neuron. The two hidden layers consisted of 128 and 64 neurons, respectively, while the output neuron was configured to perform continuous-value prediction.

B. Experimental Protocol

Our experimental protocol was designed to evaluate both the computational scalability and predictive performance of each model in a rigorous and reproducible manner. To obtain scalability measurements, each model was trained on progressively larger random subsets of the training data—specifically at fractions of 10%, 25%, 50%, 75%, and 100%. This staged approach enabled the construction of an empirical scaling curve that clearly demonstrates how the computational time requirements evolve for each algorithm as the data volume increases.

For each training run, the *wall-clock time* was recorded to quantify efficiency. All experiments used fixed random seeds to ensure that the results for deterministic models (Elastic Net and XGBoost) were fully reproducible.

After scalability testing, the final optimized versions of all models were trained on 100% of the training data to assess

their maximum predictive potential. These fully trained models were then evaluated on the held-out test data, which were never used during the training or model selection process. The final evaluation employed three standard regression metrics that together provide a comprehensive performance assessment:

- Root Mean Squared Error (RMSE): Sensitive to large errors, RMSE quantifies the standard deviation of the residuals, providing insight into prediction deviation magnitude.
- Mean Absolute Error (MAE): A robust measure of average prediction error magnitude, less sensitive to outliers and easy to interpret.
- Coefficient of Determination (R^2): Measures the proportion of variance in the target variable explained by the model, providing an indicator of goodness-of-fit.

C. Hyperparameter Configuration

A systematic hyperparameter optimization was conducted using `GridSearchCV` combined with 5-fold cross-validation to determine the optimal configuration for each model. This ensured a fair and exhaustive evaluation across different subsets of the data, balancing bias and variance in performance.

1) Elastic Net: The Elastic Net regressor was tuned over the following parameter grid:

- alpha: [0.01, 0.05, 0.1, 0.5] (Controls overall strength of regularization)
- l1_ratio: [0.7, 0.9, 0.95, 1.0] (Controls the trade-off between L1 and L2 penalties)

2) XGBoost: The XGBoost model underwent hyperparameter tuning with the following configuration space:

- n_estimators: [500, 700] (Number of boosting trees)
- learning_rate: [0.03, 0.05] (Step size shrinkage to prevent overfitting)
- max_depth: [7, 9] (Maximum depth of individual trees)
- subsample: [0.7, 0.8] (Fraction of samples used to grow each tree)
- colsample_bytree: [0.7, 0.8] (Fraction of features used per tree)

To enable GPU acceleration, the `tree_method` parameter was set to `gpu_hist`.

3) Multi-Layer Perceptron (MLP): The MLP model was not tuned through exhaustive grid search but was configured following widely accepted deep learning best practices, emphasizing regularization and convergence stability.

Architecture:

- Input Layer
- Dense (256, activation='relu') + BatchNormalization + Dropout(0.4)
- Dense (128, activation='relu') + BatchNormalization + Dropout(0.4)
- Dense (64, activation='relu') + BatchNormalization
- Dense (1, activation='linear')

Training Configuration:

- Optimizer: Adam (initial learning rate = 0.001)
- Epochs: 300 (with `EarlyStopping` patience = 20)
- Callbacks: `EarlyStopping`, `ReduceLROnPlateau`

This configuration was selected to ensure stable convergence, reduce overfitting, and maintain balanced generalization performance across different computational environments.

V. Results and Evaluation

This section presents the quantitative analysis of the conducted experiments, summarizing the results, interpretability insights, and detailed scalability observations derived from the comparative evaluation of the models.

A. Evaluation Metrics

The performance of each model was evaluated on the held-out test dataset using three standard regression metrics that collectively provide a comprehensive view of predictive accuracy and reliability:

- Coefficient of Determination (R^2): Measures the proportion of variance in the dependent variable explained by the independent variables. Values closer to 1.0 indicate a better model fit.
- Mean Absolute Error (MAE): Represents the average absolute difference between predicted and actual values, providing an interpretable measure of average prediction error in the same units as the target variable (kg).
- Root Mean Squared Error (RMSE): The square root of the mean of squared errors, which penalizes large deviations more heavily than MAE, emphasizing the model's sensitivity to large errors.

B. Compared Performance

Following hyperparameter optimization, the final tuned versions of all models were evaluated on the held-out test dataset. As summarized in Table I, each algorithm demonstrates distinct strengths when balancing predictive accuracy, computational efficiency, and scalability. The performance metrics and total training times, measured on the complete training data after model tuning, highlight these trade-offs—showing that while some models achieve superior accuracy, others offer faster convergence and better scalability under GPU or CPU configurations.

The findings indicate a clear performance hierarchy among the evaluated models. As illustrated in Fig. 1, **XGBoost** achieved the highest predictive accuracy with an impressive R^2 value of 0.9097, demonstrating its strong capability to capture complex non-linear relationships within the data. The **MLP** model followed closely, attaining an R^2 of 0.8672,

TABLE I. COMPARATIVE MODEL PERFORMANCE ON THE TEST SET

Model	RMSE	MAE	R^2	Time (s)
XGBoost (GPU)	7.9811	5.0612	0.9097	361.43
MLP (GPU)	9.6749	6.9852	0.8672	24.11
Elastic Net (CPU)	12.2405	9.4815	0.7875	36.29

which validates its effectiveness as a non-linear function approximator. In contrast, the **Elastic Net** model, despite the inclusion of polynomial features, produced the lowest R^2 value of 0.7875. This outcome suggests that the relationships within the dataset were too intricate to be accurately represented using a regularized linear approach.

In terms of computational efficiency, Fig. 2 provides a comparative visualization of the models across all performance metrics—R^2, RMSE, and MAE. The **MLP** demonstrated the fastest training time, completing in only 24.1 seconds. This superior speed can be attributed to its GPU-accelerated implementation and the use of the `EarlyStopping` callback, which effectively reduced unnecessary training epochs. Conversely, **XGBoost**, while achieving the highest accuracy, required a longer training duration due to its extensive hyperparameter search space and more complex ensemble architecture, resulting in a higher computational cost.

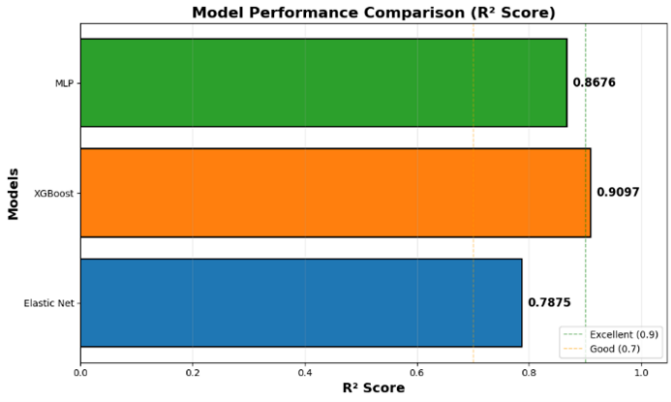

Fig. 1. Model performance comparison R^2.

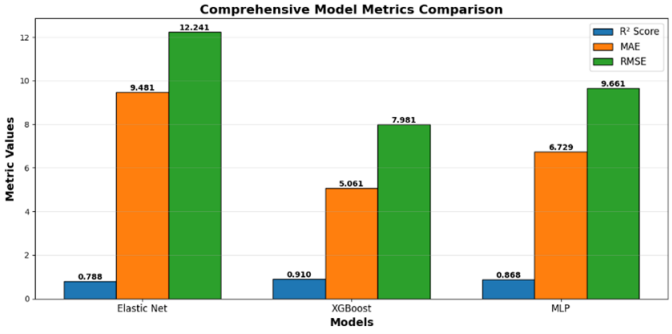

Fig. 2. Comprehensive model metrics comparison.

C. Analysis of Error and Interpretability

To gain a deeper understanding beyond aggregate metrics, an additional diagnostic analysis was conducted to examine model residuals and interpretability.

1) Residual analysis: Residual plots serve as essential diagnostic tools in regression analysis, visualizing the discrepancy between actual and predicted values. The residuals, defined as $(y_i - \hat{y}_i)$, are plotted against the predicted values to reveal systematic model behavior. In a well-calibrated model, residuals are expected to be randomly distributed around the horizontal line at zero—forming a cloud-like pattern with no discernible structure. Such a distribution indicates that the model has effectively captured the underlying data signal and that remaining deviations are primarily due to random noise rather than systematic bias.

The random scatter of points around the $y = 0$ line indicates a well-fitted model with no systematic error patterns. When examining the residual plot of our **XGBoost** model with the best performance Fig. 3, an ideal behavior is observed. The residuals are well distributed both above and below the $y = 0$ line across the entire range of predicted weights. No visible curvature is present, suggesting the absence of non-linear relationships that the model failed to capture, and no funnel-like pattern (heteroscedasticity) appears, implying that the model's error variance remains consistent across different magnitudes of prediction. The random scatter provides strong evidence that the model is unbiased, the residuals are homoscedastic, and thus the predictive validity of the model can be considered reliable.

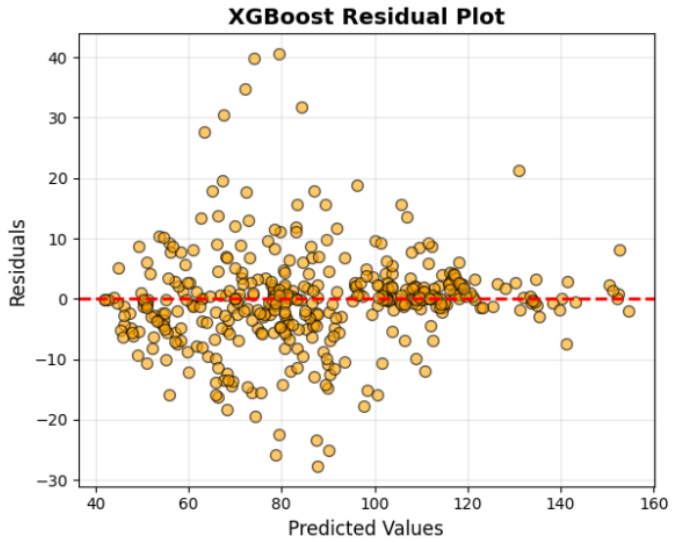

Fig. 3. Residual plot for the XGBoost model on the test set.

2) Feature importance: To further interpret the strong performance of **XGBoost**, its internal feature importance scores were examined. These scores quantify the contribution of each feature to the boosted trees.The most influential features are presented in Fig. 4, where the top fifteen attributes exhibit the greatest impact on model performance.

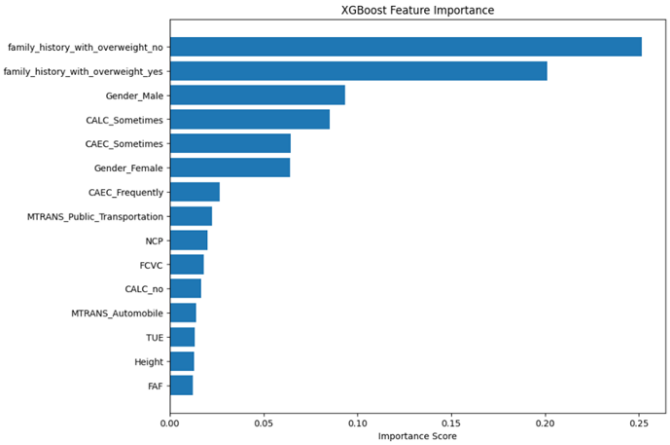

Fig. 4. Scores of feature importance of the most tuned XGBoost model.

The scores are used to show the relative contribution of each feature to the model. Height is, as expected, the most predictive of all features of being overweight. This finding is consistent with established biological principles. There is also a high rank of gender and family history with overweight, which endorses the fact that the demographic and genetic factors are the driving forces. Such lifestyle factors as FAVC (consumption of high-caloric food many times) and FCVC (consumption of vegetables many times) are also reported to be significant predictors. This provides assurance that the model has learned meaningful relationships within the data.

D. Scalability Analysis

The core objective of this study is the analysis of scalability, which quantifies the dependency of the time spent in training models on the size of a data set to be considered with each model and hardware setup. The number of training samples exhibits a near-linear increase in training time. Fig. 5 given below shows that the Elastic Net model exhibits linear and predictable scalability on the CPU. The training time grows smoothly with the amount of data added to it, so it should be a choice when dealing with smaller to medium datasets on typical hardware.

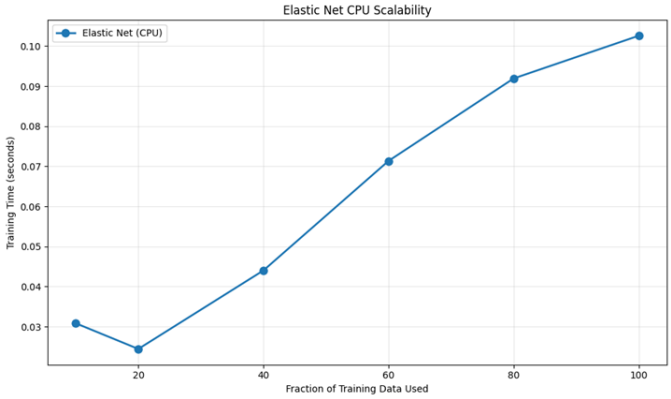

Fig. 5. Elastic Net model is scalable on a multi-core processor.

The logarithmic scale illustrates the widening performance gap between CPU and GPU computations as data volume increases. While GPU training times remain nearly constant, CPU times exhibit exponential growth. The strongest evidence for the influence of hardware acceleration is depicted in Fig. 6 and Fig. 7.

1) CPU performance: For both XGBoost and the MLP, training time exhibits super-linear—nearly exponential—growth when executed on the CPU. This demonstrates that as data volume increases, these sophisticated algorithms quickly become computationally infeasible on a purely CPU-based system.

2) GPU performance: In contrast, both models exhibit remarkable scalability when trained on a GPU. The parallel architecture of GPUs allows massive data batches (as in MLP) and feature histogram construction (as in XGBoost) to be processed with impressive efficiency. The scaling curve of the MLP, in particular, remains nearly flat, as the entire dataset can be processed within seconds. For XGBoost, GPU benefits increase further with larger datasets, since the initial overhead of data transfer becomes negligible compared to the computational gain.

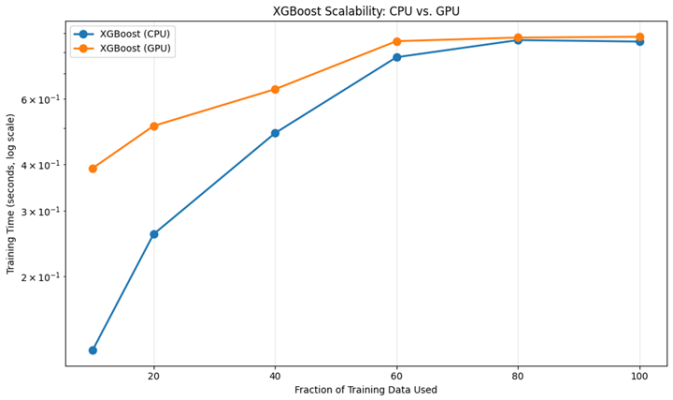

Fig. 6. XGBoost model on CPU vs. GPU. First y-axis is a logarithmic scale.

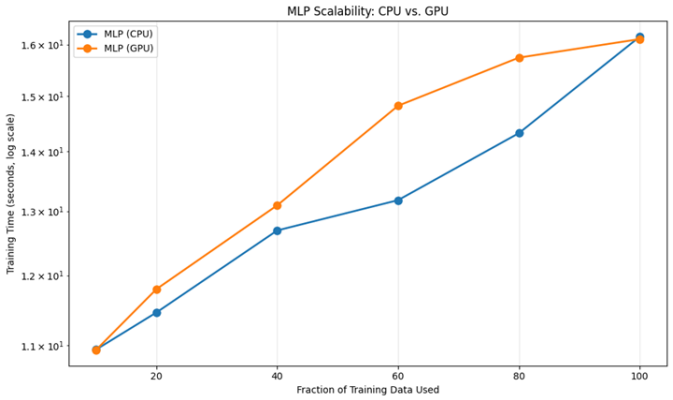

Fig. 7. Scalability of the MLP model between CPU and GPU.

VI. Discussion

The experimental results present a multifaceted view of the trade-offs among accuracy, computation, and interpretability in

contemporary machine learning. This section synthesizes the key findings to derive practical insights and recommendations.

A. Accuracy–Compute Trade-off

The results reveal a classical trade-off between accuracy and computational cost. XGBoost achieved the highest accuracy with an R^2 of 0.91 but was also the most computationally expensive to train. Its exhaustive hyperparameter search—despite parallelization—demanded substantial time resources. The MLP achieved slightly lower accuracy ($R^2 = 0.87$) but was an order of magnitude faster in training.

This presents a strategic dilemma for practitioners: whether a 4–5% improvement in R^2 justifies a fourteenfold increase in training time. In static, one-time prediction tasks where model accuracy is paramount, XGBoost's performance merits its computational cost. However, in dynamic environments with frequent retraining (e.g., streaming or production systems), the rapid training time of the MLP makes it a more practical and cost-efficient choice. The Elastic Net, though least accurate, serves as a valuable baseline due to its simplicity, speed, and interpretability, making it ideal for initial experimentation before committing to complex models.

B. The Hardware Acceleration Imperative

Fig. 6 and Fig. 7 (Scalability plots) represent one of the most significant contributions of this study. They empirically confirm that GPU acceleration is not merely advantageous but essential for scalable machine learning involving modern algorithms. The performance difference between CPU and GPU training is not incremental—it is transformative.

Without GPU acceleration, training times for MLP and XGBoost increase almost exponentially, severely restricting feasible dataset sizes and hyperparameter search depth. In contrast, GPUs enable researchers to train on larger datasets, execute more exhaustive tuning, and achieve optimal performance within seconds rather than minutes. Consequently, hardware acceleration emerges as a cornerstone for state-of-the-art machine learning research and practice.

C. Interpretability vs. Performance

The findings also reaffirm the long-standing trade-off between interpretability and predictive power. The Elastic Net functions as a white-box model—its coefficients are directly interpretable, allowing explicit inference on how each feature contributes to the prediction outcome. This makes it ideal for use cases requiring transparency and causal interpretation.

XGBoost occupies a middle ground. Although individual trees are complex, the model offers robust feature importance scores (see Fig. 4), which provide insight into the relative influence of predictors—a level of interpretability sufficient for most applied contexts.

The MLP, however, is a classical black-box model. Its deep, nested non-linear transformations make it extremely difficult to map inputs to outputs directly. While explainability methods such as SHAP (SHapley Additive exPlanations) can approximate local feature contributions, the model itself lacks intrinsic interpretability. In this study, moving from the most interpretable model (Elastic Net) to the most accurate model (XGBoost) resulted in a 12% improvement in R^2. This suggests that, in this context, the gain in performance outweighs the loss in interpretability—a trade-off often encountered in applied machine learning.

D. Limitations and Ethical Considerations

This study acknowledges several limitations. First, it relies on a single dataset; thus, generalization to datasets with different structures, dimensionalities, or feature distributions remains to be validated. Second, the hyperparameter optimization relied on grid search; more advanced techniques such as Bayesian optimization could yield superior configurations.

From an ethical standpoint, predictive models involving personal attributes (such as weight or family history) may inadvertently learn and propagate social biases. In applications like healthcare or insurance, such biases could lead to unfair outcomes for individuals based on immutable characteristics. Therefore, any deployment of such models should be accompanied by a rigorous bias and fairness audit to ensure equitable performance across demographic groups.

VII. Conclusion and Future Work

This empirical study explored the relationship between predictive accuracy, computational scalability, and hardware selection across three distinct machine learning paradigms—Elastic Net, XGBoost, and Multi-Layer Perceptron—using the Obesity dataset. Our results clearly establish that for structured, tabular data, XGBoost remains the state-of-the-art in predictive strength due to its ability to capture complex feature interactions. However, a well-optimized MLP, combined with GPU acceleration, can achieve competitive accuracy while offering dramatically faster training throughput—making it ideal for iterative or time-sensitive applications.

Most importantly, the findings highlight the transformative impact of hardware acceleration. As data volumes and model complexities continue to rise, GPU-enabled computation transitions from an optional enhancement to a fundamental requirement. The scalability analysis shows that, while CPU-based training becomes prohibitively slow with large data, GPU-based models maintain efficiency even under full dataset loads. Ultimately, model selection emerges as a multi-objective optimization problem—balancing accuracy, interpretability, training time, and computational resources. Future research should expand this benchmark to include other ensemble frameworks such as LightGBM and CatBoost, and extend interpretability analysis using model-agnostic explainers like SHAP for both global and local feature insights. Moreover, testing on higher-dimensional datasets will further clarify the boundaries of scalability and the evolving role of hardware in machine learning.

Authors' Contribution

Wan Joe Dean served as the principal contributor to this study under the supervision of Atif Mahmood for the Machine Learning Applications course. The co-authors, Adnan Qureshi, Saaidal Razalli, and Qilong Yu, contributed by reviewing the manuscript, assisting in writing, and verifying experimental results.
