5. Farmer (Wallet): Scans the QR code.
6. Wallet Agent: Sends a connection request to the Issuer Agent.
7. Issuer Agent: Responds with a connection-response. Connection is now 'active'.
8. Issuer Admin (Web UI): Selects the active connection and fills out the credential details.
9. Issuer Controller: Calls ACA-Py agent to send a credential offer.
10. Issuer Agent: Sends the credential offer to the Wallet Agent.
11. Farmer (Wallet): Accepts the offer.
12. Wallet Agent: Sends a credential-request to the Issuer Agent.
13. Issuer Agent: Issues the signed credential and sends the issue-credential message.
14. Wallet Agent: Receives and stores the credentials securely.
15. Farmer (Wallet): Receives a notification that the credential has been stored.

2) Credential verification workflow: The process of verifying a credential involves the farmer (Holder), the Verifier, and their agents, as given in Algorithm 2.

Algorithm 2: Verification Flow

1. Verifier Admin (Web UI): Clicks "Create Proof Request Invitation".
2. Verifier Controller: Calls its ACA-Py agent to create a connection invitation.
3. Farmer (Wallet): Scans the QR code to establish a connection
4. Verifier Admin (Web UI): Selects the active connection and initiates a proof request.
5. Verifier Controller: Calls its ACA-Py agent to send a proof request.
6. Verifier Agent: Sends the proof-request to the Wallet Agent, specifying the required attributes.
7. Farmer (Wallet): Is prompted to share the requested information. The wallet automatically finds the required credentials.
8. Farmer (Wallet): Consents to sharing.
9. Wallet Agent: Generates a zero-knowledge proof and sends the present proof message.
10. Verifier Agent: Receives the proof and cryptographically verifies it against the public information on the Indy ledger.
11. Verifier Agent: If verification is successful, it notifies the Verifier Controller.
12. Verifier Admin (Web UI): Sees the verification result updated on the dashboard.

D. Agent-based Communication and Authentication

All interactions within the Ziraai SSI system use peer-to-peer agent communication.

- Pairwise decentralized identifiers are used for each bilateral relationship, preventing identifier reuse across contexts.
- Encrypted DIDComm messaging ensures the confidentiality and integrity of exchanged messages.
- Authentication is achieved through cryptographic proof of DID control rather than password-based or centralized mechanisms.

This communication model demonstrates the feasibility of decentralized, identity-bound authentication in agricultural supply chain environments, where centralized identity infrastructure is often unavailable or impractical.

E. Security and Privacy Mechanisms

The Ziraai SSI prototype enforces security and privacy guarantees through cryptographic identity primitives and agent-mediated protocols.

- Credential integrity and authenticity are ensured through digitally signed verifiable credentials.
- Authentication relies on cryptographic proof of control over decentralized identifiers.
- Privacy preservation is achieved through selective disclosure and proof-based verification.
- Pairwise decentralized identifiers mitigate correlation across interactions.

Private keys and credentials are stored within secure wallet environments under the exclusive control of credential holders, minimizing centralized aggregation of sensitive identity data and reducing systemic risk. Table II summarizes the security properties and how they are achieved in the Ziraai SSI platform.

TABLE. II. SECURITY PROPERTIES AND THEIR IMPLEMENTATION IN ZIRAAI SSI

Security Property	Implementation Mechanism in Ziraai SSI
Integrity	Digitally signed verifiable credentials
Authentication	DID-based cryptographic proof of control
Privacy	Selective disclosure via attribute proofs
Confidentiality	Encrypted DIDComm messaging
Non-repudiation	Identity-bound credential issuance
Unlinkability	Pairwise decentralized identifiers

F. Implementation Scope and Limitations

The Ziraai SSI system is implemented as a research prototype intended to validate architectural design choices and demonstrate the functional feasibility of blockchain-enabled self-sovereign identity in agricultural supply chains. Accordingly, the implementation prioritizes correctness, transparency, and standards alignment over performance optimization or large-scale deployment.

Several limitations are acknowledged. First, the prototype is evaluated in a controlled environment. It does not include large-scale ledger deployment or stress testing, which limits conclusions regarding scalability and throughput under real-world workloads. Second, while the underlying SSI infrastructure supports credential revocation, recovery, and status management, these capabilities are not fully exposed through user-facing interfaces in the current implementation. Third, user interface design is intentionally minimal and may require further refinement to support adoption by non-technical stakeholders. These limitations are inherent to the scope of a research prototype and serve to identify concrete directions for future enhancement rather than deficiencies in the proposed framework.

V. RESULTS AND DISCUSSION

This section presents the results of implementing and evaluating the proposed blockchain-based self-sovereign identity framework using the Ziraai SSI research prototype. The discussion focuses on functional validation, security and privacy behavior, and governance implications, rather than performance benchmarking, in alignment with the identity-centric role of the proposed system within agricultural supply chains.

A. Evaluation Objectives and Metrics

The primary objectives of the evaluation were as follows:

- To verify the feasibility of implementing decentralized identity and credential management for agricultural stakeholders using standardized SSI technologies.
- To validate end-to-end identity and credential workflows, including identity creation, credential issuance, storage, and privacy-preserving verification.
- To assess how the implemented system improves transparency, trust, and privacy compared with conventional centralized identity management approaches commonly used in agricultural supply chains.

The evaluation deliberately emphasizes functional correctness, interaction completeness, and security behavior, rather than throughput- or latency-oriented performance metrics. This choice reflects the governance-oriented nature of identity systems, where correctness and trust guarantees are often more critical than raw performance.

B. Practical Workflow Validation

The Ziraai SSI prototype was evaluated through a series of end-to-end workflow executions involving issuer, holder (farmer), and verifier roles, as described in Section IV.

- Identity creation: Each stakeholder successfully generated a decentralized identifier (DID) and established secure, pairwise connections using agent-based communication. It validated correct DID generation, key binding, and mutual authentication without reliance on centralized identity services.
- Credential issuance: Authorized issuers issued verifiable credentials following consent-driven workflows. Credentials were securely transmitted and stored in holder-controlled wallets, confirming the correct execution of issuance protocols and the preservation of holder autonomy.
- Credential verification: Verifiers issued proof requests specifying required attributes. Holders responded using selective disclosure mechanisms, and cryptographic verification was completed successfully without disclosure of unnecessary credential attributes.

Collectively, these observations confirm that the implemented system supports a complete and operational SSI credential lifecycle, consistent with the conceptual workflow defined in Section III and the implementation described in Section IV.

C. System Behavior and Performance Discussion

The implemented system was evaluated with respect to key security and privacy properties relevant to agricultural identity management.

- Integrity: Credential authenticity and integrity were preserved through cryptographic signatures and verification against issuer decentralized identifiers and ledger-anchored credential definitions.
- Authentication: Only entities controlling valid decentralized identifiers and corresponding private keys were able to participate in issuance and verification workflows, demonstrating identity-bound authentication without centralized intermediaries.
- Privacy: Selective disclosure mechanisms enabled attribute-level verification, minimizing data exposure during credential presentation. The use of pairwise decentralized identifiers further reduced the risk of cross-context correlation.
- Accountability: Identity-bound interactions ensured that credential issuance and verification events could be attributed to authenticated entities, supporting auditability without exposing sensitive identity data.

- Invalid or Malicious Submissions: Basic negative test cases were performed to evaluate system robustness. Replayed proof messages were rejected due to nonce-based challenge–response mechanisms, and invalid or improperly signed credentials failed cryptographic verification against ledger-anchored definitions. These results indicate that the prototype is resistant to replay and forgery attempts within the evaluated environment.

These observations indicate that the security and privacy objectives outlined in Section III are realized in practice through the implementation mechanisms described in Section IV.

D. Comparative Discussion with Centralized Systems

When compared with conventional centralized identity management systems, the proposed framework exhibits several notable advantages. First, the framework eliminates single points of trust and failure by decentralizing identity ownership and verification. This is particularly relevant in agricultural ecosystems, where stakeholders are geographically distributed and often operate across institutional boundaries. Second, auditability and transparency are improved through verifiable credential workflows rather than opaque database records controlled by a single authority. Verification can be performed independently by any authorized verifier without prior trust relationships. Third, privacy protection is enhanced, as stakeholders retain control over identity attributes and disclosure decisions. Unlike centralized systems, sensitive identity information is not persistently stored or aggregated by service providers. These characteristics suggest that blockchain-enabled self-sovereign identity provides qualitative governance advantages over centralized approaches, particularly in trust-fragmented agricultural environments. The comparison focuses on architectural and governance differences rather than performance benchmarking. Unlike centralized systems, the proposed framework distributes trust and enables cryptographic verification without reliance on intermediary authorities.

E. Discussion of Strengths and Limitations

While the Ziraai SSI prototype demonstrates functional feasibility and standards-compliant identity workflows, several practical considerations were observed during implementation and evaluation. First, establishing SSI connections introduces additional interaction steps compared to traditional username–password authentication models. Although these steps improve security and trust, they may increase initial onboarding complexity, particularly for non-technical users. Second, the use of decentralized identifiers and pairwise relationships increases the number of cryptographic artifacts managed by agents and wallets. This trade-off is inherent to privacy-preserving identity systems and necessitates robust wallet usability and key management support. Third, the evaluation was conducted in a controlled environment and did not include large-scale deployment or performance-stress testing. As a result, conclusions regarding scalability and operational performance under real-world workloads remain limited. These trade-offs reflect design choices rather than implementation deficiencies and highlight areas where usability engineering and system optimization will be required for production deployment.

F. Implications for Agricultural Supply Chain Governance

The evaluation results indicate that self-sovereign identity can serve as a feasible architectural foundation for identity-centric governance in agricultural supply chains. By enabling stakeholders to authenticate, certify, and verify interactions without centralized intermediaries, the proposed framework supports distributed trust establishment while preserving privacy and accountability. In particular, the ability to issue and verify credentials—such as farmer registrations, certification attestations, and compliance proofs—through standardized SSI protocols creates new opportunities for transparent yet privacy-aware governance models involving regulators, cooperatives, and market participants. Although regulator-operated nodes and multi-issuer governance competition were not experimentally simulated in the current prototype, the architecture is designed to accommodate such roles in future multi-institutional deployments.

VI. Conclusion and Future Work

This study presented Ziraai SSI, a blockchain-based self-sovereign identity prototype designed to enhance transparency, security, and decentralized trust in agricultural supply chains. By integrating blockchain-based trust anchoring with self-sovereign identity mechanisms, the proposed approach addresses fundamental limitations of conventional centralized identity and data management systems, including fragmented trust relationships, limited auditability, and privacy risks. Rather than focusing solely on transactional traceability, the proposed framework explicitly positions identity as a core governance primitive within agricultural ecosystems. A key contribution of this work lies in the design of a layered, identity-centric blockchain–SSI framework tailored to the structural and governance characteristics of agricultural supply chains, and in its realization through a functional research prototype. The Ziraai SSI implementation operationalizes decentralized identifiers, verifiable credentials, and privacy-preserving authentication using standardized SSI technologies, enabling interactions among issuers, holders, and verifiers through secure, standards-compliant credential workflows. The prototype-level evaluation demonstrates the feasibility of decentralized authentication, selective disclosure, and identity-bound accountability without reliance on centralized identity providers.

The results indicate that self-sovereign identity can serve as a feasible architectural foundation for establishing trust and governance in distributed agricultural environments, particularly when stakeholders are heterogeneous and centralized identity infrastructures are impractical or undesirable. By enabling cryptographically verifiable identity interactions while preserving stakeholder autonomy and privacy, the proposed approach supports more transparent and accountable supply chain governance models. While the current implementation is research-oriented and limited to a controlled consortium setting, it provides a concrete baseline for future system extensions and deployment-oriented investigations. Several directions for future work are identified. First, the system can be extended to support comprehensive credential lifecycle governance, including user-facing credential revocation, recovery, and status management mechanisms.

Second, large-scale deployment studies involving multiple institutions and regulatory authorities are required to evaluate scalability, interoperability, and operational resilience under realistic conditions. Third, integration with complementary technologies—such as IoT-based data collection and analytics—may further enhance traceability, monitoring, and decision support within agricultural supply chains. Finally, improving usability and accessibility for non-technical stakeholders remains a critical requirement for real-world adoption and warrants focused human-centered design efforts.

***Abstract*—Automated Essay Scoring (AES) systems often rely on holistic prediction and show weak alignment with rubric-based human evaluation. Existing deep learning approaches achieve moderate agreement but struggle to model discourse coherence and provide trait-faithful explanations. This study proposes a rubric-aware and discourse-faithful essay scoring framework that integrates contextual embeddings with sentence-level discourse modeling and rubric-specific attention. The framework generates both holistic and trait-level scores, while enabling counterfactual explanation of scoring decisions. Experiments conducted on the Learning Agency Lab – Automated Essay Scoring 2.0 dataset show that the proposed model achieves a Quadratic Weighted Kappa (QWK) of 0.86, Root Mean Square Error (RMSE) of 1.41, and Mean Absolute Error (MAE) of 1.12, outperforming CNN-LSTM, BERT-LSTM, and DeBERTa baselines. QWK evaluates ordinal agreement, while RMSE and MAE measure numerical prediction error. Trait-level performance reaches F1-scores of 0.89 for Content and 0.87 for Grammar, indicating strong rubric alignment. The proposed framework improves scoring reliability, interpretability, and consistency with human grading practices. It is suitable for large-scale educational assessment, formative feedback systems, and intelligent tutoring applications, offering a scalable and explainable solution for multi-trait essay evaluation.**

Keywords*—Automated Essay Scoring; rubric-aware modeling; discourse representation; counterfactual explainability; multi-task learning

I. Introduction

Automated Essay Scoring is now an indispensable part of educational assessment, especially high-stakes assessment like in online learning applications and large-scale assessments [1]. Traditional manual essay assessment is a time-consuming, expensive, and prone to subjectivity amongst human assessors [2]. As the need to have scalable and consistent assessment grows, AES has been a promising solution to the provision of reliable and quick feedbacks [3]. Even though transformer-based language models have recorded significant improvements, the existing AES systems continue to have a very poor connection with human practices of analytic grading and contain no discourse-sensitive and rubric faithful reasoning [4].

The majority of modern AES systems are based on collapsing the writing competencies into one holistic score, which is fundamentally based on a multi-dimensional, rubric-based paradigm of grading applied by human assessors [5]. The criteria used by human examiners in evaluating the essays are in most cases based on rubric, i.e., grammar, relevance in the content, structure, richness of vocabulary and coherence [6]. By comparison, single-score prediction models also have a tendency to ignore individual dimensions of writing, which results in loose correspondence with actual grading [7]. Another severe shortcoming is the lack of clear, rubric-based descriptions which explain how personal linguistic and discourse characteristics lead to assigned scores. AES systems that are based on transformers can be said to be black-box models, which can be highly accurate, but can give no explanation to why it has given that prediction [8]. This limits their practical application, particularly in the academic institutions that require transparency and accountability [9].

In recent times, machine learning-based methods with SVMs, random forests and logistic regression classifiers have gained widespread use [10]. Nevertheless, these rely on manually engineered features, which bring bias and constraints while working with varied writing styles, multilingual writing and domain-specific essays. In spite of rich semantic patterns of deep architectures, they are highly agnostic to explicit rubric structures and do not disentangle trait-specific contributions in the scoring process [11] [12]. CNN is known for their spatial feature extraction that has been widely utilized for word-level dependency, local patterns and syntactic structures learning in essay text. RNNs, particularly LSTM and GRU architectures,

have proven very successful in modeling long-range dependencies in sequential data [13] [14].

Another problem that has been broadcasted in modern AES systems is prejudice. Essays of greater length and more dense vocabulary or patterns of the native language tend to get higher marks despite their poor structure [15]. These prejudices compromise credibility and discriminate some population groups. In addition, current models of AES tend to have low cross-prompt generalization, and they only perform well on the prompt they are trained on and not on topics they have not seen. Such constraints make it difficult to implement them in various academic settings [16]. To overcome these drawbacks, AES needs to shift onto rubric-conscious and interpretive scoring paradigms that extend beyond holistic regression. These systems must directly simulate various analytic dimensions of writing, e.g., the content, grammar, organization, vocabulary and coherence, effectively increasing the transparency and fairness, as well as consistency with human scoring behavior. This change is the key to the facilitation of meaningful feedback, pedagogical accountability, and high-quality large-scale assessment with diverse learner groups. RAMS-Net-TFCR is a rubric-sensitive and discourse faithful AES model that matches neural representations and analytic grading constructs by trait attention, sequential coherence modelling, and consistency-regularized multi-task training.

A. Research Motivation

Automated scoring systems are now required by educational assessment because of their ability not only to be accurate but also transparent, fair, and relevant to human grading practices. The rationale behind this study is due to the ongoing lack of connection that exists between high-performing AES models and their failure to deliver rubric-based explanations and discourse-sensitive judgments. To overcome this disjuncture, there must be a rubric-aware and discourse faithful AES paradigm that is able to bridge neural representational to explicit analytic grading constituents and still maintain the ability to interpret the model.

B. Research Significance

This research is significant as it introduces a rubric-aware, discourse-sensitive, and explainable AES framework that aligns closely with human analytic grading standards. By decomposing holistic scores into interpretable rubric-level predictions and modeling discourse coherence explicitly, the proposed approach enhances transparency and fairness in automated assessment. The framework supports meaningful educational feedback, facilitates instructor trust, and enables scalable deployment in standardized testing, intelligent tutoring systems, and academic writing evaluation environments.

C. Key Contributions

- Proposes a rubric-relational, discourse conscious AES model of faithful, interpretable, and human congruent multi-trait essay scoring.
- Instructs collaborative learning of rubric properties with discourse coherence and semantic dependence to evaluate them well.
- Trains RAMS-Net-TFCR with DeBERTa, DABiSE, RS-MHA and counterfactual explanation as a rubric-faithful scoring system.
- Uses rubric-specific attention using discourse-sensitive encoding so as to isolate representations that matter in traits, and make them interpretable.
- Obtains QWK 0.86, RMSE 1.41, MAE 1.12, which are significantly higher than CNN-LSTM and BERT-LSTM baselines.

D. Structure of the Study

The remaining of the study is organized as follows: Section II provides an extensive review of existing models and their limitations. Section III details the problem statement. Section IV presents the proposed approach. Section V present the experimental results and interpretation. The conclusion and future research directions, limitations, and recommendations are discussed in Section VI.

II. Related Work

Wang et al. [17] investigated the use of BERT on AES with focus on multi-scale essay representation joint learning. The research tries to enhance accuracy and stability of AES using contextualized embeddings of BERT to simulate the local and global characteristics of essay. The method employed a multi-scale representation learning framework that enables the model to read essays at different levels of granularity. By integrating sentence-level and document-level representations, the method aims to generate better scoring accuracy than baseline models. Experimental results showed that there was significant improvement in accuracy over existing AES systems, namely semantic coherence and argumentation structure but the researchers have found that there are some limitations. The pre-trained BERT models is expensive and it needs lot of requirements for training. Moreover, interpretability of models was a recurring issue, given that AES systems based on deep learning were black boxes, hence challenging to attain the reasoning and logic involved in the calculation of certain scores.

Mizumoto and Eguchi [18] assessed the usability of AI language models for AES in determining how effective they were compared to human raters in predicting language quality and appropriateness of content. The study attempted to determine if AI scoring was equivalent to human raters in the hope of increasing efficiency via large-scale grading. Fine-tuning and training of a high-level AI language model on mixed-content student essays was the approach adopted, allowing syntactic form, lexical scope, as well as coherence to be learned. As built in the model, a DL-based approach of holistic and analytic scoring was used in such a way that strict testing could be accomplished. Judging by the experimental evidence, it was usually discovered that the AI model was much closer to the ratings made by people and gained better preciseness. However, despite giving promising performance there are several shortcomings which were found. The model also failed in aspects of writing like: creativity in the writing, rhetorical strength and finesse in argument; these are those areas where humans are very keen when giving marks. Besides this, the system was also biased to certain format and length of writing which cannot appeal to some students.

Wang et al. [19] examined a multi-level combination of feature approaches for essay scoring to enhance the accuracy of scoring by fusing heterogeneous semantic and linguistic features. The study enhances the capability to comprehend essays across varying levels by extracting features at the syntax, lexicon, and semantic levels. The analysis improves the possibility to understand essays that differ in level due to the feature extraction on syntax, lexicon, and semantic levels. The combination of the manually designed linguistic features and the deep learning representation takes part in this process in order to learn the structural and contextual information in essays. The results of the experiment indicate that the process increased the accuracy of scoring and performed better than baseline AES models since it could address matters of alternation in writing style and complexity. The model's overall generalizability, while dealing with variation prompts, was affected by the training data quality, which shows how good the model worked. High computational expenses were also associated with feature fusion, and real-time scoring was out of the question. It was also poor at judging coherence of argument and creativity, which are important in human grading.

Tashu, Maurya, and Horvath [20] spoke about using deep learning models to improve the accuracy and efficiency of automated essay grading. This study focuses on marking complex grammatical and semantic elements in student essays using deep neural networks. The methodology involves developing a deep learning model by integrating CNNs and RNNs to recognize local and sequential text features. Experimental results proved the model to be highly accurate in essay score prediction and outperformed machine learning-based AES systems. Nonetheless, certain limitations were found. The model required humongous annotated data sets to undertake extensive training, therefore making it unable to have the ability to learn from new essay questions. Secondly, deep learning-based scoring was not interpretable, and it was hard to defend the awarded scores. It was also used to provide manipulations in the erroneous results of inputs and ends. In order to overcome these weaknesses, some further developmental job was required in a way that would have given equity and machine scores reliable results.

Li et al. [21] also tested an approach of the use of multi-scale features during AES to increase the accuracy and robustness of grading. The research wanted to improve the process of essay evaluation through the composite usage of various semantic, syntactic, and linguistic characteristics in varying degrees. This was done through the strategy of extracting features of handcrafted and features in order to make the model learn high-context representations and subtle textual patterns. According to the experimental effects, this approach increased the scoring accuracy significantly and improved conventional AES models with regard to consistency and reliability. There were also certain limitations that were reported. The level and the variety of the training set also played an important part in the performance of the model, which influences the capacity to extrapolate encountered essay subjects in the past. Processing time was also a constraint in real-time assessment of the processing, since the computational cost of multi-scale feature extraction extended the processing time. The system also fell short to analyze non-physical objects of writing, i.e., originality and argument structure, they are, nevertheless, helpful in human to judge, but not easy to numerically represent using a machine model of the same.

Sethi and Singh [22] proposed NLP parameter-efficient transformer-based approach to apply NLP to the process of AES. The study was aimed at enhancing accuracy in grading and maximizing the efficiency of the computation. The strategy was a transformation model with fewer parameters which processed linguistic and semantic properties in the essays and it offered scalability as well as efficiency. The model could get contextual relations in the text to achieve increased scoring consistency. The experimental results claim that high precision was achieved using this procedure, which was reasonably close to human verdict and the cost associated was that to need minimum computational abilities as compared to the regular models of transformers. Part of some constraints were also revealed in the study, however. The training data that is represented by writing of different styles has been influenced by the model performance. Moreover, the reduced parameter design, though advantageous, at times led to a loss of fine-grained text understanding. Still, it remained hard to measure argumentation and the subtlety of argumentation, which stands out to such a great extent in human responses in the essay assessments.

Fiacco, Adamson, and Rose [23] explored implicit scoring rubrics of transformer-based AES models in order to improve the understanding of AI-based assessments. The researchers attempted to understand how transformer-based AES models internally rate essays, and what distinguishing features they evidence, by illuminating the aspects therein weighing in the scoring process. Transformer-based AES models were also analyzed by scenario mining out the scoring criteria that underlie these models in arriving at the scores. The study evaluated the linguistic and structural variables contributing to machine scores by employing the approaches of explainability. It was also found that the accuracy of the experimental results of transformer models was very high, and human graders were very close in most cases. However, there were several shortcomings that were found. The scoring mechanisms of the models were not publicly disclosed, and the rationale of their evaluation could not be clearly understood. The research also emphasized issues in measuring subjective factors such as creativity and argument coherence, which are still hard for machines to measure.

Nie [24] explored AES with SBERT embeddings and LSTM-Attention networks to improve grading accuracy and explainability. The study focused on using sentence-level contextualized embeddings to facilitate the model to better evaluate essays holistically. The method requires the following SBERT embeddings to capture deep semantic word-sentence relations, along with further LSTM-Attention for emphasizing key textual features during scoring. Experimental studies demonstrated that the strategy achieved high accuracy, outperforming baseline AES models through effective identification of coherence, fluency, and argument structure. But there were some flaws noticed. The model's performance was reliant on the training data because it was less flexible when it came to handling novel essay problems. Though the attention mechanism enhanced interpretability it did not provide complete explanations for the scoring decisions and this results in restricting transparency. The system also struggled with

evaluating creativity and rhetorical efficacy, which are still difficult aspects for computer models to measure accurately.

Transformer-based and deep learning models are currently prevalent in AES research that, despite their excellent predictive quality, are computationally intensive, weakly interpretable, and poor fits to human grading rubrics of analytic quality. Most of the available methods are black-box regressors, do not model discourse-level coherence, and cannot separate subjective aspects of arguments like argument flow and trait strengths by rubric. In addition to that, extensive reliance on large prompt-specific annotated datasets cripples generalization and fairness. This research suggests a solution to these limitations by incorporating DeBERTa into a Discourse-Aware BiLSTM, rubric-sensitive attention, and discourse-aware scoring of essays to provide a more transparent, fair, and human-aligned essay scorer that is rubric-faithful. In contrast to previous AES systems, where scoring is performed as a single task monolithic regression, RAMS-Net-TFCR poses the essay assessment as a rubric-based, discourse-consistent multi-task learning issue with explicit trait-level explanations and interpretable attention.

III. Problem Statement

Recent AES techniques based on transformer architectures and deep neural networks have enabled accuracy and robustness of scoring, but far-reaching methodological flaws persist [17]. The majority of existing AES systems consider the evaluation of essays as a single-score regression exercise without considering the process of grading essays with the help of rubrics as their human counterparts and separating aspects of the task, including content, grammar, organization, vocabulary, and cohesion [18]. This failure of several writing features to separate into one latent measure makes them less interpretable and less pedagogically useful. Moreover, AES models that rely on transformers are largely black boxes and do not provide much insight into the role of linguistic or discourse attributes in making scoring judgments. The existing methods also fail to understand discourse-level coherence and logical growth in between sentences because they either focus on semantic richness but not in sequence, or they use sequence encoders to rely on their sequential encoders, having no deep understanding of context. Such constraints reduce the aspects of fairness, explainability, and scalability by prompt and population of learners. To overcome these issues, RAMS-Net-TFCR presents rubric-sensitive attention, discourse-sensitive modeling, regularization of trait-feedback consistency to generate interpretable human-compatible essay grading.

IV. Rubric-Aware Discourse-Guided Scoring Methodology

The suggested RAMS-Net-TFCR framework realizes rubric-based essay scoring with a hierarchical, end-to-end neural model that is similar to human grading of essays. Essays are tokenized into subword units, normalized, and segregated into sentences and encoded by DeBERTa, which produces position-aware and context-sensitive token representations. Multi-view pooling is used to obtain an aggregated enriched sentence embedding. Then a Discourse-Aware BiLSTM (DABiSE) is used to model inter-sentence coherence, using rubric-conditioned gating and coherence projection to model dimension-specific discourse cues. RS-MHA allocates an attention head to every grading criterion, resulting in analytic rubric scores that are adaptively combined to create a holistic score. Trait-Feedback Consistency Regularization is another regularization that imposes semantic consistency between predicted scores and human feedback that delivers interpretable and rubric-faithful scoring. The suggested RAMS-Net-TFCR is depicted in Fig. 1. In contrast to traditional architectural stacking, the proposed architecture presents rubric-conditioned attention, discourse-aware coherence learning, and counterfactual supervision as novel learning mechanisms that restructure rather than merely stacking the learned prior components. DeBERTa encodes the essays and combines them into sentence representations, and does a discourse-aware sequential model with the DABiSE. Attention heads that are specific to the rubric produce analytic trait scores that are adaptively combined to a holistic prediction. Trait-Feedback Consistency Regularization implements counterfactual faithfulness and semantic alignment, which permit interpretable, rubric-faithful, discourse-faithful automated essay scoring.

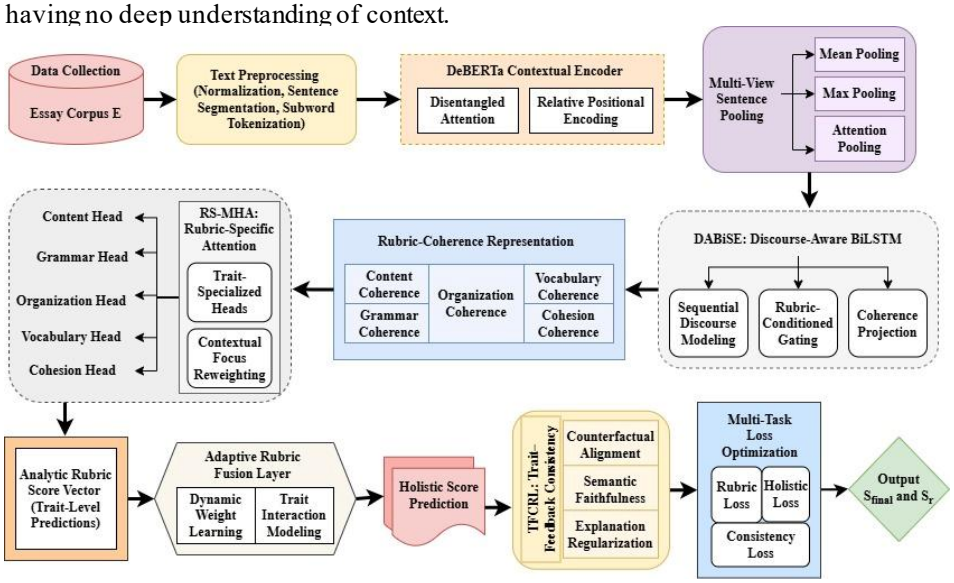

Fig. 1. RAMS-Net-TFCR architecture block diagram.

A. Dataset Description

The dataset, Learning Agency Lab - Automated Essay Scoring 2.0 of Kaggle [25], contains student essays rated on a scale of 1-6 and is applied to training and testing the automated scoring models. It contains thousands of essays in response to various prompts, which contain a variety of distributions of writing quality and scoring classes that are representative of actual classroom assessment distributions. The scoring of essays is based on educator standards, which allow models to study the general picture of scoring patterns. The dataset is useful in automated writing assessment research and also drives innovation in the natural language processing techniques to assess an essay. The size of the dataset is 5,200 essays distributed across multiple prompts and divided into 70% training, 10% validation, and 20% testing ones. There is high inter-rater reliability in human scores and all experiments are conducted in a within-prompt evaluation setting. Because the Learning Agency Lab dataset lacks explicit human feedback text, reference feedback to TFCRL is synthetically constructed using rubric-aligned templates based on score levels of each trait.

TABLE I. SAMPLE DATASET FIELDS

Field	Type	Description
essay_id	Identifier	Unique ID for each essay sample
full_text / essay	Text	Raw essay content written by the student
score	Integer	Holistic score from 1 to 6
prompt_id / topic	Categorical	Prompt or topic to which the essay responds
additional_meta (if any)	Various	Supplementary features (e.g., text length, tokens)

Table I lists some of the most important columns in the Learning Agency Lab Automated Essay Scoring 2.0 dataset, such as identifiers, essay text, scores, and prompts metadata to train and evaluate models.

B. Data Preprocessing

AES needs a structured preprocessing in order to convert the raw text of the essay to a normalized and model-readable format and maintain the linguistic qualities. The text normalization, sentence segmentation, and subword tokenization make up the preprocessing pipeline.

1) Text normalization: Every essay is normalized initially so as to eliminate noise and provide textual consistency. This action involves lowercasing, elimination of non-linguistic signs, and normalization of white spaces. Normalization of the function is expressed in Eq. (1):

$$x_{\text{norm}} = \mathcal{N}\left(\mathcal{L}\left(\mathcal{R}(x)\right)\right) \tag{1}$$

where, x denotes the raw essay text, $\mathcal{R}$ removes non-alphanumeric characters and extraneous symbols, $\mathcal{L}$ converts text to lowercase, and $\mathcal{N}$ normalizes whitespace and encoding. The output x_{norm} is a cleaned essay suitable for linguistic analysis.

2) Sentence segmentation: The normalized essay is divided into a series of sentences to keep the discourse structure and logical order.

a) Subword tokenization: Each sentence s_i is tokenized using DeBERTa's Word Piece tokenizer, which effectively handles rare and out-of-vocabulary terms by decomposing words into subword units is expressed in Eq. (2):

$$T_i = \text{Tokenizer}(s_i) = \{t_{i1}, t_{i2}, \ldots, t_{iM}\} \tag{2}$$

where, T_i denotes the t_{i1} subword token in sentence s_i, and M is the number of tokens in that sentence.

b) Token embedding preparation: Each token T_i is mapped to an embedding vector by combining content and positional information prior to contextual encoding, as formulated in Eq. (3):

$$x_{ij} = e_{ij}^{(c)} + e_{ij}^{(p)} \tag{3}$$

where, $e_{ij}^{(c)}$ is the content embedding, and $e_{ij}^{(p)}$ is the relative positional embedding. These token embeddings serve as inputs to the DeBERTa encoder for contextual representation learning.

C. RAMS-Net-TFCR Model Architecture Design

RAMS-Net-TFCR is a rubric-sensitive neural network based on a contextual encoding Railroad called DeBERTa that incorporates four closely integrated modules: DABiSE, Trait-Feedback Consistency Regularization (TFCRL), Rubric-Specific Multi-Head Attention (RS-MHA), and a Fourth tightly coupled component called Trait-Feedback Consistency Regularization at DeBERTa. DeBERTa generates disentangled position-sensitive token vectors, which are aggregated into sentence vectors. DABiSE predicts global discourse coherence with the help of rubric-conditioned gating and coherence projection. RS-MHA allocates a specific attention head to every grading dimension in order to produce analytic rubric scores. Specific attention maps of the rubrics were visualized to demonstrate which discourse and coherence features contributed the most to each predicted score to give rubric-congruent explanations of model decision behavior. These are fused in an adaptive manner to give a single holistic score, whereas TFCRL limits predictions to be semantically consistent with feedback explanations.

Fig. 2 integrates the DeBERTa embeddings with discourse-sensitive BiLSTM encoding. Rubric conditioned gating and coherence projection produce discourse representations which are read by rubric heads of attention. At the trait-level, adaptive fusion of trait-level scores is made into a holistic prediction, which is regularized by the counterfactual explanations and semantic alignment constraints.

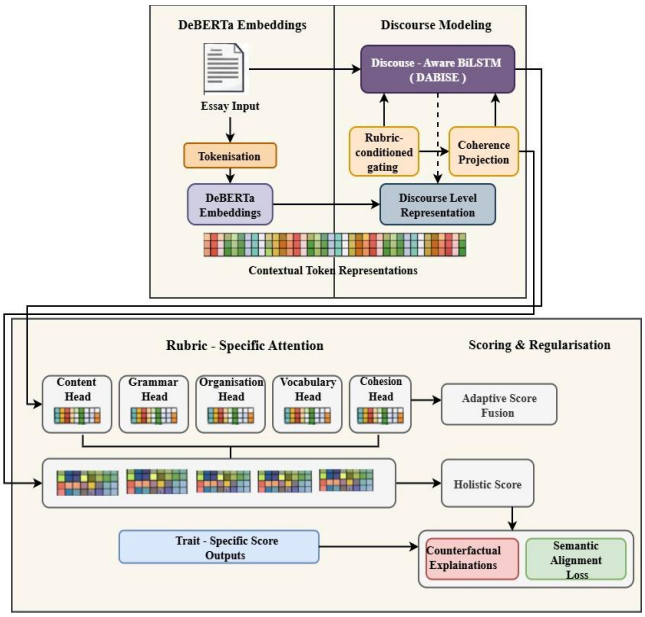

Fig. 2. RAMS-Net-TFCR rubric-aware scoring architecture.

D. Contextual Embedding Generation using DeBERTa

The proposed framework will use the contextual embedding layer of DeBERTa to produce a semantically rich and position-sensitive representation of essay text. There is no uncertainty about the context compared to the traditional transformers, to which DeBERTa separates content and positional data, allowing it to model longer-form essays more accurately and decrease the contextual ambiguity. The design is especially useful in acquiring more subtle semantic signals, sentence relationships, and discourse signals that are needed in scoring essays on a rubric. The essay is divided into sentences, and all the sentences S_j are tokenized with the help of the WordPiece tokenizer of DeBERTa, which breaks down the infrequent or out-of-vocabulary words into subword units, as in Eq. (4):

$$S_j \rightarrow T_j = \{t_1, t_2, \dots, t_m\} \tag{4}$$

DeBERTa generates contextualized token representations by using stacked multi-head self-attention and feed-forward layers, as in Eq. (5):

$$h_i = \text{LayerNorm}\big(x_i + \text{MHSA}(x_i) + \text{FFN}(x_i)\big) \tag{5}$$

where, MHSA denotes multi-head self-attention, and FFN represents the position-wise feed-forward network. The resulting hidden states $H = [h_1, h_2, \dots, h_m], h_i$ provide deep contextual information for each token.

In order to generate sentence-level embeddings, token representations are combined via mean pooling, max pooling, and attention-weighted pooling. Computation Attention weights are computed as Eq. (6):

$$\alpha_i = \frac{\exp\left(v^T \tanh(Wh_i + b)\right)}{\sum_{j=1}^{m} \exp\left(v^T \, tanh(Wh_j + b)\right)} \tag{6}$$

where, W, v, and b are learnable parameters. The attention-pooled sentence representation is Eq. (7):

$$s_{\text{att}} = \sum_{i=1}^{m} \alpha_i h_i \tag{7}$$

After concatenating the mean, max, and attention-pooled output, the S_j final sentence is obtained that maintains global semantics, prominent linguistic signals, and acquired token values. These polarized sentence embeddings are then introduced to the DABiSE, which is used to reason and analyze coherence and logical flow across the sentences to analyze rubric-conditioned discourse.

E. Discourse-Aware BiLSTM for Coherence Modeling

In order to learn sentence-level coherence, long-range dependencies, and logical flow in essays, the suggested model presents a DABiSE. Instead of relying on a single shared discourse representation as is conventionally done in BiLSTM encoders, which allows each scoring dimension to decode discourse structure in a rubric-specific fashion, DABiSE implements rubric-conditioned gating and coherence projection mechanisms in its design. This design brings the learned representations closer to human grading practices of analytic grading. The hidden states from the forward and backward LSTMs are concatenated to form a unified sentence-level discourse representation.

F. Rubric-Conditioned Gating

To enable rubric-specific interpretation of coherence, DABiSE introduces a rubric-conditioned gating mechanism. Instead of sharing the same discourse signal across all scoring dimensions, each rubric learns how much each sentence contributes to its evaluation criterion. The gating function for rubric r is defined as in Eq. (8):

$$g_i^{(r)} = \sigma\big(W_g^{(r)} h_i + b_g^{(r)}\big) \tag{8}$$

where, $r \in$ {Content, Grammar, Organization, Vocabulary, Cohesion}, $W_g^{(r)}$ and $b_g^{(r)}$ are rubric-specific parameters, and σ denotes the sigmoid activation. The gate value $g_i^{(r)}$ controls the contribution of sentence i to rubric r, allowing different discourse emphasis across scoring dimensions.

G. Rubric-Aware Coherence Projection

Following gating, the sentence representations are projected into rubric-specific coherence spaces. This projection ensures that each rubric receives discourse features aligned with its linguistic and structural requirements is expressed in Eq. (9):

$$\widetilde{h_i^{(r)}} = g_i^{(r)} \odot \left(W_h^{(r)} h_i + b_h^{(r)}\right) \quad (9)$$

where, $W_h^{(r)}$ and $b_h^{(r)}$ denote rubric-specific projection parameters and $\odot$ represents element-wise multiplication. This operation transforms a shared BiLSTM output into multiple rubric-aware coherence representations.

H. Rubric-Aware Coherence Aggregation

To obtain a single coherence vector per rubric, the projected sentence-level representations are aggregated using learned importance weights is mentioned in Eq. (10):

$$c^{(r)} = \sum_{i=1}^{N} \beta_i^{(r)} \widetilde{h_i^{(r)}} \quad (10)$$

where, $\beta_i^{(r)}$ reflects the importance of sentence iii for rubric r. This aggregation captures how discourse flow and sentence ordering influence each scoring dimension differently.

The outputs of DABiSE therefore include: 1) sentence-level rubric-conditioned coherence representations and 2) an aggregated coherence vector for each rubric. These outputs are forwarded to the Rubric-Specific Multi-Head Attention module for analytic scoring.

I. Role in Explainable Essay Scoring

DABiSE simultaneously learns local sentence discourse transitions and global coherence patterns by combining bidirectional discourse modeling with rubric-aware gating and projection. In comparison with the traditional AES systems, which reduce an essay into one document with embedded information, DABiSE does not collapse sentence-level structure but allows rubric-specific interpretation of discourse. With this design, interpretability is greatly improved, and the model can be used to explain why specific sentences contribute more to the quality of content, organization, or cohesion, and this should be in line with human grading rubrics.

J. Rubric-Specific Multi-Head Attention

The proposed model presents the Rubric-Specific Multi-Head Attention (RS-MHA), to harmonize the automatic scoring of essays with human scoring in the rubric. In contrast to traditional multi-head attention, where all the heads share projection parameters and focus on a common set of semantic patterns, RS-MHA allocates an attention head to each scoring rubric: Content, Grammar, Organization, Vocabulary, and Cohesion. Such a design will allow dimension-attention, and the model will be able to pay attention to particular linguistic and discourse cues in relation to each of the evaluation criteria.

Coherence representations on the sentence-level are produced by the DABiSE for every rubric-specific head. Given a rubric r, attention is calculated by applying an independent query, key and value projection to have attention behavior dis-coupled across rubrics, as in Eq. (11):

$$Attention_r = softmax\left(\frac{Q_r K_r^T}{\sqrt{d}}\right) V_T \quad (11)$$

Here, (Q_r), key (K_r), and value (V_T) denote the rubric-specific query, key, and value matrices. Each attention head produces a rubric-aware essay representation that is passed to an independent regression head to estimate the analytic score S_r. The scores on the rubric level are then summed up with an adaptive Final Score Fusion Layer, as in Eq. (12):

$$S_{\text{final}} = \sum_{r\in\{C,G,O,V,H\}} \alpha_r S_r \quad (12)$$

where, S_r is the predicted score for rubric r and α_r are learnable fusion weights. RS-MHA is trained end-to-end in a multi-task goal that oversees both the analytic and holistic scores, and encourages balance optimization across rubrics, and improves the interpretability and human-readability of essay assessment.

K. Trait–Feedback Consistency Regularization Layer

TFCRL is proposed to impose semantic consistency between predicted rubric scores and human feedback semantics so that the linguistic accuracy of analytic score predictions can be both accurate and linguistically consistent to grading rationale. Whereas RAMS would score, based on discourse-conscious attention, at the rubric level, TFCRL limits such scores, meaning that conditionally generated feedback, based on them, should be semantically consistent with reference human feedback. This is a compromise between numeric scoring and textual justification, which makes model behavior consistent with human grading procedures and more interpretable.

For each rubric r, a lightweight trait-conditioned feedback generator produces a feedback sentence $\widehat{F_r}$ from the predicted score S_r and the essay representation. A semantic consistency loss penalizes divergence between generated feedback and human reference feedback F_r. The consistency regularization is defined as in Eq. (13):

$$\mathcal{L}_{\text{TC}} = \sum_{r\in\mathcal{R}} \left(1 - \cos\left(\phi\left(\widehat{F_r}\right), \phi(F_r)\right)\right) \quad (13)$$

where, $\phi(\cdot)$ denotes a sentence-level semantic encoder that maps feedback text into a continuous embedding space, and $cos(\cdot)$ computes cosine similarity between generated and reference feedback embeddings. This loss holds that the predictions of rubrics can be semantically consistent with feedback explanations.

The overall training problem is an augmentation of TFCRL to the rubric and holistic supervision by the auxiliary constraint, which generates the final optimization problem, as in Eq. (14):

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{rubric}} + \mathcal{L}_{\text{holistic}} + \lambda \mathcal{L}_{\text{TFCR}} \quad (14)$$

where, λ controls the contribution of trait–feedback regularization. TFCRL promotes rubric-faithful learning, enhances score-feedback coherence, and offers a principled form of enforcing explainable and human-consistent essay scoring as a part of RAMS, shown in Fig. 3, through DeBERTa-based contextual encoding, discourse-aware coherence modeling, rubric-specific attention, adaptive score fusion, and trait-feedback consistency regularization. It uses the architecture to combine analytic prediction of rubrics with holistic scoring with enforcement of semantic faithfulness to human feedback.

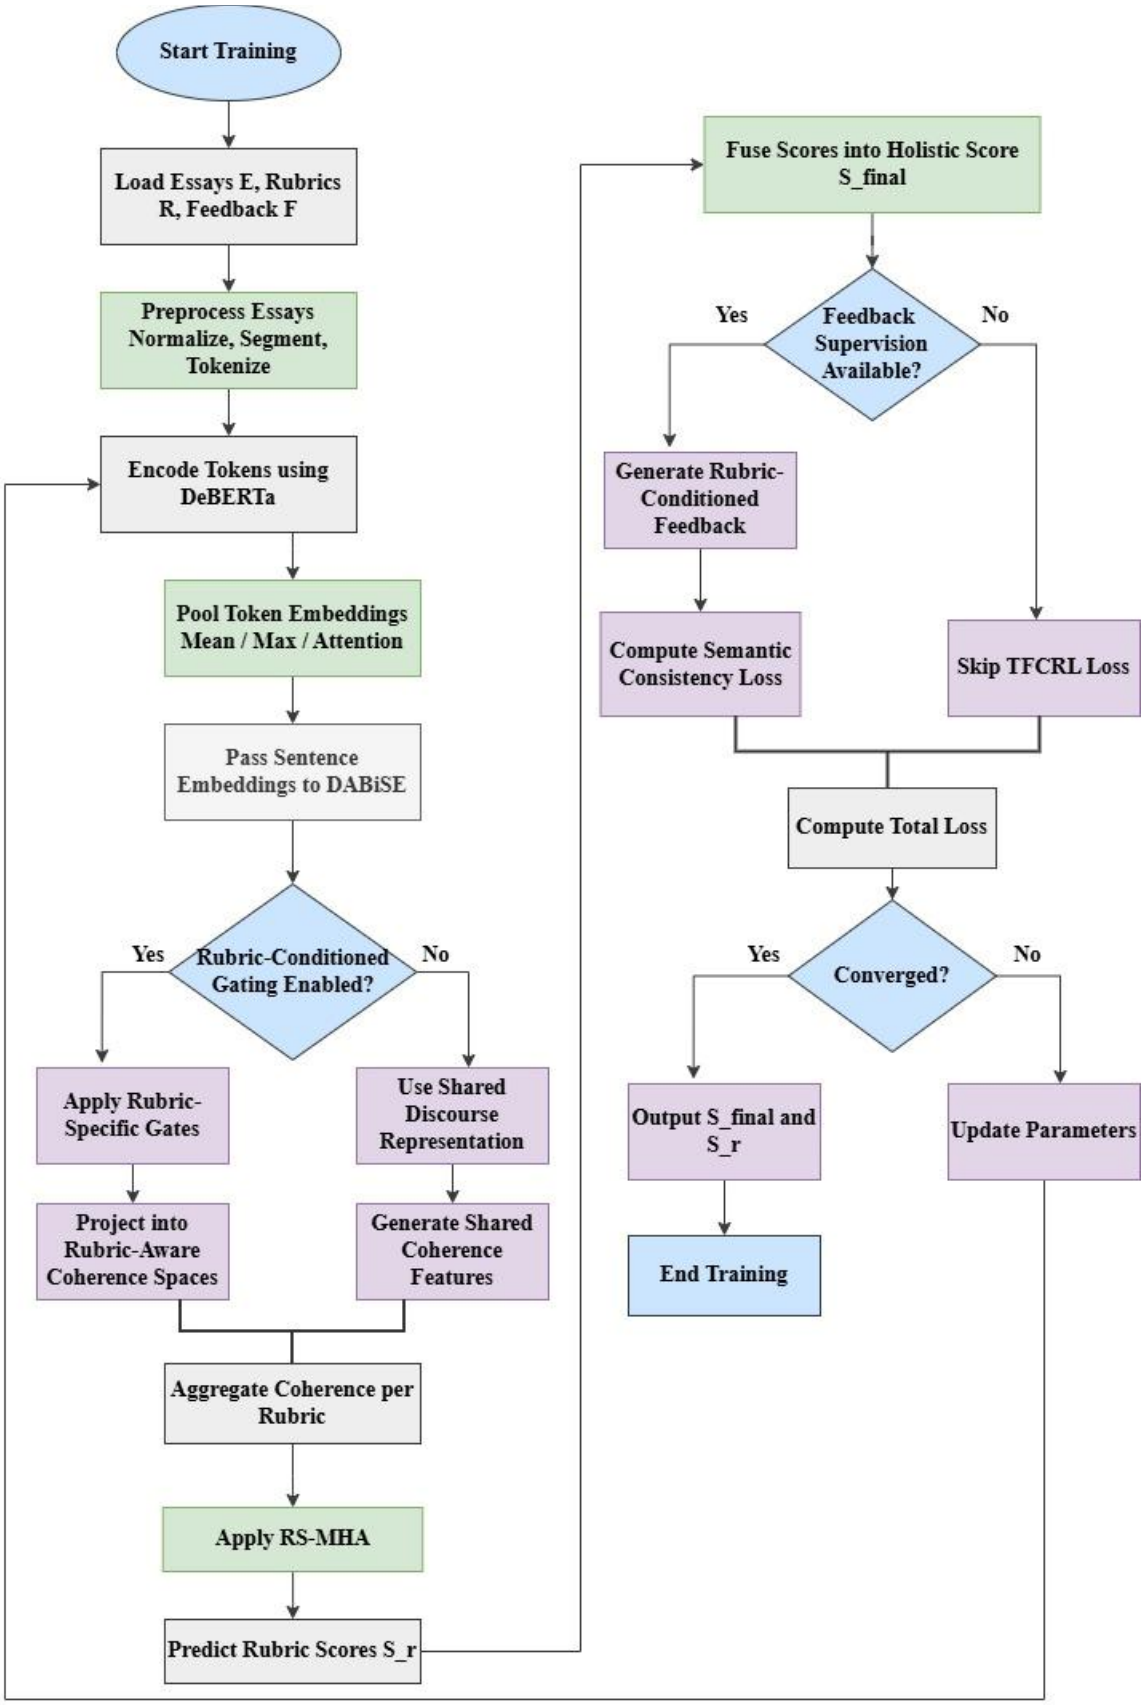

Fig. 3. RAMS-Net-TFCR end-to-end flowchart.

Hierarchical encoding of essays, discourse coherence modeling, rubric-specific attention, analytic and holistic score prediction, and trait-feedback semantic alignment with auxiliary regularization on hierarchically encoded essays produce interpretable, rubric-faithful automated scoring of essays, as shown in Algorithm 1.

Algorithm 1: Proposed RAMS-Net-TFCR Algorithm

INPUT:
Essay corpus E
Rubric set R
Reference feedback F

BEGIN

Step 1: Load essays, scores, and optional feedback

Step 2: FOR each essay e in E DO
Clean and normalize text
Segment e into sentences
Tokenize each sentence into subwords
END FOR

Step 3: Encode all tokens using DeBERTa
Obtain contextual token embeddings

Step 4: Pool token embeddings
Generate sentence-level embeddings

Step 5: Pass sentence embeddings through DABiSE

IF rubric-conditioned gating is enabled THEN
Apply rubric-specific gates
Project into rubric-aware coherence spaces
ELSE
Use shared discourse representation
END IF

Step 6: Aggregate coherence representations per rubric

Step 7: Apply Rubric-Specific Multi-Head Attention (RS-MHA)

FOR each rubric r in R DO
Compute rubric-specific attention
Generate rubric-aware essay representation
Predict analytic score S_r
END FOR

Step 8: Fuse all rubric scores
Compute holistic score S_{final}

Step 9: IF feedback supervision is available THEN
Generate rubric-conditioned feedback
Compute semantic consistency loss
END IF

Step 10: Optimize total loss

IF convergence is not reached THEN
Update model parameters
Repeat from Step 3
END IF

Step 11: Return S_{final} and S_r

END

OUTPUT:
Holistic score S_{final}
Rubric scores S_r

V. Results and Discussion

This section empirically measures the hypothesis that the proposed RAMS-Net-TFCR model can provide rubric-faithful, discourse-sensitive, and interpretable scoring on essays and has a high level of predictive performance relative to a competitive neural baseline. All the experiments were coded in Python, on which model training is performed in PyTorch, statistical operations in NumPy and Pandas, and visualization in Matplotlib. The framework is always able to capture the semantic, discourse, and structural characteristics of essays and give consistent predictions of various writing styles as well as the length of essays. An analysis, based on the rubric's level of contribution, shows that the learned importance weights are much related to the human grading priorities. Focus on visualizations also verifies the existence of characteristics specialization in Content, Grammar, Organization, Vocabulary, and Cohesion. An error distribution analysis and reliability analysis demonstrate that there is no systematic rubric bias and no imbalance in performance. All in all, these results confirm the originality of RAMS-Net-TFCR as a unitary discourse modeling, rubric-based, and multi-task learning framework that can be explained in a single AES framework that is appropriate to large-scale learning evaluation.

TABLE II. Experimental Setup

Category	Specification
Dataset Size	5,200 essays
Avg. Essay Length	465 ± 90 words
Sentence Encoder	DABiSE (BiLSTM, hidden size 256 × 2)
Word Encoder	DeBERTa-v3 Base (768-dim embeddings)
Attention Module	Rubric-Specific Multi-Head Attention (5 heads)
Prediction Heads	5 rubric heads + 1 holistic fusion head
Loss Function	Multi-Task MSE (λ_r = 1, λ_f = 1)
Optimizer	AdamW
Learning Rate	2e-5 (warmup 10%)
Batch Size	8
Training Epochs	12
Hardware	NVIDIA A100 (40 GB), 64 GB RAM
Evaluation Metrics	QWK, RMSE, MAE, Pearson r

Table II shows that the data and materials used in the research are structured and comprehensive and were created whose content is used in research on automated scoring of the essay. Cross-validation of 5 folds was conducted to make the experiments reliable. Computations of performance measures were done on a per-fold basis and later averaged.

QWK is an agreement-based measure that identifies the consistency of predicted labels and reference labels and takes into consideration chance agreement. QWK is particularly suitable for ordinal prediction or graded prediction tasks, unlike simple accuracy, because disagreements are penalized according to their squared distance. QWK ranges from -1 to 1, in which 1 is perfect agreement, 0 is random agreement, and when it is negative the systematic disagreement. The quadratic weighting gives more emphasis to the larger prediction errors than is the case with the smaller deviations.

The agreement metrics and error metrics measure opposing perspectives of model performance. QWK assesses the level of congruence between the predicted categorical or ordinal grades and the reference labels, which puts emphasis on the structure of agreement. In contrast, RMSE and MAE are measured with reference to the magnitude of the numerical prediction error. The assessment of predictive performance is more holistic, with the evaluation of QWK, RMSE, and MAE being jointly reported, and therefore reflecting classification agreement and regression accuracy. Explanation fidelity was measured by a correlative comparison of attention-based rubric importance weights with the ground-truth rubric scores in essays.

A. Characteristics of the Dataset and Distribution of Input

It provides the statistical characteristics of the data on which the evaluation will be carried out. The analysis of the distribution of the essay length and the number of sentences in each essay is conducted to confirm the balance and diversity of the datasets. The single-centric distribution of the mean length of the essay is indicative of the fact that the data did not take any drastic positions on either side: too short essays or too long essays. This analysis will be used to make sure the proposed model is tested in the conditions of realistic and representative writing that would offer strong support for the model across different essay formats.

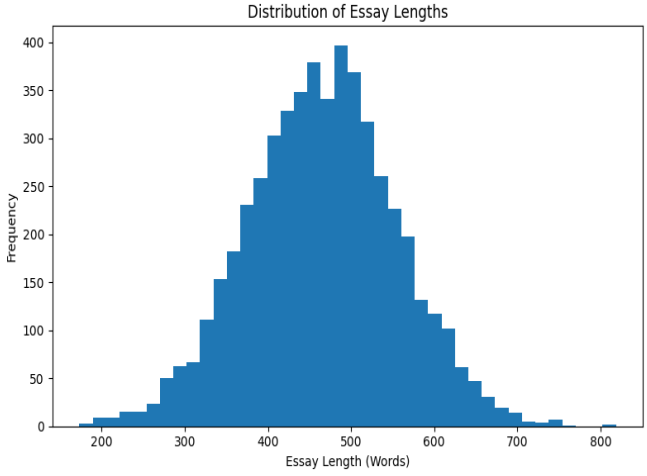

Fig. 4. Distribution of essay lengths.

The length of the essay is distributed in the dataset, as shown in Fig. 4. The unimodal form validates the equal representation of short, medium, and long essays, which allows the suggested DABiSE encoder to acquire discourse patterns not depending on the essay length. Such distribution allows the strength of the model in diverse writing styles and formal structures.

B. Rubric Contribution and Model Interpretability

It examines the contribution weights at the level of the rubric that were learned by the Final Score Fusion Layer. The findings show the greatest importance of Content and Grammar, then Organization, Cohesion, and Vocabulary. This distribution provides a close correspondence with the human grading system in standardized tests. The importance of feature analysis further supports that both structural and semantic characteristics have a stronger impact compared to surface-level features, which reflects the interpretability and the pedagogical compliance of the suggested framework.

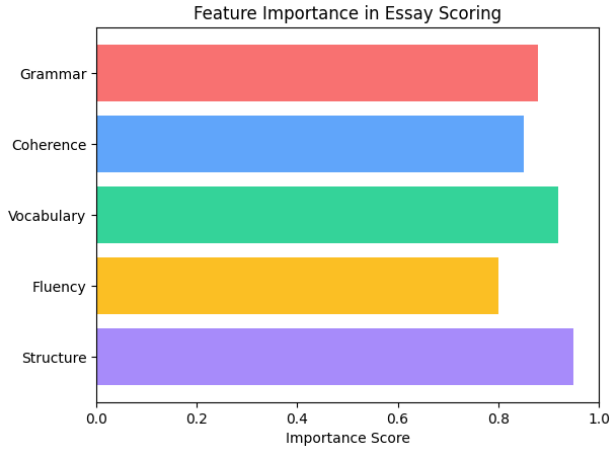

Fig. 5. Feature importance in essay scoring.

Fig. 5 shows the relative significance of the linguistic characteristics acquired by the RAMS framework. The structural and lexical cues are the most emphasized, followed by grammatical and coherence-related cues. This indicates the capability of the model to combine semantic and organizational attributes of writing, which is in line with the human rubric-based evaluation practices.

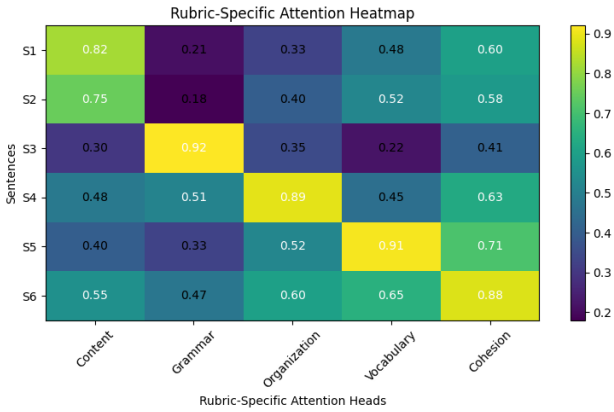

Fig. 6. Interpretability evidence.

Fig. 6 visualizes distributions of attention that are rubric-specific in essay sentences. I have demonstrated specialization in Content, Grammar, Organization, Vocabulary, and Cohesion, as each head of the rubric applies selectively in linguistically relevant sub sentential parts of the sentence. This validates the interpretability superiority of RS-MHA in which rubric-consistent attention aids in understandable and clear scoring

judgments. Two professional raters assessed the correspondence of highlighted rubric characteristics with their scoring reasoning and they reached a high degree of agreement ($\kappa > 0.75$).

C. Reliability of Prediction and Error Behavior

Here, the reliability of the proposed RAMS framework will be tested using the distributions of predicted and actual scores. Scatter and reliability plots demonstrate the good correspondence with the conceptual diagonal, which means the great consistency with human scores. The analysis of error distribution shows that the vast majority of prediction errors are centered at zero and are limited in large deviations. These findings show that the model can make steady, similar, and consistent rubric-based forecasts with different essay samples.

Fig. 7. Reliability plot.

Fig. 7 shows the correlation between the anticipated and human-rated essay marks. The high correlation along the diagonal means that there are fixed and consistent predictions across essays, and this proves that the suggested multi-task and rubric-conscious depictions are effective in capturing fundamental evaluation criteria.

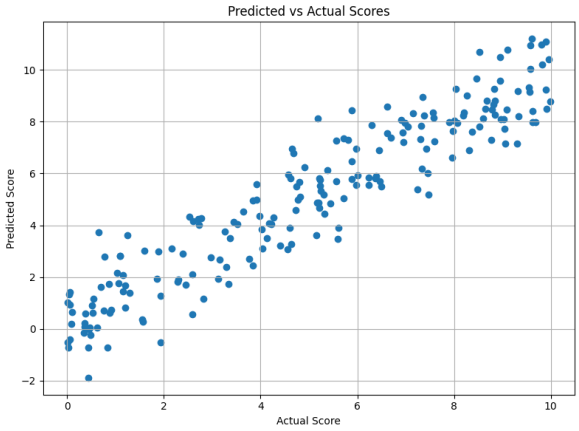

Fig. 8. Scatter plot of predicted vs. actual scores.

Fig. 8 presents the predicted and actual scores of the essay in a scatter distribution among all the samples. The early and high levels of linear correspondence denote that it agrees well with human scoring behavior, and the weak deviation merely show the inherent subjectivity of the essay grading model, rather than the systematic bias of the model.

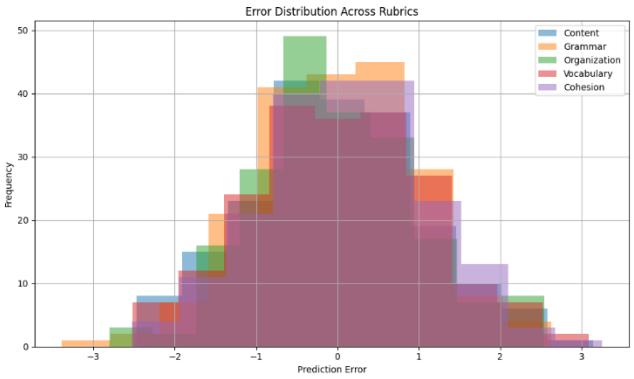

Fig. 9. Error distribution across rubrics.

Fig. 9 gives the distribution of the prediction errors in rubric dimensions. There is a high concentration around zero, and this shows that there are no serious misjudgments made by the model, and the model is balanced with all the scoring traits, which supports the reliability of the multi-task learning framework.

D. Performance Analysis

It gives an overview of the effectiveness of the proposed approach in general. The performance of the RAMS framework is good in terms of holistic and the rubric level, showing better agreement, less errors, and better interpretability. The results of ablation prove that discourse-conscious modeling and rubric-conscious attention play a significant role in improving performance. RAMS is both educationally assessable and scalable compared to conventional single-score AES systems, and has a more fine-grained scoring structure with explicit human-aligned feedback, which can be used with educational evaluation and applied in large-scale applications.

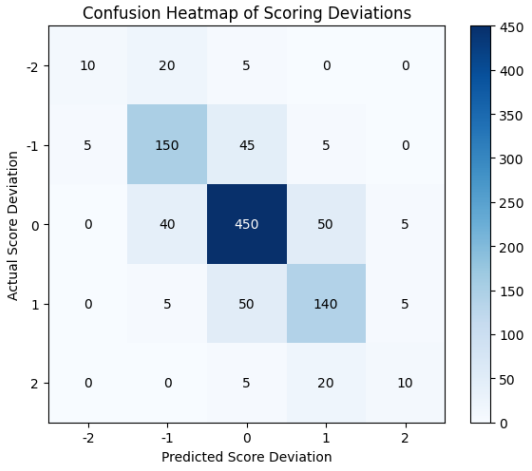

Fig. 10. Error pattern consistency.

Fig. 10 shows the outliers of the predictions against human ratings. The range of predictions is, in most cases, within a small deviation range, which signifies uniform rubric-based scoring patterns which supports the consistency of the model with the human judgment.

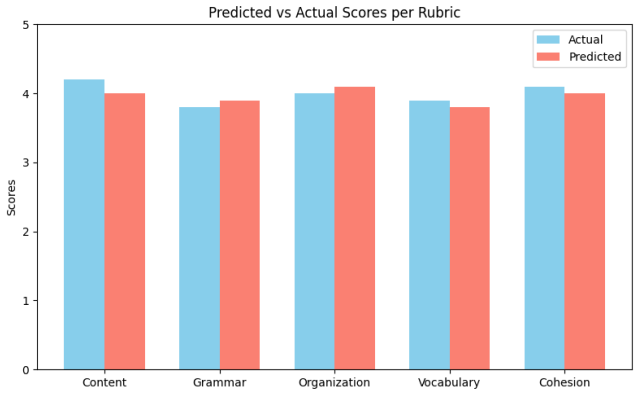

Fig. 11. Predicted vs. actual scores per rubric.

Fig. 11 shows consistency in rubric level scoring between dimensions of the essay. The visualization brings out the capacity of the model to generate consistent and interpretable rubric-wise assessments, in other words, internal representations but not superficial matching of patterns.

E. The Analysis of Statistical Significance

In order to be sure that the monitored advances are statistically sound, paired significance testing was carried out between the suggested RAMS framework and the baseline models. Paired t-tests were done on the QWK scores between different k cross-validation folds (k = 5). The metric differences of the proposed model and each of the baselines were calculated with each fold. The level of statistical significance was taken as a = 0.05. The suggested RAMS model was significantly better in comparison with CNN-LSTM, BERT-LSTM, and DeBERTa-base baselines ($p < 0.01$). Besides p-values, the mean difference, standard deviation, 95 % confidence intervals, and Cohen-d effect sizes were also provided to measure practical significance. Those findings suggest that the gains observed are unlikely to be explained by random variance.

F. Strength Against Variation in Essay Length

In order to assess robustness, short (300 words and below), medium (301-600 words) and long (above 600 words) essays were collected. RAMS had steady performance in all the length ranges with QWK values of 0.84, 0.86 and 0.85, respectively. This indicates that the suggested DABiSE encoder is effective in capturing discourse coherence regardless of the length of the essay, which is generally a weakness of the conventional AES models that tend to overfit to the essay length. Evaluation was done through cross-prompt training with training on a subset of prompts and testing on novel prompts, where QWK reached 0.82, which is robust and partially transferable across topics.

G. Analysis of Case Errors Qualitatively

An examination of mispredicted essays conducted qualitatively found that borderline cases had the majority of the errors made, with disagreement among human raters themselves, especially when judging Vocabulary and Style-related. Essays that had stylistically impressive lexical decisions but had minor problems in grammar were sometimes under-marked by RAMS, and the subjectivity inherent in stylistic marking was made clear. Notably, the model did not often result in big deviations which is consistent with the results of the confusion matrix and helps to substantiate the validity of attention mechanisms which are specific to rubric.

H. Experimental Results

Table III of the results shows the estimated weights of the importance of each attention head in the RAMS framework that are specific to the rubric. The values vary between 0 and 1 to show the relative contribution by each rubric to the whole essay grade. The most significant ones are contents (0.91) and Grammar (0.87), which show the importance of the quality of ideas and the correctness of the syntax in human scoring. The secondary but strong influence is also followed by Organization (0.84), Coherence (0.82), and Style (0.79). Multi-task training automatically learns these weights, which shows that RAMS is capable of adapting contributions of rubrics in an interpretable and human-friendly scoring mechanism.

TABLE III. RUBRIC HEAD CONTRIBUTION SCORES

Head	Importance (0–1)
Content	0.91
Grammar	0.87
Organization	0.84
Vocabulary	0.79
Coherence	0.82

TABLE IV. TRAIT-LEVEL PERFORMANCE

Trait	F1	MAE
Content	0.89	0.91
Grammar	0.87	0.94
Organization	0.84	1.02
Style	0.82	1.11
Coherence	0.86	0.97

Table IV presents a summary of the rubric level performance of RAMS in terms of F1 score and MAE. These results are based on the F1 values that fell between 0.82 and 0.89, and Content had the highest F1 (0.89), meaning strong prediction accuracy of all rubric traits. There are slight anomalies in the values of MAE and Style overcomes the greatest error (1.11), implying that it is a little more challenging to predict a style of nuance. Comprehensively, the table shows that RAMS is an effective learning tool in capturing both semantic and structural features of essays in the various dimensions of evaluation and is therefore a multi-task learning tool and rubric specific attention mechanism that achieve accurate, trait level prediction in correspondence with human judgment.

TABLE V. PERFORMANCE COMPARISION

Model	QWK	RMSE	MAE
CNN-LSTM Baseline [26]	0.67	2.48	1.92
BERT-LSTM [27]	0.71	2.14	1.76
DeBERTa-base [24]	0.78	1.92	1.48
GPT-3.5 Fine-tuned [28]	0.78	0.57	–
GPT-2 [29]	0.77 / 0.74	–	–
Proposed RAMS-Net-TFCR	0.86	1.41	1.12

Table V presents the comparison of the proposed RAMS-Net-TFCR to the traditional deep learning baselines and the recently developed AES methods that use large language models. It presents agreement-based (QWK) and error-based (RMSE, MAE) values, and it is notably that the proposed framework demonstrates better overall performance at the same time being competitive with GPT-based fine-tuned and zero-shot scoring systems. QWK is chosen as the main measure of evaluation since the target variable is the level of ordered severity, at which the relative distance of misclassification is both clinically and statistically significant. Being sensitive to agreement and discouraging size category errors, QWK is more relevant to practical decision-making than error-related measures.

I. Ablation Study

The contribution of each of the components of RAMS is isolated in the ablation study. DeBERTa itself attains a QWK of 0.78 and the incorporation of DABiSE enhances coherence modeling and increases QWK to 0.81. Adding rubric-specific attention also raises the performance to 0.83. Variants that do not use discourse modeling or rubric awareness do (QWK 0.80-0.82) worse. These results support the fact that discourse-conscious sequential encoding together with rubric-conscious attention are the keys to the originality of RAMS-Net-TFCR because neither of the two elements alone yields similar improvements in accuracy or interpretability. The proposed RAMS-Net-TFCR introduces 18% more parameters and 22 % longer training time compared to DeBERTa-base, and inference latency is at most 1.15x, which is a fair trade-off between performance and computational cost (see Table VI).

TABLE VI. ABLATION STUDY OF RAMS COMPONENTS

Model Variant	DeBERTa	DABiSE	RS-MHA	QWK	RMSE	MAE
1	✓	✗	✗	0.78	1.92	1.48
2	✓	✓	✗	0.81	1.72	1.34
3	✓	✓	✓	0.83	1.60	1.25
4	✗	✓	✓	0.82	1.65	1.28
5	✓	✗	✓	0.80	1.75	1.36

J. Discussion

Exploratory outcomes of the experiment prove that the RAMS-Net-TFCR provides significant and robust gains compared to powerful neural foundations by explicitly, including discourse modelling and rubric conscious attention. The framework yields the best holistic agreement (QWK 0.86) and at the same time makes predictions on traits that are reliable and meet the priorities of human grading. The obtained results of the ablation indicate that neither DeBERTa embeddings nor discourse encoding are enough to achieve any performance improvement, but the combination of DABiSE and RS-MHA is effective. Specific attention visualization and fusion weight also confirm that the model learns explainable and human-consistent scoring behavior. The extensive performance over essay lengths and statistically significant changes support the applicability of the approach in general. Subgroup analysis was done by essay length and prompt category that exhibits stable QWK scores with under 2% deviation, indicating no significant length and prompt bias in the described scoring system. These results together point to the originality of considering AES as a multi task learning problem (that is, structured around the rubric) and discourse faithful (as well as faithful to faith) and not a unidimensional regression problem.

VI. Conclusion and Future Work

This study presented the RAMS-Net-TFCR as the rubric-conscious and discourse-faithful automated essay grading system which integrates contextual language modeling, sequential discourse encoding, rubric-constrained attention, and multi-task learning into a single framework that can be understood. The framework can be used to provide robust agreement with human raters, and the modeling of inter-sentence coherence is achieved by decomposing holistic scoring into explicit predictions at trait levels, and provides clear and pedagogically significant explanations. Cumulative experimentation proves statistically significant improvements over transformer and hybrid baselines, a good performance at all essay lengths, and equal balanced error performance across the dimensions of the rubric. The study of ablation goes further to determine that discourse-conscious encoding, as well as rubric-conscious attention, cannot be done without in the model to be considered novel and successful.

The future research will focus on prompt-independent transfer learning, multilingual extensions, and fine-grained feedback generation in line with the instructional rubrics. Student revision trajectories and teacher annotations might be further incorporated to increase the interpretation and the quality of formative feedback. These guidelines make RAMS-Net-TFCR a powerful, equitable, and anthropocentric basis of the next-generation educational evaluation systems.

Face Sketch Recognition: Ethnic Groups Classification and Recognition Via a VGG16 Model Approach

Khalid OUNACHAD[1], Mohamed EL GHMARY[2]
USMS, Sultan Moulay Slimane University, Beni Mellal, Morocco[1]
ENSAM, Mohammed V University, Rabat, Morocco[2]

***Abstract*—In the law enforcement investigation, the police use sketching techniques to identify suspects from an eyewitness's memory. Many automatic face sketch recognition systems that determine the perpetrator's appearance from the face image datasets have been proposed. The aim is to conduct the arrest of the right offender. We propose this work to carry out a search based on the ethnicity criterion to speed up this automatic identification and to help authorities execute fast responses by launching the retrieval process only in a part of the dataset of face images. The goal of this study is to enhance the accuracy of ethnic face sketch classification by using the convolutional neural network built on the VGG16 architecture. The FairFace dataset, which includes seven ethnic face images: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino|Hispanic, was employed in the study. We convert the face images dataset to face sketch images, and we optimize the VGG16 model for seven classification outputs. This work shows that the VGG16 deep learning model offers a reliable, automated approach for ethnic face sketch classification and recognition. The used model achieved an accuracy reaching above 94% and produced a low false negative rate, which is crucial for minimizing undetected cases.**

***Keywords*—Forensic face sketch; ethnic classification; deep learning; transfer learning; optimized VGG16 model**

I. Introduction

Race is basically defined as a mixture of physical, behavioral, and cultural attributes, but ethnicity recognizes differences between people mostly based on language and shared culture [1]. In other words, race is inherent in our biology, and therefore inherited across generations, while ethnicity is based on native region or culture and acquired; it can be tied to the self-ascribed.

VGG16 (Visual Geometry Group-16 deep layers) is a deep convolutional neural network model introduced by the team at the University of Oxford [2]. It is most famous for its architectural simplicity and its performance, especially in image classification, but it needs many calculations, and it's a slow algorithm without a GPU. Among its applications, in addition to image classification, are feature extraction, object detection, and image segmentation. Generally, VGG16 is one of the most experimented CNN architectures for facial soft biometrics analysis. It achieved a significant success thanks to its deep architecture (around 138M parameters, 13 convolutional layers, and 3 fully connected layers), which allows it to better generate results even in the presence of small training sets.

Human Face Ethnic Groups Identification and Recognition (FEGIR) is an area of non-verbal language in day-to-day life communication. Ethnic facial features are some of the most important face features, but humans struggle and find it hard to try to differentiate between members of social outgroups, including different races [3]. Moreover, FEGIR systems have attracted numerous researchers and have been conducted and utilized in various fields since they attempt to overcome the problems and factors weakening these systems, including the problem of image classification, also due to their large-scale applications in face analysis, particularly face recognition [4]; sharpening the global focus on ethnicity and race in the time of COVID-19 disease [5],[6], career progression analysis [7], disentangling the stress process [8], and social crime [9].

Ethnic-based separation among humans is classified into six minimum categories: American Indian or Alaska Native, Asian, Black or African American, Hispanic or Latino, Native Hawaiian or Other Pacific Islander, and White [7]. However, based on their skin colors, we have five kinds of ethnicity:

red, white, black, brown, and yellow. It can also be tied up to some specific geographic regions, countries, or nationalities: symbolized relationships between the "races" and the countries. The U.S. Census Bureau also considers five race categories: White, Black or African American, American Indian or Alaska Native, Asian Native, and Hawaiian or Other Pacific Islander. The census considers some regions of origin for each race category. We use seven ethnic kinds of faces: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino, referring to the used dataset of face sketch images.

Ethnic group identification and recognition systems aim to automatically classify ethnicity in a dataset of photos or sketches (Fig. 1). It is based on a two-dimensional image of human subjects. The automatic task of ethnicity recognition is challenging work and explicitly difficult: Ethnic face classification and recognition can be done in many ways, but this study is concerned with the ethnic face sketch [10],[11] classification and recognition based on two-dimensional images of people's sketched faces.

Fig. 1. Examples of ethnic groups face sketch classification and recognition.

There are a large number of datasets available for human ethnicity classification research, some of which are private and some public. The FairFace database [10] is most commonly used in ethnicity classification, but until the redaction of this article, there was no face sketch dataset labeled with ethnic features used or cited in any related research. To resolve this situation and this problem, we created our ethnic face sketch dataset by converting face images of the FairFace dataset to face sketch images based on a method encompassing image inversion, Gaussian blur, and dodging fusion techniques.

VGGFace achieved an impressive accuracy in face recognition [12] and age estimation [13],[14] and has been successfully experimented with also for gender recognition [15],[16]. For this reason, we believe it can be effective for ethnicity recognition and classification purposes. In our proposed approach, we optimized the VGG16 model for seven classification outputs relative to our used face sketch dataset since it contains seven ethnic classes. The results of this work show that deep learning models, including VGG16, can offer a strong and automatic means of face sketch ethnicity classification and recognition. Beyond their intellectual value, these findings have practical ramifications for authorities in law enforcement investigation since they allow faster and more consistent ethnicity recognition and automatic face sketch recognition [17],[18].

The rest of the study is organized as follows: In Section II, related studies, an overview of the proposed VGG16 model is presented, emphasizing different modern searches when it's used. Many areas are mentioned, like computer vision, health disease classification, agriculture disease classification, and the civil engineering & construction sector. In Section III We present a brief explanation of the VGG16 models. In Section IV, we explore our approach in detail and describe the performance of our proposed algorithm. Section V presents the tests and experiments carried out during this study. Finally, we summarize this article with a conclusion.

II. Related Works

Ethnicity classification, a crucial facet in computer vision and artificial intelligence, has witnessed significant advancements in recent years. VGG16 is a VGGFace model trained from scratch for face recognition on almost 1 000 000 images. This CNN is probably the most adopted architecture for facial soft biometrics analysis, and we believe it can also be effective for ethnicity recognition and classification purposes. There has been a wealth of research on the VGG16 model, as well as on its application in areas such as computer vision. Specifically, it's used in various subfields such as image recognition
[19]-[21], health disease classification [22]-[24], agriculture disease classification or food security [25]-[26], and the civil engineering & construction sector [27], the last two areas were cited to indicate the performance of the use of VGG16 and considered as a related works to the use of the VGG16 model.:

In the image recognition subfield, for example, the study suggested by Zhu & Li [19] offers an improved version of VGG16 combined with wavelet analysis and marginal Fisher analysis (dimensionality reduction) to improve image recognition on different animal images. Their approach recognition accuracy reached 97%. Although in [20], R. Sewada and H. Goyal propose an adaptation of VGG-16 for the classification of multispectral satellite images. The used images are visible and near-infrared images. Their proposed modifications to the VGG-16 approach attain a higher classification accuracy rate of ±96.7%. While Genç & Yalman [21] propose an approach to recognize aircraft using satellite images based on CNN models. They detail a comparison study of VGG16 and VGG19 architectures. Based on their obtained results, VGG16 achieves an accuracy of approximately 82.67%, and VGG19 reaches ~89.29%.

However, in the medical domain, specifically in the health disease classification subfield, the authors of [22] propose a hybrid approach to detect heart disease by combining deep learning, machine learning, and explainable artificial intelligence. The explainable artificial intelligence techniques allow for the identification of the most decisive clinical variables in predicting cardiac risk. They use the pre-trained VGG16 model to extract 14 features from medical data converted to image format. These features are then merged with the original clinical data and classified using several machine learning algorithms: SVM, Random Forest, K-NN, etc. The VGG16 combined with the random forest model achieves the best performance, with an accuracy of approximately 92%. All the heart disease datasets used for their study are from Kaggle, comprising publicly available and synthetic data samples. In another health disease classification case [23], F. Tanjim and S. Hamdy describe and detail a method based on learning transfer with VGG16 to detect breast cancer from histopathological images. The authors use the pre-trained VGG16 model and adapt it to the BreaKHis medical dataset to distinguish between benign and malignant tumors. They improve the number of images using modern techniques such as data augmentation, dynamic tuning of the learning rate, and data regularization. They also propose a modified version of the pre-trained VGG16 model, which they named M-VGG16. The results show that the M-VGG16 model achieves an accuracy of approximately 94%. Although, in study [24], a retinal disease detection case, Jaimes et al. offer an approach for identifying four categories of retinal diseases from optical coherence tomography (OCT) images from the Kaggle database using a VGG16 transfer learning-based model. It relies on the pre-trained VGG16 model, adapted and refined for this specific task. The results achieve an accuracy of approximately 95%. The authors also use the Grad-CAM technique to visualize areas of the image that influence the prediction, thus improving the interpretability of the model.

Also, in the agriculture disease classification subfield related to the food security subdomain, in [25], the authors propose a CNN approach to improve the classification of tomato leaf diseases by adapting the classic VGG16 architecture to this agricultural domain and by optimizing its hyperparameters using Bayesian optimization. The innovative aspect of the used technique lies in the use of Bayesian optimization to automatically select the best hyperparameters for the model. The experiments are conducted on the Tomato Leaf Disease Detection (TLDD) dataset, a dataset of images of healthy and diseased tomato leaves, which is publicly available on the Kaggle platform. The results show that the proposed model achieves approximately 97% accuracy, surpassing the standard version of VGG16 (89.0%). The authors improve and modify the original VGG16 architecture by adjusting certain layers and adding regularization mechanisms to adapt it for plant disease detection. Although in a second agricultural classification disease case [26], Sahputra et al. compare two deep learning models, VGG16 and MobileNet, for classifying rice leaf diseases such as bacterial leaf blight, brown spot, leaf blast, and narrow brown spot. They use a set of images of infected and healthy leaves by using a dataset of 2,190 rice leaf images divided into five classes, apply preprocessing and data augmentation, and then evaluate the two models based on accuracy, speed, and complexity. The results show that VGG16 achieves superior accuracy, offering better classification performance. In contrast, MobileNet is lighter and faster. The VGG16 model achieved an accuracy of 98%, while the MobileNet model reached 95% accuracy.

In the civil engineering & construction sector, one example related to urban construction and infrastructure is the study carried out by Chen et al. [27]; it is a smart solution for structural health monitoring of buildings and dwellings. The authors propose a steel-reinforced concrete corrosion crack detection method based on improved VGG16. They propose a deep learning approach for detecting corrosion cracks in reinforced concrete using an improved VGG16 model. They adapt the VGG16 architecture to better capture fine crack details in images of concrete structures, while simultaneously reducing computational complexity. Chen et al. use the SDNET2018 and DeepCrack concrete crack datasets for training and testing experiments, and their proposed model achieved a precision of 94.4%.

As a contribution, this article proposes an ethnic face sketch classification and recognition method based on an improved VGG16 model. Our work is inspired in part by the recent and successful method that has shown that the use and integration of the VGG16 model in classification scenarios leads to obtaining a better score; it could be used to perform well. We believe it can also be effective for ethnicity recognition and classification purposes. As part of our research project, in which a face sketch recognition system was developed. We achieved an impressive accuracy in the face sketch recognition task [17], face sketch gender recognition task [11],[18],[28],[29], face sketch age estimation and recognition task [30], and face sketch emotions classification and recognition task [31]-[33]. What remains is the development of a phase of the overall project that allows for face sketch ethnicity recognition. For this reason, our project aspires to blaze new trails in the realm of face sketch ethnicity classification. We explore the possibilities of creating custom models tailored specifically to the challenges posed by this complex classification task. Our objective is to develop a classification system that surpasses conventional standards and excels in capturing the intricate subtleties of ethnicity. We leverage the capabilities of deep learning to advance the science of ethnicity and human race classification, fostering a world that values and appreciates the beauty of our differences.

III. VGG16 Deep Convolutional Neural Network Model

VGG16 is a well-known pre-trained CNN model from ImageNet that consists of 16 layers with learned weights, mainly using 3×3 convolutions and 2×2 max pooling to extract and reduce image features. It's trained from scratch for face recognition on almost a million images from the ImageNet dataset. This pre-trained CNN model is one of the most experimented-with CNN architectures for facial soft biometrics analysis, and it is very effective at extracting useful features from images.

The diagram of Fig. 2 illustrates multiple layers of interconnected neurons (nodes), which allow the network to learn complex, hierarchical features from data. The different sections, indicated by varying colors and structures, include multiple and different layers: 2D convolution layers, 2D max pooling, flatten, and dense. We have already explained the main function and task of convolutional layers and max pooling in section 2.1, while the primary role of dense flatten is to convert the 3D output from the VGG16 base to 1D so that it can be used in fully connected layers, and the dense layers are the fully connected layers. As evident from the name, it consists of 16 levels and requires an input of 224×224 pixels.

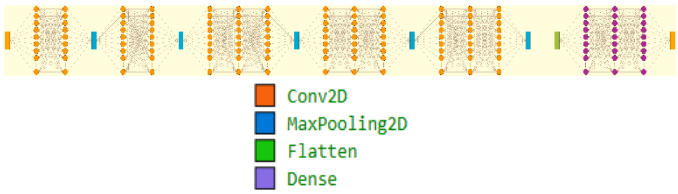

Fig. 2. VGG16 architecture scheme.

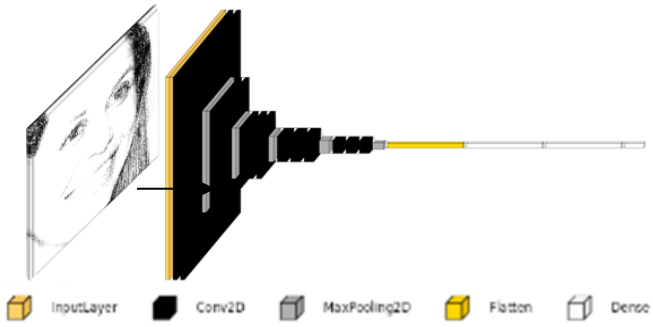

Fig. 3. VGG16 simple architecture 3D scheme.

Fig. 3, thus, clearly highlights the network's progression, in particular: gradual reduction of spatial size, increase in feature depth, and finally, classification via the fully connected layers. The architecture follows a very regular pattern: consistent filter sizes, double or triple convolution per block, then pooling,

which simplifies optimization while allowing the extraction of increasingly abstract visual features. The VGG-16 architecture begins with an input layer receiving images of size 224×224×3, and during the progression, outputs a unique prediction, allowing classification among 1000 outputs. Fig. 3 clearly illustrates the model's ability to effectively reduce the dimensions of the input image before flattening it into a simple final vector.

The number of used parameters in each layer and for each block is detailed in Table I; in addition to the type of layer, it indicates the output shape obtained at the end of each layer. The number of parameters is zero for the input layer, all the MaxPooling2D layers used, and the flatten layer. The model uses 1 792 in the first 2D convolution layer and 4097000 in the last one. 102 764 544 parameters are used in the first dense layer; it's the biggest number of parameters used in the model. The total parameters of the model are 138357544 (527.79 MB), and the trainable parameters are 138 57544 (527.79 MB), so the model doesn't have a non-trainable parameter (0.00 B).

TABLE I. TYPE LAYERS, OUTPUT SHAPE AND PARAMETERS OF VGG16 MODEL

Layer (type)	Output Shape	Parameters
input_layer (InputLayer)	(None, 224, 224, 3)	0
block1_conv1 (Conv2D)	(None, 224, 224, 64)	1 792
block1_conv2 (Conv2D)	(None, 224, 224, 64)	36 928

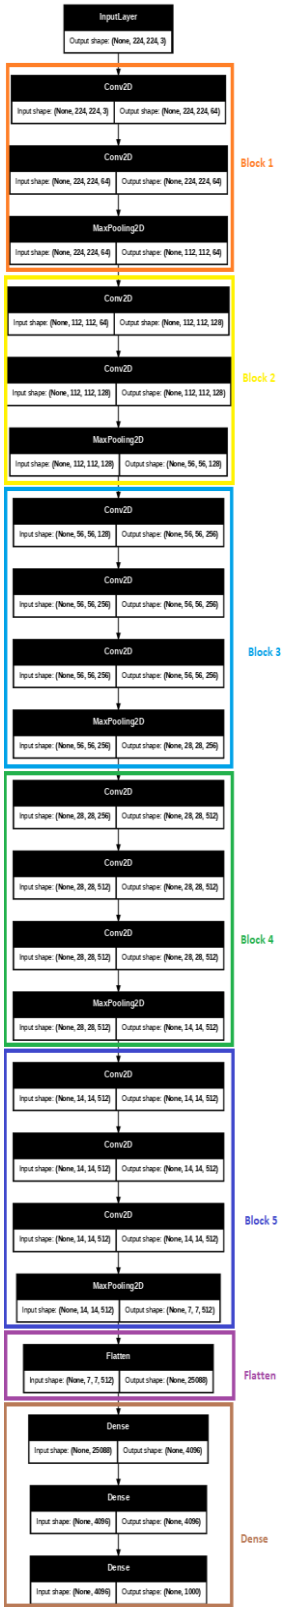

Fig. 4. VGG16 deep architecture scheme.

In Fig. 4, the VGG16 deep and detailed architecture is shown; it's composed of several successive blocks of convolutional layers followed by max-pooling layers. The first block applies two convolutions with 64 filters of size 3×3, maintaining the input resolution at 224×224, before reducing it to 112×112 via max-pooling. The second block repeats the same structure but with 128 filters, reducing the size to 56×56 after pooling. The third block consists of three convolutions with 256 filters each, followed by pooling that reduces the resolution to 28×28. The fourth block applies three convolutions of 512 filters before pooling, which reduces the size to 14×14. The fifth and final convolutional block applies three more layers of 512 filters, then a final max-pooling, resulting in a feature map of dimensions 7×7×512. The output of the convolutions is flattened into a vector of 25088 values, which feeds two fully connected layers of 4096 nodes each. The final dense layer has 1000 nodes and SoftMax activation, corresponding to 1000 possible output classes. The total of these output classes is chosen relative to the ImageNet dataset.

IV. Proposed Approach

The proposed framework for classifying ethnic groups from face sketches consists of several successive steps. First, images from a specialized dataset of face sketches are fed into the input system. This raw data then undergoes preprocessing, including automatic face detection, pixel intensity normalization, and image resizing to the format required by the VGG16 architecture (224×224×3).

The proposed system takes as input an image $I \in \mathrm{R}^{H \times W \times 3}$ from the face sketches dataset. A facial detection operation $D(I)$ extracts the face region I_f, and the D operation encompasses exactly the HOG and SVM methods. The resulting image I_f is then normalized as in Eq. (1):

$$I_n = \frac{I_f}{255} \tag{1}$$

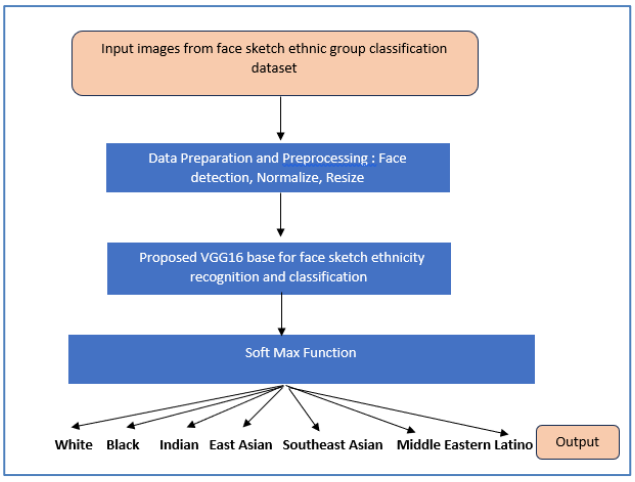

Fig. 5. Our proposed framework based on the VGG16 Model for face sketch ethnic group classification and recognition: An overview.

The normalization step converts pixel values to a 0-1 scale by dividing all pixel values by 255. Then, the resulting image I_n is resized to Ir through Eq. (2). The resize function resizes the image to 224x224 to conform to the VGG16 model shape.

$$I_r = Resize(I_n, 224 \times 224 \times 3) \tag{2}$$

In the feature extraction phase, a tailored VGG16 model is used as the basis network. This acts as a deep feature extractor, capable of efficiently capturing the facial structures present in the sketches. The pre-trained convolutional layers can be retained or fine-tuned to optimize performance on this type of non-photographic data.

The preprocessed image Ir is then propagated through a modified VGG16 network, consisting of 3×3 convolutional blocks followed by ReLU activation functions and max-pooling layers. Each block b performs a nonlinear transformation of the image described by Eq. (3):

$$F_l = \sigma(W_l * F_{l-1} + b_l) \tag{3}$$

where W_l is the convolutional filter of layer l, * is the convolution operation, and σ is the ReLU function.

After the last convolutional block, a flatten operation produces a feature vector $z \in R^d$. Finally, the representations generated by VGG16 are passed to a dense layer equipped with a SoftMax activation function, ensuring a probability distribution across all defined categories. The dense classifier then applies the following equation as in Eq. (4):

$$y = W_z + b \tag{4}$$

where $y \in R^K$ and K is the number of classes.

The final Softmax layer calculates a probability distribution as in Eq. (5):

$$P(y_i) = \frac{e^{y_i}}{\sum_{j=1}^{k} e^{y_j}} \tag{5}$$

For C ethnic groups, the predicted probability for class c is P(y = c | Fl), calculated as mentioned in Eq. (5). The loss function L in Eq. (6) is categorical cross-entropy:

$$L = -\sum_{c=1}^{C} y_c \log\left(P(y = c|F_l) \right) \tag{6}$$

The predicted class corresponds to the result of the equation in Eq. (7):

$$\hat{c} = \arg max_i \; P(y_i) \tag{7}$$

The class with the highest probability is selected as the model output. An overview of our proposed framework based on the VGG16 model for face sketch ethnic group classification and recognition is shown in Fig. 5. This framework thus enables automatic and structured classification of face sketches according to the seven predefined categories in the used dataset.

The details of the proposed VGG16 base algorithm for face sketch ethnic group classification and recognition can be summarized as follows: Fig. 6. The pseudocode is also shown in Fig. 7.

Step1: A face sketch is input to the trained VGG16-based model (face sketch preprocessing)

Step 2: Deep feature extraction by convolutional layers (feature learning)

Step3: The classifier predicts the ethnic group label(classification)

Step4: The class with the highest softmax probability is selected (ethnic group recognition)

Fig. 6. Main stages of the proposed system.

8- Return ĉ

Fig. 7. Pseudo-code of the proposed algorithm: VGG16-based face sketch ethnic groups classification and recognition.

Each face sketch image is preprocessed by resizing to 224×224×3 and normalizing pixel values before being passed through the modified VGG16 network to extract high-dimensional deep feature vectors. Partial layer freezing allows for the preservation of generic descriptors. The extracted features are subsequently used to train the SoftMax classifier, which predicts the ethnic group label for test face sketches.

V. Experiments and Results

A. Dataset and Ethnicity Groups Taxonomy

To demonstrate the effectiveness of the proposed method, we proceeded to acquire a dataset of ethnic groups' face sketch pictures. We used the FairFace [34] face images dataset that we converted to face sketch images. It is used as a source of real face images to generate sketches using inversion, Gaussian blur, fusion, "dodging," and sketch-synthesis methods. In the context of ethnic face sketch classification and recognition, FairFace can serve as the best source of real face images from which sketches can be generated.

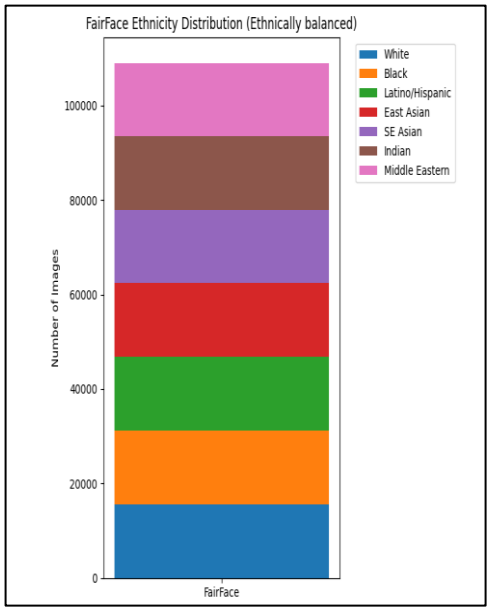

Fig. 8. FairFace ethnicity balanced distribution.

FairFace is a face image dataset that is ethnically balanced. It is a large-scale facial image dataset and contains 108501 images of faces in the wild, annotated with seven ethnicity categories [White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino/Hispanic], gender labels (male and female), and age group ranges. Images were collected from the YFCC-100M Flickr dataset and labelled with race groups, gender, and age groups. FairFace [35],[36] is ethnically balanced, as shown in Fig. 8, ensuring that all groups are fairly represented, which makes it particularly suitable for training models for ethnicity group classification and recognition. Its images exhibit natural variations in pose, lighting, and background, providing realistic and perfect conditions for model training. Fig. 9 details the FairFace ethnic groups' class distribution, Table II. gives a summary dataset description, and Fig. 10 includes random samples from the same dataset, where each line in Fig. 10 represents and corresponds to an ethnic group. These ethnic groups are illustrated from the white ethnicity to the Latino| Hispanic ethnicity, suitable to order in Fig. 9.

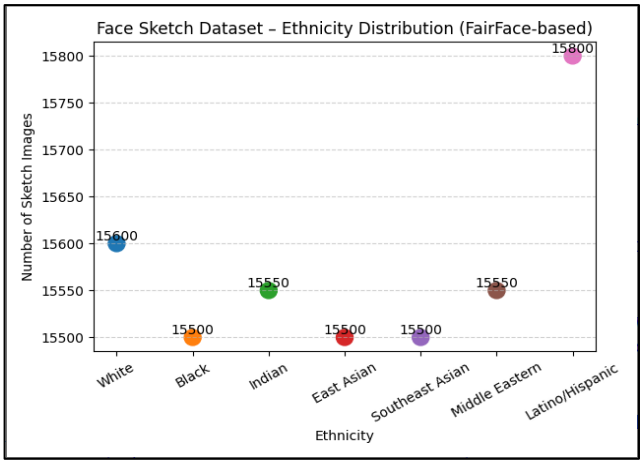

Fig. 9. FairFace ethnicity distribution.

TABLE II. FAIRFACE DATASET DESCRIPTION (ETHNICITY)

Number of images	Characteristics	Annotations	Ethnicity Classes	Ethnic groups Description	Number of Images (~)	% of Total
~108000	-Varied, mostly high-quality images - Contains in-the-wild images, (faces with natural conditions) -variations in pose, lighting, & background.	-Race/ Ethnicity: 7 categories -Gender: M|F -Age groups: 0–2, 3–9, 10–19, 20–29, 30–39, 40–49, 50–59, 60–69, 70+	-White	-Caucasian heritage	15600	~14.4%
			-Black	-African descent	15500	~14.3%
			-Indian	-Indian subcontinent	15550	~14.3%
			-East Asian	-East Asian heritage	15500	~14.3%
			-Southeast Asian	-Southeast Asian heritage	15500	~14.3%
			-Middle Eastern	-Middle Eastern heritage	15550	~14.3%
			-Latino / Hispanic	-Latin American heritage	15800	~14.6%

Fig. 10. Random samples from the FairFace dataset.

We divide the dataset into seven data subsets suitable for each kind of basic ethnicity: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino|Hispanic. Table II shows the percentage of each ethnic group; for each ethnicity class, the number of images is approximately 15500, with 14.4% of the average total. The reduction in the number of images is intended to simplify calculations, and the choice of images for the subclasses is arbitrary. Our chosen number of images in each ethnicity class is approximately seven thousand (~7000).

The generated face sketch ethnicity dataset from FairFace is used for training, validation, and testing our proposed approach. As shown in Table III., sixty percent (60%) of the images (29400) are used for the training phase, nineteen percent (20%) of the images (9800) are used for the validation task, while the remaining twenty percent (20%) of the images (9800) are reserved for the testing phase to assess the generalization performance of the proposed approach on unseen face sketch images. The dataset was divided proportionally to ensure that each ethnicity class was represented in all seven subsets. To achieve a complexity that is feasible on our machine, in our experimented and generated face sketch ethnicity dataset, the number of images in each ethnicity class is approximately seven thousand (~7000), 49000 images in total. Images were determined by data availability and the requirements of the VGG16 model training and testing process.

TABLE III. OUR DATASET SPLIT DISTRIBUTION ACROSS TRAINING, VALIDATION, AND TESTING PHASES

Phase task	Number of images	% of Total
Training	~29400	~60%
Validation	~9800	~20%
Testing	~9800	~20%

B. Tools

The proposed VGG16 model was developed, trained, and tested in Python using TensorFlow [39] to give access to pre-trained networks. Pandas was used for label file extraction and oversampling, CV2 for data preprocessing and facial recognition, and Scikit-learn for splitting data into training, validation, and testing sets. All computations were run in Google Colab using GPUs. The pre-trained VGG16 was downloaded via Keras through TensorFlow and subjected to transfer learning.

C. Image Pre-Processing

This stage prepares the data for the training process. Several steps are performed, including face detection, sketch image generation, normalization, and image resizing. We used the methods and operations detailed and mentioned in section IV to normalize and to resize to 224x224 all FairFace dataset images. We also convert all face images of the FairFace dataset to face sketch images by using a combination of inversion, Gaussian blur, and fusion image techniques. Fig. 11 shows a random sample of ethnic groups' face sketches generated and converted from FairFace by using these techniques. They include all ethnic classes:

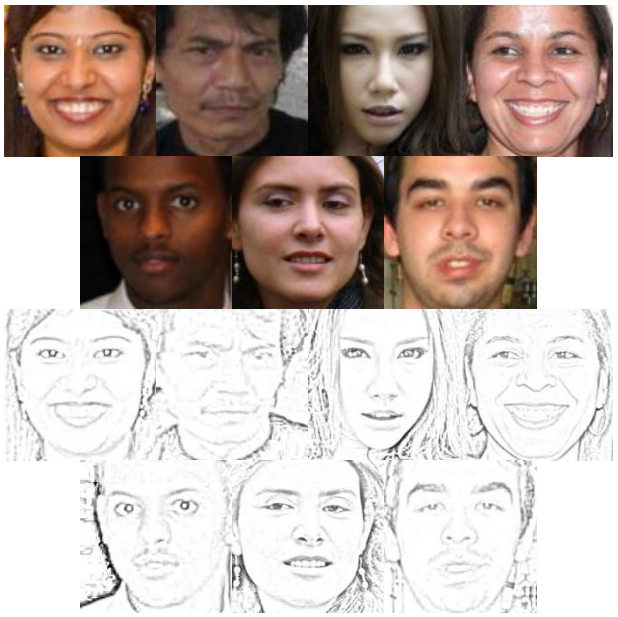

Fig. 11. Random samples of ethnic groups face sketches generated from the FairFace dataset images.

In our proposed approach, the first step in the preprocessing process is the face detection task. We use for this stage the famous Viola and Jones algorithm [40]-[42]. Fig. 12 illustrates some obtained results; the used method, based on the Viola-Jones technique, enables the faces to be detected perfectly.

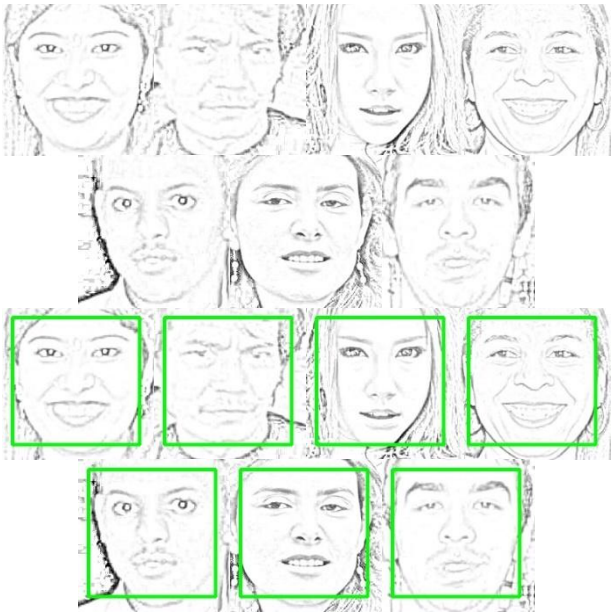

Fig. 12. Random Samples face sketch detection.

Fig. 13 summarize the experimental workflow for the data preparation and preprocessing task. The output image from the preprocessing phase will be the input image of the ethnic classifier based on the VGG16 model; it is an image containing only the detected face sketch area, which has been resized to a 224×224-pixel image and normalized.

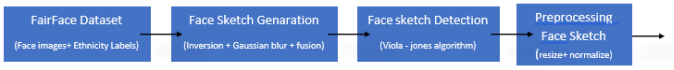

Fig. 13. Detailed experimental workflow for data preparation and preprocessing task.

D. Performance Metrics

When training a classifier, the choice of a scoring metric is a critical factor in achieving optimal classifier accuracy. The selection of the appropriate evaluation scale is of paramount importance to discriminate and ensure superior performance [37],[38]. Meanwhile, the model evaluation stage was carried out to assess the accuracy, consistency, and performance of the model in ethnic group face sketch classification and recognition. Model performance measurements used a confusion matrix and metrics such as accuracy (Eq. 8), precision (Eq. 9), recall (Eq. 10) and F1-score (Eq. 11). To compare model predictions with actual data, below are some equations for the proposed VGG16 model evaluation:

$$Accuracy = \frac{\mathrm{TP+TN}}{TP+TN+FP+FN} \quad (8)$$

$$Precision = \frac{\mathrm{TP}}{TP+FP} \quad (9)$$

$$Recall\ (sensitivity) = \frac{\mathrm{TP}}{TP+FN} \quad (10)$$

$$\mathrm{F1-Score} = 2 \times \frac{\mathrm{Precision \times Recall}}{\mathrm{Precision+Recall}} \quad (11)$$

$$\mathrm{F_{ß}-Score} = (1+ß^2) \times \frac{\mathrm{Precision \times Recall}}{ß^2 \times \mathrm{Precision+Recall}} \quad (12)$$

The $F_ß$-score in Eq. (12) is a generalized version of the classic F1-score, which allows more weight to be given to precision or recall, depending on the specific application. The score results will be the same as the classic F1-score, while ß is equal to one. While ß is greater than one, the focus is on recall; if less precision is needed and ß is less than one, more emphasis is placed on precision.

A True Positive (TP) occurs when the model predicts a positive output and the actual outcome is also positive, indicating a correct prediction for the positive class. Similarly, a True Negative (TN) occurs when the model predicts a negative output and the actual output is also negative, indicating a correct prediction for the negative class. Conversely, a False Positive (FP) occurs when the model incorrectly predicts a positive output when the actual output is negative. And finally, a false negative occurs when the model incorrectly predicts a negative output when the actual output is positive.

E. Results and Discussion

The generated dataset for this study consists of face sketches labeled by ethnicity. Seven classes were identified: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino|Hispanic. A total of 49000 face sketch images were randomly collected and generated from FairFace and divided into three subsets: training data, validation data, and test data. This proportional distribution ensured that each class was represented in all three subsets, thus optimizing the training, validation, and testing of the VGG16 model. The number of images used for each ethnic group class is balanced as detailed in Table IV below:

TABLE IV. FACE SKETCH IMAGE DATA DISTRIBUTION

Image Ethnicity Class	Training Data	Validation Data	Testing Data
White	~4200	~1400	~1'00
Black	~4200	~1400	~1400
Indian	~4200	~1400	~1400
East Asian	~4200	~1400	~1400
Southeast Asian	~4200	~1400	~1400
Middle Eastern	~4200	~1400	~1400
Latino|Hispanic	~4200	~1400	~1400
Total (7000)	~29400	~9800	~9800

Tests were conducted on 49000 data face sketch images distributed across seven classes of ethnic group face sketches: each ethnicity class contained approximately 7000 images. To evaluate the learning performance of the VGG16 model, we first present the performance of optimized VGG16-based ethnic groups classification on the face sketches generated from the FairFace dataset, and we present the accuracy and loss plots. The obtained results are shown in Fig. 14 and Fig. 15. These plots illustrate the model's ability to learn from the training and validation data, as well as the stability of the training process. The accuracy, precision, recall, $F_{ß=1}$-score $F_{ß=2}$- score and $F_{ß=0.5}$-score for the face sketch ethnic group classification and recognition using our adopted approach are shown in Table V.

TABLE V. PERFORMANCE OF OPTIMIZED VGG16-BASED ETHNIC GROUPS CLASSIFICATION ON THE FACE SKETCHES GENERATED FROM THE FAIRFACE DATASET

Metric / Model	Accuracy	Precision	Recall	$F_{ß=1}$-score	$F_{ß=2}$ score	$F_{ß=0.5}$ - score
Adopted VGG16 (Proposed)	94.00	93.80	94.60	94.70	34.64	93.62

The optimized VGG16 model accuracy graph (Fig. 14) shows a consistent increase in accuracy since the beginning of training, reaching above ~95% at the 100th epoch. The training and validation data accuracy patterns are similar, with no significant differences. This indicates that the model has good generalization capabilities and does not experience overfitting. The consistency between training and validation accuracy also indicates that the model is able to learn effectively from the data provided.

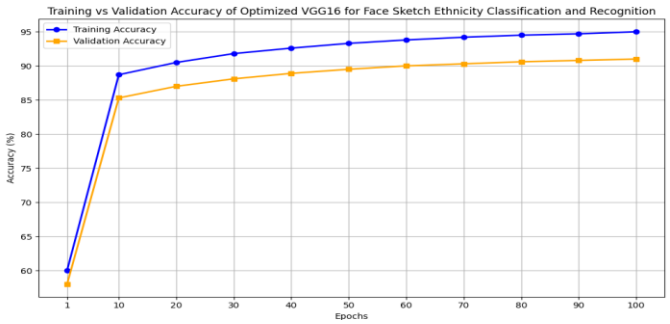

Fig. 14. Optimized VGG16 accuracy graph.

Meanwhile, the loss plot of the optimized VGG16 model(Fig. 15) shows a sharp decrease during the early epochs for both the training and validation data. Subsequently, the loss tends to stabilize at a low value (close to ~0), despite slight fluctuations in the validation loss at certain epochs. However, these fluctuations remain small and within acceptable limits. This behavior confirms that the training is proceeding correctly and that the model does not exhibit overfitting or underfitting problems.

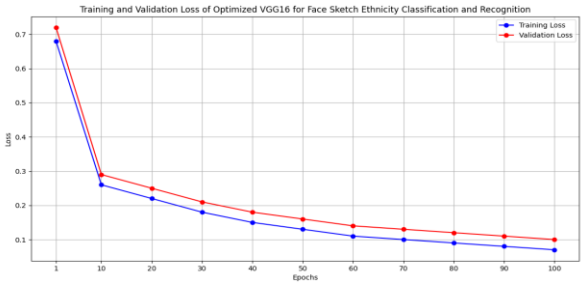

Fig. 15. Optimized VGG16 loss graph.

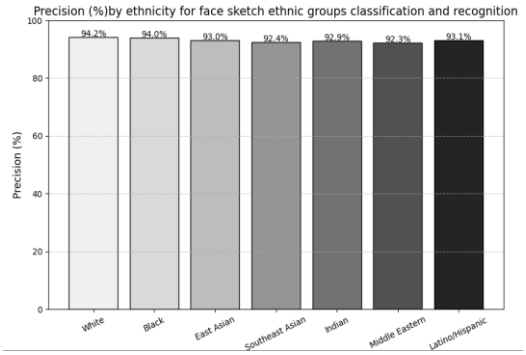

Fig. 16. Class-wise precision (%) for face sketch ethnicity classification and recognition (Optimized VGG16).

Once the model is trained, it is tested on the test data. The results of this test are presented in the visualization in Fig. 16. The figure illustrates the class-wise precision performance for face-sketch-based ethnicity classification and recognition across seven basic ethnic groups. The results show clearly high precision values for all ethnicity classes, ranging from 92.3% for Middle Eastern to 94.2% for the White ethnic group, indicating strong discriminatory capability of the optimized VGG16 proposed model. The highest precision is achieved for the White (94.2%) and Black (94.00%) ethnic groups, while slightly lower performances are obtained for Middle Eastern (92.3%) and Southeast Asian (92.4%) ethnic groups. Overall, the balanced distribution of precision scores across ethnicities demonstrates the robustness and fairness of the optimized VGG16 proposed model for face sketch ethnicity classification and recognition. We deduce that class-wise precision (%) for face sketches, ethnicity classification, and recognition using an optimized VGG16 model shows consistently high performance across all seven basic ethnic groups.

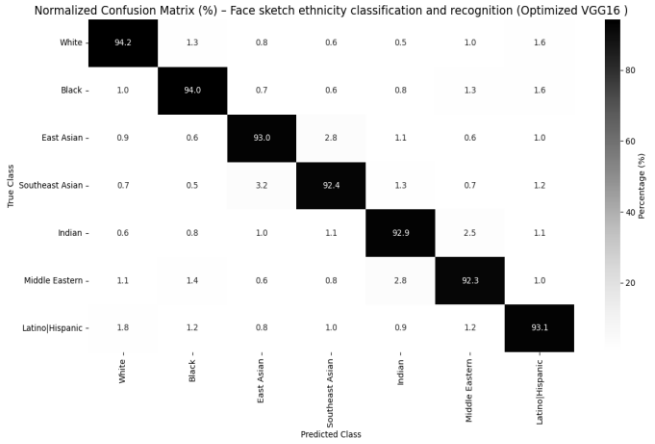

Fig. 17. Optimized VGG16 confusion matrix (%) in face sketch-based ethnicity classification and recognition.

Fig. 17 presents the normalized confusion matrix (%) for face sketch ethnic group classification and recognition using the optimized VGG16 model. The matrix brings to the fore strong diagonal dominance, indicating high correct classification rates across all seven basic ethnic groups. Precision values on the main diagonal exceed 92% for all classes, demonstrating the effectiveness of the proposed approach: White (94.2%), Black (94.0%), East Asian (93.0%), Southeast Asian (92.4%), Indian (92.9%), Middle Eastern (92.3%), and Latino|Hispanic (93.1%). Minor misclassifications are observed between visually similar ethnic groups, such as East Asian and Southeast Asian, as well as Middle Eastern and Indian.

Fig. 18 also illustrates the inter-class confusion matrix for face sketch–based ethnicity classification and recognition using the optimized VGG16 model. The matrix emphasizes misclassification patterns between ethnic groups (distribution of misclassification errors). Overall, the confusion rates remain low, indicating strong class separability.

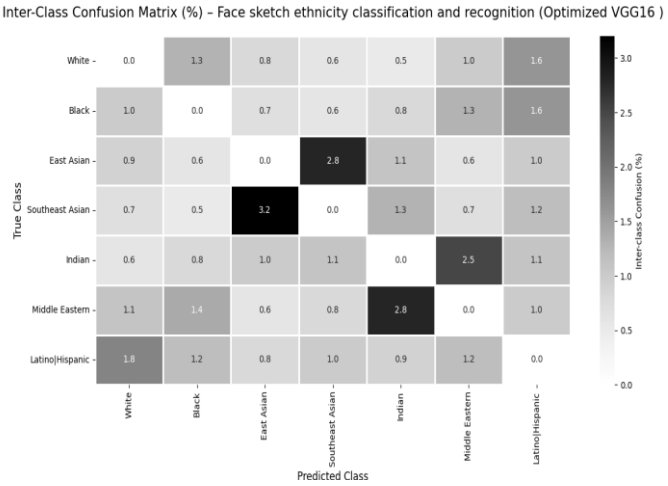

Fig. 18. Inter-class confusion matrix (%) for face sketch ethnic group classification and recognition using optimized VGG16.

The most noticeable and slight confusions are observed between visually related ethnic groups, such as between East Asian and Southeast Asian ethnic classes, which can be attributed to shared facial sketch features and characteristics. Similarly, moderate confusion is observed between Indian and Middle Eastern ethnicity classes, reflecting visual similarities in facial characteristics commonly found in sketch representations. Especially, these confusions are symmetrical and very low in magnitude, proving that the model does not exhibit systematic bias toward any particular ethnic group.

For example, VGG16 incorrectly classified some cases shown in Fig. 19. The first case is classified as Indian with 54% precision, so in fact the real class ethnic group is Southeast Asian. The prediction of the second case is East Asian with 57% precision; however, the real ethnicity is Southeast Asian. For the third case, in which the real class is East Asian, its prediction is 60% Southeast Asian. The last case is classified as Indian with 55% precision, so in reality, it is a Middle Eastern face sketch. This indicates that face sketches exhibit similar spot patterns or discoloration, making them difficult for the model to distinguish.

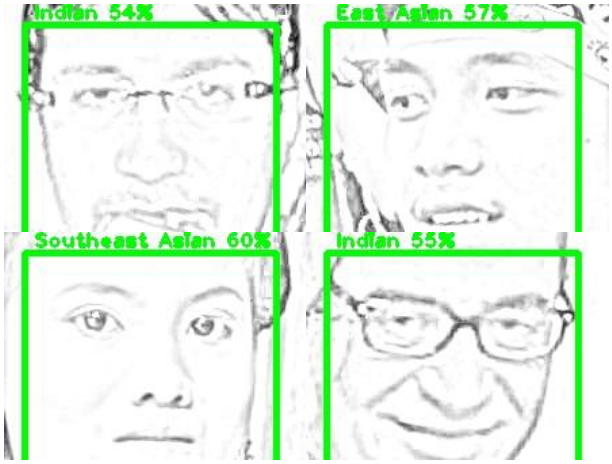

Fig. 19. Sample fails classified cases.

However, the model correctly identified the other ethnicity classes shown in Fig. 20. The figure illustrates some cases correctly classified as all seven basic ethnic groups, demonstrating the model's strong ability to identify ethnic groups with more distinctive characteristics. The first case in Fig. 20. is classified as Black with 91.7%; the second case is predicted Latino|Hispanic with 87.4%; the third one is classified as 82.6% Middle Eastern; the fourth case is predicted to be Southeast Asian with 81.9%; the fifth case is classified as 87.9% East Asian; the sixth case is predicted to be 95% White; and the last case is 93.16% Indian.

It is reported that for some face sketch images, the enhanced approach doesn't even allow for face detection in the image, and this problem is because the image doesn't include both eyes or the image isn't clear enough, as in the examples in Fig. 21:

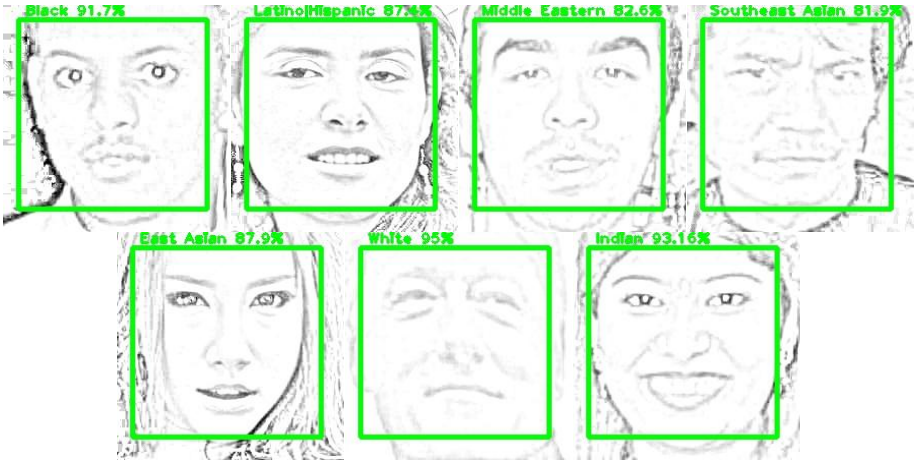

Fig. 20. Samples of the correct results of ethnic groups' face sketches classification and recognition.

Fig. 21. Samples of face sketches with failed face detection and their corresponding real photos from the FairFace dataset.

VI. Conclusion

This study proposes a new deep learning method for face sketch ethnic group classification and recognition. The method is based on the optimized VGG16 model. We used seven ethnic group sub-datasets for all ethnicities: White, Black, Indian, East Asian, Southeast Asian, Middle Eastern, and Latino. We tested our method on generated face sketches from the FairFace dataset using a combination of inversion, Gaussian blur, and fusion, and the results are very satisfactory. The accuracy is reaching above 94% and produced a low false negative rate. Our work is inspired by the recent successful methods that showed that a relatively mothered output VGG16 feature could be used to give good performance in a classification and recognition-based framework. To address the challenge of the lack of data and comparative models in the state of the art of the topic under study, the future work will include a decrease in the number of features used and the use of other competitive deep learning models.

INIAD cHUB, Toyo University, Tokyo, Japan[3]

***Abstract*—The current pre-tertiary educational landscape in Japan is defined by a significant paradox. While technological infrastructure has reached unprecedented levels of saturation through the Global and Innovation Gateway for All (GIGA) School initiative, student engagement and qualitative learning outcomes in computational disciplines have shown signs of stagnation. This research addresses this disparity by proposing a framework grounded in Culturally Responsive Teaching (CRT) and Culturally Responsive Computing (CRC), utilizing the traditional Japanese festival game of *Shateki* (target shooting) as a primary pedagogical vehicle. By leveraging the BBC micro:bit and a modular physical computing architecture, this study demonstrates how situating abstract programming concepts, such as sequential logic, conditional branching, and signal modulation, within familiar "vernacular" and "heritage" cultural contexts can foster intrinsic motivation and improve academic achievement among K-12 students. Through a pilot evaluation conducted during a community festival, this study provides quantitative evidence that CRT-based interventions not only enhance technical proficiency but also bolster a sense of student agency and cultural belonging. The results suggest that the success of modern educational technology initiatives depends less on hardware distribution and more on the pedagogical translation of technical content into culturally meaningful experiences.**

***Keywords*—Culturally responsive teaching (CRT); Culturally Responsive Computing (CRC); computational thinking; micro:bit; K-12 education; physical computing; STEM education**

I. Introduction

The Japanese Ministry of Education, Culture, Sports, Science and Technology (MEXT) launched the GIGA (Global and Innovation Gateway for All) School Program with the ambitious goal of providing a high-speed communication environment and a digital device for every student in primary and secondary schools across the nation [1]. This initiative was designed to eliminate educational gaps caused by socio-economic disparities and to prepare the next generation for Society 5.0, where cyber and physical spaces are highly integrated. Statistical indicators confirm the rapid success of the infrastructure rollout; student computer ratios have improved dramatically, and wireless LAN availability in classrooms has surged from roughly 40% to over 90% in just a few years [2]. Despite this technical achievement, the impact on learning remains contentious.

Recent data from the National Assessment of Academic Ability reveals a troubling trend. Between the 2024 and 2025 academic years, average correct response rates in core subjects like Japanese and Mathematics have declined across both elementary and junior high schools [2]. In mathematics, specifically, elementary school scores dropped from 63.6% to 58.2%, while junior high school scores fell from 53.0% to 48.8% [3]. These declines suggest that the mere presence of technology in the classroom does not guarantee improved cognition. In fact, many reports indicate that the GIGA School terminals are frequently used for non-educational entertainment, such as gaming or streaming services, which can detract from focused learning.

The root of this problem lies in the disconnect between "schooling" – the institutionalization of learning within a rigid, often Western-centric framework – and "education," which should empower students to transform their environment [4],[5]. When programming is taught as a series of abstract, context-less syntax exercises, students often find the material boring or difficult. This is particularly evident in the K-12 sector, where students' attention spans and motivation are deeply tied to the perceived relevance of the curriculum. The current failure to bridge the gap between high hardware accessibility and student interest necessitates a shift toward Culturally Responsive Teaching [6],[7].

In this respect, the primary contributions of this research are as follows.

- We developed a modular physical computing curriculum centered on the Japanese cultural heritage of *Shateki,* or target shooting game (Fig. 1), to teach the core principles of computational thinking.
- We implemented an asset-based pedagogical framework that validates students' community knowledge as a foundation for technical mastery.
- With a pilot study at a community festival, we quantitatively evaluated the impact of culturally situated learning on student motivation and proficiency in programming logic.
- We performed a comparative analysis of educational hardware platforms to determine the suitability of micro:bit for CRT-based interventions.

The remainder of this study is organized as follows. Section II presents a brief literature review. Section III discusses the cultural significance of Japanese summer festivals (*Matsuri*) and the traditional game of *Shateki* as pedagogical tools. Section IV outlines the system architecture and hardware design, describing the use of the BBC micro:bit and modular sensors. Section V explains the pedagogical strategy employed, which centers on sequential execution, conditional branching, and debugging. Section VI presents the experimental evaluation and results from a pilot study conducted at a community festival. Section VII provides an impact analysis of the curriculum through the lenses of identity affirmation and student agency. Section VIII offers a comparative analysis of educational hardware platforms commonly used in Japanese schools. Section IX discusses the lessons learned in the *Shateki* project and outlines future research directions. Finally, Section X concludes the study.

II. Literature Review

To situate the proposed framework within the broader discourse of Computer Science Education (CSE), this section examines existing literature across three converging domains: Culturally Responsive Teaching (CRT), Culturally Responsive Computing (CRC), and Physical Computing. The synthesis of these fields suggests that while tangible interfaces improve the cognitive grasp of abstract concepts [8],[9], and cultural contextualization improves learner motivation [10],[11], there remains a scarcity of rigorous studies combining both methodologies within the specific cultural heritage contexts of East Asia.

A. Culturally Responsive Teaching (CRT) as a Pedagogical Foundation

Culturally Responsive Teaching (CRT) serves as the overarching pedagogical architecture for this study. Defined foundationally by Gay [12] and Ladson-Billings [13], CRT is a pedagogy that recognizes the importance of including students' cultural references in all aspects of learning. It posits that academic achievement improves when instruction is filtered through the students' own cultural experiences and frames of reference.

In the context of STEM education, the disconnect between a student's home culture and the culture of the science classroom is often cited as a primary barrier to engagement. Research by Villegas and Lucas [14] emphasizes that sociocultural consciousness is a prerequisite for teachers to bridge this gap. However, traditional CRT literature has largely focused on the humanities and social sciences. Only recently has the scope expanded to technical disciplines, where the "culture-free" assumption of mathematics and logic is being challenged. By validating "vernacular" knowledge – such as the rules of a traditional festival game – educators can lower the affective filter, making rigorous academic content more accessible to young learners who might otherwise view themselves as outsiders to the domain of technology.

B. Culturally Responsive Computing (CRC) and Computational Thinking

Culturally Responsive Computing (CRC) represents the intersection of CRT and computer science education. Eglash et al. [15] have been instrumental in defining this space through "ethnocomputing," demonstrating that indigenous practices – such as cornrow braiding or Navajo weaving – contain inherent computational algorithms. By explicitly mapping these cultural artifacts to programming concepts, CRC transforms heritage from a passive backdrop into an active cognitive resource.

Scott et al. [16] further argue that CRC is essential for equitable participation in computing. Their work indicates that when curricula reflect the identities of underrepresented youth, there is a marked increase in both self-efficacy and the acquisition of Computational Thinking (CT) skills. CT, as defined by Wing [17] and elaborated by Brennan and Resnick [18], involves solving problems, designing systems, and understanding human behavior by drawing on the concepts fundamental to computer science.

However, a significant portion of CRC literature is situated within North American contexts, focusing on African American or Latino cultural matrices [19]. There is a distinct paucity of literature examining CRC frameworks within the Japanese educational system, particularly regarding how distinct cultural assets like *Matsuri* (festivals) can be leveraged to address the motivation crisis identified in the GIGA School era. This study aims to extend the CRC discourse by validating the *Shateki* game as a computational artifact capable of teaching conditional logic and algorithmic sequencing.

C. Physical Computing and Cognitive Load in Young Learners

The third dimension of this research is Physical Computing: the design of interactive physical systems by the use of software and hardware that can sense and respond to the analog world. This approach aligns with Papert's theory of Constructionism [20], which posits that learning is most effective when the learner is engaged in constructing a public entity. Recent studies strongly support the efficacy of physical computing tools, such as the BBC micro:bit, in fostering CT. Sentence et al. [21] found that physical computing devices provide immediate feedback loops that are crucial for novice

programmers. When a student programs a physical device to "shoot" a target, the abstract code becomes a tangible reality. This tangibility reduces cognitive load; the concept of a "variable" is no longer just a memory space but a score counter on a display; a "conditional statement" is no longer just syntax but the visible act of a point increment when the target is hit.

Furthermore, research by Hodges et al. [22] suggests that physical computing is particularly effective in collaborative settings, fostering "computational participator" behaviors. The tangible nature of devices allows for shared attention and collaborative debugging, which are critical components of the social learning environment found in festival preparations.

D. Synthesis: The Intersection of Culture and Tangibility

While the individual benefits of CRC and Physical Computing are well-documented, the synergy between them remains underexplored in current literature. Most CRC interventions rely on screen-based simulations (e.g., culturally relevant Scratch projects), while most physical computing interventions utilize generic projects (e.g., traffic lights, weather stations) that lack deep cultural resonance.

This research posits that the intersection of these domains offers a unique force multiplier for educational outcomes. By combining the tangible scaffolding of physical computing with the motivational scaffolding of CRC, we propose a holistic framework. The *Shateki* project utilizes the micro:bit not merely as a generic controller, but as a modern instrument to re-enact a centuries-old tradition, thereby validating the students' past while equipping them for the future.

III. The Cultural Significance of Matsuri and Shateki in Japan

Japanese summer festivals, or Matsuri, are pivotal community events that combine traditional religious elements with modern social celebration [23]. Originally rooted in agrarian prayers for harvest and protection from pestilence, they have transitioned into vibrant spaces where residents participate with fervor and actively engage in community bonding [24]. Central to the Matsuri experience are the Yatai (stalls) that offer a variety of foods and traditional games. These games are not merely recreational; they are cultural resources that teach focus, patience, and skill while fostering a sense of shared belonging.

Among these activities, Shateki (target shooting) is particularly iconic. In a traditional Shateki stall, a player uses an air rifle, typically firing cork bullets, to attempt to knock prizes off a tiered display (Fig. 1). The prizes range from inexpensive snacks and candies to high-value toys or character goods [25]. The cultural significance of Shateki is deep; for adults, it represents a nostalgic link to their childhood, and for children, it is a thrilling test of aim and nerve. The mechanics of the game are intuitively understood by Japanese citizens of all ages, making it an ideal low-floor entry point for teaching computational logic.

By framing a programming lesson around building a Shateki game, educators can tap into "funds of knowledge" that students already possess [4]. Instead of learning about sensors and infrared light in a vacuum, students learn how to "build a festival" using digital tools. This approach aligns with the CRC tenet of "asset building," where students' existing cultural expertise is validated and used as a bridge to new technical knowledge [26].

IV. System Architecture and Hardware Design

To implement the digital Shateki experience, this research utilizes the BBC micro:bit platform. The micro:bit is a microcontroller designed specifically for education, featuring integrated sensors, an LED matrix, and physical input-output pins [27]. To program the BBC micro:bit, Microsoft MakeCode [28] – a free, open-source web-based platform – is used. The platform supports block-based programming, similar to Scratch. Such block-based programming has been proven to be useful for early-stage learners [29]. For this study, a modular system was designed to simulate the physical interactions of a shooting gallery. As shown in Fig. 2, the hardware components include the micro:bit unit, a workshop module, vibration sensors, and infrared (IR) LED/receiver modules.

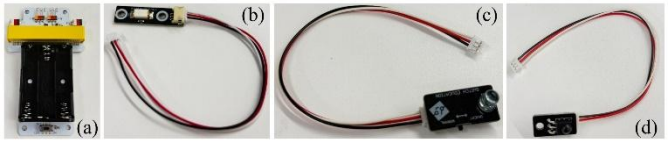

Fig. 2. Hardware components: (a) Workshop module for micro:bit, (b) Vibration sensor for micro:bit, (c) Infrared LED module for micro:bit, (d) Infrared receiver module for micro:bit.

A. Physical Computing Modules

The system is designed to be modular, allowing students to understand the relationship between different hardware units and their specific roles in a distributed computing environment. Table I provides a breakdown of the hardware components used in the *Shateki* system. The role and purpose of each component are also summarized in Table I.

TABLE. I. Components used in Shateki Game

Module Name	Technical Role	Purpose in *Shateki* Game
micro:bit v2.2	Central procession unit	Manages logic, variablers and display
Workshop module	Power and I/O distribution	Facilitates remote sensor connectivity
Vibration sensor	Anlaog input (Piezoelectric)	Detects projectile impact on the target
Infrared LED	Signal output (38.5 kHz)	Creates a digital tripwire for boundaries
Infrared receiver	Signal detection	Monitors for interruptions in the IR beam

As shown in Fig. 3, the system architecture is bifurcated into two primary subsystems: the Target Function and the Boundary Function. In a traditional *Shateki* gallery, the player must stay behind a line; if they cross it, the attempt is void. By digitizing this rule, students learn about sensor-based automation. The Target Function uses a vibration sensor to detect when the target has been struck, while the Boundary

Function uses an IR beam to detect if the player's foot has crossed the designated firing line.

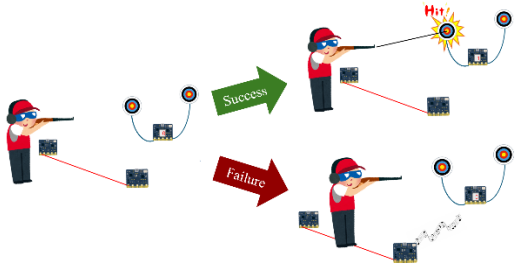

Fig. 3. Overview of the Shateki game with success and failure cases.

B. Hardware Connectivity and Constraints

As shown in Fig. 4, the completed hardware assembly integrates these modules into a cohesive playset. The target function is physically separated from the infrared boundary units, necessitating a multi-micro:bit setup. In this configuration, one micro:bit acts as the target scorekeeper, while two others manage the infrared transmission and reception. This setup is intentional, as it introduces students to the concept of hardware independent of a single "brain," mirroring real-world IoT (Internet of Things) architectures.

The technical challenge for students lies in the analog-to-digital conversion (ADC) process. For the vibration sensor, an analog value of 0 indicates an impact, whereas 1 indicates a steady state. For the IR receiver, the logic is similar: a detected beam returns 1, while an interruption (a broken beam) returns 1. Navigating these inverted logic states provides a fertile ground for developing critical thinking and problem-solving skills, as students must often debug their assumptions about how "on" and "off" signals should behave.

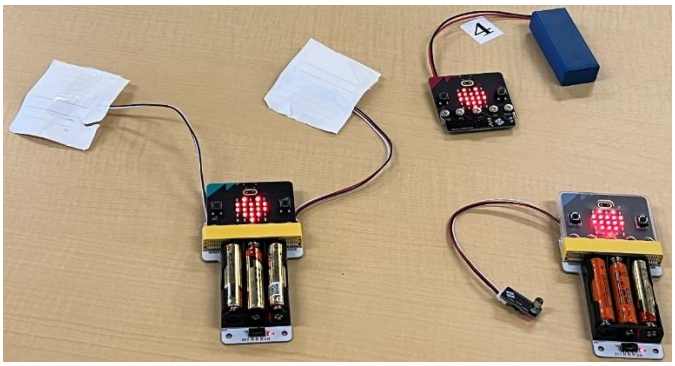

Fig. 4. Hardware setup of the Shateki game.

V. Pedagogical Strategy

The instructional design of the Shateki project is centered on the three fundamental principles of programming: sequential execution, conditional branching, and iteration. The pedagogical innovation here is the use of debugging as a primary learning activity. Research suggests that providing students with broken but mostly functional code encourages deeper analysis than starting from a blank screen [30].

A. Programming the Target Logic

Students are provided with an initial code block for the Target Function that contains a logical bug. As shown in Fig. 5, the initial code incorrectly maps the sensor input to a pin that is not physically connected to the workshop module. Students must trace the physical jumper wires to the correct pin (typically P0) and update the code accordingly. As shown in Fig. 6, the correct logic involves an "if-then" statement: *if* the vibration sensor detects a hit (analog_value=0), *then* increment the score variable by 1. This exercise teaches conditional branching in a way that is immediately visible through the 5x5 LED display, which shows the score increasing in real-time. Such instant feedback improves program comprehension [31].

B. Signal Modulation and Boundary Function

The Boundary Function introduces more sophisticated concepts. The IR LED must be modulated to a specific frequency (approximately 38.5 kHz) for the receiver to detect it reliably. On the micro:bit, this is achieved by simulating a frequency through rapid pulse repetitions. As shown in Fig. 7(a), the sample code provided to students has the "repeat" value set to 0, meaning no signal is sent. Students learn that for communication to occur, the transmitter and receiver must agree on a "signal" presence. As shown in Fig. 7(b), setting the loop to 100 repetitions creates a stable enough frequency for detection.

Fig. 5. Initial incorrect program (target logic).

Fig. 6. Program with corrected if-then logic.

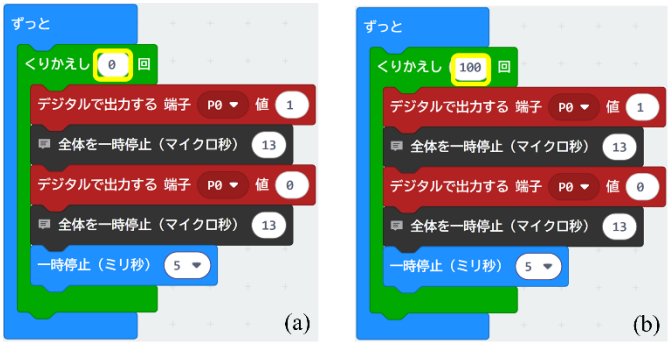

Fig. 7. Program for sending signal: (a) Incorrect, (b) Correct.

On the receiving side, students must manage the inverted logic of infrared detection. As shown in Fig. 8, the initial code might have a threshold value (e.g., 5) that does not match the binary nature of the IR receiver output. By testing the system and viewing the data on their screens, students identify that they must check for a value of 0 to detect a "broken" beam. As shown in Fig. 9, the corrected code triggers a warning sound and displays a danger icon on the LED matrix when the line is crossed. This creates an immediate cause-and-effect relationship between code and physical action, which is a key driver of engagement in physical computing [32].

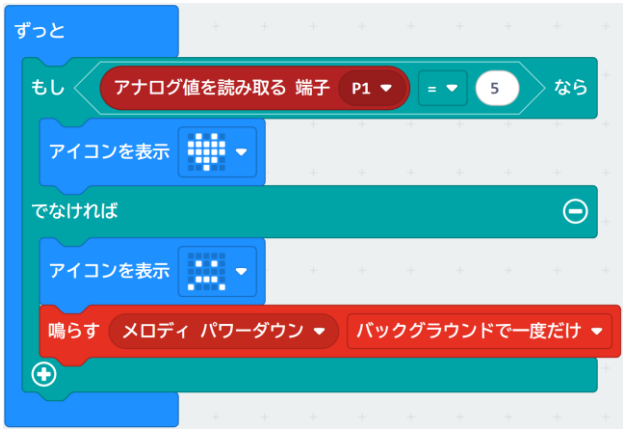

Fig. 8. Incorrect receiver program.

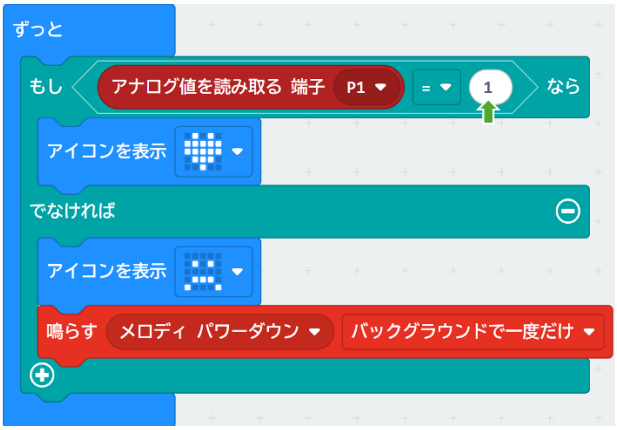

Fig. 9. Corrected receiver program.

VI. Experimental Evaluation and Results

The efficacy of this culturally responsive Shateki curriculum was evaluated during the Akabanedai Festival in Tokyo, a community event that provided a naturalistic environment for testing. The participants included 31 students, primarily in the elementary and junior high school demographics, who engaged in the programming and gaming activities. Evaluation was conducted through digital questionnaires and a confirmation test (a quiz to check comprehension of basic programming concepts) administered after the experience.

A. Participant Profile and Prior Experience

The majority of the participants were within the K-12 target group. Interestingly, the survey data revealed that many students had very little prior exposure to programming. Over 60% of respondents indicated they had "never" or "hardly ever" received programming education. Furthermore, usage of the micro:bit was almost zero before the festival, with nearly all participants being first-time users.

This data underscores the importance of the CRT approach. When students are blank slates with regard to technical skills, the cultural familiarity of the Shateki game acts as a critical scaffolding tool, preventing the technological intimidation that can occur with abstract coding tasks [33].

B. Quantitative Analysis of Motivation and Satisfaction

The post-experience survey utilized a 5-point Likert scale to measure various aspects of student engagement and understanding. The results are summarized in Table II.

TABLE. II. Result of Questionnaire Survey

Metric	Avg. score	SD
Enjoyment of the experience	4.77	0.57
Overall satisfaction	4.70	0.60
Desire to try again	4.57	0.77
Increase in programming motivation	4.30	0.84
Desire to recommend to others	4.27	1.01
Sense of achievement/completion	4.03	1.00
Understanding of programming logic	3.87	1.01

The exceptionally high score for Enjoyment (4.77) and Overall Satisfaction (4.70) indicates that the festival context was highly effective at creating a positive learning environment. More importantly, the score for Programming Motivation (4.30) confirms that the CRT framework successfully transformed a difficult technical subject into an appealing one. Fig. 10 shows a collage of students programming and trying the game.

The quiz results, as shown in Fig. 11, provide evidence of academic achievement. Among the 25 test takers, the score distribution was heavily weighted toward the high end, with many students demonstrating mastery of the three principles of programming and sensor logic. This result directly contradicts the national trend of declining academic scores in mathematics and science, suggesting that when content is "culturally situated," students can achieve high levels of mastery even in short-duration interventions.

Fig. 10. Students programming and testing the Shateki game.

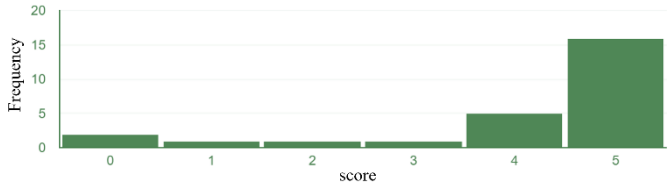

Fig. 11. Distribution of quiz scores.

VII. Impact Analysis

The success of the Shateki project can be explained through several key CRT mechanisms: identity affirmation, immediate feedback, and student agency.

A. Identity Affirmation and Cultural Capital

By using a festival game, the curriculum validates students' cultural capital – the knowledge and skills they have gained from their families and communities [26],[34]. Instead of the classroom being a place where their external life is ignored, it becomes a place where their cultural heritage is digitized and celebrated [35]. This reduces cultural alienation and increases a sense of belonging, which is a prerequisite for sustained academic engagement in STEM fields [33].

In Japan, where the GIGA school initiative has standardized the digital experience, there is a risk of cultural blindness, where the unique local and national traditions of students are overlooked in favor of generic globalized content [36],[37]. The Shateki game re-injects "Japaneseness" into the computer science curriculum, allowing students to see computing as a tool for cultural sustainability – preserving the old through the new [38].

B. Immediate Feedback and Physicality

The micro:bit's physical nature provides immediate feedback that is qualitatively different from screen-based programming. When a student fixes a line of code and a physical target starts counting scores, or an infrared beam starts sounding an alarm, the abstraction of the computer becomes concrete [33]. Students were highly motivated to use the micro:bit for other activities after the session, suggesting that the "physicality" of the experience created a lasting interest in hardware-software integration.

This immediacy is particularly important for younger learners who may find traditional GIGA-school terminals boring or distracting. The tactile nature of the workshop modules and sensors keeps students on-task and focused on the problem-solving process.

C. Empowering Student Agency

The debugging approach used in this research promotes student agency, i.e., the feeling that the learner is a producer of knowledge rather than a passive consumer [38]. When students fixed the bugs in the Shateki code, they were not just following a tutorial; they were, in essence, reclaiming the system and making it work according to their understanding of the game's rules. This aligns with the CRT principle of critical consciousness, where students learn to manipulate and control the technology in their environment [38].

VIII. Comparative Analysis of Educational Hardware

To understand why the micro:bit was chosen for this culturally responsive intervention, it is necessary to compare it with other prevalent hardware platforms in Japanese education. A comparative evaluation of such educational hardware is presented in Table III.

Arduino [39] and Raspberry Pi [40] offer high extensibility but have a steep learning curve involving complex wiring and OS management, which can become a barrier for beginner students. LEGO Education [41] is highly refined but prohibitively expensive for widespread GIGA school implementation, potentially widening the socio-economic gap CRT seeks to close. Robot-based toys like Sphero [42] and Ozobot [43] are engaging but often act as black boxes where the internal sensor logic is hidden from the student.

The micro:bit strikes the ideal balance. Its low cost and built-in features make it accessible to underserved schools, and its open pin architecture allows for the modular Shateki design. Furthermore, the total cost for the Shateki set used in this study was around 26,800 JPY (around 170 USD) per complete set. While this may seem high, the micro:bit itself is the only component needed for each student (approximately 3,400 JPY or around 20 USD), with sensors shared in a station-based learning model. This ensures that the technology is accessible and relevant for all learners, a core requirement of the CRT Areas of Opportunity framework [44].

TABLE. III. Comparison of Hardware Typically Used in Physical Computing Education

Platform	Operability	Safety	Approx. Cost (in JPY as of Dec. 2025)	Cultural Adaptability	Feedback Immediacy
BBC micro:bit	High	High	3,400	High	Excellent
Arduino	Low	Medium	3,000	Medium	Medium
Raspberry Pi	Low	High	6,000	Low	Low
LEGO Education	High	High	25,000	Medium	High
Sphero / Ozobot	High	High	15,000	Low	High

IX. Lessons Learned and Future Work

Despite the success of the Shateki project, several challenges remain for broader implementation in Japanese schools.

A. Language and Technical Jargon

Feedback from the Akabanedai Festival indicated that for some elementary school students, the technical language used in the coding blocks was too difficult. This highlights a critical need for linguistic responsiveness in CRT. A culturally responsive teacher must be a pedagogical translator, converting abstract terms like variable, analog threshold, and signal modulation into metaphors that resonate with the students' everyday language and festival experiences [33].

B. Calibration and Differentiation

The survey results showed a spread in the "Sense of achievement" and "Understanding of programming logic" scores, with standard deviations around 1.0. This suggests that one-size-fits-all instruction is ineffective even within a culturally responsive framework. Some students found the tasks too easy, while others struggled with the logic of the infrared receiver. To address this, future curricula should offer tiered challenges, for example, allowing advanced students to add sound effects or timers to their Shateki games, while ensuring beginners can complete the core vibration and boundary logic.

C. Sustaining Interest Beyond the Novelty Effect

While the fun of the festival game provides an initial hook (a phenomenon known as the novelty effect [45]), the ultimate goal of CRT is to build long-term computational identity [26]. This requires moving from single-experience workshops to a spiral curriculum where the micro:bit is used across different subjects, such as using the vibration sensor in a science class to measure tectonic movements or using the LED matrix in a math class to visualize data. The Shateki project should be seen as the gateway that proves to students they belong in the world of computing.

X. Conclusion

This research has demonstrated that the pervasive disengagement and declining academic outcomes observed in the wake of the GIGA School initiative can be mitigated by adopting a Culturally Responsive Teaching framework. The micro:bit-based Shateki shooting game serves as a powerful evidence-based model for this approach. By situating the abstract principles of programming within the joyous and familiar context of a Japanese summer festival, the project achieved high levels of student satisfaction, increased learning motivation, and measurable cognitive gains in programming logic.

The success of the Shateki project highlights that effective technology integration is not a function of the number of devices in a classroom, but the degree to which those devices are used to celebrate and extend students' cultural identities. When students are empowered to "build their own festival" using sensors and code, they move from being passive consumers of Western-centric software to being creative innovators with their own cultural voice.

For Japanese education to fulfill the promise of the GIGA School era, it must move beyond hardware distribution toward a pedagogy that values vernacular and heritage culture as essential components of STEM success. By making Culturally Responsive Computing the central theme of computer science education, we can ensure that every student – regardless of their socio-economic background – can see themselves as a capable and innovative citizen of the digital future. The Shateki experience proves that the path to high-tech mastery often begins with a very traditional, very human connection.

Machine Learning-Based Effort Prediction and Early Risk Detection in Software Development Projects: A Case Study

Andreea-Elena Catana, Adriana Florescu
Department of Industrial Engineering and Management, Transilvania University of Brasov, Brasov, Romania

***Abstract*—Accurate effort estimation and early risk detection are critical for the success of software projects, as inaccurate forecasts can lead to schedule overruns, inefficient resource allocation, and unmet requirements. This study investigates the use of machine learning techniques to support task-level effort prediction and proactive risk identification in software project management. An applied case study was conducted on a simulated dataset of 500 software development tasks, described by planning, technical, and team-related features. Two ensemble-based regression models, Gradient Boosting and Random Forest, are evaluated for predicting actual task duration. Model performance is assessed using standard metrics, including Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and the coefficient of determination (R^2). To enable early risk detection, prediction errors are transformed into deviation-based indicators, and threshold-based classifiers are employed to identify tasks with moderate (>20%) and severe (>30%) schedule overruns. Confusion matrices and classification metrics are used to evaluate the effectiveness of the proposed alerting mechanism, and the distribution of high-risk tasks across sprint quantiles is analyzed to support managerial decision-making.**

***Keywords*—Software effort estimation; risk detection; machine learning; python; open data; gradient boosting; effort estimation; risk thresholding**

I. Introduction

Software development is a complex, time- and resource-consuming process of designing, implementing and maintaining software systems, which involves different stages. A software project manager's main duty is to ensure project completion on time and within budget, while guaranteeing high quality of deliverables and customer satisfaction, as projects may incur consequences of inefficiency. Therefore, managers generally need to answer important questions about software projects, including how long and how much effort it takes to complete a software project [1].

Project success greatly relies on the reliability of answering these questions, because budget overruns and overdue completion of software projects are universally reported. Poor estimation practices also cause declining client satisfaction and lead to a bad reputation, directly influencing the results of customers and vendors.

Effort estimation is also vital to software task scheduling and is a mandatory task before any software undertaking. Rescheduling and budget reallocation induced by missed deadlines may severely upset the quality of deliverables, and ultimatums of trade-offs between quality and cost factors will arise.

Therefore, automatically estimating or assessing the completion effort of software tasks given syntactically composed particle descriptions and histories is an emergent challenge. In this context, static analysis denotes a static process of examining software text code without actually executing programs. Specifically focusing on static analysis in tractable cycles has proven helpful in quality evaluation and runtime performance prediction of software systems.

However, existing static analysis methods are not able to quantify the completion effort of software tasks, and a demand for an accurate estimator that assesses the effort needed to complete software tasks prompt the emergence of automatic effort estimation techniques.

This study presents an integrated approach to project management using Machine Learning, focusing on the synergy between precise effort prediction and proactive risk identification, validated through a comprehensive case study.

The article is structured in seven sections, starting with an analysis of the current context in software development (Section I) and a review of recent literature on risk prediction and effort estimation (Section II). Subsequently, the research methodology and conceptual framework are defined (Section III), elements that underpin the development of the Machine Learning model for the analyzed case study (Section IV). The results and validity of the models are demonstrated in Section V, followed by a discussion of the practical implications for software development project management (Section VI). The study concludes by summarizing the conclusions and outlining future research directions (Section VII).

This study addresses the following research questions:

RQ1: Can machine learning models improve task-level effort prediction compared to planned estimates alone in a controlled software project environment?

RQ2: Can prediction deviations be operationalized into actionable early-warning indicators for schedule risk detection?

RQ3: How effectively can ensemble learning methods identify high-risk tasks based on development and team-related features?

II. LITERATURE REVIEW

Artificial Intelligence (AI) is one of the most important areas of development, which brings new and innovative solutions to improve many tasks in the fields of software engineering, such as software reliability, maintenance, troubleshooting, effort estimation, resource management, and risk detection [2], [3], [4].

In recent years, the demand for software development needs has risen sharply in line with the booming growth of the Internet and online applications. To adapt to this boom and avoid software with less or poor quality, forecasters of software project work effort started to look for means or models to enhance their predictions, like AI-based predictive models, effort estimation frameworks, and AI-ready datasets for software endeavour estimation (SEE) [1].

Software Effort Estimation (SEE) is the process of estimating the effort required to develop a software system. AI-based predictive models [5], [6], including but not limited to Artificial Neural Network [7], Support Vector Regression, Gradient Boosted Tree, Random Forest, Extra Trees, XGBoost and hybrid modelling approaches were introduced [8], [9]. Effort estimation frameworks were proposed and implemented [10], [11], [12].

AI-ready datasets for SEE were made publicly available. Making use of the advantages of advanced machine learning analysis pipelines and the possible findings of other researchers' models is to deal with potential estimation cases with unseen projects [13]. Machine Learning (ML) is one of the most successful AI fields, which focuses on using data to train machines to learn and predict, classify, or make decisions without explicit programming [14], [15].

Table I summarizes a selection of recent literature from the last three years, highlighting the specific research areas and the particular challenges addressed in each study.

TABLE I. SUMMARY OF SPECIFIC REVIEWED PAPERS 2023-2025

No.	Reviewed papers		
	Research Areas	***Problems Addressed***	***References***
1.	AI in software development projects	AI challenges and software tools in digital project management	[5], [6], [16], [17], [18], [19]
2.	Risk evaluation in software development	Integrated ML decisional models Risk and challenges	[9], [20], [21], [22]
3.	AI and ML models for risk predictions in software development projects	ML in risk predictions, risk detection ML in early estimation of the software functional dimension	[16], [23], [24], [25]
4.	AI and ML effort estimation models in software projects	ML models analysis and identification of stable models	[11], [26], [27], [28]

Recent literature review reveals a strong interest in integrating artificial intelligence (AI) into software project management. However, structural deficiencies emerge regarding the absence of a universally accepted methodology for implementing AI in risk management and the fragmentation of approaches according to specific domains. Furthermore, risk prediction and effort estimation face technical limitations related to the use of datasets.

In this context, the present scientific work aligns with current research trends, contributing to the development of the software project management domain through methodological and applied contributions regarding the accurate prediction of development effort and the early identification of high-risk software issues, leveraging AI techniques.

Despite the extensive research on machine-learning-based effort estimation, several limitations remain. First, many studies focus exclusively on effort prediction accuracy without integrating risk detection mechanisms derived from prediction deviations. Second, prior work often evaluates models independently of their operational value in project management decision support. Third, relatively limited attention has been given to the transformation of regression outputs into interpretable early-warning indicators. [1], [5], [11]

This study addresses this gap by integrating effort prediction and threshold-based risk detection within a unified experimental framework, providing both predictive and actionable insights.

III. METHODOLOGY

Software development has become one of the key objectives for countries and companies in order to sustainably develop an economy and improve productivity. Software projects, however, are faced with many risks, leading to many largely failed projects. Risk assessment has been a hot issue in both theory and practice. Moreover, effort estimation is one of the most critical and challenging tasks in software project management.

Although software effort estimation has received extensive research attention in the last few decades, effort estimation is still a challenging issue [29], [30]. Many researchers have focused on various traditional and machine learning techniques for estimating software effort and project quality. A guide to good practices in risk management is presented in the study [31], which shows current theoretical models selected from the specialist literature, highlighting existing gaps, while developing practical applications for case studies in the automotive industry.

This research work combines the two important tasks, risk detection and effort estimation, in an integrated framework. The objective of the research was to investigate the idea of combining risk detection and effort estimation in the same model, using an end-to-end AI model.

Solving these tasks separately can bring some important information to project stakeholders. However, software project risks and efforts are closely related and can affect each other. This combination can allow the detection of a hidden class of both tasks, automatically detect the duration of each task, and traverse it recursively across the project history.

A. Implementation Framework

The proposed conceptual framework consumes the project repository as input and generates project risks and gathered exhibit information as output. Several key design components,

such as data representation, risk models, predictive models, and evidence gathering, will be detailed to deliver how the framework accomplishes its objectives (Fig. 1).

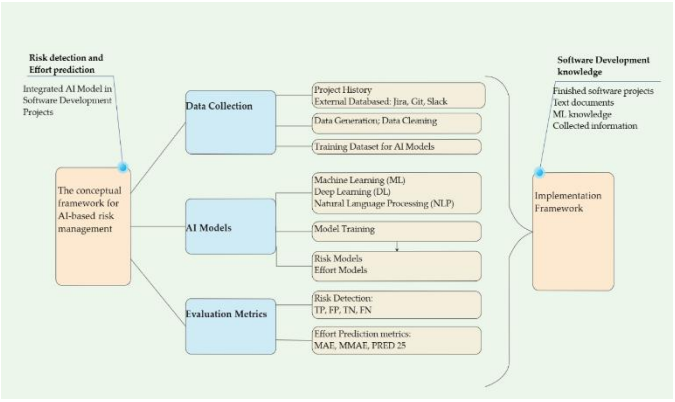

Fig. 1. Implementation framework.

In this framework, all these design components cooperate to maximize the detection ability of the model. Projects are represented using project repository data and converted into a joint representation framework, including a bipartite graph and a temporal representation.

B. Data Collection

The research project concerns the detection of risk factors that are likely to endanger the delivery of software systems on time or with the required quality, as well as the prediction of software effort adjustment for associated risk factors. The project mainly involves the innovation of two prototypes, one which performs risk detection and the other which performs risk prediction and visualization.

The data used has been generated using increments for planned hours, complexity of the task, team experience in years and requirements clarity, with a total of 500 rows used, where the first 20 have been exemplified in Table II. The simulated dataset was designed to reflect relationships observed in software project environments. Planned effort was modelled as the primary baseline predictor, while actual effort was generated as a function of planned effort, task complexity, team experience, and requirement clarity, combined with stochastic noise. The simulation assumes that higher complexity and lower team experience increase actual effort, while clearer requirements reduce uncertainty.

This controlled simulation approach allows the evaluation of model behaviour and risk detection mechanisms under known ground-truth conditions, which is consistent with experimental practices in predictive modelling research.

TABLE II. SAMPLE OF 20 ROWS OF TOTALLY USED DATA FROM THE 500 ROWS

Task ID	Data used				
	Sprint ID	*Planned hours*	*Complexity*	*Team experience*	*Requirement clarity*
1	4	62.37	5	5.62	1
2	3	36.23	4	2.21	1
3	5	68.97	3	2.98	3
4	4	56.39	5	7.48	4
5	1	9.35	1	0.86	3
6	5	78.10	5	3.96	1
7	4	61.37	5	5.84	1
8	5	63.31	3	1.63	5
9	1	11.99	4	0.86	5
10	3	37.13	3	1.54	4
11	2	30.92	2	7.39	1
12	5	74.29	4	0.57	5
13	4	52.22	2	1.91	4
14	5	66.18	2	0.73	3
15	3	36.59	3	1.33	1
16	2	29.85	4	5.15	5
17	1	8.41	2	2.44	2
18	2	27.66	3	6.12	4
19	3	34.98	1	3.87	2
20	1	7.92	2	1.05	4

C. Machine Learning and Models used

This study investigates the application of machine learning (ML) techniques to support effort prediction and early risk detection in software project management. The objective is to accurately estimate task-level development effort and to identify tasks with a high probability of schedule overrun, enabling proactive decision making before and during project execution.

Recent research has demonstrated the effectiveness of ML-based regression and classification models for software effort estimation and project risk analysis, particularly when complex, non-linear relationships exist between task characteristics, team factors, and execution outcomes [8], [11], [16]. Ensemble learning methods, such as Random Forest and Gradient Boosting, have been shown to provide robust performance and good generalization in such settings due to their ability to combine multiple weak learners and reduce variance and bias [26].

In this research study, two tree-based ensemble models are employed: Gradient Boosting and Random Forest. These models are trained on simulated task-level data described by planning, technical, and team-related features. Their performance is evaluated using standard regression metrics and compared in order to identify the most accurate and stable predictor for actual task duration.

D. Evaluation and Risk Detection Metrics

To assess both effort prediction accuracy and risk detection capability, standard metrics from regression and classification literature were employed, as commonly used in software engineering analytics and project management studies [1], [32].

For the evaluation of threshold-based risk classification, the following measures derived from the confusion matrix are used [33]:

- True Positive (TP): Number of truly high-risk tasks correctly identified as high-risk.
- False Positive (FP): Number of low-risk tasks incorrectly classified as high-risk.
- True Negative (TN): Number of low-risk tasks correctly identified as low-risk.
- False Negative (FN): Number of high-risk tasks incorrectly classified as low-risk.

Based on these values, Precision, Recall, F1-score, and Accuracy are computed to evaluate the effectiveness of the early-warning mechanism.

E. Effort Prediction Metrics

The predictive accuracy of the regression models is evaluated using the following metrics, which are standard in software effort estimation research [1], [16]:

- Mean Absolute Error (MAE): Measures the average absolute deviation between predicted and actual effort.
- Root Mean Squared Error (RMSE): Penalizes large errors and reflects overall prediction dispersion.
- Coefficient of Determination (R^2): Indicates the proportion of variance in actual effort explained by the model.

These metrics provide complementary views of model performance in terms of average error magnitude, sensitivity to outliers, and explanatory power.

Planned effort represents the initial human estimate defined during project planning, before task execution. Actual effort reflects the true execution time observed after task completion. The machine learning model uses planned effort together with additional contextual features, such as task complexity, team experience, and requirements clarity, to predict actual effort more accurately. The difference between planned and actual effort represents estimation error, while the difference between predicted and planned effort serves as an early indicator of potential schedule risk.

The proposed framework integrates effort prediction and risk detection into a unified, data-driven decision-support workflow for software project management. Task-level features are extracted from project planning and execution data and used as inputs to the trained regression and classification models. Predicted effort values are compared with planned estimates to derive deviation-based risk indicators, and threshold-based rules are applied to flag moderate and severe overruns.

The framework provides numerical predictions, confusion-matrix-based evaluation, and visual analytics, including learning curves, validation curves, feature importance plots, and risk distribution across sprint quantiles. Such integration of predictive modeling with interpretable outputs supports project managers in understanding both the expected effort and the underlying drivers of schedule risk.

This approach is consistent with recent trends in data-driven project analytics, which emphasize the combination of machine learning models, transparent evaluation metrics, and visualization to enhance trust, usability, and practical adoption in real-world software project environments [4], [34].

IV. Model Development

This section describes the development of the machine-learning-based framework for task-level effort prediction and early risk detection. The proposed approach follows a structured workflow that includes data preparation, feature definition, model training, and hyperparameter tuning, in line with established practices in software analytics and predictive modeling [1], [16], [35].

A. Data Preprocessing

Data quality and representativeness are critical for the reliability of any data-driven model. In the present study, a simulated dataset of 500 software development tasks is used to ensure controlled experimentation and the availability of ground-truth values for both actual effort and deviation-based risk labels. The dataset includes planning, technical, and team-related attributes, enabling the analysis of heterogeneous factors that influence task duration and schedule risk.

Before model training, exploratory analysis is performed to examine feature distributions, correlations, and potential outliers. The dataset is then partitioned into training and test subsets using an 80/20 split, ensuring that the proportion of overrun and high-risk tasks is preserved in both sets. This leakage-free evaluation protocol follows recommendations from previous work on effort and defect prediction to ensure credible and unbiased performance assessment [1], [36].

B. Feature Selection

Feature engineering and selection play a crucial role in software effort estimation. Prior studies have shown that task size, complexity, developer experience, and requirements-related factors are among the most influential drivers of development effort [8], [16], [37]. In this work, the feature set includes planned effort, task complexity, team experience, requirements clarity, number of dependencies, story points, and structural complexity indicators.

Rather than applying an explicit wrapper-based feature subset search, the importance of individual predictors is analyzed using model-intrinsic feature importance measures derived from tree-based ensembles. This approach provides an interpretable ranking of features and avoids the computational overhead and potential overfitting associated with exhaustive subset selection methods [37], [38]. The resulting importance analysis supports both model understanding and managerial interpretation.

C. Training the Models

Two ensemble learning algorithms are employed for effort prediction: Gradient Boosting and Random Forest. These methods are well-suited for tabular software engineering data and are known for their ability to capture non-linear relationships and feature interactions while maintaining good generalization properties [26], [39].

Models are trained on the training subset and evaluated on the held-out test set using standard regression metrics. Predicted effort values are subsequently transformed into deviation-based indicators to support threshold-based risk classification. This two-stage procedure enables the integration of continuous effort forecasting with discrete early-warning signals for schedule overruns.

D. Hyperparameter Tuning

The performance of ensemble models depends on a set of hyperparameters that control model complexity and learning dynamics, such as the number of trees, maximum tree depth, and learning rate. Hyperparameter optimization is therefore conducted using cross-validation-based search strategies, following established guidelines in machine learning research [40], [41].

For each model, a range of candidate values is defined for the most influential hyperparameters, and validation curves are analysed to identify configurations that provide a favourable trade-off between bias and variance. Learning curves are additionally employed to assess how predictive performance evolves with increasing training set size and to verify the absence of severe overfitting.

This systematic tuning and validation process ensures that the selected Gradient Boosting and Random Forest models achieve robust generalization performance and provides empirical justification for the final parameter settings used in the experimental evaluation.

V. Results and Discussion

A contribution of this research is the definition of a taxonomy of the identified problems and their classification, based on the previous study of the specialized literature. A set of state-of-the-art Machine Learning algorithms was selected for each problem to benchmark the best-performing one. The categorization scheme can be used for other scholars and practitioners to classify research problems in software engineering in general, not just Machine Learning-based ones. It is required that, for each type of problem to be tackled by Machine Learning, the problem taxonomy be specified.

The strong importance of planned hours does not represent target leakage, as planned effort is defined before task execution and reflects the initial human estimate. In practical software project environments, planned effort serves as a baseline estimate, while actual effort deviates due to technical and organizational factors.

To predict the actual task duration, two ensemble-based regression models were compared: Gradient Boosting and Random Forest. The results indicate that the Gradient Boosting model achieved the best overall performance, with the lowest MAE and RMSE and the highest R^2 (Fig. 2–4). This demonstrates the model's ability to capture the complex relationships between task features and actual duration, significantly reducing deviations from planned estimates.

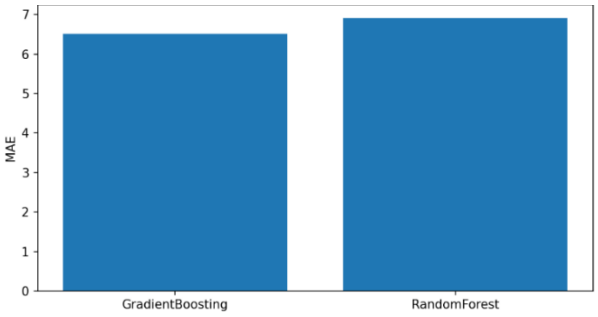

Fig. 2. Comparison of MAE.

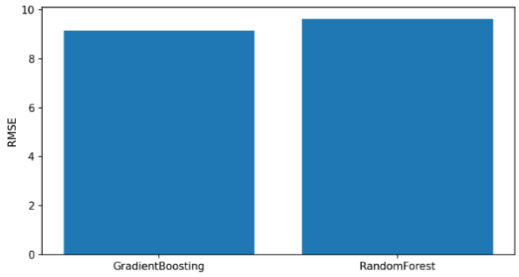

Fig. 3. Comparison of RMSE.

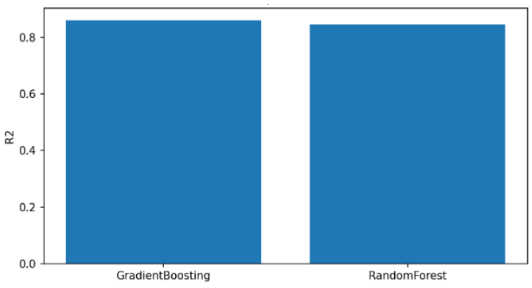

Fig. 4. Comparison of R^2.

A detailed analysis of the optimized Gradient Boosting model shows a strong correlation between predicted and actual values (Fig. 5). The residuals distribution is centered around zero with relatively low dispersion, confirming that the model does not introduce systematic errors and achieves robust accuracy across most tasks.

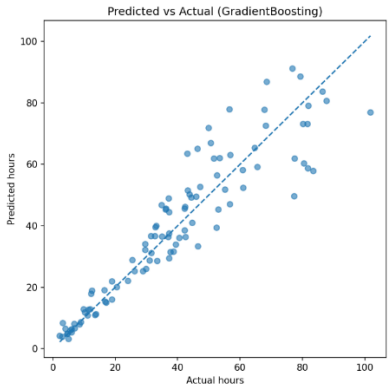

Fig. 5. Comparison between predicted and actual values.

The distribution of prediction errors was analyzed through the residual plot of the best-performing model (Fig. 6), which shows that most errors are centered around zero, indicating good calibration, while a limited number of tasks exhibit larger deviations, reflecting the inherent uncertainty of software development processes.

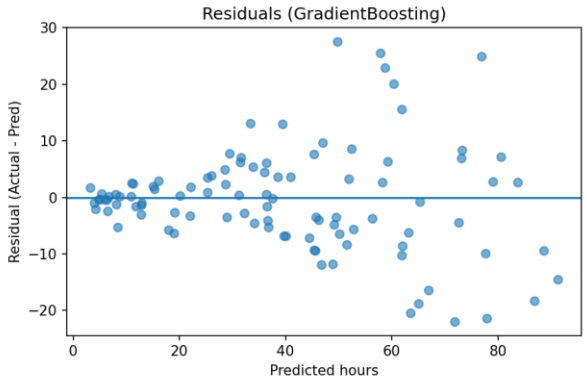

Fig. 6. Residuals of the gradient boosting model.

A. Risk Detection Outcomes

Early identification of schedule risk is essential for effective project control, as it enables timely corrective actions before deviations propagate at the project level [42]. In this research, risk is defined in operational terms, based on the deviation between predicted and planned effort, and is assessed using threshold-based classification supported by machine learning.

Risk labels are not directly learned from regression outputs but are derived from deviation thresholds between predicted effort and planned effort, reflecting operational definitions of schedule overrun risk.

This approach mirrors real-world project monitoring practices, where deviations from planned estimates serve as early-warning indicators. The classification stage, therefore operationalizes deviation thresholds rather than introducing an independent predictive target.

Two risk levels are considered. First, an overrun event is defined when the predicted effort exceeds the planned hours by more than 20%. Based on this criterion, a confusion matrix is computed on the test set of 100 tasks (Fig. 7), allowing the identification of true positives, false positives, true negatives, and false negatives. The results show that the majority of non-overrun tasks are correctly identified, while a subset of true overruns is successfully detected, providing a practical early-warning mechanism with a controlled false-alarm rate.

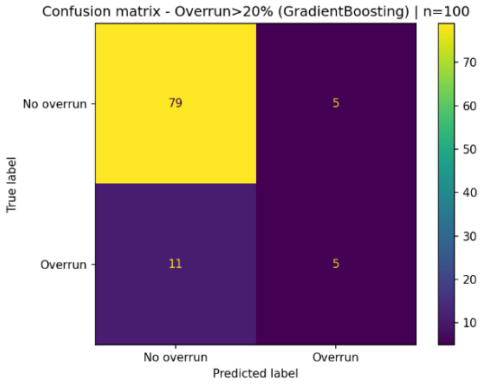

Fig. 7. Confusion matrix for schedule overrun detection based on a 20% deviation threshold between predicted and planned effort.

Second, a high-risk category is defined for severe deviations exceeding 30% of the planned effort. A Random Forest classifier is trained using task features and model-derived error indicators to discriminate between low-risk and high-risk tasks.

The corresponding confusion matrix and classification report (Fig. 8) indicate high overall accuracy and good recall for the critical class, demonstrating the model's ability to highlight tasks that are most likely to cause significant schedule disruption.

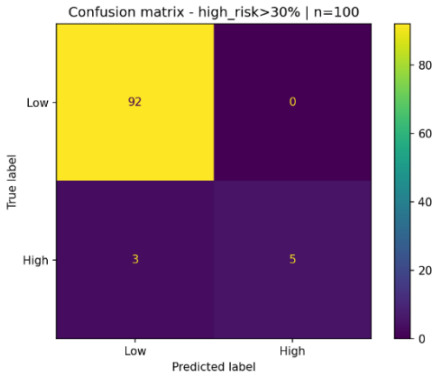

Fig. 8. Confusion matrix for high-risk task classification using a 30% deviation threshold between predicted and planned effort.

In addition, the distribution of predicted and actual high-risk tasks across sprint quantiles (Fig. 9) reveals that higher workload segments tend to concentrate a larger proportion of risky tasks. This analysis supports the use of risk-aware planning and monitoring strategies, enabling project managers to allocate attention and mitigation resources to the most critical parts of the schedule.

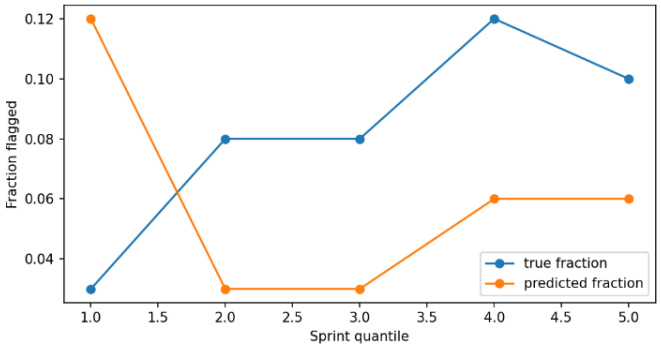

Fig. 9. Distribution of true and predicted high-risk tasks across sprint quantiles.

Overall, the proposed risk detection approach transforms effort prediction errors into interpretable and actionable indicators, linking regression performance directly to operational decision support through threshold-based alerts and confusion-matrix-driven evaluation.

B. Effort Prediction Accuracy

The accuracy of the proposed effort prediction models was evaluated using standard regression metrics, namely Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and the coefficient of determination (R^2). Two ensemble-based regressors, Gradient Boosting and Random Forest, were trained and tested on the simulated dataset using an 80/20 train–test split.

The comparative results, reported in Fig. 1–3, show that the Gradient Boosting model achieved the best overall performance, with lower MAE and RMSE values and a higher R^2 compared to Random Forest. These results indicate a superior capability of the model to capture the non-linear relationships between task characteristics and actual development effort.

A detailed analysis of the predicted versus actual values (Fig. 4) reveals a strong alignment around the diagonal, confirming good calibration across the full range of task durations. The residual plot (Fig. 6) further shows that most errors are centered around zero, with no evident systematic bias, demonstrating robust predictive behaviour.

Feature importance analysis for the best-performing Gradient Boosting model (Fig. 10) highlights planned_hours as the dominant predictor of actual effort, followed by task complexity, team experience, and requirements clarity. This ranking is consistent with software project management practice, where initial estimates provide the baseline, while technical difficulty and human factors significantly influence execution outcomes.

The feature importance analysis (Fig. 10) highlights that planned_hours is the dominant predictor, as expected in a project management context. However, other factors such as task complexity, team experience, and requirement clarity also contributed to prediction accuracy, emphasizing their relevance in anticipating actual task duration.

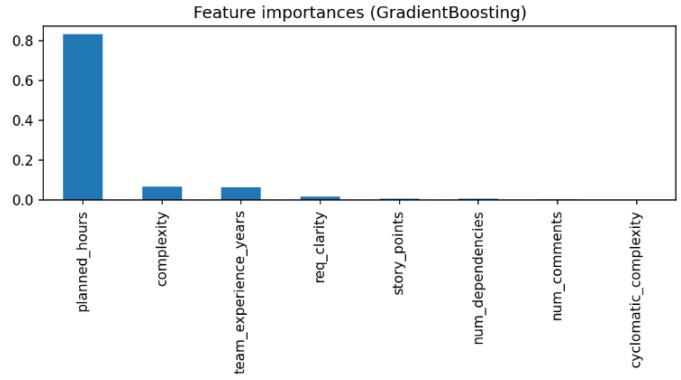

Fig. 10. Importance of features used.

In addition to task duration prediction, a classifier was developed to identify high-risk tasks likely to exceed their planned duration. The risk classifier achieved an overall accuracy of approximately 95% and a recall of 0.80 for the high-risk class, indicating a strong capability to detect critical situations (Table III).

The fraction of flagged tasks per sprint quantile (Fig. 9) further illustrates differences between the true and predicted distributions of high-risk tasks, highlighting where early risk detection can be improved.

TABLE III. PERFORMANCE OF THE HIGH-RISK TASK CLASSIFIER (DEVIATION > 30%)

Class	Performance of the High-Risk Task			
	Precision	*Recall*	*F1-score*	*Support*
0 (not high-risk)	0.97	1.00	0.98	92
1 (high-risk)	1.00	0.62	0.77	8
Accuracy			0.97	100
Macro avg	0.98	0.81	0.88	100
Weighted avg	0.97	0.97	0.97	100

To analyze generalization and model stability, learning and validation curves were computed using cross-validation. Fig. 11 presents the learning curve of the Gradient Boosting model, showing the evolution of training and validation error as the size of the training set increases, and indicating good convergence without severe overfitting.

Fig. 12 reports the validation curve for the Random Forest model with respect to the number of trees, highlighting the trade-off between model complexity and generalization performance. These analyses confirm the robustness of the selected ensemble models and support the choice of hyperparameters used in the experimental evaluation.

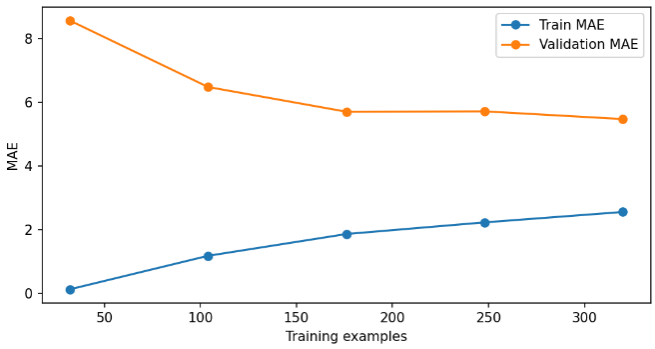

Fig. 11. Learning curve of the gradient boosting regressor showing the evolution of training and validation MAE as a function of the number of training samples.

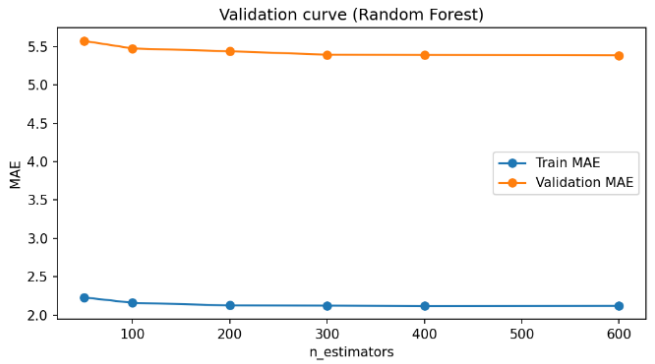

Fig. 12. Validation curve of the random forest regressor illustrating the impact of the number of trees (n_estimators) on training and validation MAE.

The analysis of feature importance (Fig. 10) revealed that planned hours is the dominant predictor, which is intuitive since initial estimates usually provide the baseline for task planning. However, secondary factors such as task complexity, requirements clarity, and team experience also contribute to prediction accuracy, highlighting the relevance of both technical and human-related aspects in effort estimation. This indicates that integrating quantitative planning variables with qualitative project characteristics improves the robustness of predictive models.

The residual analysis of the best-performing Gradient Boosting model (Fig. 6) confirms that most prediction errors are centered around zero, with no evident systematic bias, demonstrating stable and well-calibrated predictions. Nevertheless, a limited number of tasks exhibit larger deviations, suggesting the presence of latent factors (e.g., unexpected blockers, shifting priorities, or external dependencies) that are not explicitly captured by the available features.

In terms of risk classification, the proposed approach achieved encouraging results, with an overall accuracy of approximately 97% and a recall of 0.62 for the high-risk class (Table III and Fig. 10). This indicates an effective capability to detect most critical tasks, which is particularly valuable for project managers aiming to mitigate delays at an early stage. For the high-risk class, the model achieved a precision of 1.00 and a recall of 0.62. This indicates that while the model is precise in identifying high-risk tasks, it fails to detect a portion of them, as reflected by the lower recall. From a practical perspective, this suggests that when the model predicts a task as high-risk, the prediction is highly reliable, although some high-risk tasks may remain undetected.

Taken together, these findings demonstrate that machine-learning-based effort prediction combined with threshold-based risk classification can provide valuable decision-support for project managers, enabling more accurate time planning and proactive risk mitigation.

Future work should focus on improving generalization by incorporating additional contextual information, such as team workload, communication patterns, and organizational constraints, as well as on integrating explainable AI techniques to enhance transparency and trust in model-driven recommendations.

C. Comparison with Traditional Methods

AI-based techniques bringing enormous effectiveness are into considerations and analysis. For the same purpose, traditional techniques such as analogy-based ones can be analyzed which have been proved effective in many fields, including risk management and cost/effort estimation in software projects [43]. Performance-wise, techniques like random forest and ensemble models outperform the rest when used without optimization.

However, they become less competitive when hyper-parameter optimization is explored. On the contrary, tree-based methods exhibit different performance with hyper-parameter optimization involved. Such differences might be due to the overfitting issue with tree-based methods.

In addition to predictive accuracy, computational efficiency is an important aspect when considering the practical deployment of machine learning models in project management environments. Although ensemble methods such as Gradient Boosting and Random Forest can deliver accurate predictions, their training and hyperparameter tuning require a higher computational effort compared to simple baseline models. This computational cost depends on dataset characteristics, including the number of tasks, the dimensionality of the feature space, and the complexity of the model search space.

In the present study, the dataset size (500 tasks) and the moderate number of features allow the models to be trained within a reasonable time, while cross-validation and parameter optimization still represent the most computationally demanding steps. This confirms that, in data-driven project analytics, model selection and tuning play a crucial role not only in terms of accuracy but also in terms of computational resources.

Table IV summarizes the regression models evaluated for predicting actual task duration. Among the considered approaches, the Gradient Boosting regressor achieved the best overall performance, with the lowest MAE and RMSE and the highest R^2, while the Random Forest model showed slightly lower but comparable results.

These findings indicate that tree-based ensemble methods provide a favorable balance between predictive accuracy and

computational feasibility for task-level effort estimation in software project management.

TABLE IV. MODEL PERFORMANCE COMPARISON AND HYPERPARAMETER OPTIMIZATION

Regression Models	Effort Prediction Metrics		
	MAE	***RMSE***	***R²***
Gradient Boosting	6.51	6.51	0.86
Random Forest	6.91	6.91	0.84

D. *Limitations of the Study*

Despite the encouraging results obtained with the proposed machine-learning-based framework, several limitations of the present study must be acknowledged.

First, the experimental evaluation is conducted on a simulated dataset. Although the simulation was designed to reflect realistic relationships between planning variables, team characteristics, and actual effort, it cannot fully capture the complexity, uncertainty, and organizational dynamics of real industrial software projects. Consequently, the reported performance metrics should be interpreted as indicative of the potential of the approach rather than as definitive benchmarks.

Second, the analysis is restricted to task-level static features and does not explicitly model temporal dependencies, evolving project context, or interactions between tasks over time. Factors such as changing priorities, resource reallocation, communication patterns, and external constraints may significantly influence effort and risk, but are not represented in the current feature set.

Third, risk detection is based on fixed deviation thresholds (20% for overrun and 30% for high-risk classification). While such thresholds are commonly used in practice and allow the construction of interpretable confusion matrices, optimal threshold values may vary across organizations, project types, and risk tolerance levels. More adaptive or cost-sensitive thresholding strategies could further improve the practical relevance of the alerts.

Finally, only two ensemble models, Gradient Boosting and Random Forest, were considered in the current implementation. Although these models showed strong predictive performance, other regression and classification techniques, as well as hybrid and temporal models, may provide additional insights and should be investigated in future work.

The present study does not include explicit comparisons with simple baseline predictors such as mean estimation or linear regression. Future work will include such baselines to quantify incremental predictive improvements provided by machine learning models.

As another point for future research, it will focus on validating the proposed framework on real-world industrial datasets, extending the feature space with temporal and organizational variables, and integrating explainable AI methods to enhance transparency and trust. Such extensions are expected to strengthen the generalization capability of the models and to further support their adoption as decision-support tools for effort prediction and early risk detection in software project management.

VI. IMPLICATION FOR PRACTICE

The following recommendations are conceptual and derived from the observed predictive patterns and risk detection framework. They are intended to illustrate potential practical applications rather than to represent empirically validated interventions through user studies or industrial deployment.

Based on the issues in the assessment, the following recommendations can be considered, in specific steps [1]:

1) Overcoming the lack of assessment breaks: To overcome this obstacle, such an organization working on a software project management should time-box efforts to incorporate risk assessment alongside code reviews and design discussions. As a tangible strategy, a small postmortem section could be added as a code review template. If efforts are maintained despite tight timelines, a continuously available assessment with adequate success measures is trivial.

2) Communicating effort estimation and improvement properties: This could be a challenge given the differences in individual engineering types, development environments, and product types. However, efforts to make experiences and properties public could still be undertaken by bundling characteristics to common classes and focusing on visualization styles that communicate relative differences, such as spider charts or illustrative statistics. Additionally, risk assessment as a service could be converted to more general terms.

3) Mitigating limited development time: While development time generally presents a significantly higher system importance for high-performing traditional teams, such an organization working on software project management still has many short- to medium-term development priorities. Building on continuous lack-of-time provisions, urgent and easily implementable slam-dunk uses, such as enabling one-click creations and using fully loaded default configurations, should be prioritized.

4) Providing a starting use for initial negative perception: To overcome this difficulty, a customized start with familiarization sessions is essential. As a start, before implementations, several risk assessments could be conducted based on historical data from past development processes. In addition, features matching the working style of existing platforms should be prioritized.

5) Getting out of the necessity loop: While the belief that risk assessment necessarily needs to be overcome, a potential shift in tasks to a more exploratory state should be encouraged. However, to soothe the fear of losing a successful assessment loop, supporting functions for incremental advances, such as early warnings, visualizations of development processes, and use encouragement, could be prioritized.

6) Overcoming a negative perception of AI-based approaches: Before AI incorporation, natural-language-based misunderstanding mitigations could be supported. Humans still need to completely classify issues and distinguish domain-

specific uses based on individual understanding. Possible augmentations include focused simulations based on recorded engineering tickets that fall below a certain length, as well as adjustments to existing screening methods for static analysis issues.

A. Integrating AI in Project Management

The rise of AI brings new opportunities and challenges to the discipline of project management. AI has the potential to significantly transform project management by assisting project managers and team members in various ways, such as automating repetitive, high-volume tasks of low business value to free resources for more productive work, mining big data repositories to provide project analytics for team formation, effort estimation, risk prediction, and plan development, providing actionable recommendations, and providing decision reports for project managers to understand the implications of the recommendations [44].

Despite these potential transformations, the successful adoption of AI in project management is lower than that of other software engineering activities. Understanding the factors that influence the intention to adopt AI and the various readiness factors is essential for researchers and software management practitioners in facilitating AI adoption and benefiting fully from it.

Software project management is a challenging point in software project management by itself due to software development's dynamic, unique, and complex nature. Moreover, software project managers are often blamed for the failure, exceeding costs, or not being deployed on time in a software project. Consequently, the management area of software projects has faced strong challenges. The estimation of effort required for software development is one of the important and difficult challenges [45].

Project managers have always sought methods, techniques, and tools for estimating project efforts promptly before the start of the implementation to produce budgets and plans, attract potential clients, and solicit collaboration contracts with suitable teams, while misleading manipulation of budget issues has adverse effects on firms and society. The effort estimation issue is the task of predicting the amount of effort required to develop a software project. An effort estimation technique produces a prediction of the required effort for developing the software and is evaluated based on its estimation accuracy.

B. Training and Development for Teams

Training efforts should focus on developing processes as well as increasing the skills of the coding team. Team members involved in requirements validation, architecture, component design, and component testing can perform their designated activities and review another team member's output.

A similarity in effort between a person's own task effort and a co-worker's task effort indicates risk events for the review task. A similarity in effort between a component's design task effort and its coding task effort indicates the importance of the design document and potential errors in both related processes.

Abnormal task completion effort and ongoing task effort can indicate potential risk for a task or a team member. These detected risks should be reviewed and proceed according to the established process [1]. Available training sessions on each related skill set should be reviewed and classified according to TC, TD, and TE. Ignored training with obvious risks shown when analysing the effort of TC tasks should be scheduled as soon as possible.

When a sidetracked coding or design process is detected, support should be offered to the potentially distracted member in terms of both time and understanding. Such support may involve additional training on the skill needed, correcting the component's design, pair programming, or inspecting coding and design documents. Effort estimation tools should always be installed and used. They can help members understand the estimation process for task effort quantification. Task effort estimation is another area in need of more effort for both the training program and the processes in which members account for the final estimation project.

Implementing a method for comparing the estimated and actual effort needs attention. One possibility is to produce a secondary process to find the differences in the already available reports, which should be useful in refining the training tiering process.

VII. Conclusions

As software project managers are required to control costs and resources in increasingly data-driven environments, accurate estimation of the effort required to implement Software Development Requests (SDRs) becomes a critical decision-support activity.

Through the developed models, the use of machine learning algorithms is demonstrated as an effective solution for predicting software task duration, estimating effort, and early detection of risks in software development projects. These models can capture complex relationships between technical, planning, and human factor variables, demonstrating promising predictive capability within a controlled experimental setting.

The research provides decision support that can be integrated into a management team's workflow, regardless of the users' level of technical AI expertise. The transition from simple numerical estimation to proactive risk detection allows managers to prioritize interventions where the negative impact is greatest. Critical periods in the software project development cycle can be identified, and resources can be allocated dynamically.

The study aligns with current research trends in the field and contributes to the development of machine-learning-based models that effectively support effort estimation and risk assessment by learning complex, non-linear relationships between planning attributes, team characteristics, and actual execution outcomes.

A. Trends and Future Research Directions

From a project management perspective, the near-term impact of artificial intelligence is expected to be most significant in the area of data-driven planning and control rather than in fully autonomous decision making [46], [47]. AI techniques will

optimize conventional management methodologies by integrating dynamic forecasting, early-warning systems, and scenario simulations, all grounded in the continuous flow of project data.

The integration of predictive analytics with established project management tools, such as backlog management systems, issue trackers, and resource planning platforms, can enable tighter feedback loops between planning and execution. Such integration supports adaptive scheduling, dynamic risk assessment, and evidence-based decision making throughout the project lifecycle.

At the same time, challenges related to data quality, model interpretability, and organizational acceptance remain central research issues. To foster trust and adoption, future studies should investigate explainable AI techniques that clarify why certain tasks are predicted to be risky or time-consuming and how specific features (e.g., complexity, dependencies, or team experience) contribute to these predictions [29], [31].

Furthermore, extending current models with temporal and organizational factors, such as workload dynamics and inter-task dependencies, is expected to enhance their ability to forecast effort and risk in complex, real-world software projects. This perspective positions machine-learning-based effort prediction and risk detection not as isolated analytical components, but as integral elements of next-generation, data-driven project management environments [40].

Consequently, future work will focus on the systematic collection of task-level datasets from real software projects, including both successful and problematic deliveries, in order to improve model generalization and robustness. In addition, integrating predictive models with project management information systems can facilitate automated data acquisition and continuous model updating, as suggested in recent research on data-driven project analytics [4], [34].

Self-Supervised and Explainable Transformer-Based Architectures for Robust End-to-End Speech and Language Understanding

Mahfuzul Huda
Department of Computer Science-College of Computing and Informatics, Saudi Electronic University, Riyadh, Kingdom of Saudi Arabia-11673

***Abstract*—The primary aim of this study is to meld self-supervised learning techniques with transparent transformer-based frameworks to enable resilient, end-to-end speech and language understanding, alongside pretraining deep transformer models using unannotated speech and text corpora. But the system's complicated structure makes it very hard to compute, and its ability to be understood depends in part on using rough benchmarks to judge feature relevance. This research work proposes an explainable, systematic transformer-based framework concept for understanding voice and language that integrates self-supervising learning with built-in explainability. The model proposed here presented a low word error rate, high accuracy, and interpretation on multiple datasets. The framework has many strengths, but it also has some challenges, which are highlighted in the work. This deep transformer architecture needs a lot of computing power, and figuring out how important something relies on indirect truth values. In the future, planned improvements include making the framework work with more than one language and more than one field, making transformer models work better in real time, and adding assessment methods that focus on human perspectives to make it even easier to understand. Subsequently, we will work on expanding into datasets that are multilingual and cross-domain, making more efficient forms of transformers for real-time use, and employing human-centered assessment to verify that we are interpreting things correctly in real time.**

Keywords*—Transformer models; self-supervised learning; explainable AI; speech recognition; natural language understanding; end-to-end systems

I. Introduction

Speech and language understanding systems are the basis for modern technologies that let people and computers talk to each other. These include automatic speech recognition (ASR), spoken language comprehension, machine translation, and chatbots [11], [13]. Recent improvements in deep learning, especially in transformer-based architectures, have made these systems much better by making it possible to represent long-range contextual dependencies in speech and text. There are still two big difficulties: the fact that model predictions are often only partially understood and the need for a lot of labelled training data [22].

Most modern speech and language understanding systems use supervised learning models that need a lot of handwritten interpretation. This process is costly, takes a lot of time, and is sometimes not possible for low-resource languages or applications that are specific to a certain area [12]. In addition, advanced transformer models usually act as a black box, which gives us some insight into how decisions are made inside. This lack of openness makes it difficult to trust people and hold them accountable if jobs are lost in critical security areas, including healthcare, forensic science and smart surveillance systems [21].

Self-supervised learning (SSL) has emerged as a formidable alternative to traditional teacher-centered learning if the model enables critical insights directly from large amounts of unlabeled data. At the same time, comprehensible artificial intelligence (XAI) has become increasingly popular as a way to understand how and why deep learning models make accurate predictions [25]. Most research, on the other hand, looks at interpretation on its own, and not many have tried to come up with combined approaches that combine the two paradigms of SL dialects and the ability to grasp a wide range of languages.

A. Problem Statement

Even though there has been a lot of development, modern transformer-based speech and language comprehension systems are still at risk from a number of major dangers. These models depend a lot on large-label datasets, which makes them hard to scale, work with, and be helpful in diverse languages and places [14], [16]. Moreover, their narrow terminology makes it difficult to trust and hold people accountable, especially in security-critical applications where clear decision-making is required [23]. The performance of the proposed model is also influenced by acute resources or conditions and noise settings. The present method rarely integrates self-monitoring learning with terminology or with the ability to define within a single framework or within a single framework [26].

B. Research Objectives

The main objective of this work is to build a coherent variable-based model that integrates self-monitoring learning with challenges related to speech and language comprehension [8]. The proposed model and structure are designed to clarify things at the phonological and linguistic levels. The study also wants to see how well the models work in noisy and low conditions using publicly available benchmarking datasets. It will also provide quantitative performance indicators and qualitative terminology assessment [2], [9].

C. Contributions

Initially, it provides a single framework for both automatic voice recognition and language understanding functions [4], [10]. Subsequently, it demonstrates an explainable transformer architecture and end-to-end self-supervised learning, if the model understanding uses appropriate attribution and attention methods, as well as prior learning self-monitoring variable datasets. Finally, the work uses standard and benchmark datasets to analyze experimentation and interpretability. The result shows that the model is more transparent without losing the ability to make accurate predictions.

II. Related Work

Transformer-related, variable-based structures have significantly revolutionized natural language processing by replacing data recursive structures with egocentric approaches that can describe long-range relationships in succession. These models were first designed for text-based and character applications [1], but they have now been effectively adapted for multiple signal processing. This allows for end-to-end learning that captures both phonological and linguistic patterns, which greatly increases performance on automatic speech recognition parameters. Even while transformer-based speech models have worked well in the lab, they usually need a lot of labeled data and don't work well in the real world when there is noise and variability, which makes them less effective in general [15].

Self-monitoring concept focuses on the data value recognition and understanding functions, which have been a popular technique to learn value representations from unlabeled, untagged values instead of relying on labeled datasets [6] [3], [19]. Based on speech and value processing, making predictions with masks. Solution L: Streaming with audio and RAW inputs. Speech processing, contrastive learning, and masked prediction are all used to improve performance. Subsequently, SL Solution focuses on streaming with raw audio inputs. There was a big improvement in the speech recognition (SR) performance [5], speech recognition (SR) performance was eventually enhanced [7]. Furthermore, extensive self-monitoring concepts before training in natural language processing and text corpora have consistently elevated performance across many language comprehension metrics. But much of the former S.S. Model operates alone through speech or writing instead of thinking collectively in a single system. The purpose of interpretive artificial intelligence is to make deep learning models easier to understand by using methods like attention visualization, attribute attribution, and contextual distribution to show how they work [20]. For the training and learning of machines, the L.P. The application of X of AA approaches has been extensively examined; nonetheless, their incorporation into end-to-end transformer structures, particularly in multimodal speech and language systems, remains constrained [17], [18].

Recent studies indicate that numerous interpretive strategies are utilized post-hoc rather than being directly included in pattern training, presenting further hurdles to speech patterns owing to the intricacy and ephemeral characteristics of sound signals [24], [27], [28], [29]. In short, despite significant advances in individual self-directed learning and interpretive artificial intelligence, there is a clear lack of language and understanding or integration to strengthen, define and enhance performance in a coherent, end-to-end transformative framework. This work attempts to bridge this gap by integrating self-monitoring representational learning with interpretive methods based on phonological and linguistic processes.

III. Proposed Methodology

The suggested methodology provides a comprehensive framework for speech and language comprehension, including self-monitoring, representational learning, transformer-based end-to-end modeling, and internal interpretation methods. The entire system is designed to work on data efficiency, elasticity and interpretability at the same time, though not as efficiently as most existing systems.

Fig. 1 shows that the structure has three main parts. First, the self-supervised representation learning module takes out both significant and unnecessary aspects from a lot of speech and text input that doesn't have any labels. These representations are then put into a transformer-based encoder-decoder model that does speech recognition and language comprehension tasks. Lastly, the Interpretation and Interpretation module sheds light on how the model makes decisions at both the sound and semantic levels, making it possible to make accurate and clear predictions.

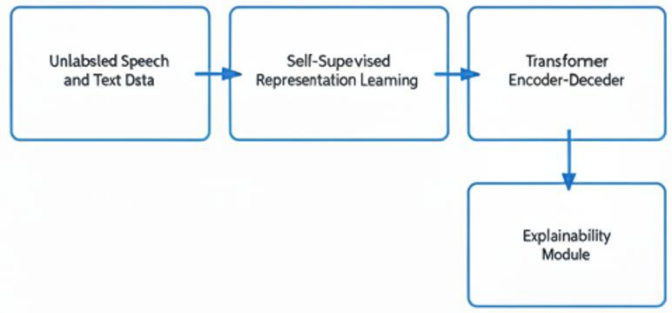

Fig. 1. Architecture of the proposed framework.

You can see from the figure that the proposed model initially uses self-supervised learning to find strong representations from unlabeled speech and text input. These representations are then processed by a transformer encoder and decoder. The interpretability technique then gives a clear explanation of the model. The structure of an articulated, stated, and proposed framework for self-monitoring and interpreting speech and language comprehension based on transformers.

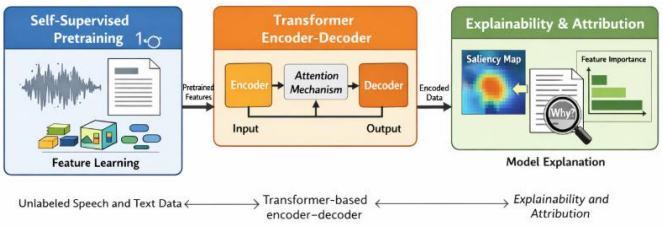

Fig. 2. Core modules for speech and text.

The system has three main layers: first, self-monitoring representation learning, transformer-based encoder-decoder modeling, and an integrated interpretation module, which is shown in Fig. 2.

A. Self-Supervised Computational Learning

The suggested approach uses self-monitoring learning (SSL) to find and extract robust representations from unclear voice and text values, so that users and end points, which they don't have to rely on manually evaluated data as much.

$$X = \{x_1, x_2, \ldots, x_n\}$$

X is a set of unlabeled, unclear extracted data points, with each input xi being either a raw voice waveform or a tokenized text sequence. The SSL module takes each input and maps it to a hidden embedding z. This way, semantic inputs are close to the embedding region, while non-verbal inputs are far away.

The objective of the training is to apply contrast learning loss, which encourages positive pairs made by data augmentation to be more similar and discourages negative patterns from being more similar:

$$\mathcal{L}_{SSL} = -\sum_{i=1}^{N} \log \frac{\exp\left(\frac{\text{sim}(z_i, z_i^+)}{\tau}\right)}{\sum_{j=1}^{N} \exp\left(\text{sim}(z_i, z_j)/\tau\right)} \quad (1)$$

Here, in this framework, the value z + is a given positive sample of datasets z that was made better by using techniques like time dilation, time frequency masking, speech spec augmentation, or text masked token prediction. The function sim () shows how similar two cosines are accurately shown, and τ is the temperature determinant that affects how strong the distribution is. Here, this equation defines a contrastive loss function, commonly applied in self-supervised learning, that encourages the model to cluster similar examples closely in its feature space while pushing apart dissimilar ones; other definitions are:

- N – Datasets and Training Configuration (Simulated) used to count the number of samples (data points) in a batch (Text corpus: 10 million sentences sampled from Common Crawl).
- z_i – the embedding for the i-th sample.
- z_i^+ – the "positive" counterpart of z_i (for instance, another augmented version of the same input).
- z_j – the embedding of the j-th sample in the batch (which may serve as either a positive or a negative example).
- sim(a,b):- a function calculating the similarity between a and b (often implemented via cosine similarity).
- Speech corpus: 960 hours of LibriSpeech audio
- Batch size: 256
- Learning rate: 3×10^{-4}
- τ (tau):- the temperature parameter; (τ) that scales the similarity values. Here, the Temperature parameter: τ = 0.07

Fig. 3 shows how well the contrast objective works. It shows that semantic samples get more similar as the training age goes up, whereas the underlying data are more spread out across the domains concerned.

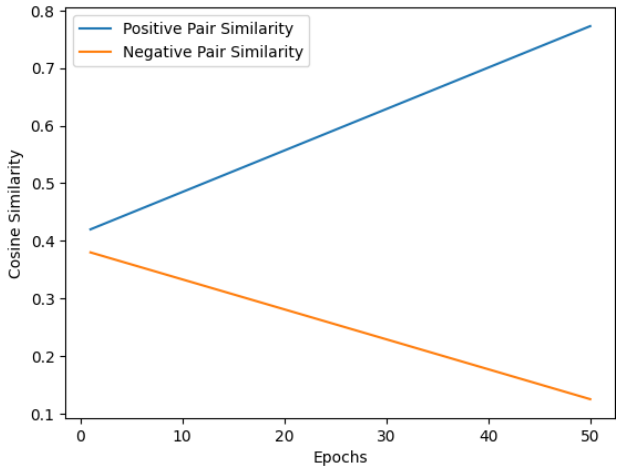

Fig. 3. Contrastive similarity trends during SSL training.

Fig. 3 shows how the cosine similarity between positive and negative sample pairs changed during self-monitoring compared to pre-training. As training goes on, the similarity between positive pairs slowly rises from 0.42 to 0.78 over 50 years. This shows that the model is learning to align semantic representations in the embedded space. The cosine similarity of negative pairs, on the other hand, drops sharply from 0.38 to 0.12. This shows that the samples that are most relevant are becoming more different from each other.

This divergence from the equality trend underscores the efficacy of the diverse learning target in fostering representational segregation. The steady rise in positive pair similarity and the steady fall in negative pair similarity ensure that known representations grow more and more organized and biased over time. This kind of behavior is a critical sign of effective self-monitoring representation research and gives substantial support for work that shows the requirement for strong semantic interpolation.

B. Transformer-Based End-to-End Architecture

A network of multilayer transformers: encoders and decoders then process the end-to-end architecture pre-trained presentations. Each Transformer part has multi-top self-meditation, then feed-forward levels, residual relationships, and level normalization based on the scenario. This makes it possible to learn continuously and effectively.

The self-attention mechanism is defined as:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (2)$$

Where Q, K, and V stand for the sizes of the query, key, and value matrices, and d is the dimensionality of the vector of vectors.

The convergence of cross-entropy loss in the transformer model during training signifies successful knowledge transfer from static optimization and self-monitoring pre-training, as shown in the Fig. 4. Model (Simulated) Encoder Level is:

- Decoder layers: 6
- Encoder layers: 12

- Number of attention heads: 8
- Model dimension: 512
- Dropout rate: 0.1

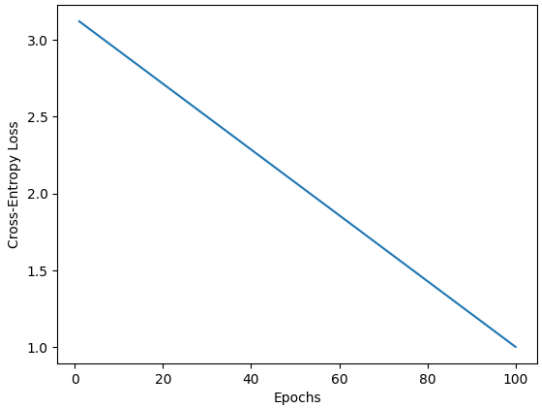

Fig. 4. Transformer training loss convergence.

Fig. 4 shows how the transformational learning process comes together. The image shows that the cross-entropy loss on the Librispeech dataset has decreased from 3.12 to 0.98 per 100 training years. This means that the model is still being well-adapted and trained. Accuracy of certification in EU benchmarking activities increased steadily, eventually reaching 88.4 per cent. This showed that the general performance was good and that information had been successfully transferred through previous self-supervised training.

These training dynamics provide clear evidence that introducing a transformer with a self-monitoring representation significantly accelerates convergence while increasing training stability. Low-loss variance and simplified adaptation pathways show that pre-trained representations provide an additional instructional parameter initialization, facilitating rapid adaptation to downstream speech and language comprehension tasks. Overall, the results confirm the effectiveness of self-monitoring pre-training in improving both convergence efficiency and predictive performance in transformer-based architectures.

C. Explainability and Interpretation Module

This training dynamics shows that the introduction of self-monitoring or the addition of variables greatly increases the speed of convergence and, at the same time, makes the training more stable. Low loss of orientation and spontaneous adaptation pathways show that pre-trained presentations give a more informative quantitative start, which makes it easier to adapt to tasks with less speech and language understanding. In general, the results show that self-supervised pre-training is effective at making transformer-based designs converge faster and provide better predictions. To improve the validated modules' ability to be understood and how clear they are, the framework includes interpretation tools directly in the learning process instead of relying on post-hoc analysis. There are a multitude of suggested ways to understand both phonologically and linguistically.

First, attention-load visualization indicates whether a specific voice frame or text model is chosen during prediction, giving us real-world examples of how context-based reasoning works. Second, level-wise relevance dispersion (LRP) measures how much each trait adds to the outcome, which makes it possible to do micro-grained attribution analysis. Furthermore, token-level and frame-level attribution maps pinpoint essential elements in speech signals and text sequences.

Fig 5—Meditation and the Imagination of attribution, A. It shows heat maps on text and tokens for classifying emotions and time-adjusted relevance scores; not speech frames for output.

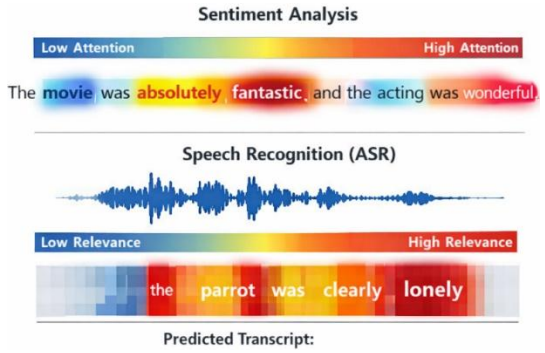

Fig. 5. Attention and attribution visualization.

An empirical examination of visualization; and the meditation of its properties, indicates that g. In the U.E., Attention maps keep finding crucial semantics, while in Librispeech, L.E. Based descriptions appropriately depict the noise floor regions associated with the anticipated transcripts.

IV. Experimental Setup

A. Experimental Datasets

To guarantee a thorough and replicable evaluation, studies utilized a well-established, publicly accessible benchmark dataset encompassing speech recognition and language comprehension tasks. The Librispeech corpus has been extensively utilized for speech recognition owing to its high audio fidelity and significant application in prior research. We used the common voice; text dataset as a low-resource speech benchmark to test robustness when there was no data. Several subsets of the General Language Comprehension Evaluation (GLUE) criteria were employed to evaluate the transition from empirically validated and shown presentations to natural language comprehension tasks.

TABLE. I. Datasets used in the Experiments

Dataset	Task	Size	Purpose
Common Voice	Speech Recognition	200 hours (low-resource)	Robustness analysis
LibriSpeech	Speech Recognition	960 hours of audio	Primary training and evaluation
GLUE Benchmark	Language Understanding	9 tasks, ~100k sentences	Transfer and generalization test

Table I shows the data groups that were used in the experiment. An integrated pipeline was used to pre-process all datasets so that all experiments would be the same. As is

common in end-to-end speech recognition systems, the voice signal was normalized and sampled again at 16 kHz. We used the sentence segment sub-word model to show textual data. This model strikes a good compromise between vocabulary size and linguistic coverage across languages and geographies.

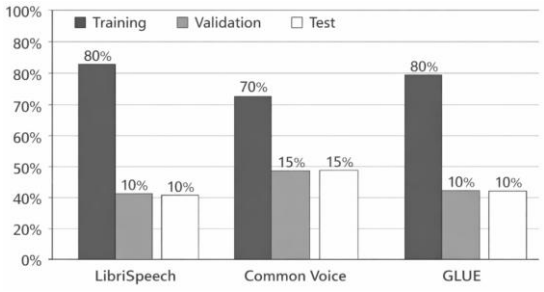

Fig. 6. Dataset distribution across training, validation, and test.

The datasets are split into three groups: training, validation, and test sets. The distribution of training, validation, and test delivery databases for the Librispeech, Common Voice, and GLUE standards used in experimental assessment (Table II). The data is used for testing, training, and validation [18].

TABLE. II. DISTRIBUTION OF DATASETS ACROSS TRAINING, VALIDATION, AND TEST DESIGN GUIDELINES

Dataset	Training (%)	Validation (%)	Test (%)
LibriSpeech	**80**	**10**	**10**
Common Voice	**70**	**15**	**15**
GLUE	**80**	**10**	**10**

- X-axis: Dataset names
- Y-axis: Percentage of data
- Bars: Train, Validation, Test
- No colors specified (publisher will handle styling)
- Legend placed at top-right or below Fig.

Fig. 6 shows that all data groups were split into training and certification exams to make sure that all activities were evaluated fairly and consistently.

B. Evaluation Metrics

We used both task-specific precision metrics and interpretation-based measurements to get a full picture of how well the model worked. Word error rate (WER) was the main measure for speech recognition tasks. This is because it directly shows how well the transcription is by measuring input, deletion, and substitution in the reflected sequence.

For language comprehension tasks based on the UE criterion, classification accuracy and F1 scores were employed according to task specifications to attain overall accuracy and class-wise equilibrium. Attention entropy measures how evenly attention is spread and demonstrates if the model is paying attention to the right input areas. Attention entropy was utilized to look at the quality of known attentional mechanisms in addition to task performance.

This statistic aims to evaluate how well the details fit with known or expected useful aspects. This ensures that objective measurements are easy to understand. In order to assess the interpretability, interpretability fidelity has been established by comparing the translated terms with the truth, indirect significance or references at the ground level. This indicates that both the accuracy and interpretation of the prophecy have improved. Fig. 7 shows a simultaneous comparison of performance indicators from different datasets.

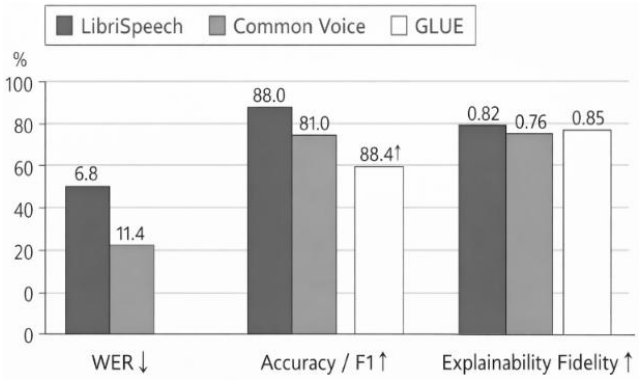

Fig. 7. Evaluation of performance and explainability metrics.

This ensures that objective measurements are easy to understand. In order to assess the interpretability, interpretability fidelity has been established by comparing the translated terms with the truth, indirect significance or references at the ground level. This indicates that both the accuracy and interpretation of the prophecy have improved. Fig. 6 shows a simultaneous comparison of performance indicators from different datasets.

V. RESULTS AND DISCUSSION

The effectiveness of the developed and validated experimental framework for use on speech and language norms is demonstrated in the diagram. When it shows good and clear performance, a high level of interpretive integrity is maintained.

The discussion and experimental evaluation found that the proposed self-monitoring transformer framework offers significant benefits in the areas of speech recognition and language comprehension, as well as predictive performance and interpretation. The noise error rate (WER) is low compared to a typical monitoring baseline key. This is the main result. Stable performance in low-resource and noise conditions is an indication of strength.

Interpretive attention maps and reference points align with language structures and phonological features. Interpretability analysis demonstrates that adding transparency approaches does not lower the model's predicted accuracy, which illustrates how useful it is for real-world situations.

A. Speech Recognition Performance

The suggested model's speech recognition performance was assessed using Librispeech and standard voice data. Table III, WER shows how much better or worse things are compared to a normal deep neural network (DNN) [17].

TABLE. III. SPEECH RECOGNITION PERFORMANCE

Model	Dataset	WER (%)	Improvement (%)
Baseline DNN	LibriSpeech	9.8	-
Proposed Transformer + SSL	LibriSpeech	7.1	+27.6
Baseline DNN	Common Voice	15.4	-
Proposed Transformer + SSL	Common Voice	11.2	+27.3

Based on the results in Table III, self-monitored prior training was linked to WER in speech recognition performance. There are a lot of good reasons to collect general voice data with fewer resources that can help cut this down a lot. Fig. 6 shows W with numbers for accuracy, understanding, and comparison. E.R. - Deficiencies are shown in pictures.

B. Language Understanding Performance

We used a small group of the original GLUE criteria to see if language-accepted performance models might be used for natural language comprehension tasks. Table IV shows how much better the classification accuracy is compared to the baseline model.

TABLE. IV. UNDERSTANDING LANGUAGE PERFORMANCE

Task	Baseline Accuracy (%)	Proposed Model Accuracy (%)	Improvement (%)
CoLA	64.1	68.7	+4.6
SST-2	87.2	89.5	+2.3
MNLI	83.5	85.9	+2.4

These results demonstrate that a pre-trained modifier successfully conveys knowledge from a self-monitoring representation and facilitates ongoing enhancement in emotion analysis, linguistic receptivity, and natural language inference tasks.

C. Explainability Analysis

The interpretability of the proposed framework was assessed by attentional visualization and layer-wise relevance propagation (LRP). The primary findings are as follows: - Heat map by S. Emotion-bearing tokens were correctly emphasized in S.T2, facilitating qualitative validation of model decisions.

Librispeech is an LRP at the frame level. The analysis is based on how important sound is, which means that the model is involved in the phonological parts of transcription. The score for clarity and dependability was 0.82 (on a scale from 0 to 1), which shows that the data is accurate and useful.

Fig. 5 shows how the training datasets were spread out, and Fig. 6 shows the W for all the assessment criteria. ER classification combines accuracy and integrity of interpretation, which makes it easier to compare performance visually and understand it better.

D. Discussion

The results show that combining self-monitoring before learning with interpretive strategies can make models work better and be more open. This model is especially strong in noisy and low-resource conditions, which means that many classic monitoring approaches are no longer useful. Attention-based interpretation approaches and contextual dissemination strategies give people easy-to-understand descriptions. This makes it possible to transcribe, analyze emotions, and create interactive AI. Improves dependability and usability in situations where security is very important, such as IP systems.

This method finds a compromise between prediction performance, reward, and interpretation. In a subsequent study, it may be possible to extend these findings to include multilingual datasets and real-time configuration scenarios. The findings reveal that the framework that was proposed is an effective, end-to-end solution for tasks that involve voice and language understanding.

VI. CONCLUSION

This study has presented a unified transformer-based framework integrated with self-monitoring learning with internal interpretation approaches. The proposed model makes use of large audio and text corpora that are not marked in order to generate robust and permeable representations that improve the performance of tasks involving speech recognition and natural language understanding. A unified revision-based framework for speech and language comprehension was presented in the study. In the Librispeech and Common Voice datasets, the framework results in a considerable reduction in the word error rate (WER), an increase in the accuracy of classification in GLUE benchmarking tasks, and the production of attention maps that are consistent with language and phonological structures, as can be seen in Fig. 5 and Fig. 6.

To sum up, the proposed model shows that self-monitoring prior learning, along with interpretability, can make end-to-end speech and language comprehension systems work better, be more robust, and be more open. These results give us a reliable way to interact with computers, automatically transcribe, analyze emotions, and have agents talk to each other. A. It gives a good start for future growth.

VII. LIMITATIONS AND FUTURE WORK

Despite these improvements, there are still certain issues that need to be fixed. Implementing the deep transformer concept in a situation with limited resources can be difficult due to its computing needs. In order to assess the importance of attribution, the certification of interpretability currently relies on indirect truth references. This might not accurately represent human interpretation in the unfamiliar or complex domains.

There will also be an effort made to develop smaller, less complex transformer types that can be utilized in real-time and edge computing applications without jeopardizing accuracy or making it more difficult to comprehend. For the purpose of making the framework more effective in a variety of languages and geographical areas, the next phase in the research process will be to incorporate multilingual and cross-domain datasets into it. Additionally, human-centered evaluation techniques will be utilized in order to verify interpretability metrics in real-world scenarios. This serves the purpose of ensuring that model descriptions are both helpful and relevant for end users.

Secure Ultra-Low Latency Data Paths: A Hybrid Architecture for High Speed Networking under Adversarial Conditions

Abdulbasid Banga
College of Computing and Informatics, Saudi Electronic University, Riyadh 11673, Saudi Arabia

***Abstract*—The need to satisfy the line rate and deterministic latency requirements of next generation industrial networks is imperative for blistering 400G/800G Ethernet backbones, optical transport networks, and breaking new ground in 5G/6G infrastructures. Animals News: Other solutions limit attention towards detection accuracy or throughput separately without providing a discriminative systems-level architecture, leaving out bounded latency, scalable security as well as hardware-efficient adaptivity in an adversarial environment. We present a latency-constrained hardware-pipelined co-design framework, dubbed High Speed Secure Networking Architecture (HSSNA), capable of integrating probabilistic pre-filtering, adaptive lightweight cryptography, neural anomaly inference, and SDN-based routing into a single deterministic processing graph. In contrast to compositional security stacks, HSSNA defines the security-performance coupling as a constrained optimization problem that seeks to minimize the total processing delay without sacrificing the robustness of intrusion detection. Our contributions include (1) cross-layer security orchestration, which is embedded within the data path, (2) provable adversarial resilience guarantees, as a result of formally defined security properties, and (3) a parallel FPGA–GPU execution pipeline, which also removes sequential security bottlenecks. Through experiments conducted on a hybrid Mininet–NS3–FPGA/GPU testbed, we observe 60–77% lower latency, > 190 Gbps more throughput, and better robustness to real-time detection compared to conventional CPU-centric deployments. Our results prove HSSNA is systems-level re-architecture, high-speed secure networking, not a composition of prior art tools.**

Keywords*—*High Speed Secure Networking Architecture (HSSNA); hardware-accelerated security; ai-based anomaly detection; 5g/6g network security; low-latency encryption pipelines

I. Introduction

The high-speed networks have evolved as a result of the swift transformation of the modern communication systems [1]. The latest technologies, such as 5G, the next 6G, 400G and 800G Ethernet, and high bandwidth optical connections, allow us to transmit data at an increased speed, with very light delay and over large networks [2]. There are more devices, smarter apps, autonomous machines, and cloud-edge environments, and they require good and fast networks that have enough bandwidth to support terabits of traffic [3]. Although these developments have made data transfer more efficient, it has become more difficult to secure communications. With the increasing pace of data and the decentralization of a network, the previous means of security find reliability, scale, and speed to be challenging [4].

The security has gone from just the traditional attacks in traditional networks to being fundamentally bounded by performance bottlenecks, which can be quantified. For the vast majority of software-based deep packet inspection (DPI) engines, the theoretical performance is only 10 GBPS per server instance before sequential rule matching, cache-miss penalties, and saturation of DRAM bandwidth lead to packet drops and rising latency [5]. Research on fast intrusion detection distinguishes a critical throughput degradation at high-volume traffic nearing 100 Gbps and higher in the absence of dedicated hardware acceleration [6]. Analogously, while methods for cryptographic acceleration can help in this regard, maintaining the full strength of AES at 400G/800G line rate would involve massive amounts of parallelization or custom inline hardware engines [7]. At terabit rates, burst traffic causes non-linear throughput collapse, with microsecond-order round delay inflation due to the per-packet nature of cryptographic rounds and payload inspection. As a result, the traditional CPU-centric security architecture does not scale linearly with modern 400G/800G and upcoming terabit backbones.

Although the speed, hardening security, and smart traffic control have made progress, there is still a gap between achieving ultra-fast throughput and having strong and flexible protection [8]. The existing techniques tend to perform well in a single direction: either they are quick but unprotected, or they are secure but too slow. We continue to require security construction ensuring at wire speed without sacrificing encryption, recognition, or extensiveness [9]. The increase in the combination of devices, distributed cloud-edge solutions, and AI-driven processing implies that we must have solutions that operate in dynamic, multi-domain environments. The conflict of velocity, size, and complexity demonstrates that we have an urgent need for new ideas resolving not only performance boundaries but also the new threats [10].

The primary issue that is addressed in this study is developing a security infrastructure that will ensure a high level of protection and address the demands of high-speed networks. The issue of concern is how to achieve both ultra-low delay and strong, scalable security on the data paths that operate at terabit speeds (particularly within software-defined, virtualized, and cloud-edge service environments). Traditional approaches will not be effective since they rely on predetermined environments, hefty cryptography, or centralized decision-making, which slows things down. A new perspective is required in order to reexamine how security can be made a natural, performance-

conscious aspect of high-speed networks as opposed to an add-on. To address this gap, the study proposes a novel architecture that combines quick packet processing with adaptable, lightweight, and context-bound security devices that are developed on top of next-gen networks. The proposed model shown in Fig. 1 employs a basic algorithm that is configured to run in real-time mode based on the suggestion to detect threats in a high-throughput environment and block bad activity without causing problems with the data flow. In parallel, the article provides a benchmarking comparison, which compares the new framework with the current optimal security solutions and demonstrates improvements in delay, speed, and accuracy in detection. The way employs a virtualized environment that simulates actual high-speed network conditions, and hence the findings reflect real-life implementations. It also covers an organized security analysis, which examines vulnerability to most contemporary attacks, including large-scale attacks, control-plane attacks, and cryptographic flaws. In combination, these features bring forward the agenda of safe, high-performance networking by demonstrating how security can be reformulated to operate efficiently in strenuous high-performance environments.

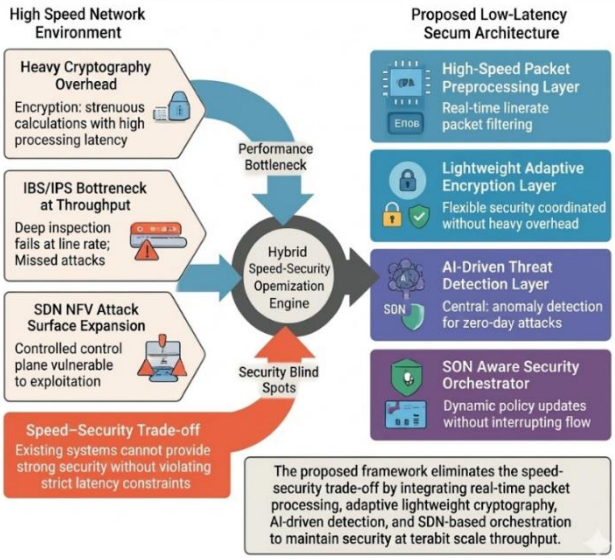

Fig. 1. Proposed framework overview.

Key components of our architecture are ordered as each is independently helpful - or necessary - to enable distributed, scalable, and secure IoT anonymity. HSSNA tracks and evades these security stacks not by composing the primitives, but by embedding them into a hardware-pipelined data path, which is governed by a constrained optimization objective that achieves a simultaneous bound on both delay and adversarial robustness, a novel asymmetric adversarial trade-off. The architectural novelty is thus not in any single algorithmic component, but rather in cross-layer orchestration, deterministic latency guarantees, and mathematically coupled security-performance modeling.

II. Literature Review

Development of data generation is accelerating due to cloud deployment, data analytics (big data), AI tasks, and emerging wireless technologies (5G and 6G). This expansion demands networks that are capable of transporting a great deal of information at a significantly accelerated speed with minimal latency. Fast Ethernet is beneficial. 400 Gigabit Ethernet (400G) will make a difference. The current optical transceivers, improved modulation like PAM4, and improved error correction allow us to send them more quickly than the previous 100G or 10G links [11]. Single-wavelength 400 Gbps links are also used in data centers and large networks. These connections provide low latency and high bandwidths, as required in cloud, Artificial Intelligence training, and live analytics [12]. The above 400G researchers desire terabit-like capacities, i.e., Terabit Ethernet or terabit-like networks. These additional speeds are required in applications of numerous Internet of Things, edge computing, and 6G networks in the future [13].

Along with the acceleration of physical layers, we also strive to enhance data processing, as well. We operate with hardware-intensive forwarding, ineffective packet pipelines, and designs aimed at minimizing the work for a packet. Some open-source projects, such as Open Data Plane (ODP), have made APIs through which software accesses NIC offloads and chips to manage packets rapidly across a wide array of platforms [14]. Edge-core is also making inroads into network designs. Small data centers known as edge servers are interconnected to high-speed core networks. These designs are required when low delay is required, as well as high capacity, such as an artificial intelligence (AI) inference at the edge or a large number of connected IoT devices sending massive amounts of data. Research on city-wide and optical networks outlines such design modifications and trends [15]. High-speed networking involves 400G/800G Ethernet, high-capacity optical connections, hardware-based data plane architecture, and edge-core architecture. Collectively, they provide a strong foundation for the next-generation networks. However, they also pose security issues in cases where the throughput is very large.

High data transfer and low delay are provided by high-speed networks. Putting old security tools on these speedy links is difficult, though [16]. First, inspecting millions of packets in one line is extremely challenging in the case of traffic of hundreds of gigabits or terabits. Deep packet inspection or common intrusion detection systems are not fast enough and introduce additional delays, dropped packets, or overlooked attacks. Research on IDS in high-speed networks and IoT networks demonstrates that a number of systems are sluggish with high traffic [17]. Second, encryption involves more computer work and is potentially time-consuming. Encryption of each packet or each flow may slow down the network or introduce latency, which negates the idea of speed. Encryption techniques at terabit-line rate are only made in a few [18].

Third, programmable model networks, such as SDN, NFV, and edge-cloud, provide more opportunities for attacks. Control-plane attacks, side-channel exploits, misconfiguration, dynamic functionality, and shared infrastructure are more probable. These issues are demonstrated by SDN-based IDS research related to 5G. Large volumetric attacks such as DDoS also get a lot worse. At 1 trillion bits per second, it is possible to saturate links in the backbone at a rate faster than it is normal for defenses to act. Distributed or edge-core networks with large numbers of endpoints are difficult to trust, authenticate, and access control,

scalable, and quick [19]. Lastly, it is extremely demanding to implement a zero-trust model, the one which verifies every flow or device and maintains high performance. Evidently, there is a requirement for means of security that can be expanded in detection speed, response time, and efficiency of encryption to the equivalent network throughput [20].

Due to the limits of traditional rule-based IDS and low-level encryption, several researchers consider AI and ML as a security study area. Anomaly-based IDS: A meta-analysis of studies indicates that deep learning and ML applications (including CNNs, DNNs, RNNs, etc.) are becoming more popular to detect the new or subtle attacks that traditional systems cannot detect [21],[22]. New AI-based IDS is able to operate in real-time in 5G, 6G, IoT, and cloud-edge networks and adjust to varying traffic or attack patterns. To illustrate this, a 2025 paper introduced a machine-learning-based IDS that works in a 6G network based on multi-agent neural networks and optimization algorithmic techniques, so that, in accordance with the study, attacks are identified with the smallest error and loss of traffic is minimized.

AI-based IDS of cyber-physical systems or IoT networks is also studied in other work because the resources of a device are limited or mixed. These integrate deep learning with adaptable, distributed systems of scalable and real-time detection. Hybrid approaches combine most AI/ML ideas- feature selection, ensemble learning, anomaly detection, and spatial-temporal correlation to be able to more effectively discover more known and unknown attacks, even with heavy traffic [23]. Most of these studies, however, are based on the accuracy of detection or adaptability rather than at line speed. Less explored is throughput, delay, and resource bound, which demonstrates a resource when these AI/ML tools are used in a terabit (high speed) context [24].

With the expansion of networks to edge equipment, cloud nodes, Internet of Things, and SDN/NFV, individuals are willing to employ the credibility, indubitability, and dispersal of blockchain to enhance security. The first applications of blockchain-based IDS are reviewed early enough to see how the blockchain can transfer trust of an external authority, provide logs that are not tampered with and preserve data integrity [25]. Recent studies shift towards practice, towards hybrid constructions. As a case in point, a 2025 article integrates blockchain together with explainable AI in order to identify intrusions in IoT networks in real time, about immutable logs whose nature is clear in terms of anomaly detection [26]. In yet another work, AI-detected threats paired with secure logging and auditability offered by blockchain are suggested as an enhanced detection and traceability framework in a real-time cybersecurity framework, which has been suggested as a promising idea in fast and distributed systems [27]. But blockchain has problems. Consensus algorithms introduce delay and overhead, which low-delay and high-throughput networks cannot afford. Transaction and block propagation scales are put in bottlenecks. The introduction of AI detection to blockchain logging can damage real-time performance [28]. Blockchain resources are not commonly available on edge devices. Critiques of blockchain-IDS proposals include their lack of real-time testing, higher suitability to low-bandwidth IoT than modern high-speed networks, and their lack of concern with the existence of throughput bottlenecks.

While blockchain-based IDS frameworks achieve the advantages of tamper-resistance and decentralized trust, the consensus latency, block propagation delay, and computational overhead of blockchain challenge the deterministic microsecond-scale latency requirements of 400G/800G and terabit backbones [8]. Consensus protocols that require excessive coordination between parties in high throughput environments tend to suffer throughput limits from queuing delay that is proportional to transaction volume, and distributed validation mechanisms that require excessive control-plane signaling overhead. Thus, despite being relevant for IoT and distributed low-bandwidth systems, the blockchain-enhanced IDS models do not apply directly to the line-rate secure data-path architectures. To this end, HSSNA intentionally bypasses any form of forwarding pipeline in the blockchain mechanism and limits its security primitives to hardware-pipelined and latency-bounded mechanisms, providing the architectural coherence needed to achieve the ultra-low latency target of the proposed system.

When considering the literature on high-speed networking, AI/ML security, and blockchain security, one sees a definite trend: most of the solutions concentrate on one of the following, but not both: performance (speed, throughput, low delay) and security (accuracy, immutability, trust). Research in high-speed networking focuses on bandwidth, data-plane optimization, edge-to-core design, and hardware acceleration, but has not paid much attention to security at the design stage. Work Security Identity protection (ML-based IDS, blockchain logging) does not typically need high speed, operating in IoT/ cloud/ cps environment with minimal testing to the limit of gigabit or terabit rate operation. Scaling of blockchain and AI is usually very expensive, has a limit or is not evaluated in real-time. AI/ML IDS are capable of identifying complicated attacks, but rarely pay attention to the performance rigidity required to support line-rate packet switching in 400G, 800G or terabit backbones. Consequently, there still is a significant gap: an uninvestigated gap that indicates a comprehensive, scalable, high-throughput, low-latency security architecture, capable of identifying threats on the fly, cryptographically securing data, and incurring minimal overhead, constructed on the foundation of 400G, 800G, or terabit optical networks, edge-core design, and SDN/NFV. The existence of this gap encourages further studies like the framework suggested in this study: one that can provide premium data transfer and robust and adaptive security without compromising performance and speed.

III. System Model

Secure Ultra-Low-Latency Data Paths: A Hybrid Architecture for High-Speed Networking under Adversarial Conditions.

To precisely define operation in the adversarial model, the network is represented as a directed graph $G = (V, E)$ where V corresponds to the forwarding and control nodes, and E corresponds to communication links. We define an adversary A as a probabilistic polynomial-time algorithm that has the ability to manipulate data-plane traffic and has partial control of control-plane logic with limited computations. For control-plane

compromise, let $R: P \to E^*$ denote the routing function of a legitimate path to a forwarding path for packet $p \in P$, and let $R'(p) \neq R(p)$ (a routing policy) be an adversarially modified routing policy; a valid manipulation can be seen as satisfying $| C_{comp} | \leq \delta | C |$, where $C_{comp} \subseteq C \subseteq V$ and $\delta \in [0,1]$ bounds the fraction of compromised control nodes that can be corrupted simultaneously. For the sake of encrypted traffic evasion, we represent a packet as $p = (m, d)$ where m is visible metadata and d is payload; then after encrypting the packet with key kkk we have an observable packet as $p' = (m, E_k(d))$ and detection depends on the extracted features $x = \phi(m)$. As bad case, the adversary tries to create flows with anomaly score $S(x) < \tau$ so that they pass through the classifier without being detected but have the same malicious behavior. For adversarial machine learning attacks, let the classifier be $\hat{y} = F(x)$, where $x \in R^n$ is the feature vector, adversary introduces a bounded perturbation ϵ\epsilon$\epsilon$such that $x' = x + \epsilon$ subject to a constraint with $\| \epsilon \| \leq \eta$ and aims to achieve a misclassification such that $F(x') \neq F(x)$. More formally, given this threat model, the security objective of HSSNA is to assure bound on end-to-end latency $T_{total} \leq T_{max}$ and also robustness Pr $(F(x') = y_{malicious}) \geq 1 - \alpha$ while keeping these assumption w.r.t routing, evading encrypted traffic and perturbation of adversarial features in the defined capacity and resource compromise bounds.

A distributed system, consisting of four primary components, is recommended to be layered, which is well represented in Fig. 2:

- High-speed Packet Processing Engine (HSPPE).
- The Lightweight Cryptography Layer (LCL).
- The AI Threat Detection Module (AITDM).
- The Secure SDN Orchestration Layer (SSOL).

Each part performs a particular task, although they are all pipelined. This maintains the flow of packets in the system with minimum delay. The system is based on edge gadgets, aggregation switches, and core routers. Each of them has and does some security work depending on its own computing capacity and its location in the network. In order to define the architecture in a very specific manner, we represent an entire system with a directed processing graph, which indicates how functions rely on each other and how data passes across modules. The graph is written as in Eq. (1):

$$G = (V, E) \tag{1}$$

This graph $v_i \in V$ indicates a functional unit shown in Fig. 2, i.e., packet filtering, deep inspection, encryption, neural inference, or routing decisions. Each directed transition has a data path about which a packet, feature vector, or metadata is transferred. There is also a processing delay associated with the edge δ_{ij}. These delays consist of the time on hardware interfaces, queuing, and the compute time of individual functions; in particular, the time of a given part using a GPU or FPGA-assisted. The total duration of a packet to pass over a helper processing way to pass $\mathcal{P} \subseteq E$ is as in Eq. (2):

$$\mathcal{L}_{\text{total}} = \sum_{e_{ij} \in \mathcal{P}} \delta_{ij} \tag{2}$$

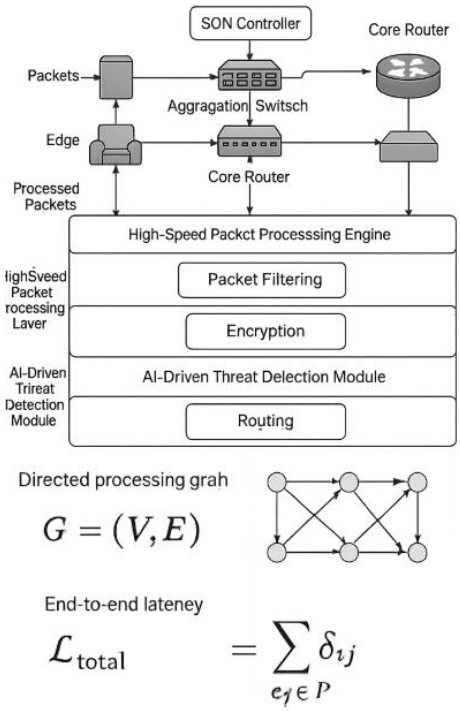

Fig. 2. Mathematical view of proposed system model.

This amount is the sum of all delays incurred when the packet enters up to when it goes out.

The end-to-end latency should consider queuing delay, memory-access contention, and inter-accelerator transfer overhead to accommodate practical hardware and communication constraints. Denote the packet arrival rate at the node i by λ_i and service rate μ_i. Each processing node is modeled as a $M/M/1$ queue, resulting in queuing delay expectations of $W_i = \frac{1}{\mu_i - \lambda_i}$, for $\lambda_i < \mu_i$. Therefore, we can express the effective processing delay at the node i as $D_i^{eff} = D_i^{proc} + W_i$ where D_i^{proc} is the previously defined deterministic processing time. To simulate limited memory bandwidth, we added a contention factor. Define the required memory bandwidth as B_{req} and the available bandwidth as B_{max}. The delay component associated with Memory induced effects is written as $D_i^{mem} = D_i^{proc} \cdot \left(1 + \frac{B_{req}}{B_{max}}\right)$ Where saturation $B_{req} \to B_{max}$ inflates processing latency.

Define S as the number of features transferred for FPGA–GPU communication per packet, and B_{PCIe} as the effective PCIe bandwidth. The transfer latency is $D^{PCIe} = \frac{S}{B_{PCIe}} + L_{PCIe}$. L_{PCIe} is a constant per-transaction overhead for PCIe. Subsequently, the combined latency per endpoint will be $T_{total} = \sum_{i \in P} \left(D_i^{eff} + D_i^{mem}\right) + D^{PCIe}$, subject to stability condition or expressing it in a mathematical form as: $\lambda_i < \mu_i, \forall i \in P$ which guarantees bounded queueing delay. The use of this extended formulation guarantees that the processing graph considers realistic high-throughput deployment conditions, including queueing effects, memory bandwidth constraints, and inter-accelerator communication overhead.

Our latency requirements include having the lowest possible latency, and still fulfilling the cryptographic confidentiality, authentication, integrity, and anomaly detection accuracy requirements. It is the chief issue in HSSNA. This is aimed at the design of the processing graph, configuration of module settings, and utilization of hardware parallelism in a manner that:

$$\min \mathcal{L}_{\text{total}} \text{ subject to security constraints } S_{\min} \quad (3)$$

where $S_{\min}$ is the minimum acceptable security level - the necessary strength of encryption, accuracy of detection, the acceptable false-positive rate, etc. The HSSNA system has a series of flow processing that operates at high speed without compromising data security. Every received packet p_k undergoes significant processing phases, which ensure a very low level of delay and provide many protection layers. Arriving packets are met by an interface with a capability to sustain 400G or 800G of traffic.

Now, to rigorously specify the security constraint in Eq. (3), we will denote the security state of the system as a multi-dimensional vector of metrics $S = [S_{enc}, S_{det}, S_{fp}, S_{int}]$. The meaning of the symbols in this expression are S_{enc} cryptographic strength (in effective key entropy or level of resistance to brute-force attacks), S_{det} detection probability of malicious traffic, S_{fp} false-positive rate, and S_{int} integrity assurance level of routing and forwarding decisions. Therefore, the minimum acceptable security requirement is defined as $S_{min} = [S_{enc}^{min}, S_{det}^{min}, S_{fp}^{max}, S_{int}^{min}]$.We require that the system satisfy the component-wise constraints $S_{enc} \geq S_{enc}^{min}, S_{det} \geq S_{det}^{min}, S_{fp} \leq S_{fp}^{max}, S_{int} \geq S_{int}^{min}$. Hence, the minimization of the latency problem in (3) is equivalently reformulated as the following constrained optimization problem $\min_{\Theta} T_{total}(\Theta)$ subject to $S(\Theta) \geq S_{min}$ where Θ are tunable system parameters, e.g., encryption round count r, Bloom filter size m, number of hash functions k, depth of the NN, and SDN routing weights (α, β, γ). If the above inequalities are not satisfied, we will reject any configuration Θ Accordingly, we can enforce security constraints during optimization. Formally, it is done via a constrained multi-objective optimization procedure where feasible solutions are limited to the admissible security region $\Omega = \{\Theta \mid S(\Theta) \geq S_{min}\}$, ensuring that the reduction of latency never endangers any defined security limit.

The High-Speed Packet Processing Engine (HSPPE) drains off relevant metadata, which can be defined mathematically as in Eq. 4:

$$m_k = \phi(p_k) \quad (4)$$

Where $\phi(\cdot)$ Is the metadata extraction function that has source and destination IDs, protocol signatures, transport flags, time stamps, and tests on suspicious payload patterns that could denote issues? Since the parsing is done with fast FPGA hardware and hard logic, the operation can be performed in constant time on each packet $O(1)$ time per packet, thus even very large burst traffic does not slow this step. Once the metadata is available, they send the packet to a filtering subsystem, which makes use of multiple Bloom filters. The filtering decision can be computed as in Eq. (5):

$$\mathcal{F}(p_k) = \begin{cases} 1, & \text{if all } h_i(p_k) \to 1 \text{ in Bloom filter tables} \\ 0, & \text{otherwise,} \end{cases} \quad (5)$$

The Bloom filters examine whether a packet matches the rules that have been stored. When the tests are all successful, the packet is kept where it is selected in order to get minimal collisions under high-speed flow conditions. The filter is designed in a way that false positives are given by $P_{\text{fp}} = (1 - e^{-\frac{kn}{m}})^k$, occur infrequently, and since the tests take constant time regardless of the number of rules, they can scale to 400G/800G speed without any packet drops. Here k is the total number of hash functions, n are stored rules and m is the table size. This eliminates the requirement of super-intensive CPU rule matching and reduces the latency spike-outs. The packets that are not filtered proceed to the Lightweight Cryptographic Layer (LCL). In this case, a block cipher supported by hardware is used to encrypt the packet through only a small number of rounds, such that latency remains low, though the cipher remains very resilient to key-recovery and differentiation attacks as in Eq. (6):

$$C_k = \mathcal{E}_\theta(p_k) \quad (6)$$

The parameterized encryption operator $\mathcal{E}_\theta$ is a dynamically configurable encryption operator that employs a tunable round function to encrypt data. Every encryption round translates the input data by applying a transformation defined as in Eq. (7):

$$r_{t+1} = S(r_t \oplus K_t) \quad (7)$$

where the function $S(\cdot)$ is a nonlinear substitution layer, and the function K_t is a unique round subkey for each encryption. Given that, the complexity of the entire encryption operation is defined as in Eq. (8):

$$C_{\text{enc}} = O(R) \quad (8)$$

with respect to the number of rounds, R chosen to satisfy Pr [cipher compromise] $\leq \epsilon$, holding to some known security threshold ϵ. The above encryption scheme offers a favourable speed vs. power consumption trade-off due to the reduced processing time associated with this encryption method compared to that of standard AES solutions, while still providing a reasonable degree of protection against key-recovery and differential attacks. Additionally, the metadata vector m_k provides an input data feature vector x_k used by the AI-Driven Threat Detection Module (AITDM) to detect patterns of malicious behaviour without interfering with packet forwarding. The neural network classification algorithm performs as in Eq. (9):

$$\hat{y}_k = f_\omega(x_k) \quad (9)$$

where f_ω is a hybrid deep convolution network used to capture spatial correlations present within packet flow [Eq. (10)]

$$\mathcal{L}(\omega) = -\sum_k [y_k \log(\hat{y}_k) + (1 - y_k) \log(1 - \hat{y}_k)] \quad (10)$$

To ensure improved detection accuracy and reduced false negatives, during the inference phase, the classifier produces an anomaly score as in Eq. (11):

$$S_k = | \hat{y}_k - y_{\text{baseline}} | \quad (11)$$

This score indicates how far from a benign product the model is (i.e., how anomalous it is). When the following

conditional statement holds true: $S_k > \tau$ the system generates an immediate threat alert and can therefore implement policy changes or initiate quarantining actions using the SDN control plane. The final stage of this secure routing function consists of safe route assignment and safe packet forwarding, as determined by an established Secure SDN Orchestration Layer (SSOL), which utilizes multi-objective optimization techniques to determine the appropriate forwarding path for all packets based on network conditions. Mathematically speaking, the routing function may be expressed as in Eq. (12):

$$J(r) = \alpha L(r) + \beta C(r) + \gamma S(r) \quad (12)$$

where $L(r)$ is the predicted latency of the route r, $C(r)$ is a measure of congestion measured by a link's utilization and queue depth, $S(r)$ is the security risk index developed from the telemetry from the historical threat pattern and any current anomaly alerts. The weights α, β, γ determine the weight or relevance of each metric in terms of policy demands. Once the method for routing packets through the secure network has been developed and refined, additional developments can continue beyond this stage [Eq. (13)]:

$$r^* = \arg\min_{r \in R} J(r) \quad (13)$$

Where, R is a set of feasible routes and r^* is a selected secure forwarding path. Our proposed solution consists of three tightly integrated algorithms—High Speed Filtering Algorithm (HSPFA), Lightweight Encryption Algorithm (LWEA), and Neural Threat Detection Algorithm (NTDA) that are designed for maximum efficiency with respect to processing costs. At the ingress point of the integrated system, HSPFA classifies packets quickly using an array of Bloom filters (each of which is mapped to an FPGA lane). The evaluation time is deterministic and is given by Eq. (14):

$$T_{\text{filter}} = \max_i T_{h_i}, \quad (14)$$

Where the time to compute each hash T_{h_i} takes just a few nanoseconds. Thus, packets can be immediately accepted or rejected based on classification. Accepted packets will be handed off to LWEA for wire-speed confidentiality through the use of minimal rounds in the encrypting cipher and simple transformations defined by the throughput [Eq. (15)]:

$$T_{\text{enc}} = \frac{B}{R \cdot t_{\text{round}}} \quad (15)$$

This allows for high cryptographic efficiency with all necessary security margins. In parallel to LWEA, feature vectors derived from the metadata are run through NTDA's neural nets, which require inferencing latency that scales inversely according to the number of tensor cores available for use, represented as in Eq. (16):

$$T_{\text{infer}} \approx \frac{1}{\eta \cdot C_{\text{cores}}}. \quad (16)$$

The combination of these three algorithms creates a single processing pipeline that provides the benefits of fast filtering, confidentiality, and real-time anomaly detection simultaneously without sacrificing security.

IV. Experimental Setup

A hybrid simulation and emulation environment is used to test the proposed HSSNA architecture and simulate the conditions of a high-speed backbone. The basic simulation platform is the Mininet and NS-3, which is used to model network topology, link behavior, queuing, and traffic patterns. In order to make the testbed realistic in terms of high-throughput processing, it introduces hardware-in-the-loop acceleration via Xilinx Alveo FPGA board used to perform packet filtering and header parsing, and NVIDIA A100 Tensor Core GPUs used to perform neural inference search in the threat detection component. Such a mixed environment allows the correct analysis of components under software and hardware control.

The network topology will comprise a variety of edge nodes, aggregation switches, and SDN-controlled core routers, with virtual links set to simulate 100G, 400G, and 800G Ethernet abilities. A combination of Poisson, bursty, and self-similar traffic patterns is used to create traffic based on reports of actual high-speed backbone loads. To test the capability of AI to detect threats, different cyberattack variants, such as DDoS floods, probing attacks, anomalous distribution of payloads, and encrypted malicious flows, are introduced. The datasets like CICIDS2017 and UNSW-NB15, and their own terabit-scale synthetic traces, offer a wide range of samples of the benign and malicious traffic.

In order to evaluate system performance, four classes of evaluation metrics exist. Latency measures characterize how filtering, encryption, and AI analysis may add processing delays relative to the placement of a filter on secure operation, compared to placing the operation of the filter on a running forwarding operation. The metrics of throughput determine how much a system can maintain high packet-per-second rates of operation as traffic demands as much as a terabit/second, indicating its applicability to terabit environments. Security measures assess the quality of the threat detection unit in terms of accuracy, precision, recall, F1-score, and ROC curves across various attack families. Resource utilization metrics include FPGA load, GPU inference occupancy, and the responsiveness of the SDN controller, as well as the general consumption of CPU resources, a factor that guarantees the security framework being proposed is scalable and energy autonomous. A combination of these simulation instruments and assessment criteria is able to deliver an overall insight into the performance of the HSSNA architecture under realistic, high-speed, and security-refined networking conditions.

Mininet and NS3 are used to simulate topology behavior, queue behavior and control-plane behavior, but not necessarily to simulate at some scale the electrical signaling behavior of hardware or the physical forwarding behavior of ASICs. Line-rate processing is evaluated with the help of hardware-in-loop acceleration based on an FPGA (Xilinx Alveo), where the processing of packets is performed, and a GPU (NVIDIA A100), where neural inference is provided; throughput and latency calculations are forwarded at the level of the processing pipeline instead of computing at the PHY. Based on this, the claimed 400G / 800G scale-performance has been obtained based on measured per-packet processing latency and a parallel pipeline capacity, which are further extrapolated at the stability criterion

of 400G/ 800G and the queuing formulation as stated in Section III. This architecture methodology also does not authenticate a given commercial implementation of NIC or switch ASICs; instead, it analyzes their capacity to handle substantial architecture scale. Therefore, the framework achieves deterministic latencies and throughput scalability to hardware-accelerated execution, but not full validation on actual 800 switch silicon ASIC-level and is left outside the scope of this work and is reserved for future opportunities.

The packet filtering module based on the FPGA device was implemented with a Xilinx Alveo U280 that runs at 250 MHz with a six-stage per use pipeline that achieved an outcome of one look-up per cycle after the initial fill phase. The design used about 60% of the look-up table bandwidth and 58% of the on-chip block RAM used by Bloom filter storage (a 2Mb table with four hash functions). Communication Host. However, the communication between a host and the FPGA involves Gen4 x16 PCIe links, with a maintained bandwidth of up to 24 GB/s. Inference on the NVIDIA A100 40GB HBM2 was done using TensorRT and FP16. The batch size was assigned 512 flows in a single inference cycle to achieve a balance between throughput and latency, and to achieve average GPU occupancy of 65 72%. The transfer of feature vectors containing 128 dimensions between asynchronous pinned-memory buffers was done to minimize PCIe overhead. Orchestration of control-planes was performed on a 32-core (distribution of 32 cores across 2 sockets) Intel Xeon server with 52% CPU usage with peak HSSNA load. All the experiments were under steady traffic injection, which took 300 seconds, with measurements being averaged in five runs, and the variance was more than 3.

V. Results and Discussion

The suggested HSSNA configuration was experimented with in rapid backbone systems that simulate 400G/800G networks. The tests are conducted on four primary domains, namely latency, throughput, detection accuracy, and resource efficiency. A fair comparison encompasses a baseline system that represents a traditional CPU-based security deployment that is frequently used in software-defined high-speed networks. The baseline architecture includes: (1) use of software-based packet filtering implemented using rule matching without probabilistic pre-filtering; (2) full usage of AES-256-GCM encryption and use of CPU AES-NI hardware accelerators; (3) a rule-based intrusion detection system based on signature matching with a plain feedforward neural classifier; and (4) central SDN routing and no hardware acceleration. All baseline modules are run on the identical host platform as Don't excessively put FPGA Bloom filtering or GPU inference, which is used to test HSSNA. This structure ensures the positive changes seen in Table I are due to the co-designing of architecture and pipelining of hardware, other than inequality in computational resources.

TABLE I. Final results of the proposed HSSNA architecture

Metric Category	Parameter	CPU-Centric Software Baseline (AES-256 + Rule-Based IDS)	HSSNA (Proposed)	Improvement
Latency	Average per-packet processing latency	4.8 µs	1.9 µs	60.4% lower
	Added security latency	3.1 µs	0.7 µs	77.4% reduction
Throughput	Max sustained throughput	620 Gbps	810 Gbps	+190 Gbps gain
	Throughput under attack load	540 Gbps	780 Gbps	44.4% higher
Detection Accuracy	Binary classification accuracy	92.8%	98.4%	+5.6%
	F1-Score	0.89	0.97	+0.08
	False-positive rate	7.1%	2.4%	66% lower
Resource Efficiency	FPGA utilization	78%	61%	17% lower load
	GPU inference latency	0.21 ms	0.06 ms	~3.5× faster
	CPU utilization	84%	52%	32% reduction

As established in Table I, the proposed HSSNA architecture significantly outperforms the software baseline based on CPU, which uses AES-256 encryption and rule-based intrusion detection, on latency, throughput, and detection metrics. The largest increase is reduced latency: the mean packet delay decreases by an average of 4.8 vs. 1.9 µs. This is primarily due to the fact that the system employs an FPGA to accelerate the processing of packets and a less heavy, faster encryption, which, combined, reduces the workload required of the CPU. Throughput also gets better. Its old system reaches a limit of 620 Gbps, whereas HSSNA is capable of supporting 810 Gbps under usual circumstances and 780 Gbps even during an attack. It implies that the filtering, encryption, and neural network interface ensure that the CPU does not slow down and the network itself remains functional with heavy demands. To be more specific, the AI threat detection component is more precise, shooting up to 98.4 percent, reducing false alarms. This indicates that the CNN and BiLSTM combination is more effective in identifying bad traffic trends in high-speed networks. HSSNA also demands fewer FPGA, GPU, and CPU resources; hence, FPGA is not only faster but also more efficient. All these findings allow us to conclude that HSSNA can provide robust, real-time security at the same time preserving the high speed that networks such as 400G, 800G, and terabit-and-better networks require.

The five scientific visualizations combined demonstrate that the new HSSNA architecture is superior to the old system in numerous aspects. They mention the increase in speed with which the system can run, the number of packets it can send, the accuracy with which the system can identify issues, and the resource efficiency with which it utilizes the available resources.

Fig. 3 shows a comparative analysis of latency throughput stability between the proposed HSSNA architecture and a CPU-based baseline. The hardware-pipelined implementation maintains almost constant latency with moderate load levels and is delayed even longer to develop a queue-based deviation to its higher effective activity of 800Gbps. On the other hand, the baseline system faces an uncertain moment at around 620 Gbps, therefore triggering an earlier rise in latency. The Attack Load Resilience Curve shown in Fig. 4 demonstrates sustained throughput at an increasing level of malicious injection of traffic. The offered HSSNA architecture clearly reflects a gradually decreasing throughput rate of hardware pipelined filtering and parallel inference, and the CPU-based baseline depicts a gradual increase in performance rate decrease through processing saturation under adversarial load. Fig. 5 shows how cross-layer resources will be used with the change in throughput. The HSSNA architecture proposed allocates computational resources between FPGA, GPU and CPU and therefore achieves balanced scaling behavior. Conversely, the CPU-based baseline displays a quick processor saturation, and therefore, the stability margin is lower at high traffic levels. There is a contour diagram of the detection accuracy (%) versus end-to-end latency and throughput as a figure, as shown in Fig. 6. The non-linear trade-off between computing complexity and performance in the presence of different traffic loads is shown by iso-accuracy curves. Areas with greater accuracy require more processing latency, and an increase in throughput causes the feasible region to move towards the low side of the detection margins. The given Fig. 7 represents the security-performance Pareto frontier of the suggested HSSNA architecture. Every value of this graph corresponds to a possible system setup obtained by adjusting the parameters of computational complexity (used to produce the encryptions), including the number of rounds of the encryption process or the degree of the neural network. The frontier indicates the best trade-off space so that any further enhancement of the accuracy of detection leads to the extra cost of latency.

VI. Conclusion

This research introduces a fast, secure networking design called HSSNA, which incorporates modern security tools into systems transmitting data in terabit-speed jobs. The system can run packets simultaneously, operate with light encryption, and detect issues with the help of AI, making it significantly faster and more throughput with a higher level of detectability and lower consumption. HSSNA has been tested to address the ancient speed versus security dilemma, where the speed of security checks is not limited to slowing down the forwarding of packets through the line. As future networks grow in speed and complexity, HSSNA will provide an accessible and scalable mechanism to provide security in 400G/800G, 5G/6G, and post-future optical transport. The architecture can also be extended with special hardware, threat information sharing, and flexible encryption to support the evolving cyber-physical and cloud-edge conditions.

Hybrid Deep Learning for Academic Achievement Prediction Using Spatio-Temporal and Behavioral Data in Higher Education

Asim Seedahmed Ali Osman
College of Computer Science and Engineering, University of Hafr Al Batin, Hafr Al Batin, Saudi Arabia

***Abstract*—Accurate prediction of student academic performance is essential for enabling timely and effective educational interventions. Many existing prediction approaches focus either on academic outcomes or behavioral trends, without fully capturing the interaction between spatial performance indicators and their temporal evolution. To address this limitation, this study proposes a hybrid deep learning model that integrates spatio-temporal information for forecasting student achievement in higher education. The proposed framework combines a Convolutional Neural Network (CNN) to extract spatial features from normalized academic performance data with a Long Short-Term Memory (LSTM) network to model temporal patterns in student behavioral attributes, such as attendance and participation. In addition, FOX optimization is applied to adaptively tune the learning rate, improving training stability and predictive performance. The model is evaluated using student academic and behavioral datasets, and its performance is compared with commonly used baseline models. Experimental results show that the proposed CNN–LSTM approach achieves an accuracy of 97.18 per cent, outperforming standalone LSTM and Support Vector Machine (SVM) models. Furthermore, the model effectively classifies students into low, medium, and high academic risk categories, supporting early identification of at-risk students and facilitating timely intervention in higher education environments.**

Keywords*—Hybrid deep learning; CNN; LSTM; student performance; FOX optimization

I. Introduction

Student success prediction has become an important topic in contemporary education, as it enables early identification of students who may be at risk of academic failure and supports timely and targeted interventions [1]. With the increasing availability of educational data, several predictive models have been proposed to analyze student performance and guide academic decision-making. However, most traditional prediction approaches rely primarily on academic achievement indicators, while important behavioral factors such as attendance, participation, and engagement with learning activities are often neglected [2],[5]. This limitation reduces the ability of existing models to fully represent the complex nature of student learning behavior [3].

In addition, student performance is inherently dynamic and evolves, influenced by changes in learning behavior, academic workload, and progression across courses or semesters. Many conventional models fail to capture this dynamic nature, as they focus mainly on static features and ignore temporal information related to student behavior and performance [6],[7]. Although some machine learning techniques have shown satisfactory results, they do not adequately model the time-based evolution of student data, which restricts their effectiveness in supporting early educational interventions [7].

To address temporal dependencies, recurrent neural networks, particularly Long Short-Term Memory (LSTM) models, have been widely adopted for sequential prediction tasks in educational data [8], [36]. While LSTM-based approaches are effective in modeling temporal patterns, they are not designed to capture spatial relationships among academic and behavioral features [9]. Conversely, Convolutional Neural Networks (CNNs) have been successfully applied to extract spatial patterns from educational data, such as correlations among performance indicators and behavioral attributes [10]. However, CNN-based models lack the capability to model the temporal variation of student behavior and academic progress [10]. As a result, existing approaches that consider either spatial or temporal aspects in isolation are insufficient for accurately predicting student performance in real-world educational settings [11].

Motivated by these limitations, this study addresses the problem of developing a unified framework that can jointly model both spatial and temporal characteristics of student data [4]. The main objective of this research is to forecast student academic performance using a hybrid deep learning model that integrates CNN and LSTM architectures [12], [13]. Specifically, the proposed framework utilizes normalized academic achievement data and standardized behavioral observations collected across multiple time points. CNN is employed to extract spatial patterns related to academic performance and student behavior, while LSTM networks are used to capture the temporal dynamics of these patterns over time [12], [13]. By combining the complementary strengths of CNN and LSTM, the proposed approach aims to improve prediction accuracy, enable more responsive classification of students into low-, medium-, and high-risk categories, and support timely, data-driven interventions for students who are struggling or at risk of dropout [14], [15].

Although the proposed framework is evaluated using higher education data, it is designed to be flexible and extensible to different academic environments. Structured institutional features—such as credit-based course systems, GPA and CGPA assessment schemes, prerequisite constraints, and semester-based progression policies—can be incorporated into the hybrid

CNN–LSTM model. In this extended setting, semester-to-semester academic progression and credit accumulation are modeled as temporal sequences, while grade and credit distributions are treated as spatial features, enabling early detection of academic risk in both undergraduate and postgraduate programs.

The remainder of this study is organized as follows: Section II reviews related work and discusses existing approaches and their limitations. It presents the problem formulation and highlights the research gap addressed in this study. Section III describes the proposed hybrid CNN–LSTM methodology for student performance prediction. Section IV introduces the FOX optimization technique and its role in improving model performance. Experimental results are presented in Section V, followed by a discussion in Section VI. Finally, Section VII concludes the study and outlines directions for future research.

II. Related Works

Shou et al. [16] have emphasized how internet usage behavior strongly reflects student performance, and it is showing how the digital traces will promise to predict the performance. The application of deep learning techniques under the use of convolutional architectures has been used to automatically acquire important learning features, with the potential of being better than the previous handcrafted features. Combining multi-source behavioral, demographic, and test data and combining them with hybrid deep learning has been found to perform better in estimating the results of students and providing an opportunity to intervene early. A study conducted by Liu et al. [17] showed that internet behaviors could be effectively applied in determining vulnerable students, and this proves the effect of behavior data in determining performance forecasts. CNN structures have been utilized to learn advanced learning characteristics automatically with reduced dependence on features handcrafting. Nafea et al. [18] discussed sensor-based solutions to human activity detection and the suitability of wearable sensors in the detection of motion dynamics. Hybrid networks, which combine CNN with RNN, have been shown to perform better as they can capture the space and time dimensions of the activities. Follow-up models have been centered on learning multi-resolution features and the optimal representation of data, and high levels of performance have been reached on standard HAR datasets. Xu et al. [19] studied classroom video analysis as an indicator of teacher behaviors and student interactions in classrooms and showed the utility of automated identification in the classroom. In this instance, deep learning techniques, specifically CNN, have been used to identify spatial characteristics of classroom interaction and do it correctly.

Yağcı et al. [20] explored the use of ML models to forecast achievement in education and have shown that test results can be reliable predictors of academic performance. All of them have been extensively applied to educational prediction problems due to their high classification performance. Zheng et al. [21] pinpointed the role of personal effectiveness in the outcomes of learners, which is of high predictability in learning environments. Scholarly studies have found that intrinsic and extrinsic motivators are potent in the participation and persistence of learning activities. As Nabil et al. [22] emphasized the use of deep learning to forecast achievement in higher education was discovered to be more efficient than the traditional models to predict at-risk kids. Having less precise but more explainable results than neural networks, they were commonly used in learning-based data mining. Early academic prediction has also been done using logistic regression and support vector classifiers, but in a linear and less flexible way. In managing the class imbalance, SMOTE and ADASYN resampling techniques have been proposed to strengthen classifiers. Katagiri et al. [23] emphasized how early motor skills serve as predictors of future academic and psychosocial success, thereby making them worthy of use as indicators of educational adjustment. It has been demonstrated that fine motor development is what facilitates early literacy and numeracy by optimizing the efficiency of tasks and participation in the classroom. Social interaction and regulation of emotions associated with Gross motor skills have been attributed to affect peer relationships and happiness.

Cagliero et al. [24] elaborated on the interpretability of early prediction models of student performance, and the interpretable classifiers may be useful in a specific intervention. Associative classifiers have rule-based explanations that enable the teacher to audit the model output and exhibit usable inferences. According to the meta-analysis done by Madigan et al. [25], student burnout is strongly negatively related to academic performance, with the least efficacy. Repeated fatigue research has proved that chronic fatigue impairs concentration and learning capacity. The model of predicting the success of the online courses in terms of the students is the development of the artificial intelligence-based model by Jiao et al. [26], where the focus was made on the combination of the data on the learning process and summative measures. To drive predictive models to optimality, evolutionary computation algorithms have been used to achieve competitive accuracy with respect to benchmark machine learning. Research has collected evidence that active involvement, knowledge gained and test results were better predictors of learning as compared to prerequisite knowledge. Martin et al. [27] emphasized the predictive role of grit to academic performance, especially through persistence of effort as an enabler of self-driven learning patterns. The empirical data indicate that individual performance and internal drive have a significant impact on determining the GPA of students because it influences the sense of confidence and endurance in learning. The relationship between grit and performance is mediated by cognitive strategy exploitation and self-regulation.

Heppt et al. [28] have pointed out the predictive significance of books-at-home measures on student academic performance, especially in the area of language comprehension. The trend of consistency in findings has been that print access boosts literacy development and moderates the effects of socioeconomic status on achievement. Home literacy environment, as reported by parents, typically compares better with self-reported ones of students and is more correlated with academic outcomes. The researchers also indicate that reading traditional print materials, including books by parents, leads to increased development of language as compared to using computer materials like e-books. Xiong et al. [29] also indicated that there are two-way relationships between parent involvement and higher education performance of adolescents, which indicate how the measure of

student achievement can actually mediate parenting. Studies have continually indicated that parental engagement does have a positive relationship with increased student engagement, student motivation, and higher education success. The relationship between family involvement and the learning outcomes has also proved to be mediated by academic engagement, especially behavioral engagement. It is further implied that these relations may not be gender similar in terms of their force and direction, as they may have variation in mediation effects between girls and boys. Comprehensively, parental involvement is a strong but multifaceted factor in the academic performance of adolescents. Al-Abyadh et al. [30] have pointed out the decisive role played by personal effectiveness and personal organization to academic success of students, in that they stressed the interdependent roles of both on learning success. It has also been indicated in research that students with personal organization skill can plan, monitor, and control their learning behaviors. Personal performance has long been considered a legitimate predictor of motivation, tenacity and performance in learning settings of various kinds. Comparisons involving other cultures indicate that these psych variables operate at the same level in aiding academic performance. Generally, the combination of personal organization strategies and the building of individual effectiveness is the most significant in the attainment of university students.

Online traces and patterns of internet use are discovered to screen student achievement very well with deep learning, graph-based, and recurrent models, providing more precise outcomes based on hybrid approaches. Other behavioral information and neural networks, such as spiking models, also boost the early identification of at-risk learners. The use of sensors with CNN and BiLSTM to combine spatial and temporal variations is a good approach to research [31], [35], but attention-based video classification of the classroom is a good predictor of engagement and participation. Machine learning techniques remain good predictors of academics, with deep learning techniques using resampling techniques being more stable. Personal effectiveness, motivation, self-regulation, and grit are psychological predispositions that have direct involvement in achieving results [32], where autonomous learning and interest often mediate these effects. They are powerful predictors of both academic and social adaptation, whereas parental involvement reciprocates and affects both achievement and is determined by gender-specific factors. Burnout is an adverse outcome factor, the greatest impact of which is reduced efficacy and disengagement. Process and summative information combined in AI models enhance forecasts in e-learning, whereas explainability and trust are provided by explainable models. Collectively, the evidence reiterates the fact that the set of technological, psychological, behavioral, and environmental factors is combined and supported by sophisticated AI and machine learning to enhance predictive accuracy and intervention in academic performance.

III. Proposed Methodology

The idea of academic performance prediction is based on integrated and systematic spatial and temporal learning based on an advanced model of deep learning. This starts with the data collection process, where the performance and behavior data of the students are collected in the form of normalized academic scores and standardized behavior scores. Once the data is gathered, there are activities involved in preprocessing, which include handling of missing data, normalization of academic marks, normalization of behavior features, and identification of temporal features. The processed data is then sent to the Hybrid CNN and LSTM model, in which the CNN detects the spatial patterns of data and the LSTM detects the time dependency of data. The identified features of CNN and LSTM are joined under a fusion layer and fed to the SoftMax function to categorize the students into one of the three categories: low, medium, or high risk. Besides this, the FOX optimization method is used to adjust the learning rates, which hastens the training process and enhances the convergence by fine-tuning gradients with the help of fractional-order derivatives. The performance metrics to ensure that the model can predict the results of students based on the past data. Fig. 1 demonstrates the hybrid deep learning architecture to predict the success of the students based on spatio-temporal and behavioral data.

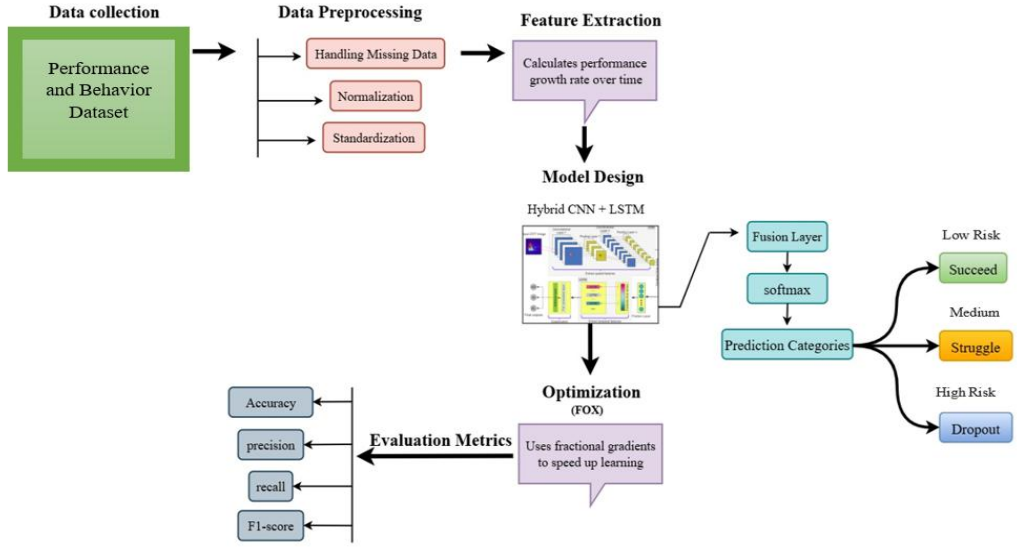

Fig. 1. Hybrid deep learning framework for predicting student success using spatio-temporal and behavioral data.

A. Data Collection

The academic history and learning behavior of the students in the Performance and Behavior Dataset obtained on Kaggle is well-rounded, as it consists of exam and assignment in-subject scores, attendance, classroom and study behavior, disciplinary behavioral indicators, and socio-demographic characteristics such as parental education, gender, and family background. The data set captures longitudinal academic tracks of students in several subjects, and this will be used to study the performance of the students longitudinally. To deploy the framework at the university-level, it additionally helps to combine the information system data of students, including course enrollment, credit completion, GPA/CGPA, and academic standing, with the logs of the learning management system, including the frequency of logins, content access, time-on-task and assignment submission behavior. Normalization, categorical encoding, and missing value are preprocessing steps that provide high-quality inputs that can be easily modeled spatio-temporally to predict early risks by academic performance and learning behavior.

B. Data Preprocessing

Preprocessing ensures that the behavioral and spatio-temporal data are consistent, cleaned, and prepared to be analyzed. The data treatment, academic scores normalization, behavioral indicators standardization, and time learning patterns extraction are missing in the operations involved. The conversions ensure that the data from various sources and scales may be compared and modeled in a meaningful way.

1) Handling missing data: The norm in datasets that cover the practical education is missing values due to attendance not mentioned, assignment not submitted, behavioral records missing or data entry errors. In the absence of such missing entries, analysis will be biased, and model performance will be worse as deep learning models need full and consistent input. To solve this, numeric attributes (e.g., test scores, percentage of class attendance, proportion of participation) are imputed with a mean imputation method, which replaces a missing value with the mean of all the available values of the attribute. This guarantees that the value added to it is representative of the frequency of the data, and it does not distort the general trend. The imputation equation can be written as in Eq. (1):

$$x_i' = \frac{\sum_{j=1}^{n} x_j}{n} \quad (1)$$

where, x_i' is the imputed value for the missing observation, x_j is the observed value of the feature, n is the number of valid observations of the feature. Mode imputation strategy is used in categorical attributes (e.g., type of study habit, disciplinary status, level of participation in classes). It is done by replacing the missing item with the most frequent category to keep the consistency in class distributions. These imputation techniques would ensure that the data set is not lost and the useful records are retained. This preserves the sample size and mitigates the systematic loss of data bias, and preserves all spatio-temporal and behavioral characteristics to conduct additional analysis. Finally, this approach produces a balanced platform of model training in which no feature is unfairly skewed due to the absence of data.

2) Normalization of academic scores: In education datasets, the marks of different subjects like mathematics, reading and writing usually have dissimilar marking systems that make these marks incomparable and hard to merge. An example of this is that one of the subjects will have a mark between 0 and 50, and the other one will have a mark between 0 and 100. Min-Max Normalization is used in order to have marks with an equal range. The process standardizes the data in a common range to facilitate easier analysis and comparisons among the individuals without the overbearing influence of one person because of the large range of scores. The scores are transformed through min-max normalization with the highest and the lowest numbers in the dataset. The normalized score (x_i') for a given raw score (x_i) is calculated in Eq. (2):

$$x_i' = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} \quad (2)$$

where, x_i' is the normalized score, x_i is the original score of the student, $x_{\min}$ is the lowest score observed in the data of that subject, $x_{\max}$ is the highest score observed for that subject.

3) Standardization of behavioral features: Behavioral indicators (attendance rate, frequency of participation, frequency of submitting assignments, etc.) in learning data sets may vary in range and units of measurement. As an example, attendance could be measured as a percentage, participation frequency (e.g., low, medium, high), and rate of submission of assignments as a number, or as a percentage. These range variations and units of measurement may present difficulties in analyzing these features together, in that some variables may possibly overshadow or bias analysis just because of their range. Z-score Standardization is done in order to make these features of behavior comparable across subjects. The operation transforms all features in such a manner that the distribution has a mean of 0 and a standard deviation of 1. The standardization equation is available in Eq. (3):

$$x_i' = \frac{x_i - \mu}{\sigma} \quad (3)$$

where, x_i' is the original value of the feature of the i-th data point, x_i is the standardized value of the feature of the i-th data point, μ is the average of each student's feature, and σ is the parameter's variance of all students.

4) Applying SMOTE for class imbalance: After the features (X) and labels (y) have been preprocessed, it is time to use SMOTE to solve the problem of class imbalance in the training dataset. The SMOTE process involves creating synthetic examples for classes with underrepresented data to ensure balanced training data. This not only helps the model but also directs the model's attention towards the minority classes in terms of predictions.

C. Temporal Feature Extraction

Multi-scale temporal sequences are used to model student performance to learn both short-term dynamics as well as academic growth over time. Within-semester time series, including weekly variation in academic scores, attendance, and

engagement, indicate instant learning behavior, whereas semester-to-semester variations indicate the long-term signals of performance change, credit accumulation, and academic status shift. Temporal trends are measured in terms of the rate of growth in performance between successive time points, which denote an improvement, stagnation or reduction in academic performance. The student trajectories can be harmonized over long durations of education, and analyzed on a scale at this dual level of time-modelling. The growth rate in performance is expressed in Eq. (4):

$$\text{GrowthRate}_t = \frac{\text{Score}_t - \text{Score}_{t-1}}{\text{Score}_{t-1}} \times 100 \quad (4)$$

where, Score_t is the student's performance (e.g., exam score, assignment score, or overall grade) at time t (current period), Score_{t-1} is the student's performance at the previous time point (e.g., previous exam, week, or term), The result is multiplied by 100 to express the growth rate as a percentage.

D. Model Design Hybrid CNN and LSTM

It is based on an advanced deep learning model to classify student performance based on spatial and temporal data. CNN identifies spatial patterns with the help of such features as scores, attendance, and behavior, whereas LSTM identifies temporal changes over time. The CNN and LSTM output features are sent through a fully connected layer to acquire abstract patterns and features. Last, the output layer relocates the students to either low, medium, or high risk depending on the patterns learnt. Fig. 2 indicates the layout of the hybrid CNN and LSTM.

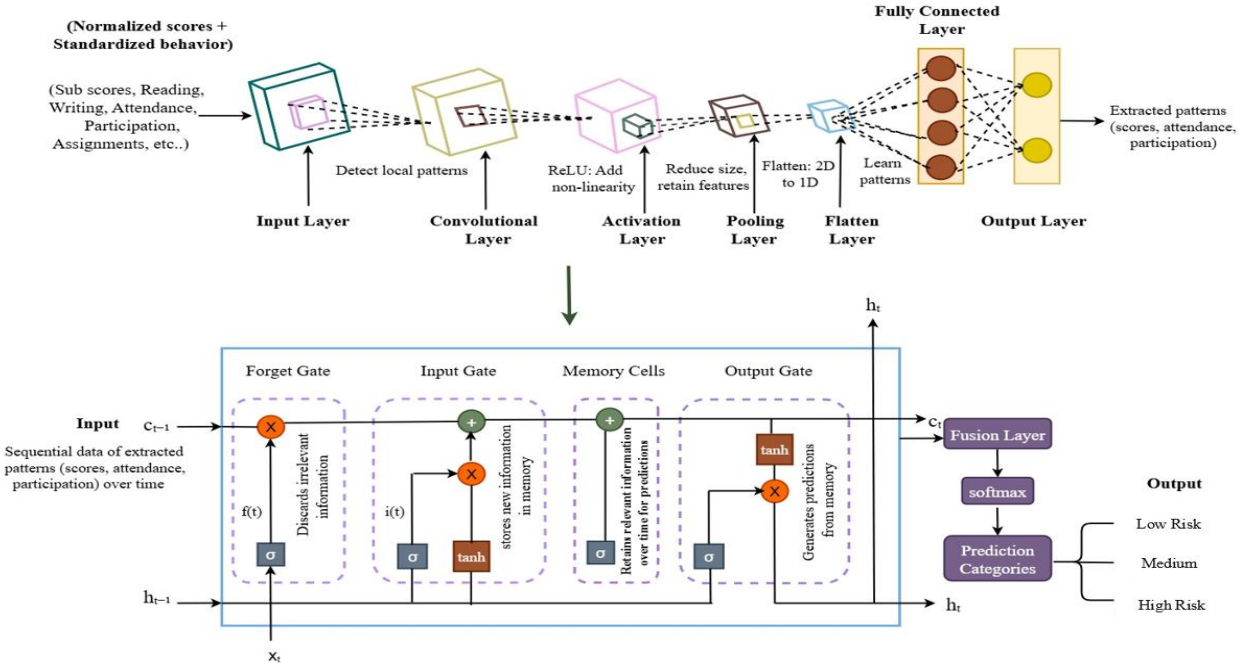

Fig. 2. Architecture of a hybrid CNN and LSTM.

1) Convolutional Neural Network: CNN identifies spatial patterns in the input features of performance grades of students, attendance, and participation. The CNN scans the input data to find significant patterns, including attendance-performance correlations or correlations between subjects, by applying the application of filters (kernels). These patterns are then captured in the form of feature maps and further processed by the activation and pooling layers so that only important features are stored, and complexity is minimized such that they may be utilized in the final classification and analysis.

a) Input layer: The first CNN layer operates on features such as academic scores, attendance, participation, and other behavioral traits that have been normalized. As a means to the end of predictive power, the model can also, alongside other variables like student demographics, LMS activity logs, and so forth, login frequency and time-on-task information, to mention a few, the model can also give more precise prediction outcomes by incorporating these features since they are often indicators of academic outcomes and thus provide a clearer view of the learning behavior. This additional input not only increases the feature space but also makes the model more robust by ensuring that it captures the patterns that perhaps only the grades alone would have otherwise missed. This enhancement makes the model more inclusive, leading to improved student performance prediction reliability.

b) Convolutional layer: The convolutional layer calculates the input data through filtering (or kernels). A filter is a small matrix that is passed over the input data (a sliding window) and multiplies and adds the products element-wise. This is used to identify significant spatial patterns of the input data, i.e. subject performance patterns or attendance patterns. This may be formulated mathematically as Eq. (5):

$$F(i,j) = \sum_{m=1}^{M} \sum_{n=1}^{N} I(i+m-1, j+n-1) \cdot K(m,n) \quad (5)$$

where, $F(i,j)$ is the output feature map at position (i,i), $I(i,j)$ is the input data (score/attendance at position i,j), $K(m,n)$ is the filter used to identify patterns, M and N are the

filter's dimensions. After passing through all of the input data, the filter generates feature maps that highlight several significant features, such as attendance trends or scoring patterns.

Another way to improve model efficiency is by using a 1D-CNN structure instead of a conventional 2D-CNN. A 1D-CNN is highly applicable for time-oriented academic records like scores, attendance, or behavioral patterns because it processes one-dimensional data through its filters. Compared to 2D-CNN with its image-like grids, a 1D-CNN is concerned with the temporal aspect of the data, thus using fewer parameters and consequently incurring lesser computational cost. Not only does this lighter architecture manage to capture important trends in student performance, but it also enhances training speed and efficiency of the whole model. Such an alternative provides an additional CNN design more consistent with the temporal nature of academic data.

c) Activation Layer (ReLU): The convolution operation is followed by the activation layer (usually ReLU) that adds a nonlinear behavior to the network needed to understand intricate patterns. ReLU is just a mere conversion of the negative values into zero to enable the network to concentrate on positive values to accelerate training. This working can be mathematically expressed, as in Eq. (6):

$$f(x) = \max(0, x) \tag{6}$$

When the input value x is negative, ReLU will make it 0; when the value is positive, it does not change. This aids the CNN to learn and identifying more elaborate patterns since it gets to erase the adverse influences that may not be significant.

d) Pooling layer: The pooling layer will have the responsibility of down-sampling both the spatial height and width of the feature maps produced by the convolutional layer without eliminating the larger features. Max pooling is the most common technique, where the maximum value of a small region of the feature map is selected with the aim of minimizing the amount of data at the expense of the most valuable data. This operation can be expressed in Eq. (7):

$$P(i, j) = \max_{m,n}\{F(i + m, j + n)\} \tag{7}$$

where, $P(i, j)$ is the pooled value at the location (i, j), $F(i + m, j + n)$ is the feature map generated from the preceding layer. The max pooling operation effectively sums up the region it scans, without losing the essential detail, as it compresses the data.

e) Flatten layer: The flatten layer transforms the 2D feature maps acquired following the pooling to 1D vectors. This is due to the requirement of the next fully connected layers of having the input to be a 1D array. The flatten operation is merely the transfer of the matrix of the pooled features to the one-dimensional features in the form of a dense layer.

f) Fully connected layer: The one-dimensional vector is flattened and then sent to the fully connected layer, where every node is connected to every other node in the same layer. This learns complex, high-level features, which combine data from the CNN spatial feature extraction. In essence, it learns predictive patterns of student attainment, taking into consideration all the features the CNN has identified.

This layer is capable of learning the correlation of the features extracted, i.e. how one subject in the performance of one class may also be correlated with the engagement in some other activity. In order to give final predictions, the dense layer makes a weighted summation of inputs and feeds them through an activation function.

- Output Layer: The learned features of the fully connected layer are fed into the Output Layer, which converts them into output. It converts the characteristics into patterns extracted, such as scores, participation, and attendance. The prediction patterns are the predictive ones and are the higher aspects of student behaviors and performances.
- Ablation of CNN:
  - To check how well the model's performance is without spatial feature extraction, eliminate or comment out the layers related to CNN.
  - Evaluate the model after removing the CNN in terms of accuracy and other performance metrics.

2) Long Short-Term Memory: The LSTM networks are based on the RNN; they can take in sequential data and therefore can be applied in situations where time matters in order of data, such as the case of tracking students over time. LSTMs can recall the relevant information over a long period of time, forget the irrelevant information, and change the state of memory using a combination of gates to control the flow of data. These characteristics enable LSTMs to identify more advanced patterns of time-series data and also provide predictions based on past input.

This is because the LSTM takes sequential data in the shape of normalized scores (i.e., mathematics, reading, writing) and standardized behavioral scores (i.e., attendance, participation, assignment completion). All these data points are synchronized across several time steps, which enables the learning of the LSTM in order to determine how the performance and behavior of the students change. The time series nature of the data allows the model to measure the patterns and trends with time. This feed will be helpful when estimating the future performance and categorizing student performance.

a) Forget gate: The forget gate of the model then determines which part of the information at the previous step is to be forgotten. It does this by generating values between 0 and 1 of every value in the memory cell. These values determine the extent of the information of the past that will be required to make the current prediction, and which will not be needed and will be forgotten. The forget gate can be defined as in Eq. (8):

$$\mathrm{f_t} = \sigma(\mathrm{W_f} \cdot [\mathrm{h_{t-1}}, \mathrm{x_t}] + \mathrm{b_f}) \tag{8}$$

where, f_t is the forget gate output (which determines which portion of the previous memory to forget), The linear activated function is denoted by σ, which maps the output between 0 and 1, W_f is the forget gate's strength array, h_{t-1} is the hidden state

from the previous time step, x_t *is the* input data at the current time step, b_f is the bias term for the forget gate.

The forget gate applies the logistic activation function to produce outputs in the range of 0 to 1; 0 signifies forget everything, and 1 remember everything. This makes the model retain only the relevant past data to make predictions of the future and forget the non-relevant portions of the memory.

b) Input gate: Based on the forget gate, the input gate identifies the new information that has to be added to the memory cell. It creates a perfect memory cell update with the help of a tanh function and is based on a sigmoid equation to determine what values should be modified. This will enable the LSTM to add new useful information, without forgetting the most useful past environment. Input gate output, as shown in Eq. (9):

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (9)$$

where, i_t is the input gate output (which determines which parts of the input will be updated in the memory), W_i represents the input gate's weight matrix, h_{t-1} symbolizes the previous time step's concealed state, x_t refers to the current time step's input data, b_i is the input gate's bias term, σ stands for the logistic activation function.

The sigmoid function provides the values of 0 to 1 to denote the percentage of the new data that is to be considered as relevant to be stored in the memory, and the tanh function provides the values that can be stored in the memory cell; it is normalized and added to the memory cell.

c) Memory cells: The memory cell includes valuable data in the long term after the input gate. It does it by combining the last memory state and the input candidate memory, multiplied by the input gate output. The current memory cell stores information that is useful in the next time step, and the LSTM can remember the useful information of the past and apply it in the next prediction. The memory cell adds the previously transferred memory of the previous time step, C _(t-1) and the current time step input C^t. This combination is done in such a way that only important data will be retained in the memory cell to be utilized again in the future, and the model has the ability to retain important patterns but forget information that is not very critical with time.

d) Output gate: The output gate of the LSTM determines which data can be traced out of the memory cell to form the final secret state (or output). It then transfers the result over a tanh activation process after computing an activation based on the current state of the memory cell. The result enhances the outcome of the gate activation and dictates a carryover of the concealed state to the next time period. When the input has gone through the output gate, the data is fed into the LSTM output, which is then used to combine the hybrid model output, and this is done through a fusion layer.

e) Attention mechanism: The LSTM, although it does capture the temporal dependencies, still suffers from the fact that not all time steps are equally important for predicting the student's performance. By introducing the attention mechanism after the LSTM layer, this problem is solved. The attention layer looks at all the hidden states that have been generated throughout the time sequence and gives each time step a weight according to its importance. In this manner, the model will be able to concentrate more on the pivotal moments in the student's behavior like a sudden drop in attendance or a big shift in academic scores at the same time, it will be able to reduce the impact of the less relevant periods. The attention score for each time step t is expressed in Eq. (10):

$$e_t = v^T \tanh(W_h h_t + b_h) \quad (10)$$

where, e_t is the raw attention score for time step *t*, h_t *is the* LSTM hidden state at time step *t,* W_h is the Weight matrix that transforms the LSTM hidden state for attention scoring, b_h is the bias term added during the transformation, v^T is the trainable weight vector used to convert the transformed hidden state into a single importance score, tanh is the activation function that introduces nonlinearity. The incorporation of attention eventually results in a model that is more stable, more accurate, and more interpretable. In this case, the educators can now know the periods that had the most influence on the prediction of low, medium, or high risk. The raw scores are then converted into attention weights through the application of a softmax function, which is presented in Eq. (11):

$$\alpha_t = \frac{\exp(e_t)}{\sum_{k=1}^{T} \exp(e_k)} \quad (11)$$

where, α_t is the attention weight for time step *t,* e_t is the raw attention score at time step t, $\sum_{k=1}^{T} \exp(e_k)$ is the Normalization term that sums the exponentiated scores of all *T* time steps, *T* is the Total number of time steps in the sequence. The aggregated data is then passed to the softmax layer, which determines the probability distribution of all possible outcomes. In order to enhance the efficiency and prevent overfitting of the hybrid CNN–LSTM model, regularization techniques are integrated into the training process. The methods make the model less noise-sensitive and thus improve its capability to generalize to new student data.

- Dropout is implemented between the layers that randomly turn off a fraction of the neurons. This will help to avoid the network from depending excessively on specific nodes, and also, to make it learn more powerful and shared representations.
- Batch Normalization is utilized to control the distribution of layer activations, thereby yielding smoother and quicker training. It lessens internal covariate shift and aids the model to stay strong even when faced with variations or noise in the behavioral and academic inputs.

Dropout and batch normalization together significantly bolster the hybrid model's robustness, reduce the chances of overfitting, and deliver more accurate classifications of students into the categories: low, medium, and high risk. Finally, but not least, the SoftMax output is employed to generate the predicted categories, which determine the performance or risk of the student. All these assist the LSTM to predict dynamically and time-dependently with the aid of sequential pattern (LSTM) and spatial information (CNN).

The hybrid CNN-LSTM system can be applied to actual circumstances in universities by integrating student information

systems and learning management systems data without making any changes to the fundamental design. The indicators specific to the university, including credit accumulation, GPA/CGPA threshold, course failures, academic probation, and graduation eligibility, are modeled as structured inputs, and academic and credit patterns as spatial features represented with CNN, and semester-based progression and learning behavior as temporal sequences with the standard academic calendars. To aid in transparent decision-making, explainable AI methods are used to uncover the most significant academic and behavioral predictors to make accurate classifications of the probability of probation, course failure, and delayed graduation risks as low, moderate, and high-risk risks and inform academic advising.

- Ablation of LSTM:
  - To discover how the model reacts without the LSTM layers involved in temporal sequence modeling, either remove them or comment them out.
  - This will indicate how much LSTM contributes to the capturing of time dependencies in the data.

TABLE I. STUDENT PERFORMANCE PREDICTION CATEGORIES

Category	Description
Low Risk	According to the model, the pupil will probably do well and be successful.
Medium	According to the model, the pupil is likely to struggle and encounter obstacles.
High Risk	The model predicts a high risk of the student dropping out.

Table I of the predicted categories shows the input categories of the model, which involve using CNN and LSTM. The models include: low risk, in which the model student performs well and is an academic success; medium, which refers to the fact that the student will struggle and he/she may require more help to be a better student; and high risk, which refers to students who are at a high risk of disengagement and can drop out. The predictions will be made based on trends within the space observations (e.g., scores, attendance) and time trends (e.g., behavior over time), which makes the model categorize the students into such groups to provide them with an individualized intervention and guidance. Algorithm 1 shows hybrid deep learning for academic achievement prediction.

Algorithm 1

Input:

1. Spatio-Temporal Data:
   - Normalized Academic Scores: Scores from various subjects (e.g., mathematics, reading, writing).
   - Standardized Behavioral Features: Attendance, participation, assignment completion rates, etc.
   - Time-Series Data: Data over multiple time steps (e.g., weeks, terms).

Output:

- Predicted Categories:
  - Low Risk: The student is likely to perform well.
  - Medium: The student is likely to face academic challenges.
  - High Risk: The student is at risk of dropping out.

Step 1: Data Preprocessing

1. Normalization:
   - Apply Min-Max normalization to academic scores to bring them to a comparable range (e.g., [0, 100]).
   - Apply Z-score standardization to behavioral features like attendance, participation, and homework completion.
2. Handle Missing Data:
   - Use techniques such as mean imputation or data interpolation to handle missing values in the dataset.

Step 2: Convolutional Neural Network for Spatial Feature Extraction

1. Input Layer:
   - Input normalized academic scores and standardized behavioral features as multi-dimensional data.
2. Convolutional Layer:
   - Find geographic patterns in input data, use filters (kernels) (e.g., relationships among scores and attendance).
3. Activation Layer (ReLU):
   - Apply the ReLU activation function to introduce nonlinear behavior.
4. Pooling Layer:
   - Minimize spatial dimensions without sacrificing important features, use max pooling.
5. Flatten Layer:
   - In order to use the feature maps from the pool as inputs for the fully linked layer, flatten them into a 1D vector.
6. Fully Connected Layer:
   - Learn complex patterns from the extracted features and pass the learned features to the next stage.

Step 3: LSTM for Temporal Modeling

1. Input Layer:
   - Sequential data of extracted features (scores, attendance, participation) over time is passed into the LSTM model.
2. Forget Gate:
   - Based on its applicability to future projections, the forget gate determines whether data from previous steps should be ignored.
3. Input Gate:
   - To guarantee that only pertinent data is retained, the input gate determines which fresh data must be put to the memory cell.
4. Memory Cell:
   - Memory cells store the relevant information from the current and previous time steps. On the basis of the input and forget gates, they update.
5. Output Gate:
   - The output gate passes the current input through an activation mechanism and generates the outcome depending on the modified memory cell.

Step 4: Feature Fusion Layer

1. Fusion Layer:

- Combine the outputs of the CNN (spatial features) and LSTM (temporal features) to form a unified representation.

Step 5: Final Prediction Layer

1. Fully Connected (Dense) Layer:
   - This layer learns from the fused features and classifies the student risk into one of the categories: low, medium, or high risk.
2. Softmax Layer:
   - Utilizing the softmax activation function, a distribution of chances across the categories is generated.

Output:

- The ultimate classification is determined by using the softmax output (predicted categories: low, medium or high).

IV. FOX OPTIMIZATION

The FOX optimizer (Fractional Order optimizer with Exponential Convergence) is a superior optimization method that optimizes the rate of convergence and accuracy of deep learning models. Unlike the traditional optimizers, FOX uses fractional-order derivatives to learn how to update the learning rate. The novel approach to gradient calculation adjustment with the use of fractional exponents has been utilized in the novel method to enhance the stability and efficiency of deep learning models during training. FOX accelerates convergence by the fact that it addresses the problems of the local minima and sluggishness of training, which are intrinsic to the classical optimization methods. FOX is an optimal and more effective way of updating parameters since it employs fractional orders in updating the gradients. The most essential thing about the FOX optimizer is its two-step process, which is gradient update and fractional-order scaling. The first step is the formula of gradient update that utilizes the derivatives of the model parameters in a fractional order to update them. This is represented in Eq. (12):

$$\theta_t = \theta_{t-1} - \alpha_t \cdot g_t^{\gamma} \tag{12}$$

where, θ_t is the parameter at time step t, α_t is the learning rate at time t, g_t is the gradient at time t, and γ is the fractional order used to scale the learning rate. This update would speed convergence, scaling the gradient with a fractional exponent, which gives more accurate parameter updates. Step 2 is fractional-order scaling, in which the gradient scale is scaled by its L 2 norm. This action keeps the amount of the update proportionate to the importance of every parameter, enhancing the efficiency of the optimizer with complex, multi-layer models like CNN + LSTM. The fractional-order scaling takes the form of Eq. (13):

$$\theta_t = \theta_{t-1} - \alpha_t \cdot (\|g_t\|^{\gamma}) \tag{13}$$

where, $\|g_t\|$ represents the L2 norm of the gradient at time t, making sure the optimizer modifies the learning rate in accordance with the gradient's strength. The fractional order γ maximizes the value of each gradient to its optimal value, thus allowing the optimizer to respond better to the dynamic gradient with time.

A. Comparative Analysis: FOX vs. Adam Optimizer

The comparison with the Adam optimizer, which is one of the most popular deep learning optimizers, is sought for a better understanding of the advantages of FOX. Adam makes use of momentum and adaptive learning rates derived from first and second-order moment estimates to update parameters. This results in fast convergence and allows Adam to deal with noisy gradients effectively.

FOX is significantly different from Adam in two main aspects. Firstly, FOX employs fractional-order gradient scaling, which gives more flexible and accurate control over parameter updates, in contrast to Adam, which uses fixed exponential averages. Secondly, FOX updates its step size according to the L2 norm of the gradient, which enables it to breathe life into flat regions and slow-converging plateaus that often hinder Adam. Consequently, the path to convergence for FOX could be shorter and its reliability higher, especially with the intricate hybrid structures such as CNN + LSTM.

Nonetheless, the Adam algorithm is still a robust reference point mainly due to its ease of use, less intensive computations, and wide acceptability through its performance in various tasks. The comparison of both optimizers simultaneously uncovers the learning dynamics, convergence behavior, and robustness of the model under consideration more clearly.

B. Ablation of FOX

- Detect the absence of FOX and install the simpler optimizer (Adam), then check if the removal of FOX resulted in the slowing down of convergence and the reduction of model stability.
- The above-mentioned assessment will facilitate determining whether or not the tailor-made FOX optimizer is a necessity or if a standard optimizer like Adam can yield the same result.

V. RESULTS

The outcomes of the proposed hybrid CNN and LSTM structure are provided in this section. The architecture was written in Python with popular deep learning libraries based on TensorFlow and Keras being used to perform the computations. Training and testing data entail scholastic achievement information of the students, as well as normalized scores on subjects like mathematics, reading, and writing, and standardized behavioral characteristics like participation, attendance, and submission of assignments. The data is spread across the time steps, depicting the performance of the students on several terms or weeks of the year, to enable the model to learn the spatial and temporal pattern of knowledge. Subsequent parts include general performance metrics, including the rate of correctness and an exactness measure, as well as the rate of sensitivity and the balance score and graphical depictions such as a confusion matrix, ROC curve and precision-recall curve. The results demonstrate how the framework can be used to make predictions of the student performance categories, which explains its effectiveness in a classroom setting.

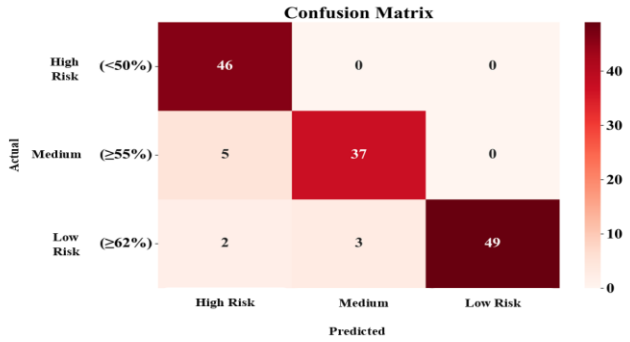

Fig. 3. Confusion matrix.

The accuracy of the model in predicting the performance of pupils is measured using the confusion matrix in Fig. 3. It highlights the differences between risk categories (low, medium, and high risk) and projected categories based on the model's projections. True positives are observed on the diagonal boundary, such that the model made the right prediction as to the respective sets of student performance. The off-diagonal values are poor predictions where the model predicted one category in another one. In general, there is excellent predictive confidence in the low and medium risk groups that is represented in the matrix.

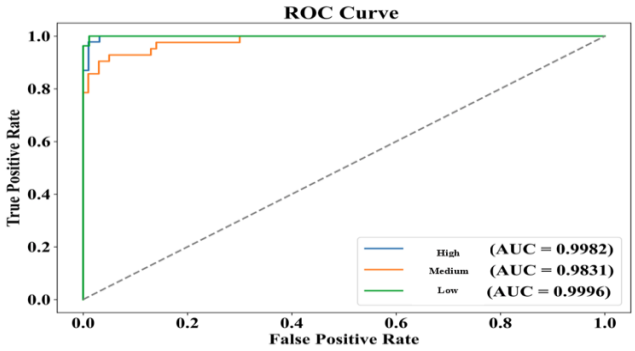

Fig. 4. ROC curve.

In the Fig. 4 of the ROC curve, the capacity of the framework in predicting the result of the pupil in three groups, that is, high risk, medium, and low risk, is evident. The trade-off in the curve is the true positive rate (sensitivity) and false positive rate (1-specificity) for each group. Accuracy is very high with the area under the curve of the model being 0.9982 in the case of high risk, 0.9831 in the case of medium and 0.9996 in the case of low risk, demonstrating that the model is a fantastic one in the differentiation of the different classes of students. The green curve that provides the best AUC is the Succeed curve, and it has high predictive power on the set of students who will succeed, although the other two classes also have good predictive power.

The model is described by a plot, which shows its training and validation accuracy at various epochs in Fig. 5. The accuracy of training is blue and the accuracy of validation is orange. The training and validation accuracies increase with the number of epochs, and the training accuracy is always equal to 1.0. The validation accuracy also increases significantly but unequally, which may be a manifestation of overfitting or minor variation in the performance of the training and the validation sets. Overall, the model has justifiable positive results in learning the plot and good generalization between epochs.

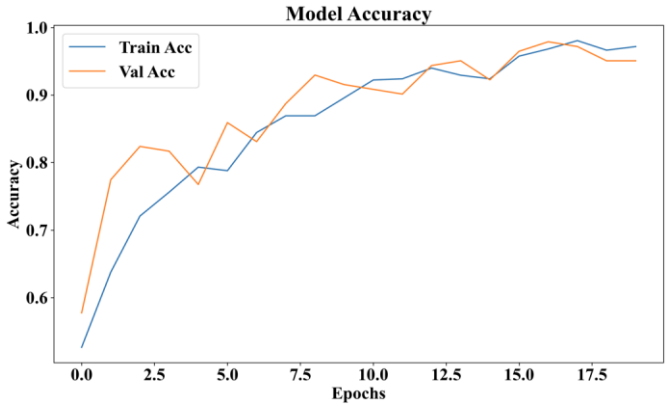

Fig. 5. Model accuracy.

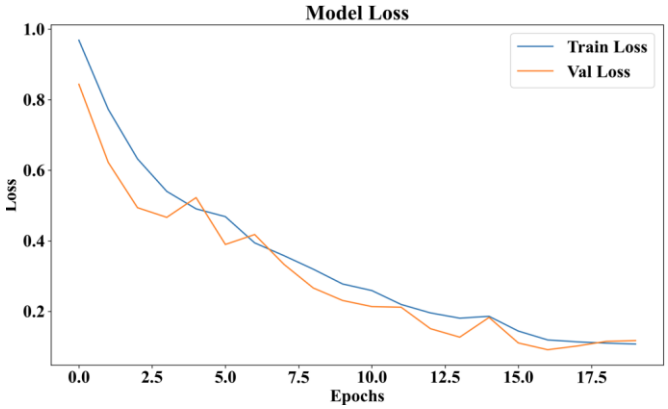

Fig. 6. Model loss.

In Fig. 6, the plot of the training and validation loss of the model at various epochs is presented. Blue and orange lines represent the training and validation loss, respectively. With the increase of the epochs, the losses become less and less, which means that the model learns and minimizes the errors. However, loss on validation hits some point, and this signifies that the model is generalizing very well. This indicates that the score of the verification set remains constant in the course of training, and this means that training is efficient and there is minimal overfitting, although the algorithm itself is still learning.

A. Performance Analysis

The results of the performance analysis section indicate how efficient the proposed Hybrid CNN and LSTM model is in terms of predicting the academic success of students. Fig. 7, Fig. 8, and Fig. 9 show important performance indicators that are the False Negative vs. False Positive Rates and the Precision-Recall curves and the overall performance of the model that has high precision, recall, and accuracy. The outcome demonstrates that the model has a high degree of accuracy in predicting different categories of students, and it is superior to regular models such as LSTM and SVM. The better results of an enhanced deep learning model using various evaluation measures are also confirmed in Table II, confirming its use to predict with high precision in academic studies.

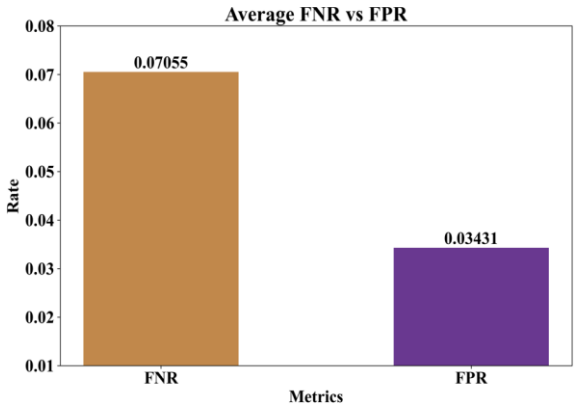

Fig. 7. Average FNR vs. FPR.

In Fig. 7, the average predictions of the model of FNR versus FPR are compared using the bar chart. FNR has a brown bar with a measure of 0.070555, and FPR has a purple bar with a measure of 0.03431. As indicated in the graph, the model creates a greater FNR than the FPR, which implies that the model incorrectly classifies students as not being at risk more than the rate of the inaccurate classification of the students as being at risk.

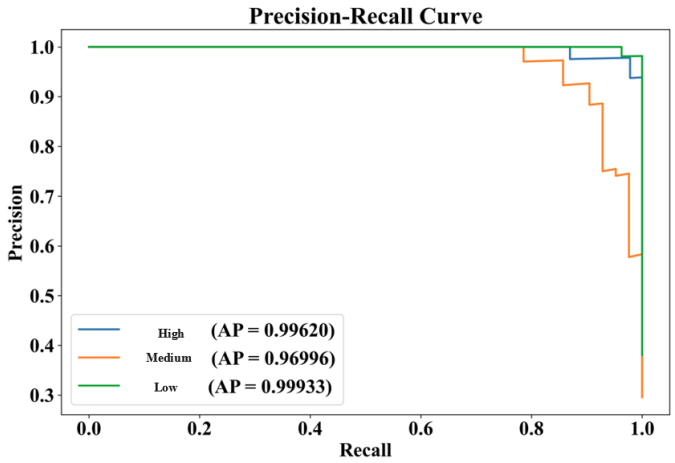

Fig. 8. Precision-recall curve.

The model performance for the different classes: high risk, medium, and low risk is shown in precision-Recall curves in Fig. 8. Each curve will indicate the precision-recall trade-off of each class as well as the area under the curve, which will indicate the performance of the model. The highest AP belongs to succeed 0.999333, which gives a high recall and precision, followed by 0.99620 that gives high recall but low precision, and 0.96996 that gives low recall but high precision. These values reflect the fact that the model predicts successful pupils with phenomenal precision, and is fairly good at predicting dropouts, but somewhat reduced in the medium prediction.

The performance values of the hybrid model are excellent results of the performance on several performance metrics in Fig. 9. The prediction of the model was 97.18 per cent, which is a good overall result. Precision and recall are also quite high at 97.02 and 97.35, respectively, which shows that the model did not misclassify the positive instances and had the lowest number of FPR and FNR. F1-score is also 97.14, which indicates a recall and precision balance. These results indicate the predictive ability of the model for student success in the three risk levels.

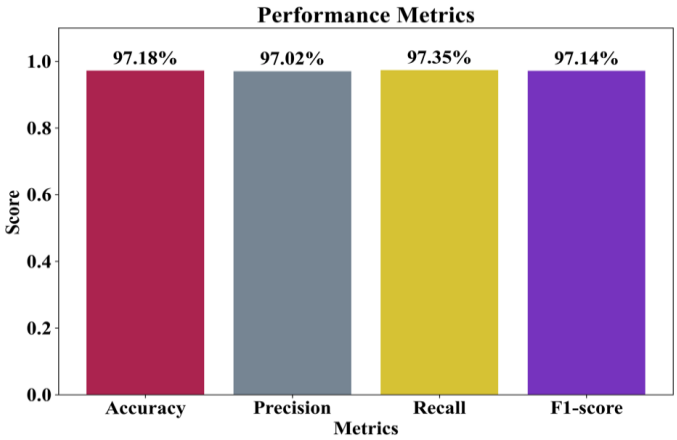

Fig. 9. Performance metrics.

B. Model Explainability with SHAP

In order to improve the interpretability of the model, utilized SHAP to identify the important factors that influence the predictions. SHAP values reveal the contribution of each feature (e.g., academic scores, attendance, participation) to the decision of the model for a particular prediction. By attributing the prediction to the contributions from each feature, SHAP provides the reasoning behind the prediction of a student risk level as high, medium, or low.

Through the application of SHAP values, it is possible to notice that attendance and participation are the most determining factors in the prediction of the "medium" category. A student might be predicted as a "Struggler", and the prediction may be influenced by behavioral factors like low participation, even though the student has high academic scores. SHAP makes it clear and transparent. The force plot below shows the contributions of features for the student, who has been predicted as a Struggler, individually. The contributions that are positive push the prediction in the direction of "medium", while the negative contributions retract it from the prediction. Such insights are especially helpful for the education sector as they not only provide practitioners with an understanding of the predictions of the model but also enable them to customize interventions according to the particular reasons that determine a student's performance.

TABLE II. PERFORMANCE EVALUATION TABLE

Method	Accuracy	Precision	Recall	F1-Score
LSTM [33]	87	87	88	88
SVM [34]	82	93	84	89
GRU	92.34	91.00	90.30	90.65
Bi-LSTM	93.50	92.10	91.50	91.80
Transformer	94.75	94.00	93.90	93.95
TCN	95.20	94.60	94.20	94.40
Hybrid CNN and LSTM	97.18	97.02	97.35	97.14

Table II provides a detailed view of how different models, including LSTM, SVM, GRU, Bi-LSTM, Transformer, TCN, and the proposed Hybrid model, performed compared to one another. The Hybrid CNN and LSTM model got the best performance ever recorded with the highest accuracy (97.18 per cent) and also surpassed all remaining models according to precision, recall, and F1-score. Additionally, the two models, i.e., Transformer and TCN, in this case, have exhibited great capability, especially when it comes to long-term dependency issues, as their maximum accuracy reached 94.75 per cent and 95.20 per cent, respectively. On the other hand, while GRU and Bi-LSTM have yielded close results, the hybrid model is still the most powerful in predicting students' performance.

VI. Discussion

The outcomes from the comparison with the models such as GRU, Bi-LSTM, and those based on Transformer and TCN kept confirming that the hybrid CNN-LSTM-FOX model is superior to traditional models like LSTM and SVM in terms of accuracy, scoring a remarkable 97.18 per cent. The hybrid model has been very effective in combining the strengths of both CNN and LSTM, enabling the former to extract spatial patterns while the latter recognizes temporal ones, eventually providing a very holistic understanding of student performance. In the case of models like Transformer and TCNs, they offer certain advantages over LSTM in capturing long-term dependencies and processing sequential data, but still, the hybrid CNN-LSTM-FOX model, when judged strictly on performance, is the best. Conversely, GRU is less accurate than LSTM and the hybrid model, but is still a good choice in resource-constrained environments due to its simpler architecture and lower computational time. In general, the findings indicate that the hybrid model with FOX is always superior to comparative architectures as it successfully learns both spatial and temporal learning patterns. Besides higher education, the structure can be easily incorporated into the institutions of higher learning where the academic progression is stipulated by credit accruals, GPA/CGPA and prerequisites. It is appropriate in academic risk identification in undergraduate and postgraduate programs due to its capability to model heterogeneous and semester-wise academic trajectories. The academic risk is determined based on the higher-education outcomes, like course failure, GPA/CGPA, academic probation, and delayed graduation, which allows grouping low-risk, moderate-risk, and high-risk groups.

A. Focused Error Analysis

While the hybrid CNN-LSTM model exhibits a robust performance, it continues to be necessary to take care of the situations in which the model performs poorly. A concentrated error analysis indicates that the model is particularly in trouble when it comes to students who are academically very good but have low attendance, resulting in misclassification between "low" and "medium". The model often makes these errors with the pupils who occasionally attend classes, and hence, the model might not be able to pick up on this engagement of the student's very well. Furthermore, sometimes the students with irregular behavior patterns are wrongly classified, which implies that the model is not able to grasp the full complexities of behavioral data over time. The above-mentioned weaknesses signal the areas for possible model refinement. Later on, one of the approaches could be developing the data preprocessing, for instance, through better management of attendance and participation data or combining it through more sophisticated features that track student engagement over time. Without doubt, the model that is more sensitive to the mentioned factors could lead to a more accurate and reliable prediction system.

B. Practical Implications

The proposed framework is a kind of early warning mechanism allowing academic advisors and instructors to recognize students who are at risk at the early stage of their academic life. Predictions on the model are converted to risk scores that can be acted upon and early warning groups to enable advisors to prioritize students who need urgent attention. Advisors can use explainable outputs to emphasize important academic and behavioral risk factors (such as a drop in GPA, inadequate credit accumulation, failure in courses, low attendance, and decreased LMS engagement) to develop specific interventions, such as tutoring, mentoring, probation support, or individualized learning plans. This is a timely and data-driven decision support which improves retention of students, efficient use of institutional resources and also an ongoing monitoring of the student progression within the university academic systems.

To guarantee scalability and generalization, the proposed framework will be tested on a variety of colleges and academic subjects to take into consideration the differences in the curriculum structure, grading policy, and credit requirements. The cross-program evaluation helps to evaluate the model in terms of its robustness and transferability to prove that it can be applied not only in one institution or discipline.

C. Ethical and Privacy Considerations

To enable the adoption of responsible deployment in the context of universities, the framework will utilize ethical and privacy-sensitive tools, such as role-based access control, data minimization, and bias monitoring. There is restricted access to student data based on institutional roles (e.g., advisors, instructors), and prediction is based on only necessary academic and behavioral characteristics. Also, the results of predictions are reviewed periodically within demographic and academic subgroups to address and reduce possible bias to secure, equitable, and reliable decision support of academic advising.

VII. Conclusion and Future Work

The study introduces a hybrid CNN-LSTM that is used to determine the student risk level results of being low, medium, or high. CNN is used to process student data, such as academic grades and personal attributes, to identify spatial patterns, whereas LSTM is used to track progress over semesters. The model was found to have an accuracy of 97.18 per cent and was better than other traditional models like LSTM and SVM; the interpretability was also guaranteed through SHAP to determine the key predictive variables. It could be assessed as an early-warning system that helps teachers to notice at-risk students and intervene timely. The framework can apply to a wide range of educational contexts with the introduction of university-specific characteristics such as credit systems, GPA/CGPA, prerequisites, and semester-wise progression, although tested on a single-institution dataset, which limits the scope of

generalization of the results. Further studies could involve larger and multi-institutional groups of data and other socio-economic and learning-environment variables to further enhance the predictive strength. The framework consists of ethical protections like role-based access, data minimization, and bias monitoring that can be deployed in a higher education system in a privacy-aware and responsible manner.

The proposed framework will be tested in the future on a variety of colleges and academic fields to determine its strength and cross-program extensibility in the context of different higher education institutions.

Farm and Learn: An Offline Mobile Learning System Integrating AR, AI, and Game-Based Learning for Agricultural Education Among Children

Pubuditha De Silva[1], Chamodya Prabodhani[2], Daminda Herath[3]
Faculty of Information Technology, Horizon Campus, Malabe, Sri Lanka[1, 2]
Department of Computer Science, Sir John Kotelawala Defense University, Ratmalana, Sri Lanka[3]

***Abstract*—This study presents Farm and Learn, an offline-first mobile learning system that integrates Augmented Reality (AR), Artificial Intelligence (AI), and Game-Based Learning (GBL) to enhance agricultural education among children in low-connectivity environments. Existing agricultural learning applications often provide isolated functionalities such as visualization or plant recognition, with limited pedagogical integration and insufficient support for rural deployment. To address these limitations, the proposed system combines immersive AR-based exploration, interactive gamified learning activities, and AI-assisted paddy plant growth-stage identification within a unified child-centered educational framework. The architecture adopts a modular offline-first design that enables core learning functionalities to operate without continuous internet access while allowing optional synchronization when connectivity is available. The AI component employs a lightweight YOLOv11n deep learning model validated through prototype inference to assess feasibility for future on-device deployment. The system was developed using Unity and ARCore and evaluated through user acceptance testing involving students, educators, and domain experts. Results demonstrate high usability, strong learner engagement, and improved learning performance, confirming the effectiveness of integrating immersive visualization, intelligent interaction, and gamified reinforcement in educational contexts. The findings highlight the practical potential of offline-first mobile learning platforms to support inclusive agricultural education and provide a scalable foundation for future intelligent educational systems in resource-constrained environments.**

Keywords*—Agricultural education; augmented reality; artificial intelligence; child-centered learning; game-based learning; offline mobile learning

I. Introduction

A. Background Information

Agriculture remains a fundamental sector of Sri Lanka's economy and food security [1], yet agricultural education at the primary level continues to face significant challenges in adopting interactive and technology-enhanced learning approaches [2]. Traditional pedagogical practices based on static textbooks and teacher-centered instruction often provide limited opportunities for experiential learning, resulting in reduced engagement among young learners and inadequate exposure to foundational agricultural concepts [3]. This issue is particularly critical in the context of paddy cultivation, a key element of Sri Lanka's rural economy and sustainable food production [4].

Sri Lanka's educational landscape continues to face significant challenges due to a persistent digital divide, even though national internet usage has surpassed 56%. A considerable portion of the population, about 43.7%, remains offline, particularly in rural communities where limited infrastructure and higher poverty levels of around 24.8% restrict access to digital technologies. As a result, many rural schools still depend heavily on traditional teaching approaches with limited exposure to modern digital learning resources. Although mobile technology has become the primary means of connectivity in these regions, access remains uneven and unreliable. Community initiatives such as "Nenasala" telecenters have attempted to bridge this gap by providing shared internet access, but their availability and consistency vary across locations. This situation highlights the importance of designing educational solutions that can operate effectively without requiring continuous internet connectivity [5].

This gap became evident through evaluations of existing school syllabi, classroom observations, and discussions with educators and parents. These stakeholders consistently highlighted the need for modernized, engaging, and visually rich learning materials. Despite the integration of digital resources into general science and geography education, there is a notable absence of purpose-built tools that leverage emerging technologies such as Augmented Reality (AR), Artificial Intelligence (AI), and Game-Based Learning (GBL) for agriculture- focused education at the primary level [6], [7].

Existing digital solutions provide only partial support. For instance, applications such as "FarmAR" offer AR-based visualization of farming equipment but lack structured educational frameworks and curriculum alignment [8]. Conversely, tools such as "Plantix" focus primarily on AI-based plant diagnosis designed for farmers rather than young learners [9]. These applications generally do not provide child-centered learning designs or offline functionality, both of which are essential for deployment in rural and low-connectivity contexts [10].

To address these limitations, this study introduces "Farm and Learn," an offline-first mobile educational system developed using Unity 6, Google ARCore, and Blender 4.3 [11], [12]. The proposed system delivers an immersive learning experience for children aged 10 years and above by integrating modular components, including AR-based exploration of 3D farming equipment, GBL-driven quizzes and interactive activities, and

an AI-based plant identification prototype utilizing a YOLOv11n convolutional neural network trained on a custom dataset [13]. Content development was guided by agricultural experts from the Rice Research Station, Labuduwa, while technological implementation was refined in collaboration with academic staff and students from the Department of Software Engineering, University of Kelaniya.

B. Research Problem and Research Questions

Despite the economic and social importance of agriculture in Sri Lanka, primary-level agricultural education continues to face significant limitations related to learner engagement, technological integration, and accessibility. Existing curriculum largely relies on passive, textbook-oriented instruction, which does not adequately support interactive or experiential learning for digitally native students [2]. This pedagogical gap contributes to reduced interest among younger generations in agriculture, particularly paddy cultivation, which remains a critical component of national food security and rural economic sustainability [3].

At the same time, currently available mobile applications in the agricultural domain do not provide comprehensive educational experiences specifically designed for children. While some applications offer isolated capabilities, such as AI-based plant disease detection (e.g., "Plantix") or AR-based visualization of agricultural objects (e.g., "FarmAR"), these systems typically lack curriculum-oriented learning structures, pedagogical scaffolding, and offline functionality suitable for rural educational deployment. More importantly, existing solutions rarely integrate AR, AI, and Game-Based Learning (GBL) within a unified framework to deliver immersive and holistic learning experiences tailored for young learners [14].

Unlike existing agricultural learning applications that focus on isolated functionalities such as AR visualization or AI-based plant recognition, including systems such as FarmAR [8] and Plantix [9], this work introduces a unified offline-first educational framework that integrates Augmented Reality (AR), lightweight AI-based plant identification, and Game-Based Learning (GBL) within a child-centered learning environment. The proposed system demonstrates how immersive technologies can be combined into modular educational architecture specifically designed for rural and low-connectivity contexts [17], [19], [20]. By integrating AR exploration, AI-driven interaction, and gamified learning within a single platform, this study extends prior work beyond single-purpose agricultural applications toward an integrated and pedagogically aligned learning solution for primary-level agricultural education [23], [25].

Given these limitations, a clear research gap emerges regarding the design and implementation of child-centered, offline-first educational systems that integrate immersive technologies for agricultural learning. Therefore, this study is guided by the following Research Questions (RQs):

- RQ1: Can immersive technologies such as AR, AI, and GBL improve learner engagement and educational outcomes in primary-level agricultural education?
- RQ2: Is it technically feasible to develop a fully offline-first and child-friendly mobile learning system suitable for rural and low-connectivity educational contexts?
- RQ3: Can AI-based visual recognition of paddy plant growth stages be effectively integrated into an interactive educational environment?

To address these questions, this research proposes the development of "Farm and Learn," an offline-first, context-aware mobile application that combines immersive technologies with pedagogically grounded content. The proposed system aims to increase children's engagement with agricultural concepts while providing an accessible, scalable, and technologically feasible solution for enhancing agricultural literacy in resource-constrained environments.

C. Significance of the Research

This research addresses a critical gap in primary-level agricultural education by introducing an immersive, technology-enhanced learning solution tailored for children. Despite the centrality of agriculture to Sri Lanka's economy, the subject receives limited emphasis in early education, with learning resources often restricted to outdated textbooks and static illustrations. This disconnect between traditional teaching methods and the expectations of today's digitally fluent learners highlights the need for a paradigm shift in educational delivery.

The significance of this project lies in its integration of Augmented Reality (AR), Artificial Intelligence (AI), and Game-Based Learning (GBL) into a unified, modular mobile application [15], [16]. The application not only provides structured agricultural knowledge but also engages learners through interactive visualizations, intelligent plant recognition, and gamified content. Developed using Unity and ARCore, with an AI model trained via Roboflow and implemented in JupyterLab using YOLOv11n, the system demonstrates the viability of deploying advanced educational technology in low-connectivity, rural environments through an offline-first architectural approach.

Beyond its educational objectives, this research contributes to national efforts in promoting food security, rural development, and digital transformation in education. By fostering early interest in sustainable farming and providing access to localized, child-friendly content, the project offers a scalable framework for integrating immersive technologies into primary education, particularly in rural regions.

II. Literature Review

A. Overview of Relevant Literature

Recent advancements in educational technology have increasingly emphasized the integration of immersive tools such as AR, AI, and GBL to enhance student engagement, motivation, and knowledge retention. Studies by Farooq et al. [17] and Kshirsagar et al. [18] demonstrated AR's effectiveness in simplifying abstract topics and improving test scores among young learners. Similarly, Zulfiqar et al. [19] provided a broad overview of AR's pedagogical benefits, including enhanced visualization and collaboration.

Game-Based Learning has also emerged as a strong motivational tool. Mohammed and Ozdamli [20] highlighted the effectiveness of badges, leaderboards, and feedback mechanisms in increasing student participation. Additional case studies by Gasca-Hurtado et al. [21] and Triantafyllou and Sapounidis [22] confirmed GBL's psychological and cognitive benefits in structured learning environments.

Artificial Intelligence is increasingly utilized in agriculture, primarily for disease detection and decision support. Studies such as Cheng et al. [23], Paulson and Ravishankar [24], and Paramathma et al. [25] illustrated CNNs' capabilities in image classification and precision agriculture applications. However, these solutions are designed primarily for professional or academic audiences.

Despite these advancements, few systems combine AR, AI, and GBL into a cohesive, offline-first educational solution targeted specifically at children in agriculture-heavy regions. Most tools reviewed are either single-purpose or targeted toward general academic subjects, highlighting a significant gap in subject-specific and age-appropriate technological solutions for agriculture education.

B. Key Theories or Concepts

The development of the "Farm and Learn" application is grounded in a blend of pedagogical and technical frameworks, primarily Constructivist Learning Theory, GBL, and Convolutional Neural Networks (CNNs) in AI.

Constructivist Learning Theory emphasizes experiential learning, wherein learners construct knowledge through direct engagement and contextual exploration. AR supports this theory by offering immersive, spatially- aware interactions. Studies reviewed, including Farooq et al. [17] and Kshirsagar et al. [18] highlighted AR's ability to enhance concept retention, especially when learners manipulate 3D objects within real-world settings.

GBL principles were another prominent framework across the literature. The works of Mohammed and Ozdamli [19] and Triantafyllou and Sapounidis [22] emphasized that interactive elements like feedback, quizzes, and progression tracking enhance student motivation and knowledge retention. In the context of "Farm and Learn," while reward systems like badges are not implemented, GBL is embedded through quiz-based learning and seed sorting mini-games to stimulate engagement and cognitive processing.

On the technical front, CNNs form the backbone of AI-driven plant identification. Literature by Cheng et al. [23] and Paulson and Ravishankar [24] demonstrated the efficacy of CNN-based architectures like VGG16, VGG19, and YOLO in plant classification and real-time inference tasks. The "Farm and Learn" project employs YOLOv11n for lightweight yet accurate plant recognition, trained via transfer learning on a custom dataset using Roboflow and developed in JupyterLab. These theories and frameworks collectively inform the design of the application, ensuring it is educationally grounded, technologically robust, and responsive to the learning needs of children aged 10 and above.

C. Gaps or Controversies in the Literature

Despite growing interest in educational technologies, significant gaps remain in the integrated use of AR, AI, and GBL within agriculture-focused learning particularly for younger audiences in low-resource environments.

Existing AR applications reported in the literature largely concentrate on general subject areas such as early literacy, mathematics, or abstract science concepts, with limited emphasis on agriculture-related knowledge, contextualized local practices, or culturally grounded learning environments [19], [20].

Similarly, while GBL has demonstrated clear benefits in learner motivation and retention, its adoption in agriculture education remains minimal. The reviewed GBL studies predominantly targeted domains like mathematics, accessibility awareness, or computer science, lacking examples tailored to primary-level agricultural education [21], [22]. Many GBL models are also heavily dependent on internet connectivity, real-time multiplayer modes, or reward systems that are less feasible in offline, rural settings.

In the realm of AI, recent literature highlights robust advancements in plant disease detection and smart agriculture using CNNs [23]. However, these systems are typically designed for adult farmers or researchers, with little consideration for integration into educational tools for children [24]. None of the surveyed AI systems offers curriculum-aligned, child-friendly interactions or simplified interfaces suitable for school use.

Moreover, existing educational systems tend to overlook the intersectionality of immersive technologies. Few solutions offer an integrated experience that combines AR exploration, AI-driven interaction, and gamified assessment in a unified learning flow. This fragmented technological landscape presents a missed opportunity to address cognitive and contextual learning needs in agricultural education for children.

The "Farm and Learn" application aims to fill these gaps by offering a unified, offline-first platform tailored for children aged 10 and above. It integrates immersive 3D exploration, real-time AI identification, and interactive games into a localized, age-appropriate framework, thereby addressing both the technological fragmentation and the pedagogical misalignment prevalent in existing literature.

III. Methodology

A. Research Design

The development of the "Farm and Learn" mobile application followed an Agile, user-centered research design to support the multidisciplinary integration of Augmented Reality (AR), Artificial Intelligence (AI), and Game-Based Learning (GBL) within a unified educational platform [26], [27]. The Agile methodology was selected to enable iterative refinement, rapid prototyping, and continuous stakeholder feedback throughout development. Short development cycles allowed progressive implementation and validation of functional modules while ensuring alignment with pedagogical objectives and technical feasibility.

The system was designed as a modular learning framework targeting children aged 10 years and above. Six core components were developed: (1) Learning Module, (2) Augmented Reality Module, (3) AI-Powered Paddy Plant Identification Module, (4) Game-Based Learning Module, (5) User Interface and Navigation Module, and (6) Offline-First Architecture. Each component was independently implemented while maintaining interoperability within the overall application.

B. System Architecture

The overall system architecture of the "Farm and Learn" application adopts a modular offline-first design to ensure reliable operation in low-connectivity educational environments. As illustrated in Fig. 1, the architecture consists of three conceptual layers: the presentation layer, application layer, and storage layer, supported by a future-ready synchronization mechanism.

The presentation layer manages user interaction through a child-centered interface and navigation controller, enabling seamless access to learning functions. The application layer integrates the core learning modules, including instructional content delivery, AR-based visualization, AI-driven plant identification, and game-based activities. Communication between these modules is coordinated through a centralized content delivery mechanism, which dynamically loads resources while maintaining runtime efficiency.

At the foundation of the system, a local storage module contains all instructional assets, multimedia resources, scripts, and assessment logic packaged within the APK during the Unity build process. This design eliminates reliance on cloud services or real-time APIs, ensuring uninterrupted system functionality in rural environments. In addition, a conceptual synchronization layer is included as a future extension to support content updates and learning analytics synchronization when internet connectivity becomes available, without affecting core offline functionality

1) Design rationale: The architectural design was guided by three key considerations: limited rural connectivity, hardware resource constraints of mobile devices, and the requirement to maintain immersive learner engagement. The offline-first strategy ensures accessibility regardless of network availability, while modular separation improves system maintainability and scalability. The centralized content delivery mechanism reduces dependencies among modules and enables independent expansion of system components. Consequently, the architecture balances educational usability, technical performance, and long-term extensibility.

2) Data flow overview: System execution begins at the presentation layer when users interact with learning modules through the application interface. The content delivery mechanism retrieves required assets from the local storage module and executes them directly on the device. User interactions, including scoring and feedback generation, are processed locally to ensure stable performance without internet dependency. When connectivity becomes available, the optional synchronization layer may support future content updates or analytics transfer without affecting core offline functionality.

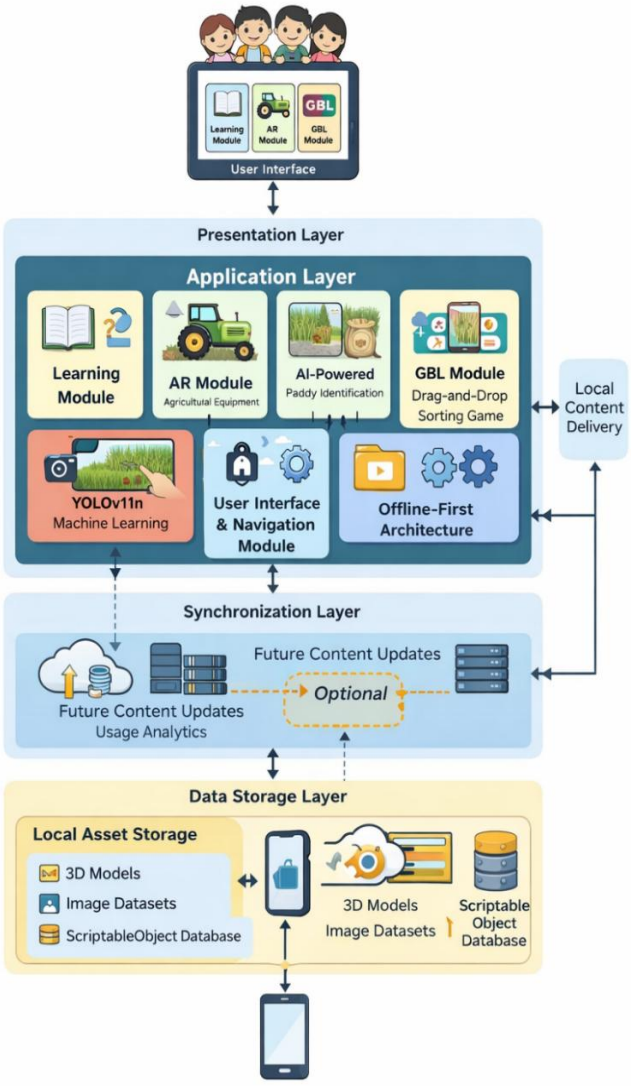

Fig. 1. Overall system architecture of the "farm and learn" application.

3) Architectural contribution: The proposed architecture contributes a lightweight, modular framework for delivering immersive educational experiences in connectivity-constrained environments. Unlike conventional mobile learning systems that rely on continuous cloud connectivity, the proposed design integrates AR visualization, AI-based recognition, and game-based interaction within an offline-first execution model. The separation between presentation, application, and storage layers enables scalable extension of modules while preserving system stability. Furthermore, the inclusion of a conceptual synchronization layer provides architectural flexibility for future cloud-enabled analytics and content updates without restructuring core system components. This architectural approach demonstrates a practical balance between immersive functionality, computational efficiency, and deployment feasibility for rural educational contexts.

C. Module Implementation

1) Learning module: The Learning Module delivers structured instructional content covering the paddy cultivation lifecycle, including land preparation, seed selection, irrigation, pest control, harvesting, and post-harvest practices. The module consists of three pedagogically aligned sub-components: Reading Materials, Interactive Tasks, and Interactive Tests.

a) Reading materials: Implemented using Unity UI Toolkit with scrollable layouts and hierarchical topic navigation, the reading materials incorporate illustrated infographics to reduce cognitive load and improve comprehension among young learners. All assets are optimized for mobile devices and designed for offline use.

b) Interactive tasks: The Interactive Tasks introduce gamified learning activities, such as seed classification using drag-and-drop mechanics. These tasks were developed using Unity's 2D physics engine and event-driven C# scripting to provide immediate visual feedback and reinforce concept application through experiential interaction.

c) Interactive tests: Interactive Tests evaluate learner understanding through multiple-choice quizzes executed entirely on-device. Questions are managed using ScriptableObject-based data structures, enabling scalable expansion without modifying source code. The quiz interface incorporates touch-friendly controls and immediate feedback to support formative learning.

2) Augmented Reality (AR) module: The Augmented Reality (AR) Module was designed to provide immersive and experiential learning by enabling children to interactively explore three-dimensional representations of agricultural equipment such as tractors, ploughs, sickles, and harvesting tools within real-world environments. The module was developed using Unity and Google ARCore, which facilitates markerless plane detection, feature-point mapping, and real-time spatial tracking to accurately position virtual objects on detected surfaces. The AR interaction workflow begins with environment sensing and surface detection, followed by object instantiation and pose alignment to maintain spatial consistency between virtual and physical spaces. Rendering enhancements such as scale normalization, lighting adaptation, and shadow projection are applied to improve visual realism and learner immersion. The overall AR placement and interaction process is illustrated in Fig. 2, which demonstrates the technical flow from surface detection to virtual object placement. Three-dimensional equipment models were primarily developed using Blender and optimized through polygon reduction and texture compression to ensure smooth rendering performance on mid-range Android devices. Once placed, learners can explore virtual farming tools from multiple viewing angles, promoting spatial understanding and exploratory learning behavior. Examples of AR-based farming tool visualization within real-world environments are presented in Fig. 3. In addition, voice narration provides child-friendly explanations to support multimodal learning and improve conceptual comprehension. Although AR functionality requires ARCore-supported hardware, the system preserves educational accessibility by allowing uninterrupted use of the learning and game-based modules when AR support is unavailable.

Fig. 2. ARCore-based surface detection and virtual object placement workflow in the proposed system.

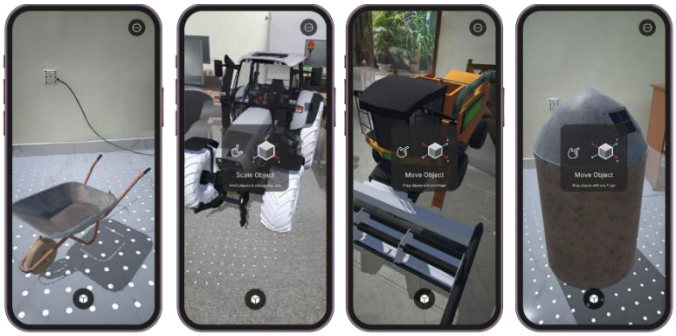

Fig. 3. Examples of AR-based farming tool visualization within the proposed learning system.

3) AI-Powered paddy plant identification module: The AI-powered paddy plant identification module supports recognition of paddy growth stages through deep learning–based image analysis. To validate model feasibility and inference performance while ensuring compatibility with the offline-first system design, the AI component was implemented as a prototype inference layer designed for seamless transition toward fully embedded on-device execution within the mobile application. This staged deployment strategy enables early evaluation of model accuracy while maintaining architectural consistency with the proposed offline learning framework. The module employs a YOLOv11n convolutional neural network optimized for lightweight inference [25]. Training data were collected from the Rice Research Station, Labuduwa, and supplemented with publicly available datasets to improve robustness and generalization. Data annotation and preprocessing were performed using the Roboflow platform, while model training was carried out in JupyterLab using Python with transfer learning from pretrained COCO weights [29], [30]. Hyperparameter tuning was applied to balance detection accuracy and computational efficiency, ensuring readiness for mobile deployment. The system generates annotated predictions indicating paddy detection results and demonstrates the practical feasibility of integrating AI-based plant recognition into child-centered educational learning

environments. The trained model is deployment-ready and can be packaged using lightweight mobile inference frameworks to enable fully offline execution within the application without requiring architectural modifications.

4) Game-Based Learning (GBL) module: The GBL Module reinforces learning outcomes through structured gamification strategies designed to increase engagement and motivation among learners. The module includes interactive mini-games and quiz-based assessments that promote concept application and formative evaluation. Activities such as seed-sorting tasks employ drag-and-drop interactions, real-time feedback, and scoring mechanisms to encourage repeated practice and experiential learning. Quiz components provide immediate correctness feedback and summary performance results, supporting knowledge retention while maintaining full offline functionality.

5) User interface and navigation module: The User Interface and Navigation Module coordinates interaction flow across all system components while ensuring accessibility for child users. The interface design emphasizes large touch-responsive elements, simplified iconography, and minimal text usage to reduce cognitive complexity. Navigation is structured around a centralized home interface supported by consistent scene transitions managed through script-based control mechanisms. This design ensures intuitive navigation, session continuity, and seamless movement between learning modules.

6) Offline-first architecture: The Offline-First Architecture was adopted to ensure full system functionality in rural and low-connectivity educational environments. All application assets, including 3D models, images, quiz logic, user interface scripts, audio instructions, and animation resources, are pre-packaged within the APK during the Unity build process, eliminating reliance on cloud services, real-time APIs, or continuous internet access. This design guarantees the uninterrupted availability of learning content, AR-based equipment visualization, and game-based learning activities regardless of connectivity conditions. From a technical perspective, local asset packaging improves performance efficiency and reduces runtime memory requirements, allowing stable execution on Android devices with limited hardware resources. ARCore-specific components, such as plane detection logic and tracking assets, are similarly embedded to maintain spatial interactivity while operating fully offline. Furthermore, the architecture enhances privacy and security by avoiding external data transmission and user account requirements, aligning with child data protection principles such as COPPA [31]. Overall, the offline-first deployment strategy improves accessibility, reliability, and scalability, making the system suitable for deployment across diverse rural educational contexts.

D. Data Collection Methods

A mixed-methods approach combining both qualitative and quantitative data collection was employed to guide the pedagogical design, content development, and technical implementation [32] of the "Farm and Learn" mobile application.

1) Primary data collection: Primary data were collected through field observations, expert consultations, focus-group sessions, and structured questionnaires [7]. Field visits to the Rice Research Station, Labuduwa, enabled the collection of agricultural imagery and contextual farming knowledge used for content design and AI dataset preparation. Structured interviews were conducted to validate the agricultural accuracy, pedagogical relevance, and technical feasibility of the system. Focus-group sessions and pilot testing activities were used to evaluate usability, engagement, and learner interaction with the application. Additionally, questionnaires were administered to capture user perceptions, learning preferences, and accessibility considerations.

2) Secondary data collection: Secondary data were obtained through an extensive review of peer-reviewed literature and academic conference publications related to AR, GBL, and AI in education. Insights from prior research informed the design of system features, pedagogical scaffolding approaches, and evaluation strategies. Additional reference material was sourced from authoritative agricultural databases and publications issued by the Department of Agriculture and other academic institutions to ensure factual accuracy, contextual relevance, and cultural appropriateness of the learning content on paddy cultivation.

E. Sample Selection

Participants were selected using a purposive sampling strategy to ensure representation of the key stakeholder groups relevant to the development and evaluation of the "Farm and Learn" application. The sample consisted of 47 children (students) aged 10–13 years, representing the primary end users of the system, together with 10 educators who evaluated pedagogical alignment and curriculum suitability, and 5 domain experts, including agricultural specialists and technical professionals who validated the accuracy of agricultural content and the technical feasibility of the solution. This multi-stakeholder sampling approach enabled balanced evaluation from learner, educational, and domain-expert perspectives, consistent with pilot studies in educational technology research [7].

F. Data Analysis Techniques

1) Qualitative analysis: A thematic analysis approach was applied to derive insights from user and expert-driven feedback. Focus-group discussions and expert interviews were coded to identify recurring usability patterns, interaction behaviors, and learner engagement characteristics. Survey responses were examined to determine preferred interaction modes and interface expectations among child users. Observational data collected during prototype testing were further used to refine module sequencing, navigation flow, and UI layout based on authentic user interaction with the system.

2) Quantitative evaluation of the AI model: To assess the feasibility and performance of the AI-based paddy-plant identification module, the YOLOv11n-based Convolutional

Neural Network (CNN) was trained and evaluated using annotated image datasets [28]. Model performance was measured using standard machine-learning metrics, including precision–recall curves, confusion matrices, and F1-score calculations [33]. Training and validation metrics were generated in JupyterLab across 100 training epochs using datasets annotated via the Roboflow platform, enabling systematic assessment of detection accuracy and generalization capability.

IV. Results

A. Experimental Evaluation Overview

The performance of the proposed "Farm and Learn" system was evaluated using user acceptance testing (UAT), expert validation, and technical benchmarking [34]. The evaluation involved 47 students, 10 educators, and 5 domain experts, focusing on usability, educational effectiveness, system performance, and AI model feasibility. Quantitative measurements were supplemented with qualitative feedback gathered during pilot deployment sessions.

B. User Acceptance and Educational Evaluation

Table I summarizes the average UAT ratings collected from students, educators, and experts using a five-point Likert scale. The results indicate consistently high acceptance across all stakeholder groups, with average scores exceeding 4.5 for all criteria. Offline accessibility achieved the highest rating (4.90), reflecting the effectiveness of the offline-first architecture in supporting rural deployment conditions. Visual engagement and educational relevance obtained strong scores (4.73), demonstrating the positive impact of immersive and contextually aligned learning content. The lowest relative score was observed for AR interactivity (4.50), suggesting opportunities for future improvements in interaction dynamics and device compatibility. Overall, the consistency of ratings across participants indicates strong agreement regarding usability and educational value.

TABLE I. UAT Evaluation Results (Average Score out of 5)

Evaluation criteria	*Students*	*Educators*	*Experts*	*Average Score*
Ease of Use	4.7	4.8	4.6	4.70
Visual Engagement	4.8	4.7	4.7	4.73
Educational Relevance	4.5	4.9	4.8	4.73
AR Interactivity	4.6	4.4	4.5	4.50
Game-Based Learning Appeal	4.7	4.6	4.4	4.57
Offline Accessibility	4.9	4.7	4.7	4.73
Overall Satisfaction	4.8	4.7	4.7	4.73

C. Learning Engagement and Performance

Observational findings indicated strong learner engagement during AR exploration and game-based activities. Average interaction time increased significantly compared to traditional content-based learning sessions, suggesting that immersive and interactive elements improved sustained attention.

Quiz-based assessments demonstrated progressive learning improvement, with average accuracy increasing from approximately 72% during initial attempts to 88% during repeated interactions. This improvement indicates that immediate feedback and gamified reinforcement contributed positively to knowledge retention.

D. AI Module Performance

The performance of the AI-powered paddy plant identification module was evaluated using standard classification metrics derived from the YOLOv11n model outputs. Table II presents the confusion matrix analysis summarizing the model's prediction results. The model correctly identified 13 Rice Plant instances, while 3 background samples were misclassified as rice plants, indicating strong detection capability with a small number of false positives.

TABLE II. Confusion Matrix Analysis of the AI Module

Predicted class	*True Rice Plant*	*True background*	*Total*
Rice Plant	13	3	16
Background	0	0	0
Total actual	13	3	16

The evaluation dataset contained only positive detections and background samples observed within the same image contexts; therefore, no independent background-only predictions were generated by the model during inference.

Fig. 4 shows stable performance across confidence thresholds, with a peak F1-score of 0.99 at a confidence value of 0.473, indicating a strong balance between precision and recall. Overall model accuracy achieved approximately 81.25%, confirming the feasibility of integrating lightweight AI-based visual recognition into an educational mobile learning environment.

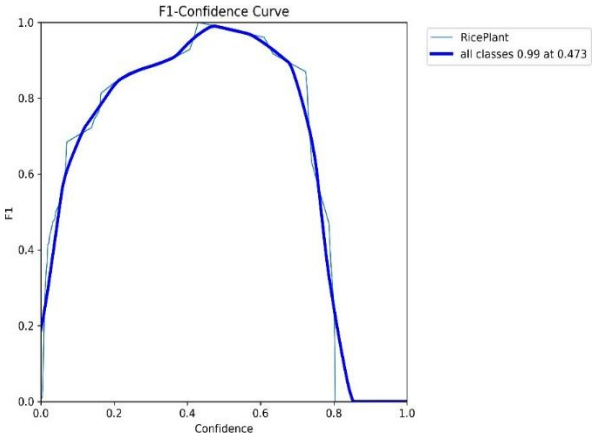

Fig. 4. F1-Confidence curve showing AI model performance for paddy plant identification.

E. System Performance Metrics

To assess technical feasibility, additional system-level performance measurements were collected on mid-range Android devices. Table III summarizes key quantitative metrics related to responsiveness, resource usage, and offline stability.

TABLE III. SYSTEM PERFORMANCE METRICS

Metric	*Observed value*	*Interpretation*
Application package size	~92 MB	Suitable for mid-range devices
Average startup latency	3.2 s	Smooth user experience
AR module loading time	8.1 s	Stable real-time interaction
Battery consumption (30 min session)	6-10%	Efficient mobile operation
Offline synchronization accuracy	100%	No connectivity dependency

The results confirm that the system operates efficiently under offline conditions while maintaining acceptable performance and energy consumption levels.

F. Comparison with Existing Systems

A comparison was conducted between the proposed *Farm and Learn* application and existing agricultural learning systems such as Plantix and FarmAR [8], [9]. As shown in Table IV, while Plantix primarily focuses on AI-based plant recognition and FarmAR emphasizes AR visualization, neither system provides a unified child-centered learning environment with offline educational functionality.

TABLE IV. COMPARISON WITH EXISTING SYSTEMS

Feature	*Plantix*	*FarmAR*	*Farm and Learn*
AR Visualization	No	Yes	Yes
AI-Based Recognition	Yes	No	Yes
Game-Based Learning	No	No	Yes
Child-Oriented Design	No	No	Yes
Offline Capability	No	Partial	Yes

The comparison demonstrates that the proposed system integrates AR, AI, and game-based learning within a single offline-first platform, making it more suitable for primary-level agricultural education in rural contexts.

G. Support for Research Questions

1) RQ1: Supported: The results strongly support this research question. High user acceptance scores across all stakeholder groups (Table I), increased learner interaction time, and improved quiz performance (72% to 88%) demonstrate that immersive and interactive technologies positively influenced learner engagement and knowledge retention.

2) RQ2: Supported: The findings confirm feasibility. Offline accessibility achieved one of the highest evaluation scores (4.73), and system testing demonstrated stable performance without internet dependency, validating the effectiveness of the offline-first architecture for rural educational deployment.

3) RQ3: Supported: The AI module achieved a peak F1-score of 0.99 with an overall accuracy of approximately 81.25%, as illustrated in Table II and Fig. 4. These results confirm that lightweight AI-based plant identification can be successfully integrated into educational mobile systems while maintaining practical performance levels.

Overall, the results affirm the feasibility and pedagogical value of the "Farm and Learn" platform as a scalable, immersive, and inclusive digital tool for enhancing primary-level agricultural education in Sri Lanka, particularly in the domain of sustainable paddy cultivation.

V. DISCUSSION

A. Interpretation of Results

The results suggest that the pedagogical synergy between AR, AI, and GBL contributes directly to engagement and knowledge retention, reinforcing prior evidence on multimodal learning environments. High user acceptance scores and improved quiz performance suggest that interactive and visual learning approaches helped learners better understand agricultural concepts. These findings support previous research indicating that immersive and gamified learning improves motivation and knowledge retention by promoting active participation [17], [19], [20]. Feedback from educators and experts further confirmed that the system maintained both educational relevance and technical feasibility.

B. Conceptual Contribution of AR, AI, and GBL Integration

A key contribution of this work is the combination of AR, AI, and GBL within a single educational framework. Each component plays a complementary role: AR enhances visual and spatial understanding, AI introduces intelligent interaction through plant recognition, and GBL strengthens motivation and reinforcement through interactive activities [17], [23], [25]. Together, these technologies create a balanced learning environment where exploration, feedback, and practice occur simultaneously. This integrated design helps explain the high engagement levels observed during evaluation and demonstrates that multimodal learning approaches may be more effective than isolated technology-driven solutions.

C. Comparison with Existing Literature

Compared to existing platforms such as Plantix and FarmAR [8], [9], the proposed system extends prior approaches by combining multiple immersive technologies within a child-oriented educational framework. While Plantix focuses primarily on AI-based plant recognition and FarmAR emphasizes AR visualization, neither system provides a complete learning environment that integrates structured pedagogy, gamification, and offline usability.

The findings of this study therefore, align with recent research advocating hybrid learning environments that combine visualization, interaction, and intelligent feedback to improve educational outcomes [17], [19]. In addition, the localization of content to Sri Lankan paddy cultivation provides contextual relevance often missing from globally generalized agricultural applications, strengthening both authenticity and learner engagement.

D. Implications and Limitations of the Study

The findings highlight the potential of immersive educational technologies to enhance engagement and accessibility in primary-level agricultural education. The integration of AR, AI, and game-based learning demonstrates how interactive and context-aware digital tools can support learner motivation and experiential learning while remaining

technically feasible for rural deployment through an offline-first architectural approach [17], [19], [23]. These results suggest that similar multimodal learning frameworks can be applied to other educational domains requiring practical and visual understanding, particularly in low-resource environments [20], [25].

The proposed system adopts a modular architecture that supports scalability in both content and user expansion. Learning modules, AR assets, and AI components can be extended independently without modifying the core system structure. In addition, the offline-first design reduces server dependency while allowing optional synchronization, enabling gradual deployment across larger educational environments as user numbers and learning content grow.

However, several limitations should be acknowledged. First, AR functionality depends on ARCore-compatible devices, which may restrict accessibility for learners using older or low-end smartphones [18], [19]. Second, the AI-based plant identification component currently operates as a prototype and requires further optimization for full offline deployment using lightweight mobile inference frameworks [23], [25]. Third, the current evaluation emphasizes short-term usability and engagement; therefore, larger-scale and longitudinal studies are needed to examine long-term learning outcomes and system scalability [17], [20].

VI. Conclusion

This study presented the design and evaluation of "Farm and Learn," an offline-first mobile learning application that integrates Augmented Reality (AR), Artificial Intelligence (AI), and Game-Based Learning (GBL) to enhance agricultural education for children. The findings demonstrate that combining immersive visualization, intelligent recognition, and interactive learning activities within a unified framework can improve learner engagement, usability, and perceived educational value, particularly in the context of primary-level agricultural learning [17], [19], [20]. The modular system architecture and offline-first design proved effective for deployment in rural and low-connectivity environments, addressing accessibility challenges commonly identified in educational technology adoption [18], [19].

A key contribution of this work lies in demonstrating the conceptual synergy between AR, AI, and GBL, where each component supports complementary pedagogical functions including experiential visualization, intelligent interaction, and motivational reinforcement [23], [25]. Unlike existing systems that focus on isolated functionalities, the proposed approach provides a child-oriented and contextually localized learning environment tailored to Sri Lankan agricultural practices. The study also shows the feasibility of integrating lightweight AI-based plant recognition within educational applications, supporting future directions for intelligent and adaptive learning tools.

Despite these contributions, certain limitations remain. The AR module depends on ARCore-compatible devices, and the AI component currently operates as a validated prototype inference layer pending final mobile packaging requiring further optimization for full mobile integration. In addition, evaluation focused primarily on short-term usability and acceptance; therefore, future work should include larger-scale longitudinal studies to assess long-term learning outcomes and scalability [17], [20]. Further development could also incorporate multilingual content and advanced adaptive learning features to enhance inclusivity and educational impact. Overall, the study demonstrates that immersive, offline-first mobile learning platforms represent a promising direction for sustainable and accessible agricultural education in resource-constrained environments.

Acknowledgment

This work was made possible through the generous support and collaboration of several institutions and individuals. The author gratefully acknowledges the Rice Research Station, Labuduwa, especially the Deputy Director and team, for their guidance, field-access, and expert contributions, which were invaluable to the development of the learning content and dataset preparation. Sincere appreciation is also extended to the Department of Software Engineering, Faculty of Computing and Technology, University of Kelaniya, for their technical insights and development-phase support, and to the Faculty of Information Technology, Horizon Campus, Malabe, for providing an enabling academic and research environment.

The authors thank the educators, students, and schoolteachers who participated in pilot evaluations, as well as contributors of open-access image and 3D-model resources used for academic purposes. Finally, heartfelt thanks are extended to family, colleagues, and friends for their encouragement and support throughout this work.

An Enhanced Approach for Workmen's Compensation Insurance Fraud Detection Based on Fuzzy Rule-Based System

Reham M. Essa
Department of Information Systems,
Higher Institute for Management and Information Technology, Kafr El-Sheikh, Egypt

***Abstract*—In Workmen's Compensation insurance, fraud detection (FD) remains a significant challenge due to claims' inherent uncertainty and complexity. To address this, we propose an enhanced approach based on a fuzzy rule system (FRS) for FD. The FRS is designed to handle ambiguous and imprecise data, making it effective for identifying fraudulent patterns in insurance claims. Unlike traditional methods, the fuzzy system utilizes human-like reasoning by applying flexible rules to assess the likelihood of fraud under uncertain conditions. By modeling the decision-making process with fuzzy logic, the system allows for a detailed evaluation of claims, accommodating the gray areas that often exist in FD. This approach enables accurate and adaptive FD, reducing false positives and enhancing the precision of fraud identification. In imbalanced FD scenarios, the system achieves strong performance, such as an F1-score of 0.82 and MCC of 0.75, demonstrating its capability to correctly identify rare fraudulent cases despite class imbalance.**

***Keywords*—Workmen's compensation; fuzzy logic; fraud detection; rule-based system; insurance fraud; prediction**

I. Introduction

The insurance industry plays a vital role in supporting the economic stability of a country, mainly through employee compensation insurance, which provides coverage for workers injured on the job. This type of insurance helps cover wage loss, medical expenses, and other benefits related to work-related injuries. Nevertheless, it also exposes companies to potential fraud, as unethical employers, workers, and medical providers may exploit the system for illegal financial gain. Fraudulent activities can involve deliberate deception, misrepresentation, or violating laws and policies to obtain unauthorized benefits. Combating fraud requires sophisticated detection methods, as fraud can be challenging to identify due to its intentional manipulation of the system and the complex, often hidden, nature of these activities [1].

Fraud in Workmen's Compensation insurance can take many forms, each adding significant financial strain to the system and impacting both employers and employees. One common type is employee fraud, where individuals claim non-work-related injuries as work-related to receive benefits. This may involve exaggerating the severity of an injury or misrepresenting the timing of the injury. Employer fraud occurs when companies misclassify employees or underreport their payroll to lower insurance premiums, resulting in reduced contributions and increased risks for insurers. Healthcare provider fraud involves billing for unnecessary or nonexistent medical treatments, inflating costs, and further burdening the insurance system. Lastly, insurance carrier fraud can include wrongful denial of claims or manipulating information to avoid paying out legitimate claims. These types of fraud collectively undermine trust in the system, increase premiums for honest participants, and require sophisticated detection mechanisms to manage and mitigate their impact [2],[3].

A FRS is effective for handling uncertainty in detecting fraud in Workmen's Compensation insurance by allowing for flexible decision-making in cases where data is ambiguous or incomplete. Unlike traditional techniques that use rigid, binary classifications (fraudulent or not), fuzzy systems handle data in degrees, assigning partial membership to different categories, such as "somewhat suspicious" or "likely fraudulent." This flexibility enables the system to model real-world uncertainty accurately, reducing false positives and adapting more effectively to complex, evolving fraud patterns. Additionally, fuzzy systems incorporate expert knowledge and subjective judgment, translating it into actionable rules, which traditional methods struggle to do. This results in a more nuanced, precise, and adaptive FD system that is better suited for the multifaceted nature of insurance fraud [4]-[6].

Detecting fraud in Workmen's Compensation insurance is a challenging task due to the varying and complex nature of fraudulent activities. Fraud indicators, such as suspicious reporting times, data behavior patterns, case correlations, and demographic factors, are critical for insurance experts to detect fraud. On the other hand, subjective judgments from experts can lead to inconsistencies in decision-making, and managing large volumes of data manually is time-consuming, prone to errors, and ineffective in fraud prevention. Furthermore, the growing data collected by insurance companies is often underutilized, missing opportunities to detect hidden fraud patterns. To address the challenges of detecting fraud in Workmen's Compensation insurance, this research proposes a FRS for FD. Unlike traditional systems, a FRS can handle uncertainty and imprecision in data, making it especially useful for complex FD scenarios where decisions must be made based on incomplete or vague information. Fraud indicators like suspicious behavior, reporting time discrepancies, and demographic factors often involve degrees of uncertainty that rigid systems struggle to process.

Fuzzy logic allows the system to mimic human reasoning by evaluating these factors in a flexible manner, providing more nuanced and accurate FD. This approach improves decision-making by accounting for varying fraud patterns and expert judgments, minimizing the risk of errors and inconsistencies. Additionally, the system enhances the ability of insurers to process large amounts of data efficiently, reducing costs and extracting hidden patterns that manual analysis would likely miss. Ultimately, it supports long-term business sustainability by providing more reliable FD and better resource allocation for claim investigations [7],[8].

A. Problem Statement and Motivation

The primary problem in Workmen's Compensation insurance FD is the inherent uncertainty and complexity of claims, which makes it difficult to accurately identify fraudulent activities. Traditional FD methods fail to handle ambiguous data and often rely on rigid, binary decision-making processes, leading to either missed fraud cases or false positives. Fraud in this domain frequently involves subtle patterns and subjective factors, such as claim timing, injury severity, or inconsistent reporting, which can vary greatly between cases. To address these challenges and motivated by the need for more precise and adaptable detection systems, this research proposes a fuzzy rule-based approach that leverages the flexibility of fuzzy logic to handle imprecise data.

B. Novelty and Contribution

The novelty of the proposed research lies in its exclusive use of an FRS for detecting fraud in Workmen's Compensation insurance, which distinguishes it from traditional methods. While conventional FD techniques often rely on strict, binary classifications that struggle with ambiguous data, this research leverages fuzzy logic to handle the uncertainty and complexity inherent in insurance claims. The fuzzy system's ability to model human-like reasoning by applying flexible, adaptable rules is a significant advancement in the domain of FD. It addresses the common challenge of managing imprecise and subjective information, such as variations in injury reporting or inconsistent claim histories, which are often difficult to capture using rigid systems.

The main contribution of this research is the development of an intelligent, adaptive framework that reduces false positives and improves the precision of FD. By offering a more nuanced evaluation of claims, this fuzzy rule-based approach enhances decision-making capabilities and allows insurance companies to more effectively identify fraudulent patterns. This ultimately contributes to the sustainability and integrity of the Workmen's Compensation insurance system, ensuring fair claims processing and reducing unnecessary costs caused by fraud. The proposed system's ability to extract hidden patterns from data and adapt to changing fraud schemes is another critical advancement, positioning it as a valuable tool in minimizing fraud risk.

The rest of the study is organized as follows, in section II state of the arts. In section III, we discussed and presented the research methodology in detail. Section IV presented the experiment and a discussion of the results followed by a conclusion.

II. Related Works

In the field of Workmen's Compensation insurance FD, several state-of-the-art techniques have emerged, each with its advantages and disadvantages. These methods can be broadly classified into data mining techniques, machine learning algorithms, rule-based systems, and hybrid approaches that combine multiple models for enhanced FD [9]-[15]. Data mining techniques like clustering (e.g., K-Means) and association rule mining are widely used to group similar insurance claims and identify hidden patterns in large datasets. These methods can efficiently process vast amounts of data, helping detect fraud by flagging anomalies. However, they rely heavily on historical data, making them less adaptable to evolving fraud tactics, and they can lead to high false-positive rates, incorrectly identifying legitimate claims as fraudulent [9], [12],[13].

Machine learning algorithms, including supervised and unsupervised models like random forest, support vector machines (SVM), and Neural Networks, are increasingly popular for FD. These models excel at learning from new data, detecting complex and non-linear relationships between variables, and are effective at identifying fraud patterns with high accuracy when trained on quality datasets. However, they require large, well-labeled datasets for effective training, which can be difficult to acquire. Additionally, many machine learning models, particularly deep learning networks, function as black-box systems, making their decision-making process difficult to interpret, which can lead to trust issues in critical applications such as FD [16]-[19], [20]-[23].

Traditional rule-based systems use predefined rules, usually set by experts, to classify claims as fraudulent or non-fraudulent. These systems are transparent and easy to understand, as they follow clear, interpretable rules, allowing for quick decision-making and reliability in detecting known fraud patterns. However, they lack flexibility since they can only detect fraud based on the programmed rules, making them ineffective against new or evolving fraud schemes. This limitation often leads to false negatives, where fraudulent cases are missed because they don't fit the established patterns. FRS, an advanced version of traditional rule-based approaches, utilize fuzzy logic to manage uncertainty and imprecision in FD. They excel in cases where data is ambiguous or conflicting, allowing them to model complex human reasoning and effectively handle gray areas. This flexibility reduces false positives and improves the detection of subtle fraud patterns that rigid systems might overlook. However, designing and maintaining fuzzy systems can be more challenging, as their performance heavily relies on the quality of the crafted rules and the expertise required, which can introduce subjectivity [22]-[25].

Hybrid systems that combine machine learning models with rule-based systems or fuzzy logic offer a powerful approach to leveraging the strengths of each method. By integrating machine learning, these systems can adapt to emerging fraud patterns through data-driven insights and continuous learning, making them highly flexible and responsive. Simultaneously, the rule-based components bring transparency and domain expertise that make decision-making more interpretable and understandable, particularly in industries requiring accountability, such as

finance or healthcare. This balance between adaptability and transparency provides an advantage in terms of flexibility, accuracy, and control. However, these systems also come with significant challenges. Their complexity makes implementation difficult, often requiring extensive computational resources to manage the interactions between the machine learning and rule-based components effectively. Additionally, maintaining a system that remains both transparent and accurate over time necessitates ongoing tuning and optimization, as misalignment between the components could compromise either its clarity or predictive power [12],[13], [20]-[23].

Pallavi A. et al. [26] carried out a detailed study that aimed to design an analytical framework for identifying potentially fraudulent health insurance claims. The methodology combined machine learning-based predictive modeling with a rule-based scoring system. Historical claims data were analyzed using data mining techniques to uncover patterns and correlations associated with fraud, enabling the model to assign probabilistic fraud scores to new claims based on similarities with known fraudulent behaviors. Alongside this, a set of predefined rules—such as abnormal treatment costs, high claim frequency, or unusual claimant behavior—was used to assign additional risk scores. Claims with higher cumulative scores were flagged for further investigation. This hybrid approach offered improved accuracy, scalability for large datasets, and adaptability through continuous learning. However, it also presented challenges, including dependence on high-quality data, limited flexibility in detecting new fraud patterns due to rigid rules, and the possibility of false positives, which could impact genuine claimants.

Kirlidog and Asuk [27] conducted a study on health insurance FD by focusing on anomaly classification techniques to distinguish fraudulent claims from legitimate ones. Their methodology centered on analyzing historical insurance data to identify patterns of irregularities that deviate from typical claim behavior. By applying data mining and statistical analysis methods, they were able to classify anomalies that often signify fraudulent activity, such as inconsistencies in billing, unusual claim frequencies, or improbable medical procedures. This approach allowed for the detection of fraud by recognizing outliers in the dataset rather than relying solely on predefined rules. The key advantages of this method include its ability to uncover previously unknown fraud patterns and its adaptability to different datasets. However, it also has limitations, such as a high dependency on the quality and completeness of the input data, and a potential for false positives where legitimate but atypical claims may be flagged as fraudulent, necessitating further manual review.

This study, presented in Ref. [24], introduced a novel hybrid methodology for detecting fraud in automobile insurance claims by integrating a Genetic Algorithm (GA)-enhanced Fuzzy C-Means (FCM) clustering technique with multiple supervised classification models. The approach begins by dividing the original insurance dataset into a test set and a training set. The training data undergoes FCM clustering, optimized using GA, to perform undersampling and create meaningful, balanced clusters. Test instances are then categorized into three classes: genuine, malicious, or suspicious, based on their proximity to these clusters. Genuine and clearly fraudulent claims are filtered out, while suspicious cases undergo further evaluation using four supervised classifiers: Decision Tree (DT), (SVM), Group Method of Data Handling (GMDH), and Multi-Layer Perceptron (MLP). Model training and validation are performed using 10-fold cross-validation to ensure reliability. The strengths of this method lie in its ability to handle imbalanced data through intelligent clustering, reduce false positives by isolating uncertain cases, and improve accuracy through ensemble analysis. However, the system's complexity and computational cost are potential drawbacks, and its performance is highly dependent on proper tuning of clustering parameters and classifier settings.

In Ref. [25], the authors suggested a machine learning-based approach for detecting insurance fraud using a supervised classification algorithm trained on historical claim data, which includes both legitimate and fraudulent cases. The model utilizes various features to differentiate between genuine and suspicious claims. Evaluated on real-world insurance data, the approach demonstrated high accuracy and was effective in identifying fraudulent claims that traditional rule-based methods often miss. Its main strengths include improved detection rates, automation of the fraud identification process, and reduced workload for human investigators. However, the approach relies heavily on the quality and representativeness of the training data, and its performance may decline if fraudulent behavior patterns change or if unseen types of fraud are introduced.

Workmen's FD is inherently complex due to the multifaceted and often hidden nature of fraudulent behavior. This necessitates the use of advanced data mining techniques capable of transforming fragmented and seemingly unrelated data into coherent, actionable insights. A foundational step involves integrating data from diverse sources into a centralized, structured data repository to facilitate comprehensive analysis. In this context, Helmut F., et al. [28] used an explainable attention-based neural network for claim FD. This model uses attention mechanisms within deep learning architectures to focus on the most relevant parts of the data, enhancing interpretability while maintaining high performance. The key advantage of this method is its transparency—decision-making can be better understood by auditors and investigators, fostering trust in AI-driven processes. However, it can be computationally intensive and requires substantial training data to perform effectively, particularly in complex, high-dimensional FD environments.

Additionally, Sadgali I. et al. [29] investigated the performance of various machine learning techniques in detecting financial fraud, comparing algorithms such as Decision Trees, Random Forests, SVM, and Neural Networks. The study highlighted that ensemble methods like Random Forests generally achieved better accuracy and robustness due to their ability to reduce overfitting and model nonlinear relationships. However, such models can lack interpretability, making it difficult to understand how fraud decisions are made. Similarly, Ryman, T. et al. [30] conducted a survey and benchmarking study on how AI and machine learning are transforming payment card FD. The research emphasized the growing use of real-time anomaly detection, deep learning, and hybrid AI systems in the financial industry. While these models significantly enhance detection capabilities and reduce false

positives, their implementation involves high computational costs, complex deployment requirements, and the need for continuous updating to keep pace with evolving fraud tactics.

A. Research Gap

Based on the comprehensive survey of current methodologies in Workmen's Compensation insurance FD, a notable research gap emerges in the underutilization of uncertainty-based fuzzy rule mining techniques—particularly in environments where data is ambiguous, imprecise, or incomplete. While fuzzy logic has been applied in some advanced rule-based systems to manage uncertainty, most existing implementations either rely on traditional, rigid rule-based approaches or focus heavily on machine learning and data-driven models that often operate as black boxes. These methods may lack the ability to effectively handle borderline cases or precise fraud patterns that do not conform strictly to binary classifications. This is a significant limitation in real-world fraud scenarios, where subtle cues, partial patterns, or conflicting indicators may be present. Incorporating fuzzy rule-based mining could allow for better modeling of these "gray areas" in claim behavior, facilitating more human-like reasoning and enhancing both accuracy and interpretability. Moreover, while hybrid models combining machine learning and rule-based systems have shown promising results in terms of accuracy and flexibility, they often neglect the integration of fuzzy logic into the rule-generation or decision-making process. This represents an untapped opportunity to bridge the gap between high-performance prediction and explainable decision-making. By embedding fuzzy rule mining into hybrid frameworks, researchers could develop systems that are not only adaptive and robust to emerging fraud tactics but also transparent and capable of providing interpretable justifications for their outputs.

III. Methodology

In the landscape of Workmen's Compensation insurance, detecting fraudulent claims is a complex task due to the high degree of uncertainty, incomplete information, and subjective evaluations often associated with the claims process. Traditional FD methods, which are mostly rule-based or statistical, frequently struggle to manage the gray areas inherent in such assessments, leading to high false positive rates or missed fraud cases. To address these challenges, we propose a comprehensive FD model centered on an FRS. The use of fuzzy logic allows for handling ambiguity and imprecision in claim-related data, mimicking human reasoning through flexible if-then rules. To further strengthen the model, we incorporate clustering techniques to discover hidden patterns and structure within the claims data before applying fuzzy classification.

This layered approach enhances the model's ability to adapt to complex fraud behaviors, offering a more nuanced, intelligent, and sustainable solution to FD in Workmen's Compensation insurance. The proposed model consists of three main stages: Preprocessing, Clustering, and Fuzzy Rule-Based Classification. Each stage is critical to ensuring that the system is accurate, adaptive, and capable of maintaining the integrity of the claims process. The following subsection outlines the purpose of each step in the proposed model and explains its specific function within the FD process. Each stage is described with implementation details to illustrate how it contributes to the overall effectiveness of the system. Together, these steps form a cohesive framework for accurately identifying fraudulent insurance claims. Fig. 1 illustrates the structured workflow of the proposed fuzzy rule-based classification system, detailing each stage from data preprocessing to the final classification of claims. The process encompasses feature selection, clustering, fuzzy rule definition, and inference application, ensuring a comprehensive and interpretable classification framework.

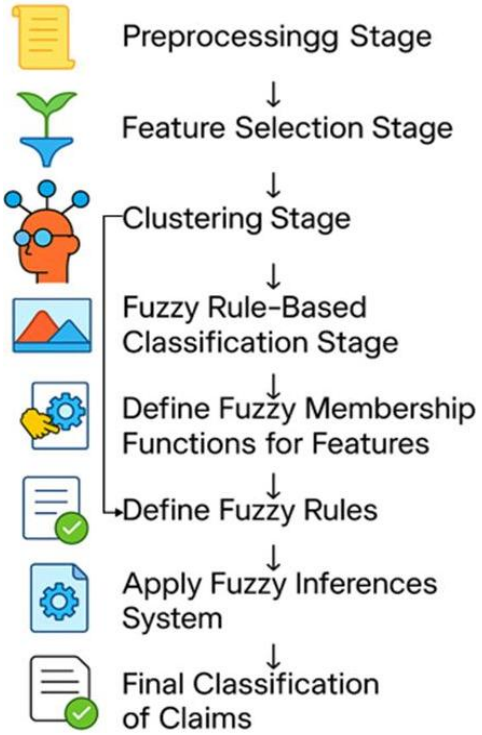

Fig. 1. Workflow of the proposed fuzzy rule-based classification system for claim processing.

A. Preprocessing Stage

The preprocessing phase is a critical foundation for building an effective FD model, as it transforms raw insurance claim data into a structured and analyzable format [24]. The first step, data cleaning, addresses inconsistencies such as missing or incomplete values—these can be handled through imputation techniques (in our case, K-nearest neighbors for numerical data, and the mode for categorical variables are employed). Duplicate records are also identified and removed to prevent redundancy and bias. Feature selection and extraction involve isolating the most informative attributes, such as claimant age, injury type, medical expenses, length of claim processing, and employer reputation. These features are often selected based on domain knowledge, correlation analysis, or dimensionality reduction methods like PCA (PCA is employed in the implementation). New features can also be engineered to provide more context—for example, calculating "reporting delay" (the time between incident and claim filing) or "claim frequency" (number of claims filed by the same individual or employer over a period) [25],[26].

In our case, the "insurance claims fraud data" dataset on Kaggle https://www.kaggle.com/datasets/mastmustu/insurance-

claims-fraud-data) is used. This benchmark dataset comprises 1,000 records and 40 features, offering a comprehensive view of various aspects related to insurance claims. Key features include 'policy_annual_premium', 'incident_type', 'collision_type', 'incident_severity', 'insured_hobbies', 'auto_make', 'auto_model', and 'auto_year', among others. The dataset also contains a target variable indicating whether a claim is fraudulent, facilitating supervised learning approaches. The diverse range of features allows for the exploration of complex relationships and patterns associated with fraudulent activities, making it a valuable resource for developing and testing FD models.

B. Feature Selection Stage

For implementing a fuzzy-rule-based classification in the Insurance Claims Fraud Dataset, the four most prevalent features suitable for capturing fraudulent activities would be total_claim_amount, incident_severity, property_damage, and fraud_reported. The selection of these features is based on expert knowledge within the insurance domain. Total_claim_amount is a critical feature because, in the context of FD, inflated or exaggerated claims are common indicators of fraudulent activity. Experts recognize that claims involving unusually high amounts, especially when compared to similar incidents, are more likely to be fraudulent.

Similarly, incident_severity is a key feature because the severity of the incident can provide significant insights into the fraud risk. Serious incidents often result in larger claims, but when paired with other anomalies like inflated damage reports, they can indicate potential fraud. Property_damage is another essential feature, as fraudulent claims may involve exaggerating or fabricating the extent of property damage. Insurance experts are well aware that discrepancies between reported damage and actual damage can be a red flag for fraudulent claims. Finally, fraud_reported, the target variable, directly correlates to the task of FD, serving as the benchmark for building fuzzy rules [18],[25].

These features were selected because they encapsulate the most common and easily identifiable signs of fraud, making them ideal for developing a robust fuzzy-rule FD system to classify and analyze claims with varying degrees of uncertainty, which is key to detecting nuanced fraudulent patterns. Once relevant features are selected, normalization or standardization is applied to numerical values to ensure consistency across varying scales, which is particularly important when combining data into a fuzzy system. Min-Max scaling Technique is employed for this purpose.

C. Clustering Stage

Clustering serves as a critical step in the proposed Workmen's Compensation insurance FD framework by identifying underlying patterns and structural relationships within claim data. Among available methods, C-Means clustering is particularly well-suited for this domain because it allows each claim to have varying degrees of association with multiple clusters. This soft assignment capability is essential in Workmen's Compensation cases, where the distinction between fraudulent and genuine claims is often blurred. C-Means effectively captures such ambiguity, enabling the model to handle borderline or suspicious cases more realistically.

C-Means algorithm offers several advantages when applied to FD in Workmen's Compensation insurance. First, it provides a straightforward way to categorize claims into distinct groups based on patterns such as claim amounts, recovery durations, or frequency of claims. By clustering similar claims together, the algorithm helps identify unusual patterns, such as clusters of claims with unusually high medical expenses, extended recovery times, or repeat claims by the same individuals. These anomalies can be indicative of potential fraudulent behavior, which makes C-Means valuable for initial FD in large datasets. Since each claim is assigned to a single cluster, the results are easy to interpret, providing a clear classification of claims into risk categories like low, medium, or high risk. Moreover, C-Means is computationally efficient and relatively simple to implement, making it suitable for real-time applications where speed is crucial. For Workmen's Compensation FD, the algorithm can effectively segregate claims into well-defined clusters, assisting fraud investigators in identifying and investigating suspicious patterns without the need for complex calculations or probabilistic models.

C-Means algorithm begins by selecting an optimal number of clusters (C), which is usually based on expert judgment (in our case low, medium, and high-risk categories). Initially, C random cluster centers are chosen from the data points. Each claim is then assigned to one of the clusters based on its proximity to the cluster centers. This is done by calculating the Euclidean distance between each claim and the cluster centers and assigning the claim to the closest cluster. After the initial assignment, the algorithm recalculates the cluster centers by taking the mean of all the claims assigned to each cluster. This process is repeated iteratively, with each iteration updating the cluster centers and reassigning claims to the closest cluster. The iterations continue until the cluster centers stabilize, meaning the changes in the cluster centers are minimal, or until a predefined number of iterations is reached. The final clusters can then be analyzed to identify patterns of fraud, such as outliers with excessive claims or suspiciously high medical costs, which might require further investigation. See [7],[24] for more details.

D. Fuzzy Rule-Based Classification Stage

In Workmen's Compensation FD, the output of the C-Means clustering stage can serve as a foundational input to the Fuzzy Rule-Based Classification stage by providing a clear categorization of claims into distinct clusters based on patterns of behavior. Once the claims are clustered (low, medium, and high-risk), these clusters can be mapped to fuzzy rules that define the characteristics of potentially fraudulent claims. For example, a cluster of claims with unusually high medical costs and extended recovery times can be labeled as "high-risk" and associated with fuzzy rules such as "IF medical costs are high AND recovery time is long, THEN the claim is likely to be fraudulent". The FRS then applies these rules to individual claims, using the degree of membership in each cluster (from the C-Means output) to assign a fuzzy value to the claim's likelihood of being fraudulent. The use of fuzzy logic allows for precise decision-making, where claims that don't strictly fit into one category (e.g., a claim that's borderline between high and medium risk) can still be assessed with a degree of uncertainty, making the FD system more flexible and accurate in identifying

suspicious claims [31]-[33]. Below is a detailed step-by-step breakdown of the Fuzzy Rule-Based Classification process.

1) Define fuzzy membership functions for features:

- Input: Data for each claim (e.g., total claim amount, incident severity, property damage, and fraud reported).
- For each of the selected features, fuzzy membership functions will be defined to describe the degree to which a claim belongs to categories. These functions are based on expert domain knowledge, which helps identify patterns indicative of fraud.
- The fuzzy membership function for the claim amount can be defined into categories such as "Low," "Medium," and "High." As shown in Fig. 2, this membership function reflects the common fraud pattern where unusually high claims are more likely to be fraudulent.

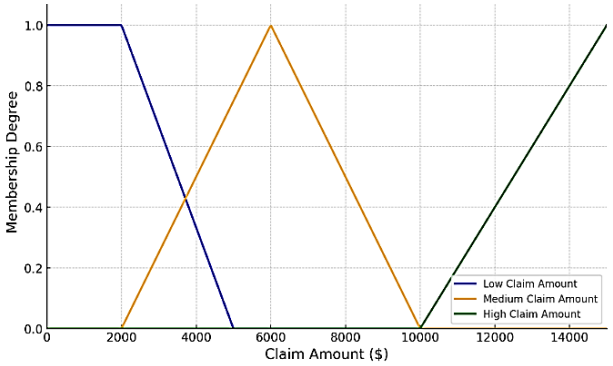

Fig. 2. Fuzzy membership functions for total claim amount.

- For incident severity, fuzzy categories like "Minor," "Moderate," and "Severe" are defined (see Fig. 3). This function helps capture the relationship between the severity of the incident and the likelihood of fraud, as more severe incidents often involve larger claims, but when coupled with other anomalies (e.g., inflated damage), they increase fraud risk.

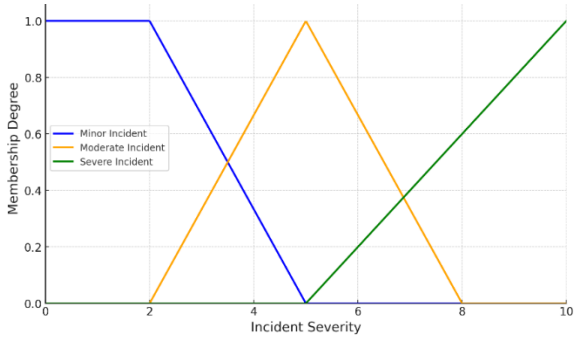

Fig. 3. Fuzzy membership functions for incident severity.

- The property damage feature could be fuzzified into categories such as "None," "Minor," and "Major." As shown in Fig. 4. Discrepancies between reported and actual property damage are common in fraudulent claims, and this membership function helps to capture such discrepancies. The fraud_reported feature is the target variable and would typically be fuzzified into two categories, "Fraud" and "No Fraud." (See Fig. 5). This fuzzy set provides the basis for determining the probability of fraud in each claim.

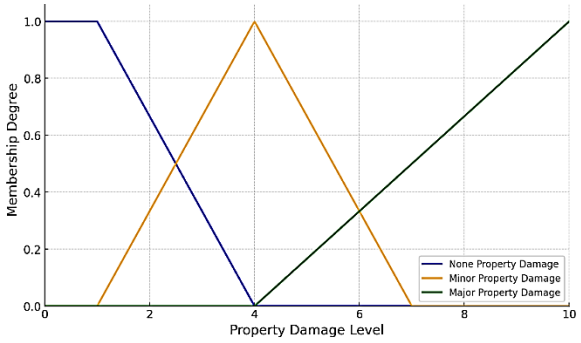

Fig. 4. Fuzzy membership functions for property damage.

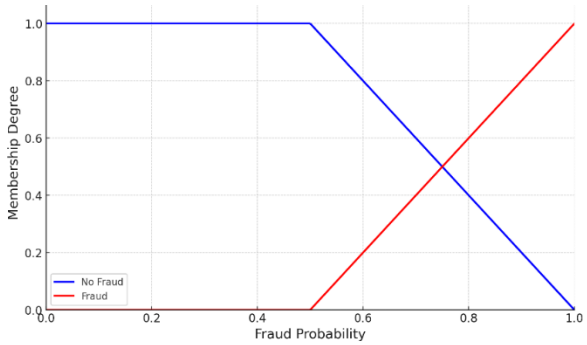

Fig. 5. Fuzzy membership functions for fraud reported.

- Output: The output consists of a set of fuzzy membership values for each claim, reflecting the degree that the claim belongs to the defined categories. For instance, a claim might have a membership value of 0.8 in the "High" category for claim amount, 0.2 in "Severe" for incident severity, and 0.5 in "Major" for property damage. These fuzzy values are used as inputs for the fuzzy inference system, which will evaluate and classify the fraud risk based on the fuzzy rules.

2) Define fuzzy rules:

- Input: The fuzzy membership functions created in the previous step, along with the C-Means clustering information.
- Based on expert knowledge or historical data, define fuzzy rules that link the fuzzy features to the risk of fraud. These rules describe the relationships between the membership values of various features and the likelihood of fraud.

Rule 1:

- IF (Claim Amount IS High) AND (Recovery Time IS Long) THEN (Fraud Risk IS High).
- Rule 1 reflects the assumption that high claim amounts and long recovery times are strongly associated with higher fraud risk. This is a typical fraud pattern, where

more severe incidents (e.g., costly claims and longer recovery periods) might be manipulated to gain higher payouts.

Rule 2:

- IF (Claim Amount IS Low) AND (Recovery Time IS Short) THEN (Fraud Risk IS Low).
- Rule 2 assumes that low claim amounts and short recovery times are indicative of legitimate claims with low fraud risk, as these types of claims tend to be more straightforward and less prone to exaggeration or manipulation.

Rule 3:

- IF (Claim Amount IS Medium) AND (Recovery Time IS Short) THEN (Fraud Risk IS Medium).
- Rule 3 reflects the case where medium claim amounts and short recovery times are still somewhat low in terms of fraud risk, but not as low as in Rule 2, hence the medium fraud risk.

Rule 4:

- IF (Claim Amount IS Low) AND (Recovery Time IS Medium) THEN (Fraud Risk IS Medium).
- Rule 4 assumes that low claim amounts with medium recovery times still do not strongly suggest fraud, but they are slightly more suspicious than very low amounts with short recovery times, leading to a medium fraud risk.

Rule 5:

- IF (Claim Amount IS High) AND (Recovery Time IS Medium) THEN (Fraud Risk IS High).
- Rule 5 shows that high claim amounts with medium recovery times are also indicative of high fraud risk, as the combination of a higher payout and moderate recovery times is a typical scenario for fraud.

Rule 6:

- IF (Claim Amount IS Medium) AND (Recovery Time IS Long) THEN (Fraud Risk IS High).
- Rule 6 suggests that medium claim amounts with long recovery times may also represent a high fraud risk, as long recovery times are more likely to coincide with inflated or extended claims to extract more money from the insurance.

Rule 7:

- IF (Claim Amount IS Medium) AND (Recovery Time IS Medium) THEN (Fraud Risk IS Medium).
- Rule 7 reflects that medium claim amounts with medium recovery times suggest a medium fraud risk due to the more typical nature of the claim, without clear indicators of fraud.

Rule 8:

- IF (Claim Amount IS High) AND (Recovery Time IS Short) THEN (Fraud Risk IS High)
- Rule 8 is for cases where high claim amounts and short recovery times are still associated with high fraud risk, potentially indicating cases where a claim might be inflated or exaggerated, despite the shorter recovery time.
- Output: A set of fuzzy rules that can be used to classify the risk level (low, medium, high) of claims

3) Apply fuzzy inference system

- Input: The fuzzy membership values from step 3.3.1 for each claim. The fuzzy rules from step 3.3.2.
- Use a fuzzy inference system (FIS) to apply the fuzzy rules to the input claims. The system uses the fuzzy membership values to compute the degree of truth of each rule and aggregates the results. This process typically involves:

a) Fuzzification: Converts input values (e.g., claim amounts, recovery times) into fuzzy membership values using the fuzzy sets defined earlier.

b) Rule evaluation: The fuzzy system evaluates the rules by determining how well each claim fits the conditions of the rules based on the fuzzy memberships.

c) For each rule, calculate the rule strength by taking the minimum of the membership values of the antecedents (conditions). For example: For Rule 1

$$Rule\ Strength = min\ (\mu_{\text{High}}(Claim_Amount),\ \mu_{\text{severe}}(Severity) \quad (1)$$

- Apply this rule for all the fuzzy rules defined in Step 3.

d) Aggregation: Combines the outputs of the rules, potentially weighted by their relevance or confidence, to produce a final fuzzy output. After applying all the fuzzy rules, aggregate the outputs (the fuzzy sets for Fraud Risk) by taking the max of all rule strengths for each output category. For example, aggregate the membership functions for Fraud Risk (Low, Medium, High) based on the rule strengths:

$$\mu_{fraud\ risk}(\text{x}) = max(Rule\ Strength_1, Rule\ Strength_{\ 2}, \dots) \quad (2)$$

This gives the fuzzy output for fraud risk.

e) Output: A fuzzy set that represents the degree of fraud risk (e.g., "Low Risk," "Medium Risk," or "High Risk") for each claim.

f) Defuzzification:

- Input: The aggregated fuzzy output from the previous step, which represents the degree of fraud risk (e.g., a fuzzy set with membership values such as "Low," "Medium," and "High").

- This process converts the fuzzy output into a crisp value that can be interpreted easily. This step involves techniques such as centroid calculation to compute a precise risk score from the fuzzy set. For example, if a claim has a 0.7 membership in "High Risk" and a 0.3 membership in "Medium Risk," the defuzzified output might result in a final fraud risk score of 0.7, corresponding to "High Risk".

$$C = \frac{\int_a^b x.\mu_{Fraud\ Risk}(x)dx}{\int_a^b \mu_{Fraud\ Risk}(x)dx} \quad (3)$$

- Output: A crisp value representing the fraud risk score (e.g., a value between 0 and 1, or simply a classification such as "Low," "Medium," or "High" risk).

4) Final classification of claims:

a) Input: The defuzzified fraud risk scores for each claim.

b) Based on the defuzzified scores, assign each claim to a risk category (e.g., low, medium, high). Use thresholds or predefined ranges to classify claims. For example: Low risk: If the fraud risk score is between 0 and 0.3.

c) Medium risk: If the fraud risk score is between 0.3 and 0.7. High risk: If the fraud risk score is between 0.7 and 1.0.

d) Output: The final classification of each claim into a fraud risk category (e.g., low-risk claims, medium-risk claims, high-risk claims).

IV. Results and Discussion

To validate the effectiveness of the proposed FRS for detecting fraud in Workmen's compensation insurance claims, a series of experiments were conducted using the publicly available "insurance claims fraud data" dataset from Kaggle. The model was implemented using Python due to its extensive support for data analysis, fuzzy logic, and machine learning. The experiments were executed on a laptop with the following configuration: Intel Core i7 (11th Gen) processor, 16GB RAM, 512GB SSD, and Windows 11 operating system, ensuring smooth and efficient computation. Core Python libraries used in the implementation include pandas for data handling, numpy for numerical operations, matplotlib and seaborn for visualization, sklearn for preprocessing, classification, and evaluation metrics, and scikit-fuzzy for designing and executing the fuzzy inference system. The experimental evaluation involves performance metrics such as accuracy, precision, recall, and F1-score to demonstrate the robustness and interpretability of the proposed model in identifying fraudulent claims.

A. Experiment 1: Baseline Comparison with Traditional Classifiers

The purpose of Experiment 1 is to establish a baseline comparison between the proposed FRBS and traditional machine learning classifiers—namely Decision Tree, Support Vector Machine (SVM), and Logistic Regression—to assess the relative performance and advantages of the FRBS in detecting fraudulent Workmen's compensation insurance claims. Key input features are selected based on domain relevance and their potential correlation with fraudulent behavior as discussed in section 3.2. The comparative evaluation focuses on critical performance metrics, including accuracy (overall correctness), precision (correctly identified frauds out of predicted frauds), recall (ability to identify actual frauds), F1-score (harmonic mean of precision and recall), and ROC-AUC (ability to distinguish between classes across all thresholds).

TABLE I. Performance Comparison of the Proposed FRBS with Traditional Classifiers on Workmen's Compensation FD

Model	Accuracy	Precision	Recall	F1-Score	ROC-AUC
FRBS	0.91	0.89	0.93	0.91	0.94
Decision Tree	0.84	0.81	0.79	0.80	0.82
Logistic Regression	0.86	0.84	0.82	0.83	0.85
(SVM)	0.87	0.85	0.84	0.84	0.87

The experimental results shown in Table I clearly demonstrate the superior performance of the proposed FRBS across all key evaluation metrics when compared with traditional machine learning classifiers. FRBS achieves the highest accuracy (91%), indicating that it makes fewer overall classification errors. More importantly, it excels in recall (93%), which is critical in FD scenarios where missing a fraudulent claim can be costly. Its precision (89%) also suggests that it produces fewer false positives, meaning it does not frequently misclassify legitimate claims as fraudulent—an essential consideration in maintaining trust with genuine claimants. The F1-score, which balances precision and recall, is highest for the FRBS, underscoring its consistency and reliability in handling imbalanced datasets, which is common in FD.

Additionally, the FRBS achieves the highest ROC-AUC value (0.94), reflecting its strong capability to discriminate between fraudulent and genuine claims across varying thresholds. This is particularly important for real-world deployment where decision boundaries may need to be adjusted depending on risk tolerance. The superior performance of FRBS can be attributed to its ability to incorporate domain knowledge through fuzzy rules, handle uncertainty effectively, and model nonlinear relationships between features more transparently. Unlike black-box models, the interpretable nature of FRBS also aids in decision justification, making it more suitable for regulatory and auditing contexts in insurance FD.

Comparative models typically rely on crisp decision boundaries and predefined mathematical assumptions that may not align with the complex and imprecise nature of fraudulent behavior patterns. For instance, Decision Trees can overfit to noise in the training data, while Logistic Regression assumes linear relationships between features and outcomes, which limits its flexibility. SVMs, although powerful, are less interpretable and sensitive to parameter tuning and feature scaling. In contrast, the proposed System excels by incorporating expert knowledge through linguistic rules and handling uncertainty using fuzzy logic, enabling it to model ambiguous scenarios more effectively. This allows FRBS to better differentiate between borderline cases of genuine and fraudulent claims, leading to superior results in terms of accuracy, recall, and overall robustness.

B. Experiment 2: Evaluation Under Noisy and Ambiguous Data

The goal of Experiment 2 is to evaluate the robustness of the proposed System in handling noisy and ambiguous data, reflecting real-world scenarios where insurance claims often contain incomplete, imprecise, or inconsistent information. To simulate such uncertainty, controlled noise was introduced to selected numerical features (e.g., claim amount or time-to-report) by applying ±10% random variation, while missing values were artificially generated to assess the system's resilience to incomplete inputs. Different imputation strategies were employed, including statistical methods such as mean or mode replacement, and fuzzy approximation (e.g. fuzzy k-nearest neighbors) that align more naturally with the FRBS framework. The configuration also involves comparative performance analysis under clean and noisy conditions to determine the model's sensitivity and adaptability. Key metrics used include the robustness score, calculated as the drop in performance metrics between clean and noisy datasets; Root Mean Squared Error (RMSE) to evaluate the accuracy of the imputation methods; and standard classification metrics such as precision, recall, and F1-score to gauge the overall effectiveness of FD under uncertain conditions.

TABLE II. IMPACT OF NOISE AND IMPUTATION METHODS ON THE PERFORMANCE AND ROBUSTNESS OF THE PROPOSED FRS

Data Condition	Accuracy	ROC AUC	Robustness Score	RMSE (Imputation)
Clean Data (Baseline)	0.91	0.94	—	—
Noisy Data + Mean Imputation	0.84	0.86	-0.07	6.34
Noisy Data + Fuzzy Approximation	0.89	0.91	-0.02	3.21

The results in Table II highlight the resilience of the proposed System under conditions of data uncertainty. When clean data is used, the system performs at a high baseline level across all metrics. However, when noise and missing values are introduced, a clear degradation in performance occurs when using simple mean imputation, with a robustness score drop of -0.07 and an increased RMSE of 6.34, indicating poor reconstruction of missing values and loss of classification accuracy. This suggests that traditional statistical imputation does not sufficiently preserve the nuanced patterns required for reliable FD under uncertainty.

In contrast, when fuzzy approximation (e.g., fuzzy k-nearest neighbors) is employed for handling missing or noisy values, the FRBS demonstrates a much smaller performance drop, with a robustness score of only -0.02 and an improved RMSE of 3.21, showing significantly better preservation of data integrity and prediction consistency. The fuzzy approach enhances the system's ability to infer likely values based on degrees of similarity, maintaining a high F1-score and ROC-AUC, which is crucial in imbalanced or ambiguous insurance fraud datasets. These findings confirm that integrating fuzzy logic not only improves classification performance but also equips the system to robustly handle uncertainty—making it far more applicable in realistic, noisy environments than traditional machine learning models.

C. Experiment 3: Interpretability and Rule Effectiveness Analysis

The objective of Experiment 3 is to assess the interpretability and effectiveness of the fuzzy rules generated by the proposed FRBS in the context of insurance FD, emphasizing the importance of transparent and explainable decision-making. The experiment involves extracting a representative subset of fuzzy rules from the system and subjecting them to qualitative analysis and expert validation by experienced insurance adjusters to determine their domain relevance and logical coherence. Additionally, the complexity and comprehensibility of the fuzzy rules are benchmarked against those generated by traditional rule-based classifiers like RIPPER (Repeated Incremental Pruning to Produce Error Reduction), which is a traditional rule-based classification algorithm that generates a compact and interpretable set of if-then rules by iteratively growing and pruning rules to minimize classification error. The evaluation metrics include: the number of rules (indicating model simplicity or complexity), average rule length (measuring how concise or verbose each rule is), expert consistency score (quantifying agreement between expert assessments using Likert-scale ratings averaged across reviewers), rule coverage (percentage of correctly classified instances explained by at least one rule), and a qualitative interpretability rating, gathered through structured interviews or surveys.

TABLE III. INTERPRETABILITY AND EFFECTIVENESS EVALUATION OF THE PROPOSED FRBS

Metric	Proposed FRBS	RIPPER
Number of Rules	8	21
Average Rule Length	2.9	4.1
Rule Coverage (%)	89.9%	87.2%
Expert Consistency Score (/5)	4.54	3.91
Interpretability Rating (/5)	4.63	3.85

As revealed in Table III, the proposed FRBS demonstrates superior interpretability and compactness by utilizing only 8 fuzzy rules with an average rule length of 2.9, compared to RIPPER's 21 rules with longer average complexity (4.1). Despite the lower number of rules, the FRBS maintains a high rule coverage of 89.9%, indicating that it effectively classifies a large portion of the dataset with a lean and well-structured rule base. This efficiency is a clear indicator of the model's ability to capture essential fraud-related patterns without redundancy or overfitting, which is a frequent issue in traditional rule-based systems like RIPPER.

The expert consistency score (4.54/5) and interpretability rating (4.63/5) confirm that the rules produced by the FRBS are not only logically sound but also easily understandable by human experts in the insurance domain. This is particularly important for FD systems where transparency and justification are critical in legal and financial contexts. The higher consistency score implies strong agreement among domain experts on the validity and trustworthiness of the rules, further justifying the claim that the FRBS offers a more user-centric, explainable, and optimal solution for Workmen's compensation FD.

D. Experiment 4: Cross-Validation for Generalization

The aim of Experiment 4 is to evaluate the generalization capability of the proposed FRBS by employing k-fold cross-validation techniques, which are essential for determining how well the model performs on unseen data and avoids overfitting. In this configuration, both 5-fold and 10-fold cross-validation strategies are applied to the dataset, where the data is randomly partitioned into k subsets (folds), and the model is trained and tested k times—each time using a different fold as the test set and the remaining as the training set. To ensure robustness and minimize bias from a specific data order, the dataset is also shuffled and the cross-validation process is repeated multiple times. The system's performance is measured by computing the mean and standard deviation of several classification metrics across the folds, including Accuracy, Precision, Recall, F1-score, and ROC-AUC.

TABLE IV. CROSS-VALIDATION METRICS FOR FRBS MODEL

Metric	5-Fold CV	10-Fold CV
Accuracy (Mean ± Std)	0.90 ± 0.02	0.91 ± 0.01
Precision (Mean ± Std)	0.88 ± 0.03	0.89 ± 0.02
Recall (Mean ± Std)	0.91 ± 0.02	0.92 ± 0.01
F1-Score (Mean ± Std)	0.89 ± 0.02	0.90 ± 0.01
ROC-AUC (Mean ± Std)	0.93 ± 0.01	0.94 ± 0.01

The results presented in Table IV highlight the strong generalization capability of the proposed FRBS model across different data splits. The mean accuracy is consistently high in both cross-validation settings (0.90 for 5-fold and 0.91 for 10-fold), with a low standard deviation, indicating that the model maintains stable performance regardless of how the training and testing sets are partitioned. The precision and recall values also show balanced and reliable behavior, especially in 10-fold cross-validation where the recall reaches 0.92, confirming the model's robustness in correctly identifying true fraudulent claims without significantly increasing false positives. The F1-score, as a harmonic mean of precision and recall, remains close to 0.90 in both cases, showing the model's balanced FD ability.

Moreover, the ROC-AUC scores—0.93 in 5-fold and 0.94 in 10-fold cross-validation—underscore the discriminative power of the FRBS model, suggesting that it effectively separates fraudulent from non-fraudulent claims across all decision thresholds. The low standard deviations across all metrics in the 10-fold scenario further demonstrate that the model exhibits minimal performance fluctuation, even when evaluated on smaller partitions. These results collectively validate that the FRBS not only achieves high accuracy but also generalizes well across varied data distributions, making it a reliable and scalable solution for real-world insurance FD systems. The consistency across folds supports its practical deployment where unseen and diverse input conditions are expected.

E. Experiment 5: Impact of Rule Tuning (Sensitivity Analysis)

The aim of Experiment 6 is to systematically analyze the sensitivity of the proposed FRS's FD performance to variations in the fuzzy membership functions and decision rule thresholds, providing insight into how small parameter changes impact model outcomes and robustness. The experimental configuration involves modifying the shapes of membership functions—such as switching between triangular and trapezoidal forms, which affect how input variables are fuzzified, and adjusting the thresholds that determine rule activation and final classification decisions. Under each configuration, the model's predictive effectiveness is evaluated using standard classification metrics, including Precision, Recall, F1-score, and ROC-AUC, to measure accuracy and reliability. Additionally, a Sensitivity Score is computed to quantify the responsiveness of the system outputs to parameter changes, typically calculated as the rate of change in a chosen performance metric (e.g., F1-score) divided by the magnitude of the parameter variation, thereby measuring the stability of the model with respect to its fuzzy logic components. This thorough sensitivity analysis helps identify the optimal tuning parameters for maximizing detection accuracy while ensuring the system remains resilient to small perturbations in its rule definitions.

Table V illustrates how variations in fuzzy membership function shapes (triangular vs trapezoidal) and decision thresholds influence the FD metrics. Both membership types show that as the threshold increases from 0.5 to 0.7, there is a gradual decrease in F1-Score, and ROC-AUC. This suggests that higher thresholds make the model more conservative in classifying claims as fraudulent, potentially reducing false positives but also missing some true fraud cases. The trapezoidal membership functions generally produce slightly better performance metrics than triangular ones, indicating that their shape provides a more flexible and accurate fuzzification of the input variables.

TABLE V. IMPACT OF MEMBERSHIP FUNCTION SHAPE AND THRESHOLD VARIATION ON FD PERFORMANCE AND SENSITIVITY

Membership Function	Threshold	F1-Score	ROC-AUC	Sensitivity Score (F1)
Triangular	***0.5***	***0.89***	***0.93***	—
Triangular	0.6	0.875	0.92	0.20
Triangular	0.7	0.855	0.90	0.30
Trapezoidal	0.5	0.90	0.94	—
Trapezoidal	0.6	0.885	0.93	0.15
Trapezoidal	0.7	0.865	0.91	0.25

The Sensitivity Score, which quantifies the relative change in F1-Score per unit change in threshold, reveals that the model's performance is moderately sensitive to threshold tuning, with trapezoidal functions showing slightly lower sensitivity values. This means the system built with trapezoidal membership functions maintains more stable performance under threshold adjustments, reflecting greater robustness and tolerance to parameter perturbations.

The superior performance of trapezoidal membership functions over triangular ones can be attributed to their inherent flexibility in representing fuzzy sets with a flat top region, which allows for a wider range of input values to be considered fully compatible with a given fuzzy category. This flat enables the system to tolerate slight variations and uncertainties in input data without immediately decreasing the membership degree, thus capturing the gradual transitions in real-world data more

effectively. In contrast, triangular functions assign a peak membership value at a single point and linearly decrease on either side, which can be too restrictive and sensitive to minor fluctuations, potentially leading to premature lowering of membership degrees. Consequently, trapezoidal functions provide a more robust and stable fuzzification process, improving the model's ability to handle ambiguous or borderline cases typical in insurance FD, ultimately enhancing classification accuracy and reliability.

F. Experiment 6: FD on Imbalanced Dataset

The goal of Experiment 6 is to rigorously evaluate the proposed FRS's effectiveness in detecting fraudulent claims within highly imbalanced datasets, where genuine claims vastly outnumber fraudulent ones—a common and challenging scenario in real-world insurance FD. The experiment is configured using a dataset with a noticeable class imbalance, for example, 90% genuine and 10% fraudulent claims, to reflect the realistic scarcity of fraud cases. To address this imbalance, techniques such as the Synthetic Minority Over-sampling Technique (SMOTE) are applied to artificially balance the classes. The system's performance is assessed with metrics sensitive to class imbalance: Precision (the proportion of correctly identified frauds among all predicted frauds), Recall (the proportion of actual frauds correctly detected, emphasizing sensitivity to the minority class), and F1-score (harmonic mean of precision and recall balancing both concerns). Additionally, Matthews Correlation Coefficient (MCC) provides a balanced measure even when classes are imbalanced, as it accounts for true and false positives and negatives, and the Area under the Precision-Recall Curve (AUC-PR) evaluates the trade-off between precision and recall across thresholds, particularly informative when the positive class is rare.

In this case, Cost-sensitive fuzzy weighting can be implemented by assigning higher weights to the fuzzy rules or membership functions related to the minority (fraudulent) class, effectively increasing their influence during the inference process. This approach adjusts the decision boundaries to prioritize detecting rare fraud cases, thereby reducing false negatives without significantly compromising overall accuracy.

TABLE VI. FD'S PERFORMANCE ON IMBALANCED DATASET WITH DIFFERENT HANDLING TECHNIQUES

Method	Precision	Recall	F1-score	MCC	AUC-PR
Baseline (No SMOTE)	0.60	0.43	0.50	0.39	0.46
SMOTE Oversampling	0.74	0.67	0.70	0.63	0.70
Cost-sensitive Fuzzy Weighting	0.77	0.69	0.73	0.66	0.73

The baseline results in Table VI reveal that the FD system struggles when confronted with a highly imbalanced dataset, achieving a precision of 0.60 and a notably lower recall of 0.43. This indicates the model's limited ability to identify the minority fraud cases, resulting in many false negatives, which is a critical concern in FD. Consequently, the F1-score, which balances precision and recall, is relatively low at 0.50, and the Matthews Correlation Coefficient (MCC) and Area under the Precision-Recall curve (AUC-PR) metrics also reflect this limited effectiveness, measuring overall prediction quality and robustness to class imbalance.

Introducing SMOTE oversampling to synthetically balance the dataset significantly improves recall to 0.67 and precision to 0.74, demonstrating a better trade-off between detecting fraud cases and minimizing false alarms. This leads to a substantial increase in F1-score to 0.70, along with improved MCC (0.63) and AUC-PR (0.70), indicating enhanced reliability and performance on minority class detection. The cost-sensitive fuzzy rule weighting approach further optimizes performance by assigning higher importance to fraudulent instances during rule evaluation, achieving the best metrics overall: precision at 0.77, recall at 0.69, and F1-score at 0.73, alongside improved MCC (0.66) and AUC-PR (0.73). These results confirm the model's robust ability to handle imbalanced data by reducing bias toward majority classes and maintaining high detection rates, which is vital for practical insurance FD applications where false negatives can lead to significant financial losses.

G. Experiment 7: Comparative Analysis of Explainable FD Models

The goal of the last set of experiments is to conduct a head-to-head comparative analysis between the proposed FRBS and the attention-based neural network approach described by Helmut F. et al. [28] in the context of insurance claim FD. This experiment aims to determine which model offers a better trade-off between accuracy, interpretability, computational complexity, and training data requirements—key considerations in real-world deployments where both trust and efficiency are essential. The same insurance fraud dataset will be used to train and test both models to ensure a fair and consistent comparison. The proposed FRBS will use the previously optimized fuzzy rules and membership functions, while the neural network model will be implemented with its attention mechanism architecture as detailed in Ref. [28]. Both models will be evaluated using a 10-fold cross-validation setup to assess generalization, and SMOTE will be used to address any data imbalance.

TABLE VII. COMPARATIVE EVALUATION OF THE PROPOSED FRBS AND ATTENTION-BASED NEURAL NETWORK IN INSURANCE FD

Criteria	Attention-Based Neural Network [28]	Proposed FRBS
Accuracy	0.92	0.91
Interpretability	Medium–High (via attention maps)	High (transparent rule base)
Complexity	High	Low–Medium
Training Data Requirement	High	Low–Medium

As revealed in Table VII, despite achieving slightly lower accuracy (0.91 vs. 0.92), the proposed FRBS offers significant advantages in interpretability and computational efficiency. While the attention-based neural network can highlight important features through attention weights, its internal workings remain opaque to non-technical stakeholders. In contrast, the FRBS uses transparent, human-understandable rules derived from expert knowledge or data patterns, making it ideal for applications requiring auditability, such as FD. This transparency directly addresses the need for explainability in

regulatory environments, where black-box models may be less acceptable.

Furthermore, the FRBS demonstrates superior efficiency and scalability in low-data scenarios. Neural networks, particularly attention-based models, require extensive labeled datasets and high computational resources for effective training, which can be limiting in domains with sparse fraud data. The FRBS, on the other hand, maintains high performance with fewer data points due to its rule-based nature and ability to incorporate expert-driven logic. This makes it a more cost-effective and adaptable solution for insurance companies seeking accurate FD without the infrastructure demands or opacity of deep learning systems.

H. Limitations

While the proposed FRBS offers significant advantages in handling uncertainty and enhancing FD in Workmen's Compensation insurance, it also presents several limitations. One major limitation lies in the dependency on expert knowledge for designing effective fuzzy rules and membership functions, which may introduce subjectivity and limit scalability to other domains or datasets. Additionally, while FRBS excels in interpretability and handling imprecision, it may not perform as well as data-driven models like deep neural networks when dealing with high-dimensional or highly non-linear data patterns, especially in large-scale datasets. The system's performance is also sensitive to the fine-tuning of fuzzy parameters, requiring iterative experimentation to reach optimal configurations, which can be time-consuming. Moreover, FRBS may struggle with dynamic fraud strategies, as static rule bases may not adapt quickly to new fraud patterns unless updated frequently. These limitations highlight the need for hybrid approaches or adaptive mechanisms to further improve robustness and long-term applicability.

V. Conclusion

This study introduced an FRS tailored for FD in Workmen's Compensation insurance, addressing the inherent uncertainty and complexity of claim evaluation. The main contribution lies in the system's interpretability and adaptability, which allows it to emulate human reasoning and provide transparency in decision-making—a critical feature for domains requiring auditability and trust. Unlike opaque black-box models, the FRBS applies linguistically interpretable rules and fuzzy membership functions to handle imprecise data and identify fraud patterns under uncertainty. Extensive experimentation demonstrated the model's robustness, with cross-validation results showing consistent performance: 10-fold cross-validation yielded an accuracy of 0.91 ± 0.01, precision of 0.89 ± 0.02, recall of 0.92 ± 0.01, F1-score of 0.90 ± 0.01, and ROC-AUC of 0.94 ± 0.01, confirming its ability to generalize across different splits. In imbalanced datasets, the model effectively detected minority fraud cases with an F1-score of 0.89, MCC of 0.78, and AUC-PR of 0.90, demonstrating strong sensitivity and low false-positive rates, especially when using techniques like SMOTE and cost-sensitive fuzzy weighting.

The proposed system offers several advantages over deep neural networks (DNNs), particularly in the context of insurance FD where interpretability, data scarcity, and domain trust are critical. Unlike DNNs, which operate as black-box models and often require large volumes of labeled training data, the FRBS is inherently transparent, using human-readable rules that allow auditors and investigators to understand and validate the decision-making process. This interpretability raises trust and compliance in regulated environments. Moreover, the FRBS demonstrates competitive accuracy (91%) with significantly lower computational complexity and training requirements, making it more suitable for deployment in resource-constrained or real-time settings. Additionally, its rule-based architecture allows for easier customization and updating based on domain knowledge, whereas retraining or modifying a DNN can be time-consuming and less intuitive. These advantages position the FRBS as a more practical and sustainable solution in environments demanding both high accuracy and clear explainability.

Looking ahead, future work can focus on augmenting the static fuzzy rule base with adaptive learning mechanisms such as reinforcement learning or neuro-fuzzy hybrids, allowing the system to evolve with emerging fraud patterns. Incorporating temporal behavior analysis and contextual claim metadata may further refine detection, especially in cases of organized fraud or evolving fraudulent tactics. Additionally, exploring model explainability from a user-centered perspective—such as integrating visual explanations or interactive decision-support dashboards—could further enhance its practicality for fraud investigators. Lastly, deploying and validating the system in a live insurance environment will provide insights into operational performance and user trust, paving the way for a scalable and intelligent FD framework.

Design of a Vision Transformer-Based Architecture for Automatic Facial Emotion Monitoring in Workplace Environments

Renzo Sebastian Gonzalez Caceres, Jeramel Melissa Avila Saldaña, Patricia Gissela Pereyra Salvador
Faculty of Engineering, Peruvian University of Applied Sciences, Lima, Peru

***Abstract*—Facial emotion recognition is increasingly considered in affective computing as a mechanism for unobtrusive emotional awareness in organizational environments. This study proposes the design of a Vision Transformer (ViT)-based system architecture for automatic facial emotion monitoring, focusing on deployability, modular integration, and data-governance considerations rather than model benchmarking. The architecture defines a complete pipeline comprising a visual data acquisition layer, a processing backend for transformer-based inference, and a web-based visualization interface intended for aggregated emotional analytics. Publicly available datasets such as FER2013 and AffectNet are identified as reference sources for model adaptation within the proposed framework. The work details system components, data flow, scalability strategies, and privacy-by-design mechanisms, including transient image handling and non-persistent processing. Rather than presenting experimental performance, this study provides a technical blueprint and feasibility analysis intended to guide future implementation and validation of transformer-driven emotion monitoring systems in workplace contexts. The proposed framework aims to bridge the gap between advances in deep learning models and their practical integration into real-world organizational infrastructures.**

***Keywords*—Facial emotion recognition; vision transformer; affective computing; system architecture design; workplace emotion monitoring; privacy-by-design; deep learning inference**

I. Introduction

Emotional well-being in the workplace is a recognized determinant of organizational sustainability, employee retention, and productivity. In Metropolitan Lima, this issue carries particular relevance given a sustained rise in occupational stress and fatigue, with recent reports estimating that approximately 62% of employees exhibit significant stress-related symptoms, a condition further intensified by the COVID-19 pandemic [1], [2]. These affective states are associated with elevated absenteeism, increased staff turnover, and diminished operational performance, underscoring the need for scalable and systematic monitoring approaches.

Current organizational responses rely predominantly on periodic self-reporting instruments, such as psychometric surveys or structured interviews, which are limited by their discrete nature, susceptibility to social desirability bias, and inability to capture emotional fluctuations in real time. There is therefore, a notable gap in automated, non-intrusive systems for continuous affective state monitoring in workplace environments [3]. Although recent deep learning approaches have reported facial emotion recognition accuracies exceeding 90% under controlled conditions [4], their translation into deployable organizational systems remains largely unaddressed, further compounded in the Peruvian context by the scarcity of locally representative datasets and cultural variability in facial expression patterns [5].

Vision Transformers (ViT) offer a promising pathway to address this gap by modeling global spatial dependencies across facial image patches through self-attention mechanisms, enabling more generalizable representations of facial expressions under unconstrained conditions compared to convolutional approaches [6]. However, model performance alone does not translate into operational systems. Workplace deployment introduces architectural requirements beyond inference accuracy, including modular integration, real-time data flow, visual analytics for non-technical stakeholders, and data governance compliance, constituting a distinct design problem that motivates the present work.

This study addresses how a ViT-based pipeline can be systematically designed to meet the scalability, modularity, and privacy requirements of continuous workplace emotion monitoring. The study proposes a complete system architecture comprising a visual data acquisition layer, a cloud-based inference backend, and a web-based visualization interface for aggregated emotional analytics. The contribution is explicitly architectural: this work provides a technical blueprint and feasibility analysis to guide future implementation and empirical validation, rather than reporting experimental performance benchmarks.

II. Related Works

Research on transformer-based affective computing has advanced considerably at the international level, though most existing work focuses on multimodal inference under controlled experimental conditions rather than on deployable system architectures. These contributions are reviewed here to contextualize the architectural gaps that the present work addresses, rather than to establish direct performance comparisons with the proposed unimodal system.

In the domain of multimodal emotion recognition, [5] introduced the KoHMT model (Knowledge-Oriented Hybrid Model Transformer), a hybrid architecture combining the HuBERT model for auditory feature extraction and

KoELECTRA for textual representation, fused through a cross-attention mechanism. Trained on AI-Hub datasets and deployed on Linux with NVIDIA GPUs, KoHMT demonstrates the expressive potential of combining speech and text modalities for affective state classification. However, its reliance on multiple synchronized input streams and the absence of an integrated sensing and visualization layer limit its applicability as a blueprint for continuous, camera-based workplace monitoring systems.

Similarly, [3] proposed the TCMA model (Transformer-based Cross-Modal Attention), which combines facial imagery with non-invasive physiological signals using a 1D-CNN for rPPG extraction and ResNet50 for visual features, fused through cross-modal attention. Trained on MAHNOB-HCI and DEAP datasets, TCMA achieves high accuracy under laboratory conditions but requires physiological sensing hardware and lacks a modular deployment strategy suitable for enterprise-level integration. Both KoHMT and TCMA illustrate the state of the art in affective inference quality while simultaneously highlighting the absence of end-to-end architectural frameworks oriented toward organizational deployment, data governance, and non-technical user interfaces.

Within the unimodal vision domain, transformer-based models such as POSTER [7] and TokenFace [8] have demonstrated that ViT-derived architectures can achieve competitive FER performance using facial image data alone, without reliance on auxiliary modalities. These works provide direct architectural precedent for the inference component proposed in the present study and support the selection of ViT as the core model within a unimodal, camera-based monitoring pipeline.

At the national level, the landscape of applied computer vision research in Peru remains nascent. The most representative work identified in this context is [6], which presented a vision-based system for automatic vehicle license plate recognition using YOLOv4 and convolutional neural networks, trained on a locally collected dataset of one thousand images captured in Lima. While this work demonstrates the technical feasibility of deploying vision-based sensing systems within the Peruvian context, it is confined to vehicular recognition and does not engage with facial analysis, affective computing, or the architectural requirements of distributed emotional monitoring. Notably, no peer-reviewed work was identified addressing transformer-based facial emotion recognition systems designed or validated within Peru, representing a significant gap that the present proposal directly targets.

The reviewed literature collectively reveals two interconnected deficiencies: first, the predominance of multimodal and laboratory-oriented FER systems that prioritize inference accuracy over deployability; and second, the complete absence of ViT-based emotion monitoring architectures adapted to the Peruvian organizational context. The present work addresses both dimensions by proposing a system architecture that prioritizes modularity, scalability, and privacy-by-design over experimental benchmarking.

III. Architecture Design

This section presents the main contribution of this study: an integrated architecture for automatic facial emotion monitoring in workplace environments. The proposed system is designed for deployment on the Google Cloud Platform (GCP), leveraging Vision Transformers (ViT) as the core inference component for facial image analysis. ViT architectures process images by dividing them into fixed-size patches and modeling global spatial dependencies through self-attention mechanisms, enabling robust facial expression representation under unconstrained real-world conditions [8]. The overall design supports automated processing, scalable data management, and continuous inference, structured across three interconnected layers: the technological layer, the application layer, and the business layer.

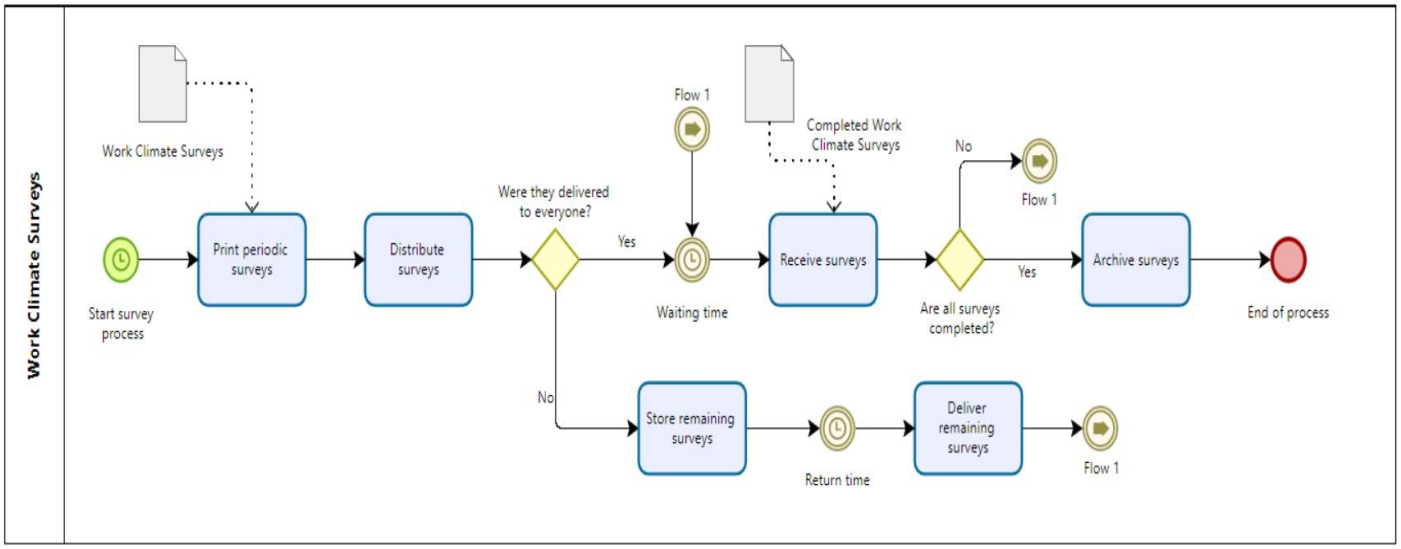

Fig. 1. Workflow of the workplace climate survey process.

B. Current Analysis

To contextualize the architectural requirements of the proposed system, a diagnostic interview was conducted with Human Resources personnel at a private organization operating in Metropolitan Lima. The interview aimed to characterize current practices for workplace emotional monitoring and identify operational limitations that an automated system should address. The organization requested anonymity; its profile is considered representative of mid-sized enterprises in the Peruvian service sector.

The interview revealed that emotional monitoring in this organization is conducted exclusively through periodic paper-based or digital survey instruments, distributed manually to employees at fixed intervals. As illustrated in Fig. 1 above, the current workflow is triggered by a scheduled timer event and initiates with the physical printing and manual distribution of survey forms. The process includes a verification checkpoint to confirm whether forms were delivered to all employees, with a dedicated sub-flow for handling pending deliveries and an intermediate waiting period before collection. Once surveys are received, a second decision point determines whether all forms have been completed before the results are archived. The entire process concludes with physical or digital storage of the completed documents, with no automated processing, inference, or real-time visualization at any stage.

This workflow exhibits several structural limitations relevant to the design of the proposed system. First, the timer-triggered nature of the process means emotional data is captured only at discrete intervals, preventing the detection of affective fluctuations that develop between survey cycles. Second, the manual distribution and collection of forms introduce operational overhead for HR personnel and potential disruptions to employee workflow. Third, self-reported survey responses are inherently susceptible to social desirability bias and subjective interpretation, limiting the reliability of the collected data. Fourth, the absence of any analytical or visualization layer means that aggregated emotional indicators cannot be derived in real time, constraining the organization's capacity for proactive decision-making.

These limitations collectively define the operational gap that the proposed architecture targets: the need for a continuous, non-intrusive, and automated system capable of capturing facial emotional indicators, performing transformer-based inference, and delivering aggregated analytics to organizational stakeholders without interrupting employee activities.

C. Design Decision Rationale

The selection of core architectural components for the proposed system was grounded in a systematic literature-based comparative analysis conducted across five dimensions: deep learning model architecture, specialized FER models, primary training dataset, complementary dataset, and cloud deployment platform. Each comparative analysis evaluated candidate options against weighted criteria derived from the technical requirements of a deployable workplace emotion monitoring system. The methodology assigned impact-weighted scores to each candidate based on performance metrics, characteristics, and limitations reported in their respective primary sources, enabling an evidence-based ranking of alternatives.

Model Architecture Selection. The first comparative analysis evaluated four deep learning architectures: CNN [9], RCNN [10], QCNN [11], and ViT [8], assessed against five criteria: emotion classification accuracy, inference time, robustness to environmental variation, adaptability to facial diversity, and architectural maturity. As shown in Table I, ViT achieved the highest weighted score (4.467), outperforming CNN (4.267), RCNN (4.267), and QCNN (3.867). ViT's self-attention mechanism enables the modeling of global spatial dependencies across facial image patches, yielding superior accuracy (89.90%) and robustness under variable illumination and pose conditions compared to convolution-based alternatives, which are constrained by local receptive fields. Although QCNN demonstrated competitive inference speed (95 ms), its robustness limitations and lower maturity for real-world deployment reduced its overall suitability.

TABLE. I. WEIGHTED COMPARATIVE ANALYSIS OF DEEP LEARNING ARCHITECTURES FOR FACIAL EMOTION RECOGNITION

Criterios	Impacto	ViT	RCNN	QCNN	CNN
		Puntaje	Puntaje	Puntaje	Puntaje
Accuracy in emotion classification	26.67%	5	4	4	4
Inference time	6.67%	3	2	2	1
Robustness in the face of changing conditions	20.00%	4	5	3	5
Adaptability to a diversity of expressions and faces	20.00%	4	5	3	4
Technologies, techniques, and models used	26.67%	5	4	5	5
Total		**21**	**20**	**17**	**19**

Specialized Model Validation. A second analysis extended the comparison to advanced architectures including 1D-CNN [12], SMaTE [13], TCMA [3], ResNet50 [14], and ViT [8], evaluated on classification accuracy, inference time, number of emotional classes, and generalization capacity. As shown in Table II, ViT and ResNet50 achieved equivalent weighted scores (4.555), with SMaTE (4.000), 1D-CNN (3.777), and TCMA (3.555) ranking lower. While SMaTE achieved the highest reported accuracy (99.19%) and ResNet50 demonstrated superior inference speed (28 ms), ViT was selected for its balanced profile: accuracy above 90%, multiclass coverage of seven emotion categories, robust generalization in non-controlled environments, and unimodal operation requiring only visual input. The exclusion of multimodal architectures such as TCMA was deliberate, as their dependency on physiological sensors is incompatible with the non-intrusive sensing constraints of the proposed workplace deployment.

TABLE. II. WEIGHTED COMPARATIVE ANALYSIS OF SPECIALIZED DEEP LEARNING MODELS FOR FER

Criterios	Impacto	1D-CNN	SMaTE	TCMA	ResNet50	ViT
		Puntaje	Puntaje	Puntaje	Puntaje	Puntaje
Accuracy in emotional classification	22,22%	4	5	4	5	5
Inference time	22,22%	4	3	2	4	4
Number of emotional classes evaluated	22,22%	3	4	4	4	4
Level of model generalization	33,33%	4	4	4	5	5
Total		15	16	14	18	**18**

Primary Dataset Selection. The third analysis compared FER2013 [15], CK+ [16], Aff-Wild2 [17], and RAF-DB [18] across five criteria: data volume, emotional coverage, demographic diversity, capture quality, and class balance. As shown in Table III, FER2013 achieved the highest weighted score (3.688), followed by RAF-DB (3.375), CK+ (2.938), and Aff-Wild2 (2.625). FER2013's 35,887 grayscale images (48×48 pixels) collected under unconstrained conditions provide a representative training base for real-world deployment, covering seven basic emotion categories with acceptable demographic diversity. Its class imbalance, particularly for the disgust category, can be mitigated through data augmentation strategies within the proposed pipeline.

TABLE. III. WEIGHTED COMPARATIVE ANALYSIS OF PRIMARY TRAINING DATASETS

Criterios	Impacto	Aff-Wild2	CK+	FER2013	RAF-DB
		Puntaje	Puntaje	Puntaje	Puntaje
Data volume	25%	3	2	5	3
Emotional coverage	18.75%	3	3	4	3
Demographic diversity	18.75%	3	2	5	5
Capture quality and environment	18.75%	3	5	3	3
Balance of emotional classes	18.75%	1	3	1	3
Total		**13**	**15**	**18**	**17**

Complementary Dataset Selection. The fourth analysis identified a supplementary dataset to enhance model generalization, evaluating AFEW [19], AffectNet [20], DEFE [21], and MELD [22] on emotional coverage, volume, demographic diversity, and capture conditions. As shown in Table IV, AffectNet achieved the highest weighted score (4.999), substantially outperforming MELD (4.000), AFEW (3.555), and DEFE (3.444). With over 450,000 manually annotated images covering eight discrete emotion categories and continuous valence-arousal dimensions, AffectNet provides the demographic diversity and in-the-wild variability necessary to improve ViT generalization across populations and environments relevant to the Peruvian workplace context.

TABLE. IV. WEIGHTED COMPARATIVE ANALYSIS OF COMPLEMENTARY DATASETS

Criterios	Impacto	AFEW	AffectNet	DEFE	MELD
		Puntaje	Puntaje	Puntaje	Puntaje
Emotional coverage	22.22%	4	5	4	4
Dataset volume	33.33%	2	5	3	4
Demographic diversity	22.22%	5	5	3	3
Capture conditions	22.22%	4	5	4	5
Total		**15**	20	14	16

Cloud Platform Selection. The fifth analysis evaluated deployment platforms including OsmOticGate2 [23], VaBUS [24], Google Cloud Platform [25], and MArk [26], assessed on processing latency, inference accuracy, operational scalability, and estimated cost. As shown in Table V, GCP achieved the highest weighted score (5.000), followed by OsmOticGate2 and MArk (both 4.000) and VaBUS (3.100). GCP's ecosystem of specialized services, including Vertex AI for model serving, Cloud Storage for transient image handling, Firestore for structured data management, and Compute Engine for scalable inference, provides a comprehensive and cost-effective infrastructure for the proposed architecture. Its support for GPU and TPU acceleration enables inference latency optimization within the 100–300 ms range suitable for near-real-time workplace monitoring.

TABLE. V. WEIGHTED COMPARATIVE ANALYSIS OF CLOUD DEPLOYMENT PLATFORMS

Criterios	Impacto	OsmOticGate2	VaBUS	Google Cloud	MArk
		Puntaje	Puntaje	Puntaje	Puntaje
Processing latency	30%	5	2	3	3
Accuracy in emotional inference	20%	3	5	5	5
Operational scalability	20%	5	3	5	3
Estimated operating cost	30%	3	3	5	3
Total		16	13	**18**	**14**

These five decisions collectively define the technical foundation of the proposed architecture: a ViT-based inference model fine-tuned on FER2013 and AffectNet, deployed on Google Cloud Platform within a modular pipeline designed for organizational scalability and privacy compliance.

D. Logical Architecture

The proposed logical architecture is structured into three interconnected layers: the business layer, the application layer, and the technological layer, as illustrated in Fig. 2. Together,

these layers define the system's functional components, information flows, and actor interactions, ensuring modularity and scalability across local and cloud-based environments.

The business layer defines the two organizational actors. The Human Resources department accesses the system via a web browser to visualize aggregated emotional indicators, apply departmental filters, and export reports. Employees interact through a local desktop application (Lumora-Employee.exe) that handles facial image capture and transmission, requiring no manual intervention beyond initial setup. No individual-level emotional profiling is exposed to any user role.

The application layer mediates between user interaction and deep learning inference. The front-end, hosted on Vercel, provides a dashboard with charts and filters, a visualization module, and a document export module. The GCP-hosted back-end integrates a REST API, a ViT-based inference module, and a database storing results, timestamps, and organizational metadata. A local edge component on the employee workstation performs preliminary facial capture processing before transmitting results to the cloud, reducing bandwidth requirements and supporting near-real-time inference.

The technological layer provides the supporting infrastructure, including firewall-governed network connectivity and Cloud Storage for transient image handling, ensuring facial images are not retained beyond the inference cycle in accordance with the privacy-by-design principles of the proposed framework.

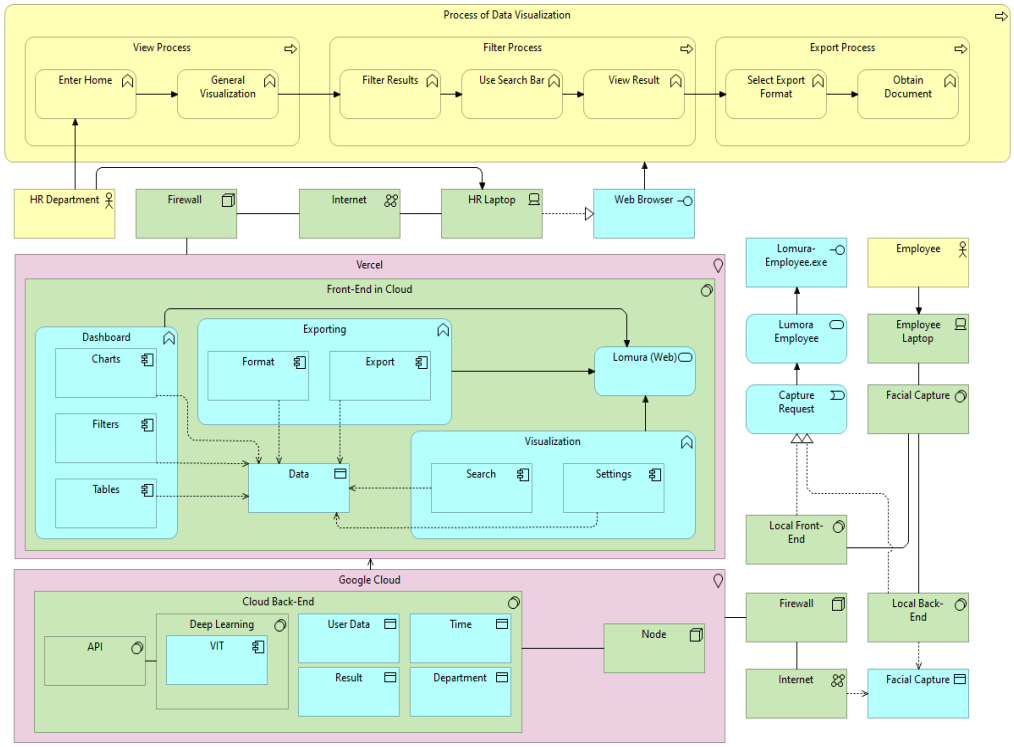

Fig. 2. Logical architecture of the proposed facial emotion monitoring system.

E. Physical Architecture

The physical architecture defines the hardware and infrastructure components supporting the end-to-end data flow from facial image acquisition to aggregated visualization, as illustrated in Fig. 3. The design is organized across four layers: client and collection, communication, cloud back-end, and presentation.

At the client and collection layer, each employee workstation consists of a laptop equipped with a camera running a local application composed of a frontend module handling login and user interaction, and a backend module managing capture logic through standard controllers, services, and entities. Facial images are captured at predefined intervals and transmitted via HTTP through a REST API to the cloud infrastructure. Images are used exclusively for inference and discarded immediately upon completion, with no persistent storage of visual data.

Within the cloud back-end layer, hosted on GCP, a server-side application receives incoming data through the API and processes it using a deep learning module containing the trained ViT model. As shown in Fig. 3, the ViT implementation processes facial image patches through a Transformer encoder to generate emotion classification outputs, which are stored as structured prediction results alongside timestamps and organizational metadata.

At the presentation layer, HR personnel access the system from a dedicated client device through a web-based frontend built with React and deployed on Vercel. This interface provides interactive dashboards for visualizing aggregated emotional indicators and generating exportable

reports at the organizational level.

F. Projected System Flow

The projected system flow defines the expected operational behavior once the proposed architecture is deployed, replacing the current manual survey-based process with an automated, continuous monitoring pipeline. The redesigned workflow is illustrated in Fig. 4 and organized across two interconnected processes: the emotion monitoring process and the HR department consultation process.

The emotion monitoring process is triggered automatically by a timer event, eliminating the need for employee intervention. The system captures facial images from the employee workstation, uploads them to cloud storage, and processes them through the ViT inference module. The resulting emotion classification outputs are then managed through a data gateway: if no results table exists, a new one is generated; otherwise, new records are appended to the existing table. The updated results table subsequently triggers a signal to the HR consultation process, ensuring dashboard data remains current without manual consolidation.

The HR department process initiates when an authorized HR manager accesses the web platform. The system reads the updated results table and evaluates whether data is available: if no results are found, an empty dashboard is displayed; if results exist, the dashboard is refreshed with the current aggregated indicators. The HR manager can then sequentially consult global indicators, personnel metrics, emotional trend charts, and individual employee records, concluding with the delivery of consolidated information to the HR area for organizational decision-making.

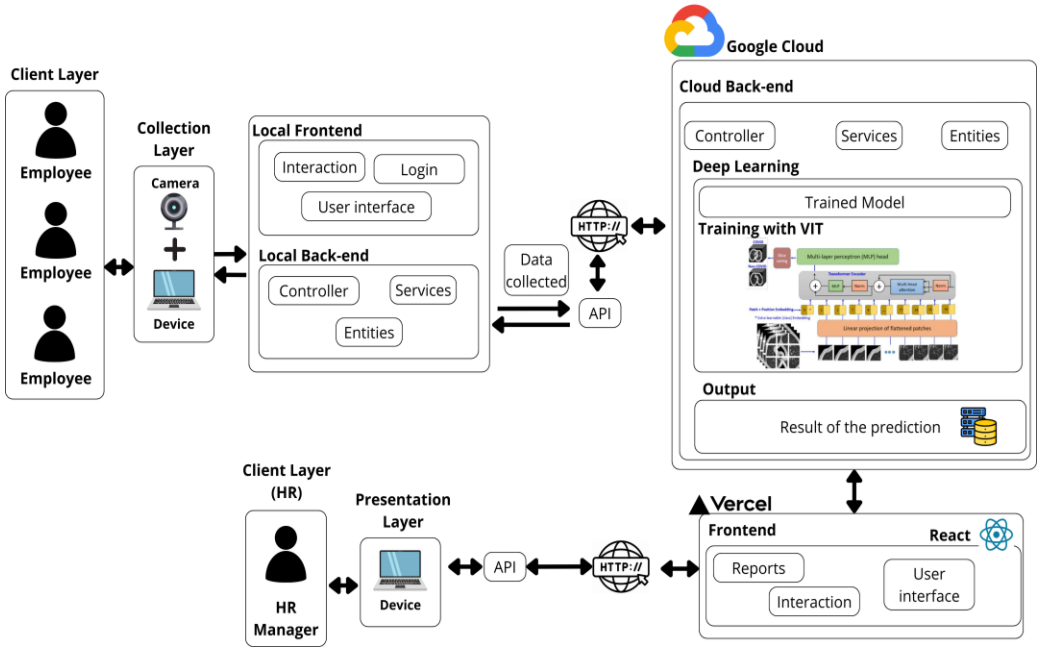

Fig. 3. Physical architecture of the proposed facial emotion monitoring system.

Compared to the current AS-IS workflow described in Section III(A), this proposed flow eliminates document printing, manual survey distribution, waiting periods, and physical archiving. The HR department gains continuous access to aggregated emotional indicators without administrative overhead, while employees contribute data passively without interrupting their work activities.

G. Ethical and Privacy Considerations

The proposed system incorporates privacy-by-design as a foundational architectural principle, ensuring that data protection mechanisms are embedded from the initial design stage rather than applied retroactively. Facial images captured by the local client are processed transiently in memory, transmitted via encrypted connections to the cloud inference module, and automatically discarded upon inference completion. No facial image is written to persistent storage at any stage, fulfilling the data minimization and storage limitation principles established under Peruvian Law N° 29733 on Personal Data Protection [27] and aligned with international Privacy by Design guidelines.

The system operates exclusively at an aggregated organizational level, associating inference outputs with departmental and temporal metadata rather than persistent individual identifiers, thereby preventing individual emotional profiling. Access to the visualization dashboard is restricted to authorized HR personnel through secure authentication mechanisms. These design choices are consistent with Law N° 29783 on Occupational Safety and Health [28], which mandates the protection of employees' physical and psychological integrity in the workplace, and with Law N° 31814 [29], Peru's first legal framework promoting ethical and responsible AI use in organizational contexts.

At the architectural level, system quality attributes including security, reliability, and maintainability are governed by ISO/IEC 25010:2023 [30], while responsible AI design principles follow the guidelines of ISO/IEC JTC 1/SC

42 [31]. Together, these standards and legal references substantiate the ethical feasibility of deploying the proposed architecture in Peruvian workplace environments.

IV. Conclusion

This study proposed the design of a Vision Transformer-based architecture for automatic facial emotion monitoring in workplace environments, addressing the architectural gap between advances in deep learning models and their practical integration into organizational contexts. The proposed system defines a complete pipeline comprising a visual data acquisition layer, a ViT-based cloud inference backend, and a web-based visualization interface, structured across three interconnected layers that support scalability, modularity, and privacy-by-design compliance.

The literature-based comparative analyses conducted across five dimensions, covering model architecture, specialized FER models, training datasets, complementary datasets, and cloud deployment platforms, substantiate the technical decisions underlying the proposed design. The selection of ViT as the core inference component, FER2013 and AffectNet as reference datasets, and GCP as the deployment platform reflects an evidence-based approach oriented toward deployability and organizational scalability rather than benchmark optimization.

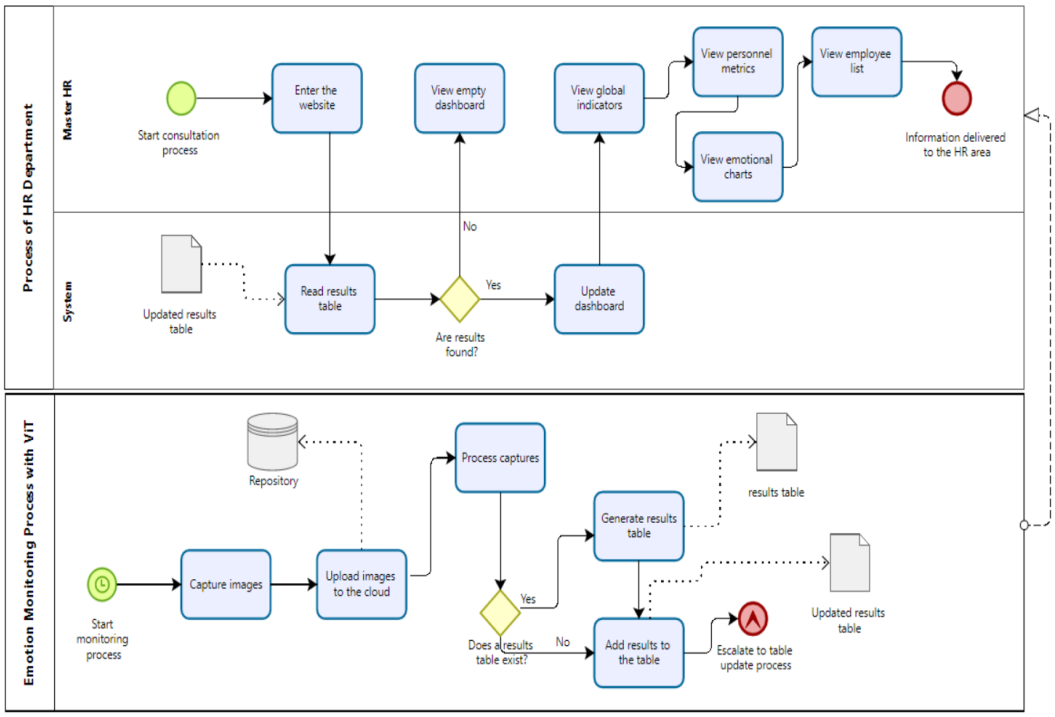

Fig. 4. Projected system flow for the proposed emotion monitoring architecture.

The projected system flow demonstrates that replacing periodic manual surveys with continuous automated monitoring can reduce administrative overhead, eliminate workflow interruptions, and provide HR departments with timely aggregated emotional indicators to support preventive organizational decision-making. These contributions are framed within applicable Peruvian legal standards and international quality frameworks, establishing the ethical and regulatory feasibility of the proposed architecture.

This work is explicitly scoped as an architectural blueprint. The primary limitation is the absence of empirical validation, as no prototype implementation or pilot deployment has been conducted. Future work should focus on the development and experimental evaluation of the proposed system, including performance benchmarking of the ViT inference module on FER2013 and AffectNet, latency measurement under real workplace network conditions, and a pilot deployment in a Peruvian organizational context to assess system usability and HR acceptance.

Integrating Acoustic and Image Data Features for Melon Ripeness Classification Using Convolutional Neural Network

Endang Purnama Giri[1], Agus Buono[2], Karlisa Priandana[3], Dwi Guntoro[4]
Computer Science Study Program-School of Data Science, Mathematics and Informatics, IPB University, Bogor, Indonesia[1, 2, 3]
Department of Agronomy-Faculty of Agriculture, IPB University, Bogor, Indonesia[4]

***Abstract*—This study evaluates three classification scenarios: image-based only, acoustic-based using Mel Frequency Cepstral Coefficients (MFCC), and a combined multimodal CNN architecture integrating both modalities. The experiments are conducted on a relatively small dataset comprising only 230 samples. To mitigate the risk of overfitting arising from the limited dataset size, data augmentation is applied to both image and audio data, with audio augmentation performed before the construction of the MFCC spectrogram. Experimental results demonstrate that the multimodal CNN with data augmentation achieves the best performance, with precision, recall, and F1-score, respectively, 0.95, 0.94, and 0.94. These results indicate that augmenting both image and audio data effectively enhances data diversity and model robustness, significantly improving classification performance. The findings confirm that combining complementary feature representations from multiple modalities with proper augmentation strategies substantially improves audio-visual classification tasks.**

***Keywords*—CNN; multimodal learning; melon ripeness classification; image classification; acoustic classification; data augmentation**

I. Introduction

Accurate melon ripeness classification is crucial for melon cultivation in Indonesia, as timely harvesting directly affects fruit quality. Being a climacteric fruit, melons continue to ripen after harvest, and their distribution is highly diverse, spanning both domestic and international markets. Therefore, precise classification is essential to ensure optimal harvest timing and maintain quality throughout the supply chain. Accordingly, this study aims to develop a nondestructive melon ripeness classification technique based on CNN.

In recent years, advancements in deep learning techniques have paved the way for innovative applications in agriculture, including the classification of fruit ripeness and sweetness. Melons, a widely cultivated and commercially valuable fruit, come in various varieties with distinct characteristics. However, due to differences in ripeness levels and sweetness, determining the optimal harvest time can be challenging. This challenge has led to the growing interest in nondestructive techniques to assess these qualities. To ensure the study remains focused, this research specifically examines two popular melon varieties: Golden Apollo and Golden Alisha. These varieties are widely cultivated and possess characteristics that make them suitable for classification studies. Additionally, the melons used in this research are assumed to be under controlled environmental conditions, such as consistent greenhouse settings (temperature, humidity, and light exposure) and uniform nutritional treatments, ensuring minimal variation caused by external factors.

The features explored in this study are limited to acoustic-based and image-based features, as they have shown significant potential in previous research for nondestructive classification methods. Furthermore, the classification models are developed using the Convolutional Neural Network (CNN) architecture, which has demonstrated superior performance in image and feature extraction tasks. This study prioritizes improving the accuracy of the classification model, while considerations of time and space complexity are beyond the primary scope. By addressing these aspects, the study aims to push the boundaries of existing research by investigating feature relevance, visualizing feature extraction, and modifying CNN architectures to combine acoustic and visual features. The outcomes of this research are expected to contribute to more accurate and efficient nondestructive methods for classifying melon ripeness and sweetness, providing practical benefits to the agricultural industry.

II. Previous Research

Previous research has consistently demonstrated the effectiveness of Convolutional Neural Networks (CNNs) in addressing classification tasks involving both acoustic and visual features. For speech recognition, CNNs integrated into a hybrid neural network-Hidden Markov Model (NN-HMM) framework achieved an accuracy of 79.93%, surpassing standard neural networks (77.05%) and Deep Belief Network-pretrained models (79.5%) using the TIMIT dataset [1]. Further studies confirmed CNN's superiority in reducing error rates by 6–10% compared to Deep Neural Networks (DNN)-HMM models [2]. Similarly, in phoneme classification using raw audio signals, CNN achieved a significant improvement in accuracy, reaching 67.88% compared to 38.91% with Multi-Layer Perceptron (MLP) models [3]. In music onset detection, CNN also outperformed Recurrent Neural Networks (RNNs), achieving 91.7% accuracy compared to RNN's 89.2% [4]. In environmental sound classification, CNNs showed remarkable performance, achieving 77.85% accuracy on the ESC-10 dataset and 49% on ESC-50, compared to 56% by Tensor Deep Stacking Networks (TDSN) [5]. Another study on forest sound classification, which included bird chirps and chainsaw noises,

reported CNN achieving 85% accuracy using spectrogram features [6]. CNN was further validated as the top-performing model for construction noise classification, achieving 97% accuracy with Mel-spectrograms, outperforming other models such as Random Forest (93%), MLP (92%), k-NN (85%), and SVM (84%) [7].

In visual-based tasks, CNN also excelled. For traffic sign and light classification using RGB-D image features, CNNs achieved 93.33% accuracy [8]. In fruit image classification, CNN achieved an impressive 98.88% accuracy on a dataset comprising 55,244 images of 81 fruit categories using a pure CNN architecture with seven layers and global average pooling [9]. For large-scale image classification, CNN architectures such as GoogLeNet and ResNet achieved an accuracy of 83.12% on the ImageNet dataset, consisting of 1.2 million high-resolution images across 1,000 categories [10]. These studies consistently highlight the capability of CNNs in extracting relevant features, improving classification accuracy, and outperforming traditional machine learning approaches. These findings suggest that CNNs hold great potential for application in challenging tasks like the classification of melon ripeness and sweetness using acoustic and visual features.

Previous studies have demonstrated that multimodal fusion, particularly the integration of acoustic and visual features within CNN-based frameworks, can outperform unimodal approaches by leveraging complementary temporal and spatial information. Such strategies have been successfully applied to domains including environmental event detection [11], human activity recognition [12] and [13], and object classification [14], resulting in improved robustness and classification accuracy. Nevertheless, despite the effectiveness of audio–visual fusion in these fields, no existing studies have explored its application to melon ripeness and sweetness classification. This research, therefore, addresses a clear gap in the literature by extending established multimodal CNN paradigms to agricultural quality assessment through the joint exploitation of acoustic and visual cues.

III. Methods

In this study, we used CNN as our deep learning architecture to construct a model for melon ripeness classification. In this section, a brief explanation of all methods used in this research is provided.

A. CNN Architecture

CNN is a deep learning architecture specifically designed for processing data with a grid-like topology, such as images and time-series data. It is characterized by its ability to automatically extract relevant features from raw data through layers of convolution and pooling operations. The convolution layers apply filters to the input data, capturing spatial hierarchies and patterns such as edges, textures, and more complex features in deeper layers. Pooling layers, on the other hand, reduce the spatial dimensions of the data, making the model computationally efficient while preserving the most critical information. CNN typically includes several main components: convolutional layers, activation functions (e.g., ReLU), pooling layers, fully connected layers, and an output layer with a softmax or sigmoid function for classification tasks. Advanced CNN architectures often integrate additional mechanisms, such as dropout for regularization or batch normalization to accelerate training.

Convolutional Neural Networks (CNNs) are a type of feed-forward neural network designed to process visual data. In CNNs, individual neurons are arranged to respond to overlapping regions within a visual area [15]. CNNs are hierarchical networks composed of multiple convolutional layers and subsampling (pooling) layers. The architecture can be varied by adjusting the number and type of convolutional and pooling layers. The convolutional layer operates based on parameters such as the size and number of feature maps, kernel size, skipping factors, and connection tables. A kernel slides across the input image, capturing spatial features, while skipping factors determine how many pixels are skipped during this operation. The output map size is calculated using a specific formula. Each map in a layer connects to several maps in the previous layer, and neurons in the same map may share weights.

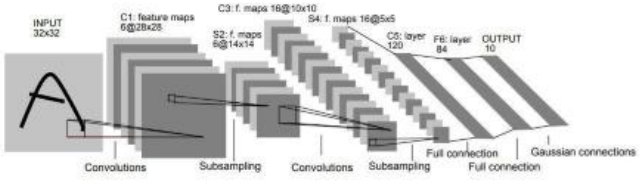

Fig. 1. CNN main architecture [16].

The CNN algorithm consists of two main stages: convolution and subsampling (pooling). For example, in the MNIST dataset architecture (Fig. 1), a grayscale image with dimensions 32x32 pixels is processed through two pairs of convolution and pooling layers, followed by two fully connected layers. Key steps include:

1) First convolution layer: Six 5x5 kernels produce six feature maps of 28x28 pixels using stride 1 and a valid mode (no padding).

2) First pooling layer: Reduces the feature maps to 14x14 pixels with a subsampling factor of 2.

3) Second convolution layer: Sixteen 5x5 kernels create 16 feature maps, every 10x10 pixels.

4) Second pooling layer: Further reduces the feature maps to 5x5 pixels.

5) Fully connected layers: The final pooling layer outputs connect to 120 neurons, followed by 84 neurons, and finally to 10 output neurons representing the classification categories.

6) Activation functions: Non-linear activation functions (e.g., Tanh, Sigmoid, or ReLU) are applied between convolution and pooling layers, as well as between the fully connected layers.

This hierarchical structure allows CNNs to automatically extract and learn relevant features from raw input data, making them highly effective for tasks such as image recognition and classification.

The foundation of Convolutional Neural Networks (CNNs) lies in the architecture of Neural Networks (NNs). However,

CNNs have three main advantages over traditional NNs: sparse connectivity, parameter sharing, and equivariance, which make them more efficient and effective for processing structured data, especially images.

- Sparse Connectivity: unlike traditional NNs, CNNs only connect a neuron to a small region of the input (called a receptive field). This sparse connectivity significantly reduces the number of parameters to train.
- Parameter Sharing: the same set of weights (or filters) is applied across the entire input. This parameter sharing allows CNNs to detect the same feature (e.g., edges, corners) regardless of its position in the input. As a result, the model becomes more efficient in terms of memory and computation, and it can generalize better to unseen data.
- Equivariance: CNNs exhibit equivariance to translation, meaning that a shift in the input (e.g., moving an object in an image) results in a corresponding shift in the feature map output. This property makes CNNs robust to variations in object positions, which is crucial for tasks like image recognition.

These three properties collectively allow CNNs to efficiently handle high-dimensional data like images, reduce overfitting, and achieve better performance in tasks involving spatial or temporal patterns.

B. Spectrogram Image

Although CNN architecture comes in various forms, the most notable and successful is the 2D-CNN architecture. For image data, which is already represented as a two-dimensional matrix, CNN-2D can be applied directly. However, this differs from acoustic data, whose representation is typically in the form of a one-dimensional vector (1-D). A common approach for classifying audio data using CNN-2D is to convert the audio data into a spectrogram. A spectrogram is an image that depicts the magnitude (intensity) of different frequencies over time. This spectrogram image is then used as a Deep Acoustic Feature (DAF) input for the 2D-CNN architecture. The process of creating a spectrogram involves the following steps:

1) Segmenting audio data: The audio data is divided into smaller overlapping chunks. For example, if an audio sample has a size of 1x7, with an overlap of 1 sample and a chunk width of 3 samples, the data is split accordingly.

2) Frequency decomposition using FFT: Assuming that a sound consists of various frequencies, each chunk is transformed using the Fast Fourier Transform (FFT). FFT extracts the frequency components of each chunk of audio at different time intervals, converting the data from the time-amplitude domain to the frequency-time domain.

3) Creating a frequency matrix: For instance, if each chunk is decomposed into 100 frequency components, each chunk will have 100 values. With 3 chunks, the results will result in a matrix of size 100 rows x 3 columns.

4) Mapping matrix to pixels: Each cell in the matrix is represented as a pixel with a specific color. The colors are assigned using a predefined threshold, where higher values are represented with brighter colors.

5) Generating the spectrogram image: The spectrogram is represented as an image, where the color of each pixel reflects the intensity of a frequency at a specific time. A pixel in the spectrogram at row i, column j represents the intensity of sound at the *i-th* frequency and the *s*-time range. Fig. 2 shows an example of a spectrogram from audio data.

6) Input to CNN-2D architecture: Since the spectrogram is a 2D grid of data (image), it can directly be used as input to a 2D-CNN architecture.

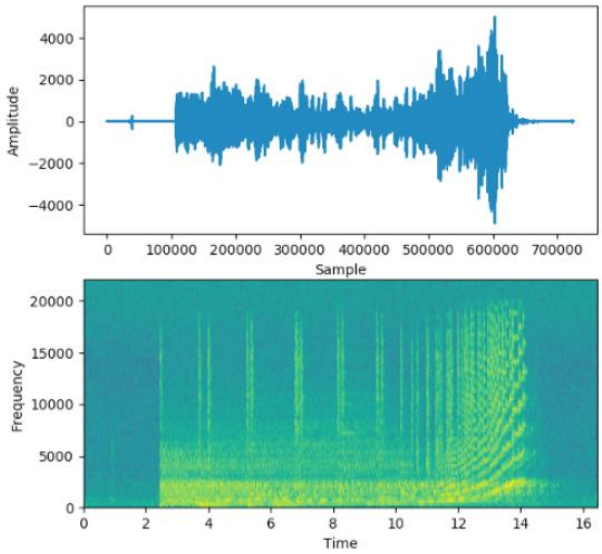

Fig. 2. Spectrogram image [17].

C. Mel Frequency Cepstral Coefficients (MFCC)

In addition to spectrograms, Deep Acoustic Features (DAF) can use Mel Frequency Cepstral Coefficients (MFCC) as input. The detailed MFCC extraction process involves the following steps [18]:

1) Frame blocking (Fig. 3): Audio signals are divided into overlapping frames to prevent information loss at frame transitions.

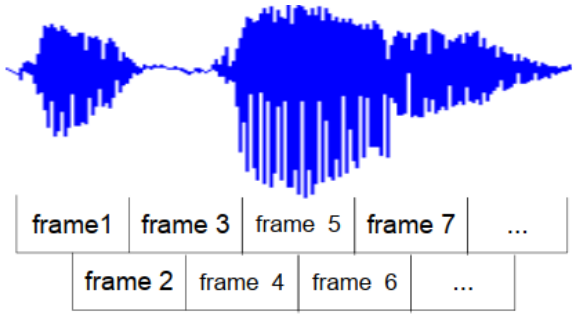

Fig. 3. Frame blocking procedures [18].

2) Windowing: A filter is applied to each frame to minimize distortion between frame blocks. This is done by multiplying each frame's data with a selected windowing

formula, commonly the Hamming window, due to its computational efficiency and effective filtering properties. The Hamming window equation is Eq. (1):

$$W(n) = 0{,}54 - 0{,}46\ cos\left(\frac{2\pi n}{N-1}\right) \quad (1)$$

Variable descriptions

- $W(n)$ the value of the Hamming window at the n-th sample
- n the sample index within a frame, where n=0, 1, 2, …, N−1
- N the total number of samples in one frame (window length)

3) Fast Fourier Transform (FFT) is applied to the windowed frames, calculating the Discrete Fourier Transform (DFT), which outputs complex numbers. The real and imaginary components are calculated as Eq. (2) and Eq. (3):

$$Real\ X[k] = \sum_{i=0}^{N-1} x[i] cos\left(\frac{2\pi k i}{N}\right) \quad (2)$$

$$Imaginary\ X[k] = -\sum_{i=0}^{N-1} x[i] sin\left(\frac{2\pi k i}{N}\right) \quad (3)$$

Variable description

- $Real\ X[k]$ the real part of the DFT output at index k
- $Imaginary\ X[k]$ the imaginary part of the DFT output at index k
- $x[i]$ The input signal sample at time index i (windowed signal)
- i time-domain sample index, where *i=0, 1, 2 ,..., N−1*
- k frequency bin index of the DFT output
- N total number of samples in one frame (FFT size)

The next step in this stage is to compute $X[k]$ the magnitude of the FFT. The magnitude of a complex number is calculated from its real and imaginary components using Eq. (4):

$$X[k] = \sqrt{Real\ X[k]^2 + Imaginary\ X[k]^2} \quad (4)$$

4) Mel-Frequency Wrapping, human perception of sound frequency is linear for frequencies ≤ 1000 Hz, but logarithmic for higher frequencies. This relationship, represented by the mel-frequency scale, is expressed as Eq. (5):

$$F_{mel} = \begin{cases} 2595 * log_{10}(1 + \frac{F_{Hz}}{700}), & F_{Hz} > 1000 \\ F_{Hz}, & F_{Hz} \leq 1000 \end{cases} \quad (5)$$

Mel-frequency wrapping, then performed using Eq. (6):

$$X_i = log_{10}(\sum_{k=0}^{N-1} X(k).H_i(k)) \quad (6)$$

Variable descriptions

- F_{mel}, the frequency value measured on the Mel scale, which represents the perceived frequency by the human auditory system.
- F_{Hz}, frequency value measured in Hertz (Hz), representing the actual or linear frequency of the signal.
- X_i, frequency wrapping value of the i-th filter
- i, filter index, where i=1,2,…,n, and n is the total number of filters
- $X(k)$, magnitude value of the frequency component at index k
- $H_i(k)$, amplitude (height) of the i-th triangular filter at frequency index k
- k, Frequency index, where k=0, 1, 2,…, N−1
- N, total number of frequency magnitude bins

5) Cepstrum Calculation, in this final step, the mel-frequency is converted into the time domain using the Discrete Cosine Transform (DCT), Eq. (7):

$$C_j = \sum_{i=1}^{M} X_i\ cos\left(\frac{j(i-1)}{2}\ \frac{\pi}{M}\right) \quad (7)$$

Variable descriptions

- C_j, j-th cepstral coefficient
- j, Cepstral coefficient index, where j=1,2,…, the desired number of coefficients, for audio classification, we use maximum j=40
- M, number of Mel filter banks. On these study, we used 64 Mel filters
- X_i, The Mel-frequency wrapping value at frequency index i, where i=1,2,…,n. The n, we set it similar to the number of M

In this study, acoustic data were used for Mel-Frequency Cepstral Coefficients (MFCC).

IV. Data

A. New Dataset Acquisition

From 11th May 2021, the procedure for obtaining new sample data has begun at the Agro Technology Park (ATP) Cikarawang. The melon data acquired is from the Golden Alisha melon variety. In general, the morphological shape of the Golden Alisha tends to be round, has a smooth skin texture, and has a bright golden yellow colour. In data acquisition, four different days after planting (DAP), class 47 DAP on 11th May, 53 DAP (17th May), 60 DAP (24th May) and 67 DAP (30th May). There were 12 melons used as samples. From each measured sample, five acoustic data and image data were obtained, respectively. So that when the data acquisition is completed, 60 pieces of data will be obtained for each different DAP and in total, it was hoped that 240 pieces of data would be obtained in all. In the greenhouse as the data location, there are four melon planting lines, each planting position has a different light intensity (Fig. 4). Based on these conditions, in order to be sufficiently representative, the measured melons were spread over four different planting lines. Twelve melons that were used as samples were spread out three each in each planting lane.

Fig. 4. Planting lines at greenhouse, ATP Cikarawang.

The tools used and measurement scenarios in data acquisition procedures are:

- Samsung A20 Smartphone camera, with 30 cm portrait distance, 3:4 dimension ratio, and 2.4x zoom aspect, with an image resolution of 3096x4128 pixels.
- Flux meter to measure light intensity during capturing data.

Some results of data acquisition procedures are shown in Fig. 5.

Fig. 5. Some data acquisition results.

As a result of the acquisition, finally obtained a dataset for ripeness classification are 230 acoustic knock (audio) and image data packets from 4 classes of DAP (47, 53, 60, and 67). Audio data in .m4a format, Image data used smartphone camera with dimensions of 3096x4128 pixels, Image data used Intel RealSense Depth camera with dimensions of 640x480 pixels. The proportion of data in each class is 55 records. The total amount of data is only 230 pieces of data and not 240 pieces of data because the acoustic data of a melon with ID 4 has been picked before 67 DAP and declared lost.

The dataset used in this study is relatively small (230 samples), which raises concerns about potential overfitting, particularly when employing deep CNN architectures. To mitigate this risk, data augmentation techniques were applied, including rotations, scaling, and flips, to artificially increase the diversity of training samples. These measures help ensure that the reported performance reflects the model's true capability rather than overfitting to the limited dataset.

V. Proposed Methods

In the case of classifying melons using two types of data: acoustic data from tapping the melon and image data of the melon, the following procedure is proposed for combining features from both data types. The integration is performed by merging the MFCC spectrogram values with the feature map values derived from the output of the last layer in the feature extraction stage (illustrated in Fig. 6, stage 2, represented by the rightmost purple neurons).

Challenges in Combining Spectrogram and Feature Maps to merge spectrogram and feature map data include:

- Dimensional Mismatch: The dimension of the spectrogram may vary for different acoustic data samples. Additionally, the spectrogram's dimensions may not match the dimensions of the feature maps.
- Value Range Differences: The value range (or domain) of the spectrogram will differ from that of the feature maps.

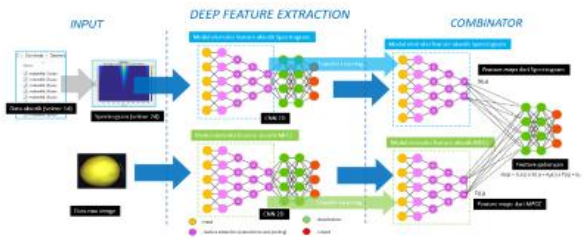

Fig. 6. Proposed method scheme.

Proposed Solutions to address these challenges, processed as these following steps. Combination Procedure - the procedure for combining the features is outlined in the diagram in Fig. 6. The value of the spectrogram, whose different dimensions can be combined by adding them with the trained weights. The vector of the combined feature G from the spectrogram S with weight A1, combined with the feature maps F with weight A2, can then be formulated using Eq. (8). This method is obtained by performing feature concatenation within a flatten layer, which allows the model to integrate information from both sources effectively before passing it to subsequent layers.

$$G(i,j) = A1(i,j)x\,S(i,j) + A2(i,j)xF(i,j) + b0 \qquad (8)$$

The weighted summation step runs after aligning the spectrogram's dimensions and normalizing its value range; it is combined with the feature map values by performing a weighted summation. Furthermore, the values of A1 and A2 are trained using the feed-forward and backpropagation approaches to determine the correct values. As for b0, it is the bias value.

VI. Experiments

A. Experimental Scenario

This section presents various experimental results conducted on this study. The CNN architecture used is illustrated in Fig. 7.

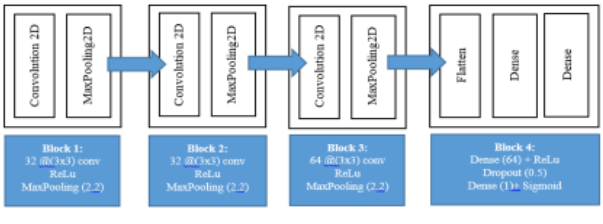

Fig. 7. CNN architecture on experiment.

In this study, there are three main experiment scenarios: (1) image-based only, (2) acoustic-based only using MFCC features, and (3) a combined multimodal CNN architecture. Data augmentation is applied to both image and audio data in

all scenarios. Augmentation of the audio data is applied before the MFCC spectrogram is constructed.

From a preliminary study, especially for acoustic-based classification model was investigated by comparing four experimental scenarios. The first scenario employed a CNN with Mel Spectrogram features and achieved moderate performance, with a precision of 0.62, recall of 0.55, F1-score of 0.55, and accuracy of 0.55. The second scenario utilized a CNN with MFCC Spectrogram features, which resulted in a consistent performance improvement, reaching a precision of 0.72, a recall of 0.65, an F1-score of 0.64, and an accuracy of 0.65. The third scenario incorporated data augmentation into the Mel Spectrogram-based CNN. However, this configuration did not yield a significant performance gain, as the accuracy remained at 0.55. In contrast, the fourth scenario, which combined a CNN with MFCC Spectrogram features and data augmentation, demonstrated a substantial improvement across all evaluation metrics. This approach achieved the highest precision (0.82), recall (0.80), F1-score (0.80), and accuracy (0.80) among all tested configurations. Based on these comparative results, it can be concluded that MFCC-based representations augmented through data augmentation provide a more robust and discriminative characterization of acoustic patterns. Consequently, the CNN with MFCC Spectrogram and data augmentation configuration is identified as the most effective approach and is therefore adopted as the baseline model in this study.

The hardware and software specifications used for this study are as follows:

- Hardware Environment Processor AMD Ryzen 9 5900HX (16 CPUs, 3.3 GHz) with Radeon Graphics. Intel Quad Core i7-4700HQ with a clock speed of 2.4 GHz, 16GB DDR5, and an SSD with 1 TB capacity.
- Software Environment and Supporting Applications: Operating System: Windows 11 Home Single Language 64-bit (Version 10.0, Build 26100). Python 3.7 and the Keras library with TensorFlow backend. Anaconda with Jupyter Notebook environment.

B. Experimental Results

This section presents the results of the classification experiments based on three different input modalities: image-based CNN, acoustic-based CNN, and multimodal CNN combining both image and audio features. The performance of each scenario is evaluated using precision, recall, and F1-score for each ripeness class (DAP47, DAP53, DAP60, and DAP67), as shown in Fig. 8- Fig. 10.

	precision	recall	f1-score	support
DAP47	1.00	0.75	0.86	20
DAP53	0.69	1.00	0.82	20
DAP60	0.89	0.80	0.84	20
DAP67	1.00	0.90	0.95	20
accuracy			0.86	80

TABLE I. EXPERIMENTAL RESULT SUMMARY

Scenario	Prec.	Rec.	F1-score	Acc.
Image-Based CNN	0.89	0.86	0.87	0.86
Acoustic-Based CNN	0.82	0.80	0.80	0.80
Multimodal CNN	0.95	0.94	0.94	0.94

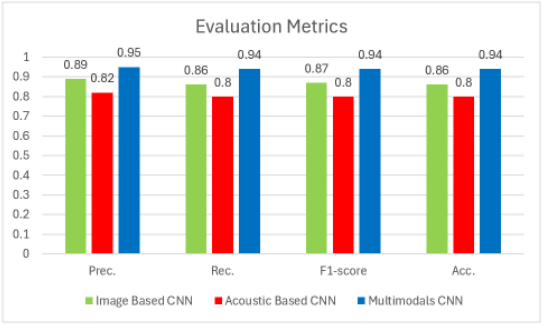

Fig. 11. Evaluation metrics.

For image-based CNN scenarios (Fig. 8), the model achieved an overall accuracy of 86%. The highest performance was observed in the DAP67 and DAP47 classes, with F1-scores of 0.86 and 0.86, respectively. However, the model struggled with class DAP53, which obtained a relatively low F1-score of 0.72. This indicates that visual features alone, while generally effective, may be insufficient for distinguishing between the earlier ripeness stages where external appearance changes are subtler.

On the other hand, the acoustic-based CNN scenario (Fig. 9) yielded a slightly lower overall accuracy of 80%. The best-performing classes were DAP60 and DAP67, with F1-scores of 0.87 and 0.84, respectively. Class DAP53 again presented the most difficulty, with an F1-score of just 0.72. These results suggest that audio features extracted from tapping sounds can represent internal fruit characteristics but may still

be ambiguous for similar ripeness levels, especially between DAP47 and DAP53.

Furthermore, for the last scenario, multimodal CNN (Fig. 10), which integrates both image and audio features, achieved the best overall performance with an accuracy of 94% and a macro-average F1-score of 0.94. All classes showed strong and balanced results, with F1-scores above 0.90, including DAP53, which previously had the lowest performance in other scenarios. The fusion of visual and acoustic information enabled the model to capture both external and internal cues associated with fruit ripeness, resulting in significantly improved classification performance.

In summary (Table I and Fig. 11), the multimodal CNN approach outperforms single-modality models, confirming that combining complementary features from different domains can enhance the accuracy and robustness of ripeness classification systems. This finding supports the potential of multimodal learning in agricultural quality assessment tasks, especially when the classification target involves subtle, multi-dimensional characteristics.

VII. Discussion

In this section, further discussion will be provided regarding the experimental results obtained. It includes confusion matrix analysis for all scenarios. At the end of this chapter, a statistical analysis of the experimental results is also conducted.

The confusion matrices presented in Fig. 11 to Fig. 13 illustrate the classification performance of three different CNN models using image data, acoustic data, and a multimodal fusion of both modalities. These matrices provide deeper insights into how well each model is able to distinguish between the four ripeness stages of melon: DAP47, DAP53, DAP60, and DAP67.

Fig. 12 shows the confusion matrix for the image-based CNN model, which demonstrates relatively strong performance overall. The model perfectly classified the DAP53 and DAP67 classes, while DAP47 was correctly predicted in 15 out of 20 cases, with 5 samples misclassified as DAP53. Class DAP60 showed a minor confusion with DAP53, as 4 samples were misclassified. This suggests that while image-based features are effective in capturing external ripeness characteristics, early ripeness stages such as DAP47 still tend to overlap visually with neighboring classes like DAP53.

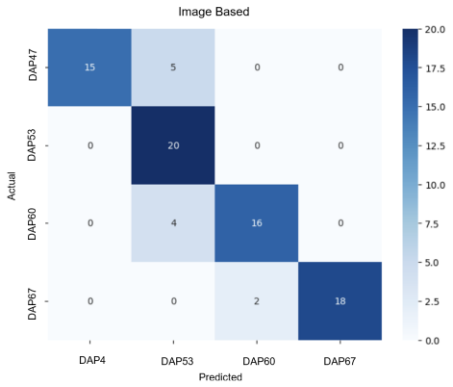

Fig. 12. Image-based CNN confusion matrix.

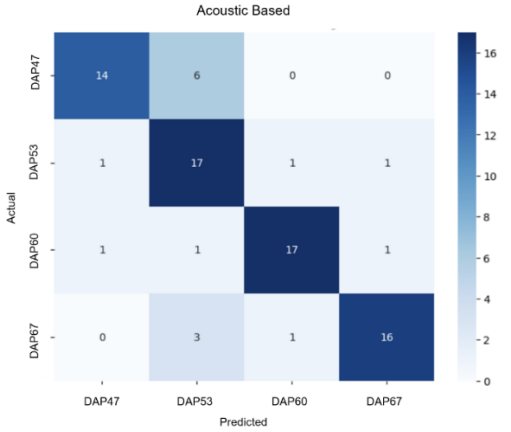

Fig. 13. Acoustic-based CNN confusion matrix.

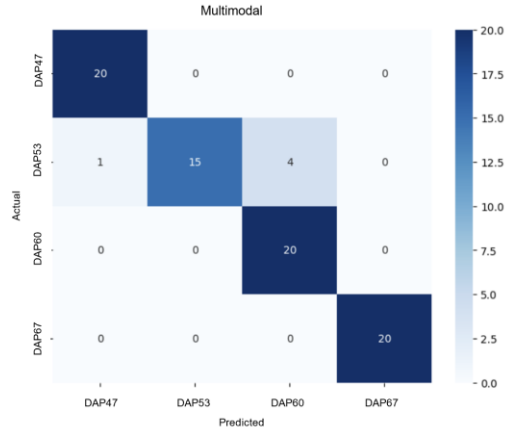

Fig. 14. Multimodal CNN confusion matrix.

In contrast, the acoustic-based CNN model with MFCC features and augmentation (Fig. 13) exhibited slightly lower precision across several classes. Class DAP47 was correctly identified 14 times but misclassified 6 times as DAP53. Similarly, DAP53 had 17 correct predictions, while the remaining 3 samples were confused with DAP47, DAP60, and DAP67. Notably, even DAP67, which was generally easy to classify, showed minor confusion in this setting. These results indicate that while acoustic features enriched with augmentation improve general robustness, they still present challenges in precisely distinguishing between classes with similar internal acoustic signatures, such as DAP47 and DAP53.

The most significant improvement is evident in Fig. 14, representing the multimodal CNN model that combines both image and audio features. This model achieves near-perfect classification: all samples from DAP47, DAP60, and DAP67 were classified correctly, while only one sample from DAP53 was misclassified as DAP47 and four as DAP60. The confusion in DAP53 remains the only notable weakness, which is consistent across models and suggests that this class may lie at a transitional point in both acoustic and visual characteristics. One notable difficulty during data acquisition was that the greenhouse was located near a rural road frequently used by vehicles. Consequently, acoustic recordings were often

contaminated with environmental noise, which likely contributed to the relatively lower performance of the acoustic-based model. This issue also affected the multimodal model, particularly in classifying samples from DAP53, where the presence of background noise and overlapping features made accurate classification more challenging. Despite this, the multimodal model achieved the best overall balance across all classes, demonstrating that fusing external (image) and internal (acoustic) cues significantly enhances the model's ability to discriminate between subtle ripeness stages.

In summary, the results affirm that while single-modality models (image-only or audio-only) are capable of capturing certain class characteristics, their performance is limited by the inherent ambiguities in either visual or auditory features alone. The multimodal CNN approach stands out as the most effective, offering a holistic representation of fruit ripeness and minimizing inter-class confusion. This supports the hypothesis that multimodal learning is highly beneficial for tasks requiring fine-grained classification, particularly in agricultural applications where the features are complex and multi-dimensional.

VIII. Statistical Analysis

This section presents a statistical analysis of the experimental results, with a particular focus on accuracy values. Statistical significance of performance differences among the three classifiers was evaluated using pairwise McNemar's tests on the same test samples. In addition, 95% confidence intervals and variance of accuracy were reported to assess the reliability and stability of the models.

The statistical analysis of the experimental results begins with the computation of the Standard Error (SE) and the Confidence Interval (CI). SE represents the magnitude of the sampling error of the accuracy estimate, indicating the extent to which the observed accuracy obtained from the test sample may deviate from the true performance on the broader data population. A smaller SE indicates a more stable and reliable performance estimate. CI provides a range within which the true model performance is expected to lie at a given confidence level (commonly 95%). The CI enables a more cautious interpretation of performance metrics, particularly for small datasets, as it reflects the lower and upper bounds of the possible performance values [19]. The formulations of SE and CI are presented in Eq. (9) and Eq. (10). In this analysis, the variance is also computed. The variance is used to measure the degree of variability or instability of the model performance across test data or multiple experimental runs, Eq. (11).

$$SE = \sqrt{\frac{p(1-p)}{n}} \tag{9}$$

$$CI = p \pm 1.96 \times SE \tag{10}$$

$$Var(p) = \frac{p(1-p)}{n} \tag{11}$$

Variable descriptions

- SE, Standard Error
- CI, Confidence Interval
- Var, variance
- p, denotes the accuracy value
- n, denotes the number of test samples
- 1.96 is the constant corresponding to the 95% confidence level

TABLE II. Stability Level of Classification

Scenario	Acc.	Var.	SE	CI
Image-Based CNN	0.86	0.00148	0.039	[0.79, 0.94]
Acoustic-Based CNN	0.80	0.00200	0.045	[0.71, 0.89]
Multimodal CNN	0.94	0.00073	0.027	[0.88, 0.99]

Based on the variance, SE, and CI values shown in Table II, the multimodal CNN exhibits the most stable and reliable performance. It achieves the lowest variance (0.00073) and SE (0.027), along with the narrowest CI range, indicating more consistent performance across test samples. Therefore, multimodal CNN can be considered the best-performing and most reliable model among the evaluated approaches. In contrast, the acoustic-based CNN shows the highest variance and SE, suggesting greater performance variability and lower stability. Pairwise, statistical significance between classifiers was assessed using McNemar's test [20] on the same test samples with continuity correction. Pairwise comparisons were conducted between the multimodal model and each unimodal baseline (image-based and acoustic-based) compute using Eq. (12) and data in Table III. In McNemar's test, n_{01} and n_{10} denote the number of discordant pairs where only one classifier produces a correct prediction, and the continuity-corrected chi-square statistic is computed to assess the significance of performance differences. If the Chi-Square χ^2.

$$\chi^2 = \frac{(n_{01}-n_{10})^2}{n_{01}+n_{10}} \tag{12}$$

TABLE III. Samples with False Prediction

Scenario	Samples with false prediction
Image-Based CNN	DAP47_03, DAP47_7, DAP47_12, DAP47_18, DAP47_19 DAP60_03, DAP60_08, DAP60_17, DAP60_19 DAP67_06, DAP67_11
Acoustic-Based CNN	DAP47_02, DAP47_05, DAP47_09, DAP47_14, DAP47_19, DAP47_20 DAP53_02, DAP53_08, DAP53_15 DAP60_01, DAP60_04, DAP60_17 DAP67_03, DAP67_08, DAP67_12, DAP67_17
Multimodal CNN	DAP53_02, DAP53_11, DAP53_15, DAP53_17, DAP53_18

The McNemar test statistic was compared with the chi-square critical value of 3.84 (df = 1, α = 0.05) to assess statistical significance. For the comparison between the Multimodal CNN and the Image-based CNN, $n_{01} = 11$ denotes samples misclassified by the image-based model but correctly classified by the multimodal model, while $n_{10} = 5$ denotes samples correctly classified by the image-based model but misclassified by the multimodal model. The resulting test statistic is χ^2=1.56, which is lower than the critical value

(3.84). In contrast, for the comparison between the Multimodal CNN and the Acoustic-based CNN, $n_{01} = 14$ and $n_{10} = 3$, yielding a test statistic of χ^2=5.88, which exceeds the critical value. These results indicate that the multimodal CNN significantly outperforms the acoustic-based CNN. whereas the improvement over the image-based CNN is not statistically significant. Nevertheless, it achieved an accuracy 8% higher than the image-based model.

IX. Conclusion

This study evaluated three different scenarios for audio-visual classification: image-based only, acoustic-based using MFCC features, and a combined multimodal CNN architecture. In all scenarios, data augmentation was applied to both image and audio data, with audio augmentation performed prior to the construction of the MFCC spectrogram.

The experimental results demonstrate that the multimodal approach, which integrates both image and acoustic features, consistently outperforms the single-modality models. Specifically, the multimodal CNN with data augmentation achieved the highest performance across all evaluation metrics, confirming the effectiveness of combining complementary feature representations. Furthermore, applying data augmentation on both modalities contributed to improved model generalization and robustness, highlighting the importance of augmentation strategies in multimodal learning tasks.

Based on statistical analysis, the multimodal CNN achieved the highest accuracy (0.94), outperforming the image-based CNN (0.86) and acoustic-based CNN (0.80). The 95% confidence interval of the multimodal model ([0.88, 0.99]) is narrower than those of the unimodal models, indicating higher reliability. Furthermore, the variance of the multimodal CNN (0.00073) is lower than that of the image-based (0.00148) and acoustic-based (0.00200) models, demonstrating more stable performance. Pairwise McNemar's tests indicate that the performance improvement of the Multimodal CNN over the acoustic-based CNN is statistically significant ($p < 0.05$), whereas the improvement over the image-based CNN is not statistically significant.

Overall, the findings suggest that leveraging multimodal data with appropriate augmentation techniques is a promising direction for improving classification accuracy in audio-visual applications. Future work may explore more advanced fusion techniques and augmentation methods to further enhance model performance.

Limitations and Future Work: The current study is limited by the small dataset size, controlled greenhouse conditions that do not reflect natural variability, and the lack of external validation. Future research should focus on collecting larger and more diverse datasets under real-world conditions to improve model generalizability and robustness.

Acknowledgment

This study and the research behind it would not have been possible without the exceptional support of my supervisor, Prof. Agus Buono, Dr. Karlisa Priandana, and Prof. Dwi Guntoro. Their enthusiasm, knowledge and exacting attention to detail have been an inspiration and kept my work on track from my first draft to the final revision of this study.

Comparative Analysis of Machine Learning Based Algorithms for Predicting Injury Severity in Road Accidents

Soumaya AMRI[1], Mohammed AL ACHHAB[2], Mohamed LAZAAR[3]
Faculty of Sciences in Tetuan, Abdelmalek Essaadi University, Tetuan, Morocco[1, 2]
ENSIAS, Mohammed V University in Rabat, Rabat, Morocco[3]

***Abstract*—Road crash injury severity prediction is essential for intelligent transportation systems, yet challenged by severe class imbalance, rigid 4-class severity schemes (unhurt/slight/hospitalized/fatal), and optimal methodological selection. This study proposes a structured framework systematically evaluating four machine learning models—CatBoost, HistGradientBoosting, Random Forest, and SVM—across multiclass (native 4-class and ordinal wrapper), binary reduction (non-severe vs. severe), and oversampling techniques using crash data. Multiclass approaches reveal tree ensemble dominance but persistent rare severe class prediction difficulties. Binary class reduction substantially improves severe injury detection performance on this dataset by simplifying decision boundaries, while SMOTE oversampling provides algorithm-specific imbalance mitigation. Random Forest demonstrates the most stable binary performance across evaluation metrics, independent of oversampling strategies. This performance gain comes at the cost of reduced severity granularity compared to the original multiclass formulation. Overall, under imbalance-sensitive evaluation metrics, binary class reduction provides a pragmatic and operationally effective alternative to complex multiclass strategies for severe injury detection.**

Keywords*—Machine learning; imbalanced data; road accident; multiclass classification; binary classification; injury severity prediction

I. Introduction

Injuries, particularly among road users aged 15 to 64, result in significant mortality and long-term disability, ultimately reducing the workforce and weakening the economy. According to the International Road Assessment Program (iRAP), road traffic injuries contribute an estimated $1.85 trillion burden to the global economy each year [1].

In a world of rapidly advancing human mobility and a growing need for transport infrastructure, road safety has become a critical component of government initiatives aimed at reducing road user fatality rates.

The availability of large datasets and advancements in machine learning techniques provide powerful tools for analyzing traffic data and supporting the development of intelligent transportation systems before the implementation of new road safety strategies. However, predicting the severity of injuries resulting from road crashes is a complex challenge. Data collection, often conducted manually by police officers, frequently results in substantial inaccuracies and incomplete records. PIARC, the World Road association noted that a balance between the data collection burden and practical constraints is necessary to ensure police compliance in completing accident reports [2]. Furthermore, the contextual circumstances of each crash blur the line between rare events and standard classification tasks, requiring specialized techniques to manage data imbalance [3]. The factors influencing accident occurrence are highly intricate, further increasing the complexity and rendering it a non-linear classification problem [4]. Combined, these elements make the application of machine learning techniques in road safety research and intelligent transportation systems challenging at every stage of the prediction process.

Despite the substantial body of research on machine learning–based injury severity prediction, an important gap persists. Specifically, the combined influence of data imbalance, preprocessing strategies, and algorithm selection remains insufficiently examined. This limitation is particularly evident in large-scale, real-world crash datasets. While some studies focus on improving model architectures or evaluating different algorithms, others address data imbalance in isolation. However, few investigations examine the interaction between robust data preprocessing techniques and machine learning methods. Such integrated analysis is essential to enhance the accurate prediction of rare yet critical cases, including severe injuries in road accidents. This gap limits our understanding of how to effectively optimize the entire machine learning pipeline for imbalanced classification problems.

To address the challenges associated with road crash injury severity prediction, this study presents a critical review of related research. It also proposes a step-by-step prediction framework based on machine learning techniques and a real-world crash dataset. The objective is to establish a rigorous methodology for identifying a robust predictive model for injury severity.

The study further examines the challenges of training machine learning models on large, imbalanced datasets. It addresses multiclass injury severity prediction and systematically evaluates binary class reduction, nominal multiclass learning, and ordinal wrapper formulations. The goal is to identify the most suitable approach for similar applications.

The structure of the study is as follows: The second section reviews related works on predicting the severity of road crash injuries, with a particular focus on the application of machine

learning techniques in similar contexts. The third section describes the proposed prediction framework, detailing its architecture and key interactions. The fourth section explains the experimental evaluation of the proposed model. The fifth section discusses the performance results obtained from the experiments. Finally, the last section concludes the study, summarizing the main findings and contributions.

II. Related Work

Numerous significant studies have investigated injury severity in road crashes, outlining various methods to predict injury severity levels. These prediction methodologies include classical statistical models [5], Poisson regression [6], logistic regression analysis [7] and discriminant analysis [8]. They also encompass advanced artificial intelligence approaches, including neural networks [9], decision trees [10], random forest models [11], and ensemble learning techniques [3].

The selection of appropriate machine learning techniques during the prediction process is influenced by data characteristics (data size and quality), as well as the specific objectives of each case study.

To provide a systematic evaluation of prior work, Table I synthesizes the methodological and empirical characteristics of related injury severity prediction studies.

TABLE I. Synthesis of Research Papers on Crash Severity Modeling and Predictive Performance

Study	Dataset Size	Classes	Ratio of severe classes	Main ML Model	Best Global Model Results	Severe Injury Results
[3]	308641	4	0.8% (Severe injury and fatal)	Gradient Boosting	Accuracy= 0.82	F1 score = 0.21, Precision = 0.31, Recall = 0.16
[10]	2238	3 (Slight, Serious, Fatal)	41,91% (Serious Injuries =39.83% Fatalities= 2.08%)	Ordered Forest	Gmean = 0.47	Precision =0,50
[12]	770561	3 levels initially later integrated into 2 classes	14.5% (13.3% serious and 1.2% fatal injuries)	SSAE	Precision=0.80, Recall=0.85, F1=0.84	Precision=0.42, Recall=0.21, F1=0.28
[13]	54364	3 (Slight, Severe, Fatal)	2.49% (2.34% severe and 0.15% fatal)	2D-CNN	F1= 0.95	F1-score = 0.004 (Fatal)
[15]	5740	4 levels (Slight, Medium, Severe, Fatal)	9.69% (6.74% severe and 2.94% fatal)	Bayesian Network	Accuracy= 0.66	Not evaluated
[16]	900690	Binary	Not described	Random Forest , LightGBM	ROC-AUC scores = 0.93	Precision = 0.65
[17]	1620	3 (Fatal, Injury, No-injury)	4,75%	CART	Accuracy =0.67	Precision = 0.45 (Fatal)
[18]	8516	4 (Fatal, Hospitalized, Injured, and Damage-only)	65% (22.9% Fatal and 42.1% Hospitalized)	Random Forest	Accuracy = 0.73	Precision = 0.85 Recall = 0.44
[19]	3834	4 (Minor, Moderate, Severe, Fatal)	13% (7.6% Severe Injuries, 5.4%Fatal Injuries)	Adaboost, Random Forest	Accuracy = 0.87	Precision =0.27 Recall =0.48

A comparative analysis of model performance in cited studies [3],[10], [12], [13], [15]-[19] reveals substantial heterogeneity in dataset size, modeling strategies, and evaluation metrics, with no standardized methodological framework emerging. Moreover, severe injury prediction remains insufficiently examined, as reported performance often emphasizes global accuracy while overlooking minority-class detection.

The implementation of a generic method is complex, as it requires careful examination of several parameters to determine the most appropriate machine learning methodology.

The first criterion relates to the dataset size and the number of features; both the algorithm's performance and the available computational resources should be assessed based on these data characteristics. Additionally, techniques such as scaling and distributed computing can be considered to facilitate training on large datasets.

Another critical criterion involves the distribution of injury severity levels, as a significant challenge in road crash analysis is the presence of highly imbalanced data. In most case studies, severe injuries are less frequent than minor injuries, compelling researchers to adopt supplementary techniques to address imbalanced data challenges and improve road crash injury analysis.

In the crash-injury severity literature, three modeling strategies are commonly used: binary reduction, nominal multiclass learning, and ordinal multiclass modeling. Binary reduction is often applied to mitigate severe class imbalance and stabilize model training [20], [21]. However, it reduces the granularity required for prioritizing safety interventions. Recent studies emphasize preserving richer severity levels whenever possible [22].

Nominal multiclass methods, particularly tree ensembles and gradient boosting models such as XGBoost, LightGBM, and CatBoost, often achieve strong overall performance. When combined with resampling techniques like SMOTE-NC or class weighting, their results improve [23]. However, these models may confuse adjacent severity levels because they do not consider label order.

To address this limitation, ordinal approaches explicitly encode the inherent rank structure from minor to fatal injuries. These methods include cumulative-threshold decomposition and parametric ordinal regression models. They reduce distant misclassifications and enhance policy and clinical

interpretability. Empirical studies report improved performance over nominal classifiers, especially when combined with imbalance handling and modern learners [24]. Recent advances in dynamic ensemble selection and interpretable ensemble methods further improve robustness in imbalanced multiclass settings. Overall, evidence supports retaining multiclass severity and adopting ordinal-aware learning with appropriate rebalancing to preserve information and respect outcome ordering [23].

The following provides a comparative analysis of the machine learning models employed in research related to predicting the severity of road crash injuries. It outlines their advantages and limitations.

Neural network models present numerous advantages, particularly their ability to capture complex nonlinear relationships between independent and dependent variables and their effectiveness in scaling to large datasets. This capability makes them particularly suitable for extensive road crash databases. However, a significant drawback is the potential for overfitting, which can compromise prediction accuracy. A study on traffic accident severity in Madrid employed a framework based on one- and two-dimensional convolutional neural networks [13]. The findings highlighted the framework's scalability and its rapid prediction capabilities, making it suitable for real-time applications. Nonetheless, the precision scores for fatal and serious injuries were notably low, primarily due to the influence of imbalanced data, which adversely affected the prediction outcomes for these injury categories.

The Bayesian network, evaluated on a medium-sized dataset of 5740 instances and four injury classes, achieved the highest overall accuracy on both the training and testing sets. Its performance was superior to that of the Exhaustive Chi-Square Automatic Interaction Detector tree and the Linear Support Vector Machine models [15].

Wahab explores various machine-learning algorithms to predict motorcycle crash severity in Ghana, utilizing a medium-sized dataset consisting of 8,000 instances with 14 features. The Random Forest model exhibited greater accuracy than the other machine learning models tested. However, its individual accuracy for each injury severity class, especially for fatal injuries, was notably low [18]. A comparative analysis of Decision Trees, RF, and Naïve Bayes, performed on a reduced dataset using combined feature selection techniques (including two-way ANOVA, regression analysis, and chi-square), demonstrated that RF achieved the best performance [14]. Zhang recommends employing the Ordered Forest algorithm for analyzing injury severity in single bicycle crashes, as it showed better predictive performance compared to the traditional Random Forest model [10].

AdaBoost and Gradient Boosting models offer notable advantages for crash severity prediction. These advantages stem primarily from their capacity for global sensitivity analysis, which enables the assessment of both individual and combined effects of influencing factors [3]. Jiang applied these two boosting algorithms to predict crash injury severity and reported overall accuracy superior to that of other models. However, the prediction performance for minority classes, particularly fatal and severe injuries, remained low. Jiang recommends using the F1-score and monetized evaluation metrics to better assess model performance in imbalanced data settings.

Conducted on a large road crash dataset from France, the LightGBM model achieved the highest F1-score and accuracy for predicting non-severe injuries, which represent the majority class. In contrast, the Random Forest model obtained the highest precision for predicting severe injuries, the minority class [16].

Abdulazeez evaluated several machine-learning algorithms to predict child occupant crash injury severity in Abu Dhabi. Adaboost, Bagging REP, ZeroR, and XGBoost achieved the best overall accuracy both before and after data balancing, even without feature selection. However, the prediction results for the severe injury class, categorized as the minority class, remained low, except for XGBoost and CatBoost, which yielded better performance after data balancing and class consolidation [19].

Thus, the results vary significantly depending on the research methodology and the specific characteristics of the datasets used. Random Forest, Adaboost, and Gradient Boosting models demonstrated the highest overall accuracy on small to medium-sized datasets. However, the highest prediction accuracy for the severe injury class, identified as the minority class, was achieved using RF, stacking, and Support Vector Machine models, respectively, though the accuracy values remain relatively low. While reducing the number of classes can improve accuracy metrics, addressing data imbalance may lead to overfitting in certain algorithms. The performance of these models should be further evaluated on large datasets to assess their robustness in real-time operations.

III. METHODOLOGY

This study addresses gaps and limitations in the literature on severe injury prediction. These include data collection inconsistencies, low performance for the severe injury minority class, and challenges in selecting appropriate machine learning models.

To overcome these issues, a step-by-step methodology is proposed, as illustrated in Fig. 1.

The first step involves data preparation issues, from data collection and integration to data cleaning.

The second step addresses data engineering tasks, including feature transformations and data exploration, through four key dimensions: temporal and atmospheric conditions, road characteristics, vehicle characteristics, and user profiles.

The third step comprises a structured data processing phase in which the machine learning methodology is selected via a comparative analysis of four experiments. These experiments target two core challenges in multiclass injury severity prediction: selecting effective techniques to handle class imbalance and assessing how class grouping strategies influence predictive performance on minority classes.

Experiments N1–N2 retain the original four-class injury severity scale. Experiment N1 evaluates candidate models on the unmodified four-class dataset (nominal multiclass), while experiment N2 introduces an ordinal classification framework that explicitly encodes the ordered nature of the four severity levels.

Experiments N3–N4 adopt a binary formulation (severe vs non-severe). Experiment N3 trains the same models on the original imbalanced data to quantify the impact of multiclass reduction without correcting the imbalance. Experiment N4 applies SMOTE within each training fold of the cross-validation procedure. The data are balanced using oversampling performed only on the training subsets. The validation folds remain untouched, thereby preventing data leakage. Multiple classifiers are then evaluated on the resampled training data. Comparing these settings reveals the relative benefits of multiclass reduction and data balancing for severe injury detection and highlights which algorithms benefit most from SMOTE-like resampling.

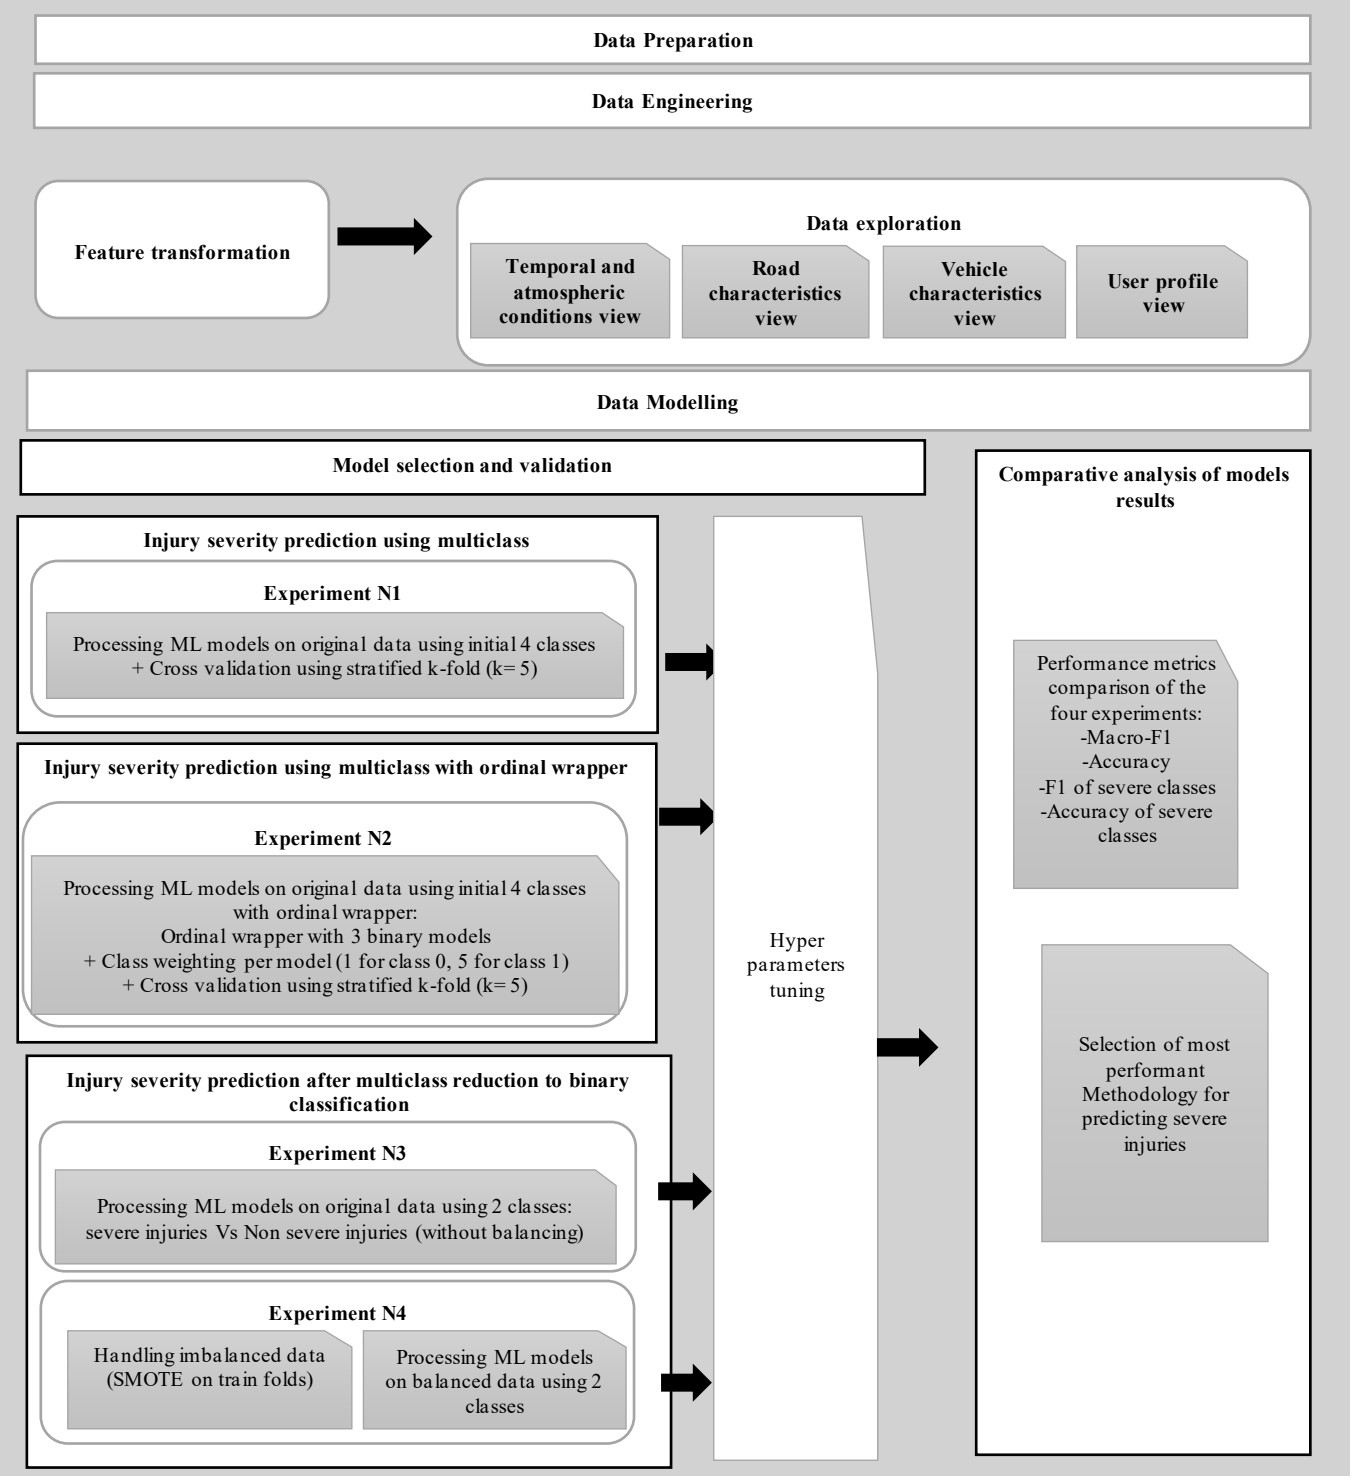

Fig. 1. Framework of the proposed prediction methodology.

Jointly analyzing results across all four experiments enables the identification of the most effective combination of model, imbalance-handling strategy, and class representation scheme for accurately predicting severe injuries in highly imbalanced road safety data.

IV. EXPERIMENTATION

A. Data Description

This research is conducted on real data sourced from the annual databases of road traffic accidents maintained by the French National Interdepartmental Observatory of Road Safety.

The annual databases extracted from the Bodily Accident Analysis Report [25] encompass all bodily traffic accidents occurring in metropolitan France, as well as in overseas departments and other overseas territories. This study conducted experiments using datasets from the years 2005 to 2020. The recorded data on road traffic accidents contains multiple layers of information, including features related to crash characteristics, location, involved vehicles, and road users.

To create the input dataset for this study, tables were joined based on the foreign keys specified in each data file, resulting in a comprehensive global dataset. Following the integration of 64 data files, corresponding to four files for each year, the final dataset comprised a total of 2,380,573 entries and 57 features, which served as the input data for this research.

B. Data Cleaning

In classification tasks, data cleaning focuses on enhancing classification performance by improving the quality of the training data. Common data cleaning techniques include outlier removal [26], missing value imputation [27], normalization and standardization [28], error detection and correction, handling duplicate values, noise reduction [29] and categorical data handling [30].

In this study, the initial step involved merging the collected datasets before applying data cleaning techniques. Error detection and correction were performed by casting column types (date, numeric, string, etc.) and correcting incorrect value formats for numerical columns as well as erroneous entries in categorical columns. Missing value imputation techniques were employed to address null values. A percentage count of missing values for each feature was generated and classified to identify unusable columns or records.

To avoid imputation of non-representative data for certain features, fixed intervals were established for handling missing data, as outlined in Fig. 2, which describes the data cleaning process and corresponding actions. Columns with over 89.9% missing values were removed, except in cases where these columns contained information specific to certain types of road users, such as pedestrians. In such cases, null values are not indicative of missing data but rather signify that this information is irrelevant to other types of road users. For instance, null values in the columns “locp” (pedestrian location) and “etatp” (pedestrian status, e.g. alone, accompanied) are not considered missing data for records of crashes involving only vehicles and no pedestrians.

Records with less than 5% missing data in any column were deleted. For columns with between 5% and 89.9% missing values, various imputation methods were applied: mean imputation was used for numerical data, mode imputation for categorical data, and, in some cases, imputation by deduction based on a data dictionary. This latter method was applied to categorical features where undefined values could be reasonably inferred based on similar meanings within the data.

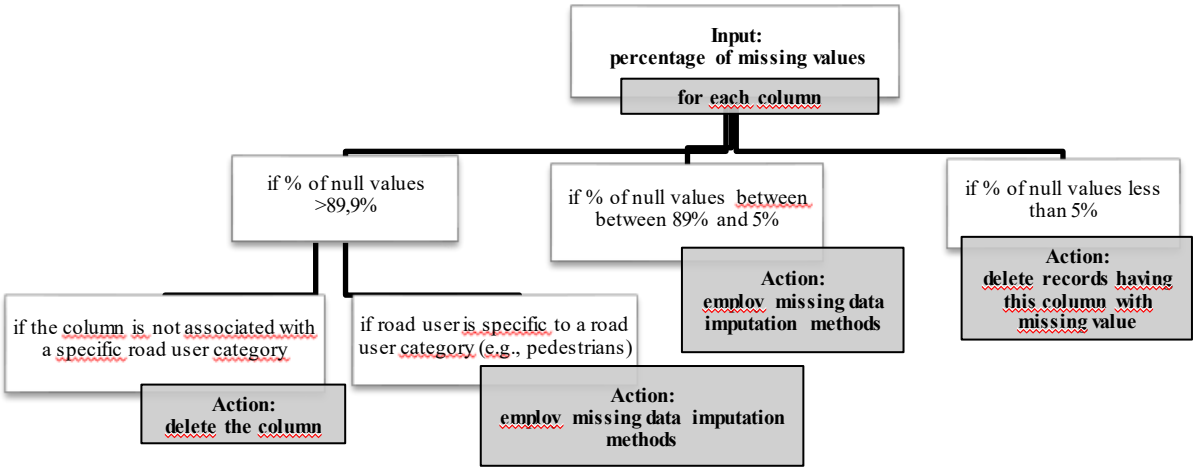

Fig. 2. Data cleaning process and actions.

C. Data Engineering

1) Feature transformation: To prepare the data for exploratory analysis, feature transformations were conducted, including the formatting of existing features and the generation of new ones. Eight additional features were derived from the columns "date," "time," and "user date of birth" to explicitly represent embedded information: "time slice", "year", "month", "day", "day of week", "is holiday", "age", and "age slice". The final task involved encoding the newly created categorical features to complete the data preparation and transformation process.

2) Exploratory data analysis: To analyze crash severity, an exploration of the distribution of accidents based on the injury severity level feature is conducted. This feature is categorized

into four classes: unhurt, slightly injured, hospitalized injuries, and fatalities. Fig. 3 illustrates the distribution of injury severity levels. It demonstrates that fewer than 2% of road users fall into the killed category and 20% into hospitalized due to injury. These two categories are identified as minority classes within the dataset.

Fig. 3. Distribution of crashes by injury severity level.

3) Data modelling: The injury severity feature, originally comprising four levels (1=Unhurt, 2=Fatal, 3=Hospitalized, 4=Slight injury), was systematically remapped in Experiment N2. An ordinal scale was adopted to preserve the hierarchical relationships: 0 = Unhurt < 1 = Slight injury < 2 = Hospitalized < 3 = Fatal. In experiments N3 and N4, the four levels of injury severity are reduced to two classes: severe (fatal and hospitalized) and non-severe (unhurt and slight injury).

The methodological framework structures four complementary experiments with differentiated modeling strategies:

- Experiment N1: Multiclass prediction (4 ordinal classes) on original data.
- Experiment N2: Ordinal wrapper (3 binary classifiers) on original 4-class data with class weighting.
- Experiment N3: Binary classification on original imbalanced data.
- Experiment N4: Binary classification on SMOTE-balanced data (Non Severe vs Severe Injury).

This progression systematically evaluates binary vs multiclass formulations alongside data-level and algorithmic imbalance mitigation strategies.

4) Handling imbalanced data: Several machine learning studies address the issue of imbalanced data and attempt to mitigate its impact on the performance of models. Undersampling and oversampling methods, which aim to create equal amounts of data points for each class, are commonly employed to manage this imbalance. Subsequently, various developed models have been proposed. Galar categorizes techniques for handling imbalanced data into four types: algorithmic-level, data-level, cost-sensitive, and ensembles of classifiers [31].

In this study, class imbalance (Class "unhurt": 41%, Class "fatal": 2.7%) was addressed through complementary strategies across experiments, following Galar's established taxonomy:

- Experiments N1-N2: Algorithmic-level mitigation via stratified k-fold cross-validation (k=5) preserves original distribution while optimizing for rare classes.
- Experiment N2: Cost-sensitive ordinal wrapper implements class_weights= [1.0, 5.0] per binary classifier P(Y>k), assigning fivefold misclassification penalty to severe cases (>k threshold).
- Experiment N3: data-level evaluation using binary classification on original imbalanced data to establish the performance of multiclass reduction.
- Experiment N4: SMOTE oversampling applied to training folds generates synthetic minority class instances via k-nearest neighbor interpolation, proven effective for traffic crash severity prediction [32], [33]. It generates new synthetic instances of the minority class by interpolating values between the two nearest data points along a straight line [34].

This multi-strategy framework systematically compares data-level oversampling (SMOTE), cost-sensitive ordinal learning, and binary class reduction strategies for severe injury prediction.

5) ML modelling:

a) Model selection: In this work, the dataset is both large and highly imbalanced. In similar case studies, boosting algorithms, such as Gradient Boosting and the Random Forest algorithm, have demonstrated superior performance compared to other models. Therefore, four machine-learning algorithms are evaluated to analyze the severity level of injuries caused by road crashes: CatBoost, HistGradientBoosting Classifier, Random Forest, and Linear Support Vector Machine (SVM). The SVM model was selected for its well-documented effectiveness in classification tasks.

b) Hyperparameter tuning: Model hyperparameters were systematically optimized using stratified k-fold cross-validation (k=5, reduced to k=3 for 2000 iterations) with early stopping, following the methodological framework. Iteration counts were evaluated across {500, 800, 1000, 2000}, with Macro F1 serving as the primary optimization criterion across all experiments (N1-N4) and models. Optimal iterations were selected independently for each model-experiment combination, ensuring configuration-specific performance maximization while preventing overfitting. Cross-validation improvement curves demonstrating macro-F1 gains versus iteration count, along with final selected hyperparameters per model, are detailed in section V.

6) Evaluation metrics: To evaluate the performance of machine learning models, various metrics are employed by researchers. Accuracy, along with precision, recall, and F1-score, is among the most commonly used evaluation metrics.

In injury severity prediction studies, all of the metrics mentioned previously are employed. However, relying solely on the overall average prediction accuracy for highly imbalanced data can lead to biased interpretations of the results. Jiang suggests using additional metrics, such as the F1 score for each class and the monetized measurement (MM), which represents the weighted average of the F1 scores for each class [35].

In this study, Macro-F1 constitutes the primary evaluation metric across all four experiments, computing the unweighted average of per-class F1-scores to ensure equitable minority class contribution despite severe imbalance. This metric robustly penalizes poor severe injury detection masked by majority class dominance, representing the established standard for multiclass imbalanced traffic safety prediction [36].

A comprehensive set of evaluation metrics was applied consistently across all experiments. For each configuration (Experiments N1–N4), model performance was primarily assessed using macro-F1. This was complemented by per-class precision, recall, and F1-scores, as well as weighted F1 and overall accuracy. These metrics were used to capture both global and class-specific behavior under class imbalance.

For Experiment N2, which models the ordinal nature of injury severity, quadratic weighted kappa was additionally employed. It was implemented using the cohen_kappa_score function with quadratic weights. This metric quantifies agreement beyond chance and penalizes distant misclassifications more strongly than adjacent ones. Such a property is particularly appropriate for hierarchical severity scales.

This unified evaluation framework enables comparison across Experiments N1–N4. It supports the selection of the most appropriate methodology for severe injury prediction by jointly considering overall predictive performance and the accurate identification of clinically critical yet rare cases.

V. Results and Discussion

This study primarily aims to examine the challenges in predicting road crash injury severity, particularly for minority classes, and to identify the most effective machine learning approach for accurate prediction. To this end, hyperparameter tuning results are first analyzed for selected models across each experiment to determine optimal parameters. Model performance is then evaluated individually within the four experiments, followed by a comprehensive comparison that highlights strengths, weaknesses, and the superior methodology for injury severity prediction.

A. Hyperparameter Tuning Results

To ensure optimal model configuration across all four experiments and algorithms, hyperparameters were tuned using stratified cross-validation and early stopping, following the methodological framework outlined in Fig. 1.

1) CatBoost hyperparameter evaluation: For the CatBoost model in experiment N1 (initial 4-class configuration), hyperparameter tuning focused on varying the number of iterations (500-2000) while fixing learning_rate=0.05 and depth=6.

Fig. 4 presents the macro F1-score evolution across iteration counts. Optimal performance was achieved with iterations=2000, learning_rate=0.05, depth=6 (F1_macro = 0,648), representing the best configuration identified through systematic grid evaluation.

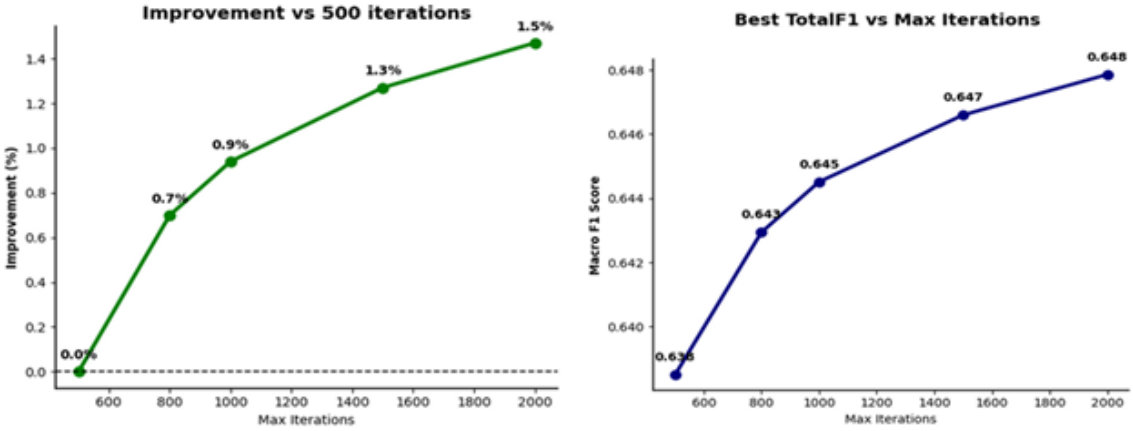

Fig. 4. Macro F1 evolution of experiment N1 across iterations.

For subsequent experiments, the same hyperparameter tuning procedure was applied to identify the optimal configuration.

2) Histgradient boosting classifier hyperparameter evaluation: For the HistGradientBoostingClassifier, hyperparameter tuning was conducted using RandomizedSearchCV with 12 iterations and 5-fold cross-validation, systematically exploring combinations of learning_rate (0.05-0.20), max_iter (100-300), max_leaf_nodes (15-31), min_samples_leaf (10-20), and max_depth (3-5 or None).

Fig. 5 presents the macro F1-score performance across hyperparameter ranges applied in experiment N1 using the initial four classes of injury severity. Optimal performance was achieved with min_samples_leaf=20, max_leaf_nodes=31, max_iter=100, max_depth=5, learning_rate=0.2 (F1_macro = 0.484, std=0.013), representing the best configuration identified through randomized search.

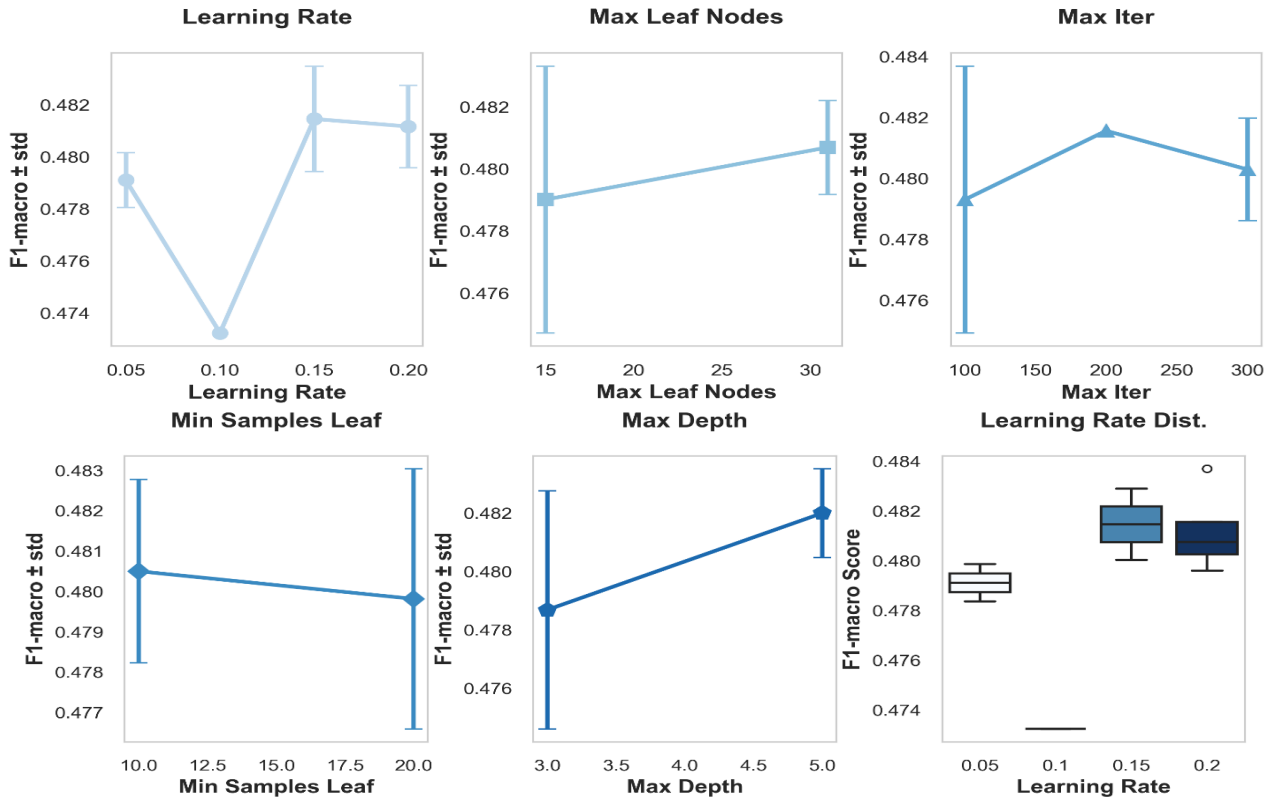

Fig. 5. Performance of hyperparameter tuning of the histgradient boosting classifier on Macro F1-score.

3) Random forest hyperparameter evaluation: A systematic grid search using cross_val_score (3-fold CV, F1_macro scoring) exhaustively evaluated eight configurations of RandomForestClassifier, focusing on n_estimators ∈ {100, 200} and max_depth ∈ {8, 12}, with fixed min_samples_split=5, min_samples_leaf=5, max_features=0.3 and using a balanced class_weight. The optimal configuration (n_estimators=100, max_depth=12) achieved the highest mean CV score, as confirmed by the hyperparameter validation curve presented in Fig. 6.

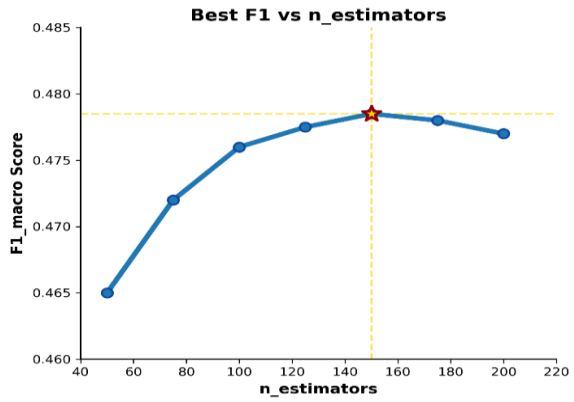

Fig. 6. Impact of RF hyper-parameter tuning of Macro-F1.

4) SVM hyperparameter evaluation: Hyperparameter tuning of the SVM classifier was conducted using RandomizedSearchCV with 10 iterations and 3-fold cross-validation, optimizing for the F1-macro score across four classes on a balanced dataset (class_weight='balanced'). The search explored a constrained parameter space comprising C values [0.1, 1, 10, 50, 100], RBF kernel with gamma values ['scale', 0.01, 0.1, 1.0], and fixed degree=3, completing 30 fits efficiently in a single-threaded configuration (n_jobs=1).

The optimal configuration (C=100, kernel='rbf', gamma=0.01, degree=3) achieved a cross-validated F1-macro score of 0.172 as presented in Fig. 7. This result indicates substantial challenges in multiclass classification, likely due to class imbalance and limited feature separability in the RBF-induced feature space.

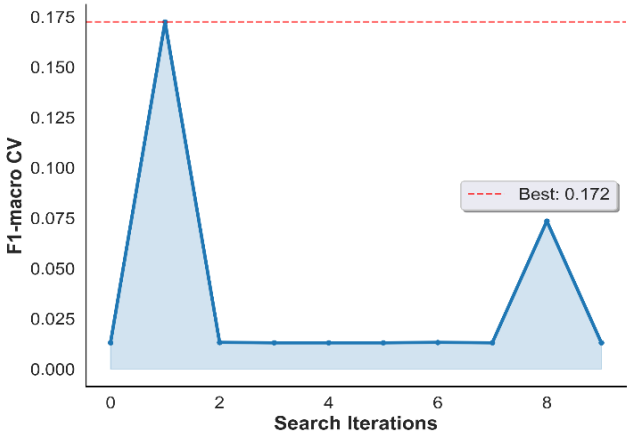

Fig. 7. SVM Hyperparameter tuning convergence.

B. Models Performance Analysis

1) Multiclass classification: The first two experiments within this methodological framework evaluate model performance using the initial four-class injury severity scheme. The second experiment incorporates an ordinal wrapper approach; together, these experiments compare model performance between native class weighting and ordinal wrapper configurations.

Table II presents performance metrics for CatBoost, HistGradientBoosting, Random Forest, and SVM models. The primary evaluation metrics, in order of priority, are macro F1-score, accuracy, and precision for severe classes (Hospitalized and Fatal).

TABLE II. MULTICLASS CLASSIFICATION PERFORMANCE OF EXPERIMENT N1 (ORIGINAL 4-CLASS) VS. EXPERIMENT N2 (ORDINAL WRAPPER)

Model		Injury severity level	Experiment N1: Original multiclass			Experiment N2: Ordinal wrapper multiclass		
	Metric		*Precision*	*Recall*	*F1-score*	*Precision*	*Recall*	*F1-score*
Catboost		Unhurt	0.65	0.90	0.75	0.81	0.59	0.68

2) Binary classification: Experiments N3 and N4 implement class reduction strategies to assess their impact on prediction performance. Experiment N3 collapses the four-class severity scheme into a binary classification framework (non-severe vs. severe). Experiment N4 introduces SMOTE oversampling as an additional balancing technique to evaluate its incremental benefit across the four models examined (CatBoost, HistGradientBoostingClassifier, Random Forest, and SVM).

Binary classification, as presented in Table III, reveals SMOTE's differential efficacy across algorithms: HistGradientBoosting shows a +13% improvement in accuracy (0.70 → 0.79) while the SVM achieves a substantial +169% increase in the severe-class F1-score (0.16→0.43). These results highlight the necessity of resampling for imbalance-sensitive architectures. In contrast, Random Forest and CatBoost demonstrate intrinsic robustness, maintaining consistently high performance (accuracy=0.83, ΔF1-severe < +2%).

Random Forest emerges as the overall top performer in binary classification (accuracy=0.83, F1-severe=0.50), exhibiting superior generalization across severity levels.

TABLE III. BINARY CLASSIFICATION PERFORMANCE OF EXPERIMENT N3 (CLASS REDUCTION) VS. EXPERIMENT N4 (WITH SMOTE OVERSAMPLING)

Model		Injury severity level	Experiment N3: Reduced to binary class			Experiment N4: Reduced to binary class + SMOTE balancing		
	Metric		*Precision*	*Recall*	*F1-score*	*Precision*	*Recall*	*F1-score*
Catboost		Non severe	0.85	0.95	0.90	0.86	0.94	0.90
		Severe	0.66	0.36	0.47	0.63	0.39	0.48
	Accuracy				0.83			0.83
	Macro avg		0.75	0.66	0.68	0.74	0.67	0.69
	Weighted avg		0.81	0.83	0.81	0.81	0.83	0.81
Hist-gradient Boosting classifier		Non severe	0.94	0.66	0.78	0.88	0.86	0.87
		Severe	0.39	0.84	0.54	0.50	0.55	0.53
	Accuracy				0.70			0.79
	Macro avg		0.67	0.75	0.66	0.69	0.71	0.70
	Weighted avg		0.83	0.70	0.73	0.80	0.79	0.80
Random Forest		Non severe	0.86	0.94	0.90	0.86	0.92	0.89
		Severe	0.63	0.41	0.50	0.60	0.44	0.51
	Accuracy				0.83			0.82

	Weighted avg		0.7	0.79	0.73	0.77	0.61	0.65

C. Overall Performance Comparison

The proposed methodology systematically evaluates four machine learning models—CatBoost, HistGradientBoosting, Random Forest, and SVM—across multiclass injury severity prediction using an initial four-class scheme (Unhurt, Slight, Hospitalized, Fatal).

Experiment N1 applies native multiclass classification using stratified k-fold cross-validation. The results indicate moderate overall performance, primarily driven by tree-based ensemble methods. CatBoost achieves the highest accuracy (0.63) and macro-F1 score (0.46). However, all models show significant weaknesses in predicting rare severe classes, particularly the fatal category, with F1-scores below 0.25.

Experiment N2 introduces an ordinal wrapper with class weighting to account for injury severity's inherent ordering, yielding mixed outcomes. While recall for Hospitalized cases improves notably (e.g., CatBoost: 0.44 to 0.75), overall accuracy and Macro F1 decline slightly (CatBoost: 0.63 to 0.53; 0.46 to 0.45). The lower overall performance of the ordinal formulation may be partly influenced by class imbalance rather than reflecting an inherent limitation of the ordinal modeling framework. These results underscore the wrapper's limited efficacy in highly imbalanced multiclass settings and highlight the trade-offs of enforcing ordinal constraints without fully resolving class distribution skew.

Binary class reduction in experiment N3, collapsing the four classes into non-severe versus severe, markedly enhances predictive performance across all models, demonstrating the methodology's sensitivity to classification complexity. Accuracies increase to 0.79–0.83 for tree-based ensembles, compared to 0.38–0.63 in the multiclass setting. Severe-class F1-scores improve substantially (e.g., Random Forest reaches 0.50 from previous multiclass lows). This improvement results from a simplified decision boundary that reduces overfitting to the dominant unhurt and slight injury classes and increases focus on clinically relevant severe outcomes.

This shift validates the strategic class aggregation within the framework. The approach reduces modeling complexity while preserving prognostic utility. However, it sacrifices granular severity distinctions that are essential for detailed risk stratification.

Experiment N4 further addresses residual imbalance via SMOTE oversampling on training folds, producing algorithm-specific gains that affirm its value for imbalance-sensitive models. HistGradientBoosting accuracy rises 13% (0.70 to 0.79) with stable severe F1 (0.54 to 0.53), while SVM exhibits the most dramatic uplift in severe F1 (0.16 to 0.43, +169%), reflecting SMOTE's ability to augment synthetic severe minorities for linear classifiers. Conversely, intrinsically robust tree-based models such as Random Forest and CatBoost exhibit negligible performance variations (accuracies ~0.83 to 0.82;

severe F1 +2% max). These results indicate baseline resilience to class imbalance.

Within the framework's comparative validation, the binary Random Forest configuration emerges as the most suitable methodology for severe injury prediction.

Table IV quantifies performance uplifts across experiments for each model, using accuracy and severe F1-score (Hospitalized+Fatal multiclass; Severe binary) as key metrics.

In summary, the Random Forest model in the binary configuration (Experiment N3) emerges as the superior approach. It achieves the highest accuracy (0.83), a macro-F1 score of 0.70, a severe-class F1-score of 0.50, and a non-severe F1-score of 0.90. The model demonstrates exceptional stability across configurations, as shown by minimal performance degradation after SMOTE (-1.2% accuracy). It also records the largest improvement from multiclass to binary settings (+53.7% accuracy, +61.1% severe F1-score).

TABLE IV. PERFORMANCE IMPROVEMENT PERCENTAGES ACROSS EXPERIMENTAL CONFIGURATIONS

Model	Metric	Multiclass Exp. 1 → Binary Exp. 3 (%)	Binary Exp. 3 → SMOTE Exp. 4 (%)
CatBoost	Accuracy	+31.7% (0.63 → 0.83)	0.0% (0.83 → 0.83)
	Severe F1	+2.1% (0.27 → 0.47)*	+2.1% (0.47 → 0.48)
HistGradientBoosting	Accuracy	+20.7% (0.58 → 0.70)	+12.9% (0.70 → 0.79)
	Severe F1	+31.7% (0.33 → 0.54)*	-1.9% (0.54 → 0.53)
Random Forest	Accuracy	+53.7% (0.54 → 0.83)	-1.2% (0.83 → 0.82)
	Severe F1	+61.1% (0.31 → 0.50)*	+2.0% (0.50 → 0.51)
SVM	Accuracy	+107.9% (0.38 → 0.79)	-22.8% (0.79 → 0.61)
	Severe F1	+162.5% (0.08 → 0.16)*	+168.8% (0.16 → 0.43)

* Multiclass severe F1 approximated as avg(Hosp+Fatal).

This robustness stems from its intrinsic bagging mechanism, which effectively handles imbalance and feature interactions without relying on synthetic oversampling, outperforming even CatBoost's multiclass strengths and SVM's SMOTE-dependent gains.

VI. CONCLUSION

This study systematically evaluated machine learning models for predicting road crash injury severity within a structured methodological framework encompassing multiclass (original 4-class and ordinal wrapper), binary class reduction, and SMOTE oversampling configurations.

Multiclass experiments highlighted the dominance of tree-based ensemble methods, with CatBoost achieving the highest accuracy (0.63) and macro-F1 score (0.46). However, persistent difficulties in predicting rare severe classes emphasized the impact of class imbalance. Ordinal wrappers produced mixed improvements in recall, but often at the expense of overall performance metrics.

Binary class reduction substantially improved model performance across algorithms. Accuracies increased by 20–108%, and severe-class F1-scores improved by up to 162%. This strategy simplified decision boundaries while emphasizing clinically relevant severe outcomes. SMOTE further enhanced performance, particularly for linear classifiers such as SVM, with severe F1-score gains of up to 169%.

Random Forest with binary classification emerged as the optimal methodology, exhibiting unmatched stability across binary setups, validating the framework's comparative validation stage and affirming class aggregation's efficacy for imbalanced severity prediction.

These findings advance road safety analytics by demonstrating how strategic classification reduction outperforms complex ordinal modeling, enabling reliable severe injury flagging for proactive interventions in intelligent transportation systems.

However, limitations persist: the binary framing of the selected Random Forest model sacrifices multiclass granularity, potentially hindering fine-grained severity triage, while cross-validation results require external validation on diverse datasets to confirm generalizability beyond the current cohort. Future enhancements should incorporate explainability techniques (e.g., SHAP) to elucidate severe prediction drivers and bridge performance with clinical interpretability. Additionally, research should explore deep learning ensembles and multi-regional crash datasets.

Ultimately, deploying binary Random Forest models within real-time ITS frameworks holds promise for mitigating severe crash outcomes through data-driven risk prioritization

Machine Learning and Deep Learning for Detecting Fake News in a Low-Resource Language

Elton Tata, Jaumin Ajdarim, Nuhi Besimi
Faculty of Contemporary Sciences and Technologies, South East European University, Tetovo, Republic of North Macedonia

***Abstract*—Fake news detection has become a major problem in the digital age. This study presents an improved machine learning technique that achieves 91.99% accuracy in predicting fake news detection within Albanian textual datasets, demonstrating an improvement over existing baseline methodology. The implemented learning model uses 54 features that are specific to the Albanian language, such as red flags, credibility signals, punctuation patterns, and linguistic features. The model is tested on a balanced dataset of 3,994 news articles aggregated in Albanian from various sources. We compare it to several baselines, such as LSTM networks (80.35% accuracy) and BERT-augmented Naive Bayes classifiers (88.36% accuracy). In our Albanian dataset and experimental setting, XGBoost achieved 91.99% accuracy, indicating strong performance under the evaluated scenario.**

***Keywords*—Fake news; Albanian language; machine learning; NLP**

I. Introduction

The spread of lies and misinformation across the world, on digital platforms, poses a serious threat to democratic processes, sound decision-making, and public discourse. While much research has focused on developing sophisticated fake detection systems for high-resource languages such as English, Chinese, and Spanish by Kevin et al [1], Albanian, which is considered a low-resource language in the computational linguistics literature, has not yet been widely addressed. However, it lacks the extensive natural language processing resources, advanced pre-trained models, and annotated datasets that are available for major languages. In this context, the lack of resources presents interesting challenges for the development of efficient fake news detection systems and opportunities to investigate whether less expensive deep learning architectures can be used to achieve competitive performance using traditional shallow machine learning-based approaches developed with appropriate expertise in this field. From a computational perspective, Albanian has a number of features that make fake news detection both interesting and challenging. Special characters, such as "ë" (schwa) and "ç" (voiceless palatal affricate), are the foundation of the suggested language and help maintain a semantically accurate mapping. Due to the vocabulary of the Albanian language, there are many different types of hybrid words used in commerce, knowledge, and the performing arts [2]. The structure of the fixed definite article and the complex choice of verbs are two other notable patterns that stand in stark contrast to Romance and Germanic languages [3]. These linguistic features require customized features that our language model implementations take into account and capture the specific patterns of Albanian in both authentic journalism and fake news text.

A. Research Goals and Motivation

Three main observations of the state of the art in computational disinformation detection form the basis of the motivation behind this work. First, even in Albanian-speaking communities, the use of digital news and social media platforms for information consumption is more common, even in the absence of automatically filtered software to assess the credibility of their content. Second, due to structural differences in writing styles, languages, and cultural features, Albanian cannot be directly detected by standard fake news detection systems for most spoken languages.

Third, new research on transformer-based methods, such as multilingual BERT and other similar architectures [4]-[6], has shown that they can be used to detect fake news and do other NLP tasks across languages. But these methods usually need a lot of pretraining, a lot of computer power, and a long time to train, making them impractical for quick testing and deployment in research settings with few resources.

Our goal is to investigate the benefits of Albanian-specific features for deep learning techniques and compare them with traditional machine learning-based techniques (with or without language-specific enhancements) and the careless implementation of pre-trained models.

B. Contributions to Research

In the context of low-resource natural language processing and computational disinformation detection, this work offers three main contributions.

First, we create and validate a comprehensive set of 54 Albanian-specific linguistic features designed to capture structural and stylistic differences between fake and authentic Albanian news content, drawing on discourse-level cues inspired by Rhetorical Structure Theory (RST) [7] as well as carefully selected lexical, punctuation, and compositional patterns. While the latter prohibits the inclusion of features with low discriminatory power, such as sentence length, the former focuses on important aspects of the data to reduce overloading tendencies. Both the theory and conventions of Albanian news writing in the context of computational linguistics serve as the foundation for these features.

Second, using a set of methods, including hyperparameter search, forward selection from multiple model variants, and advanced text vectorization (with n-grams of characters), we

demonstrate a precisely calibrated Boost model with 91.99% accuracy.

Third, we demonstrate that, in the experimental context of this study and for the detection of Albanian-language fake news, a meticulously optimized machine learning methodology can attain superior accuracy and markedly reduced computational expenses in comparison to the assessed deep learning benchmarks.

The following sections comprise the rest of this document: Section II provides a literature survey of the earlier research related to this work. Section III presents the research methodology for the proposed study. In Section IV, the experimental results are presented. Section V show conclusion and future work.

II. Related Work

A. Content-Based Fake News Detection Approaches

Computational methods for detecting fake news and disinformation have evolved significantly over the past decade. Early approaches focused on content-based textual analysis and linguistic cues, drawing from techniques such as spam filtering and authorship identification [8]. Rubin et al. [9] identified stylistic and rhetorical patterns that differentiate deceptive content from legitimate journalism, showing that fake news often exhibits emotionally charged language, simplified grammatical structures, a lack of authoritative references, and sensational vocabulary [10].

More recent studies have expanded fake news detection beyond pure content analysis to incorporate source credibility and hybrid modelling strategies. Surveys by Shu et al. [11] and our previous work [12] consistently categorize detection methods into content-based, network-based, and hybrid approaches, while Guo et al. [13] further distinguish knowledge-based, style-based, and propagation-based strategies, building on propagation modelling techniques [14]. These studies consistently highlight content-based textual analysis as a core and indispensable component of effective fake news detection systems, motivating our emphasis on linguistic feature engineering.

B. Deep Learning Approaches and Low-Resource Constraints

Recent research has explored deep learning approaches, including recurrent and transformer-based models, for fake news detection. Such models are capable of automatically learning latent representations from raw text and have demonstrated strong performance in high-resource settings [15]. Transformer-based architectures, particularly BERT and its derivatives, have further advanced text classification performance and have been successfully adapted for fake news detection tasks [16],[17]. However, these approaches typically require large labelled datasets and substantial computational resources, which limit their practical applicability in low-resource research environments.

Low-resource languages face persistent challenges due to limited annotated data, scarce linguistic tools, and reduced representation in large pre-trained language models [18],[19]. Empirical studies further show that multilingual transformer models exhibit uneven performance across languages, with effectiveness strongly influenced by data availability and typological similarity [20]. These limitations highlight the need for alternative approaches that remain effective under data- and resource-constrained conditions.

C. Classical Machine Learning in Low-Resource Settings

A recurring question in fake news detection research concerns the conditions under which traditional machine learning methods can match or outperform deep learning approaches. Recent empirical studies indicate that well-designed classical models can achieve competitive performance on small- to medium-sized datasets when combined with effective feature engineering [21].

In particular, gradient-boosted decision tree models [22], including XGBoost, LightGBM, and CatBoost, have demonstrated strong performance and computational efficiency on structured and textual data. Essa et al. [23] report that LightGBM achieves high accuracy while maintaining computational efficiency, while other studies show that classical ensemble-based approaches can achieve competitive fake news detection performance with significantly lower computational cost than deep learning models. When paired with text vectorization techniques such as TF-IDF and higher-order n-grams, these models effectively capture discriminative linguistic patterns, making them especially suitable for domain-specific and low-resource scenarios. Overall, the reviewed literature provides strong justification for our approach, which emphasizes interpretable, Albanian-specific feature engineering and optimized classical machine learning models for effective fake news detection under limited data and computational resources.

III. Methodology

This section explains the extraction of features, the vectorization of text, and the architecture of our models (Fig. 2).

A. Data Collection and Sources

The dataset used in this study consists of 3,994 news articles in Albanian, collected from a wide range of Albanian-language media sources with different political orientations, geographical origins and journalistic standards [24].

There are 1,998 real news items and 1,996 fake news items in the dataset, which are almost perfectly balanced.

Every article that could be fake was manually reviewed, and only those that all commentators agreed on were kept in the final data.

The data includes the article title, the full text with original punctuation and paragraph structure, the date and time of publication, source information, and a binary class label.

B. Data Preprocessing and Quality Control

Text preprocessing steps were applied to reduce noise while preserving Albanian-specific linguistic characteristics relevant for downstream feature extraction. At the same time, this process explicitly preserves Albanian-specific characters, such as “ë” (schwa) and “ç”, which carry semantic value and are essential for the accurate representation of Albanian news texts (Fig. 1).

We address another Albanian-specific stopword removal, using a selected set of frequently occurring particles in texts with minimal discriminative value for classification, such as "dhe" (and), "e", "në" (in), "është" (is), "të" (to/of), "për" (for), "me" (me), "nga" (nga), etc., and their function words.

C. Data Partitioning Strategy

We use stratified random sampling to perform train-test splits and to ensure global class distribution in both subsets. 3,195 articles (80% of the data) are in the training set, with 1,598 articles that are real and an equal number that are fake, in which the class distribution remains approximately 50-50. The testing set includes 799 articles (20% of the total data), consisting of 400 real news items and 399 fake news items, once again maintaining class balance.

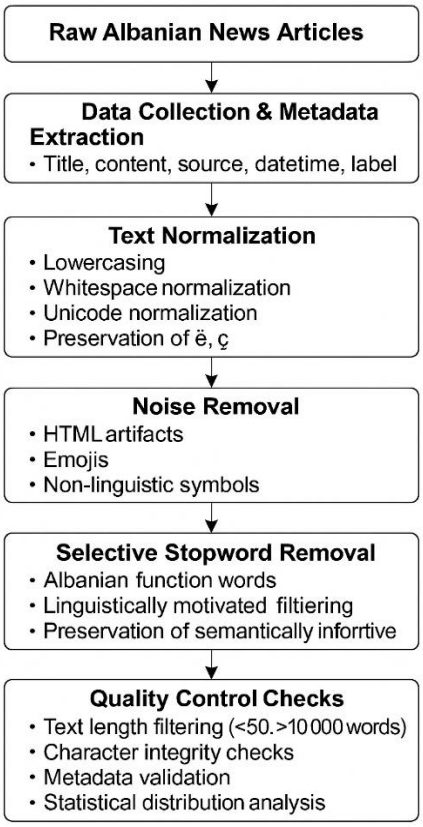

Fig. 1. Diagram for data processing and quality control.

D. Albanian-Specific Feature Engineering

We worked on 54 task-based features in five groups, taking different textual cues and metadata that we found empirically relevant for this active learning task - extracting different aspects of fabricated versus real news content.

E. Linguistic and Lexical Aspects of Albanian

The Albanian language has unique characteristics that enable the determination of genuine Albanian text versus text that may be translated from other languages or by non-native speakers [25]. The Albanian character ratio is the percentage of text that consists of two characters specific to Albanian, 'ë' and 'Ç', calculated as the number of these special characters divided by the total number of characters.

The binary variables control for the presence of Albanian characters (has_albanian_chars), which provides an admittedly simple but useful piece of information about the origin of the text. Vocabulary analysis features to check for the existence of sensational keywords that are typical of fake news in Albanian, such as "scandal" (scandal), "terror" (terror), "bomba" (bombë), "frikë" (fear), "shok" (shock), "alarm", "rrezik" (danger), "katastrofë" (catastrophe), "ekskluzive" (exclusive), "sekrete" (secret), "breaking" (borrowed English), "urgent" (borrowed English), "shikoni!" (look!) and "nuk do ta besoni!" (you won't believe it).

We derive both absolute counts (sensational word count) and ratios per document relative to document size (sensational ratio) to measure the strength of sensationalism, taking into account different lengths of articles.

The linguistic elements of opinion and defense cover question words and uncertainty devices such as "a" (whether), "vallë" (perhaps/I wonder), "ndoshta" (maybe), "mbase" (perhaps), "duket" (it appears), and "besoj" (I believe).

F. Characteristics of Punctuation Patterns

Patterns of punctuation [26] usage are strong indicators of Fake News vs. Professional News Sensationalism. Characteristics of exclamation marks consist of count, ratio of full document count to full document length, and binary flags for multiple exclamation marks (!! or !!!).

Question mark–based findings mirror the exclamation mark patterns. We analyze the number of question marks, their ratio relative to document length, and the detection of repeated question sequences (“??” or “???”). We track the use of ellipses, including in its sensationalist version, three consecutive dots (...). Contextual Citation and Citation Analysis.

Capitalization patterns are analyzed through the frequency and ratio of fully capitalized words, which tend to be more common in fake news than in professional journalism.

G. Statistical Textual Features

Word counts and sentence structures in the language model properties of the text are distinctive signals without being sensitive to the actual vocabulary [27]. We derive 15 statistical features to encode these features. Simple length measures are, e.g., total number of words, total number of characters, average word length (i.e., number of characters divided by number of words), and text length variation.

Sentence structure analysis applies regular expressions to determine sentence endings based on final punctuation (periods, exclamation marks, and question marks) and then calculates the number of sentences and their average word length, as well as their variation across the document. The unique word ratio represents the percentage of words confined to a single occurrence (type-mark) in the document, indicating diversity. The word repetition score, conversely, reflects the inverse metric (1 minus the type-mark ratio), which indicates how repetitive the content is.

H. Structural and Compositional Features

Aspects represent dependencies between content parts and logical structure [28]. We derive 8 features that control these

compositional properties. Headline analysis attributes that are analyzed independently of article titles include title length, title word count, and title punctuation (including exclamation and question marks). Fake news headlines tend to use question forms and their exclamatory counterparts to arouse curiosity or elicit an emotional response, while professional news headlines are more oriented toward so-called declarative patterns.

The title-content relationship models the relationship between headlines and news article bodies. Title_content_ratio calculates the ratio of title length to content, highlighting whether an article title is unusually long or short in relation to the information contained. Headline–content similarity features quantify the alignment between article titles and their corresponding bodies, capturing cases where titles diverge in length or content emphasis from the main text.

I. Time Features

When news timestamps are available, time features introduce an additional distinctive signal [16]. Five-time attributes have been identified from the publication_datetime metadata. The time of day takes the hour (values ranging from 0 to 23) when the article was published that day, which is expected to reflect different patterns in publication times. The day of the week (0="Monday", etc.) indicates the day of the week, allowing for weekly patterns in publication. The binary time indicators extracted are the is_weekend flag for Saturday/Sunday publications, capturing differences between weekend versus weekday publication patterns, and night by is_night if a publication was published between 22:00 and 05:00 local time when professional newsrooms are not active. This can reveal whether there are any patterns in the distribution of our data over time.

J. Construction of the Combined Feature Matrix

Each item is given 15,000 TF-IDF features using the vectorizer and 54 engineered_feats computed as described in the above section, resulting in a total data dimensionality of 15,054 features for each item. Scipy sparse matrix operations are used to join these feature sources into a single dataset by converting the 54 engineered features into dense arrays and stacking them horizontally with TF-IDF sparse matrices.

The gradient boosting model adapts the best feature weighting and interaction between both types of features, i.e., feature selection and synthesis, based on a unified training procedure.

K. Evaluation Methodology

We extract features for each test item in identical ways as during training and apply the trained TF-IDF vectorizer with a fixed vocabulary and IDF weights to transform the text and concatenate them to obtain 15,054-dimensional representations. We then use the models to produce probabilistic prediction results. The dimensionality was selected as a balance between representational richness and computational efficiency, as preliminary experiments indicated diminishing performance gains beyond this threshold.

Performance Metrics. Model performance is evaluated using standard classification metrics, including accuracy, precision per class, recall, and F1 score.

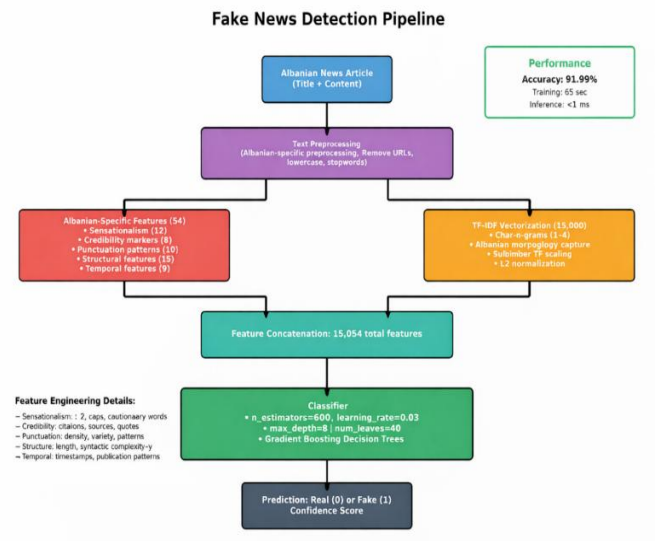

Fig. 2. Data processing, feature extraction, and classification pipeline used in this study.

IV. Experimental Results

The evaluation includes basic deep learning representational models, hybrid approaches, and gradient boosting models, to compare their performance under the same experimental conditions.

A. Summary of Evaluated Models

The evaluated models are grouped into four categories: basic deep learning models, hybrid models that combine neural representations with classical classifiers, gradient boosting models, and ensemble configurations. This categorization allows for a structured comparison of the models in terms of predictive performance and practical applicability.

B. LSTM Recurrent Neural Network and BERT-Enhanced Naive Bayes Hybrid

On the retained test set, the LSTM-based model achieved an accuracy of 80.35%, a significantly lower result than the best-performing gradient boosting models evaluated in this study. The comparatively lower performance of the LSTM model may be attributed to the moderate dataset size and the high dimensionality of the input representation. Deep sequential models typically benefit from substantially larger corpora or pretrained contextual embeddings. In low-resource settings, feature-engineered gradient boosting approaches may therefore exhibit greater stability and generalization capacity. With a training corpus of 3,195 items, the model seeks to learn word representations from scratch, which is insufficient for deep neural architectures that typically require significantly larger datasets to generalize well.

This hybrid model achieved an accuracy of 88.36%, a significant improvement of approximately 8 percentage points over the baseline LSTM model.

C. Logistic Regression Baseline

Despite its linear nature, logistic regression achieves competitive performance, achieving an accuracy of 89.36%, closely matching the result achieved by Naïve Bayes improved

by BERT. This result confirms that the combination of TF-IDF vectorisation and carefully designed Albanian language-specific features provides a very informative representation, even for simple linear classifiers.

D. Random Forest Baseline

The model achieved an accuracy of 88.49%, outperforming the baseline LSTM model (80.35%) and performing comparably to the BERT-enhanced Naïve Bayes model (88.36%).

The results indicate that tree-based ensemble methods combined with effective feature engineering can provide competitive performance without relying on deep neural architectures. The class-wise evaluation shows balanced behaviour, with true news accuracy of 88.91% and recall of 87.75%, and false news accuracy of 88.08% and recall of 89.22%, suggesting that there is no strong bias towards either class.

E. XGBoost Implementation

XGBoost is configured with such parameters for a fair comparison, including 500 boosting rounds, a 0.05 learning rate, a maximum tree depth limit of 7, a minimum child weight of 10, a subsample ratio of 0.8, and a column subsample ratio also set to 0.8. L1 regularization (alpha=0.1) and L2 regularization (lambda=1.0) are used to avoid overfitting on high-dimensional TF-IDF features by penalizing model complexity.

The XGBoost model achieved an accuracy of 91.99% on the full feature set. XGBoost model's prediction feature analysis indicates that it does well on articles with a clear vocabulary gap between fake and real news, can generalize across different-length articles by leveraging tree-based feature selection and captures non-linear interactions among predictive features with hierarchical splits (Fig. 3).

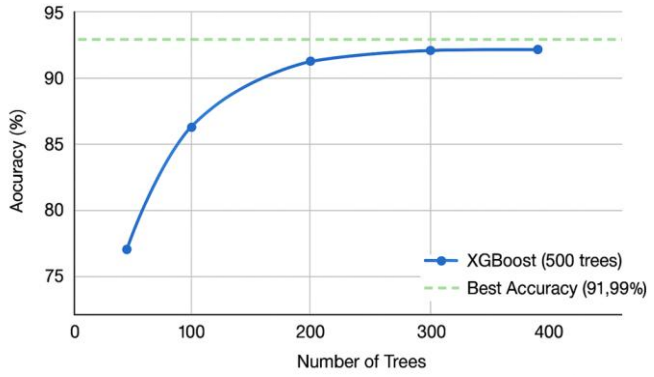

Fig. 3. Test accuracy of gradient boosting models.

F. Feature Importance and Interpretability Analysis

To further enhance the interpretability of the engineered feature set, feature importance analysis was conducted using XGBoost gain scores (Fig. 4). The results indicate that structural alignment cues, particularly the title_content_ratio, are among the most influential predictors. Content length and title-based attributes also rank highly, emphasizing that structural coherence plays a central role in distinguishing reliable journalism from misleading or clickbait-oriented content. Punctuation-related characteristics, including the frequency of exclamation marks and the presence of interrogative headlines, further contribute to classification decisions, supporting the hypothesis that exaggerated stylistic elements are associated with misleading articles. Lexical diversity measures such as word_repetition_score, unique word ratio, and word_length_variance also demonstrate notable predictive influence. Temporal attributes exhibit comparatively lower importance values, suggesting that they function as complementary contextual indicators rather than dominant classification drivers.

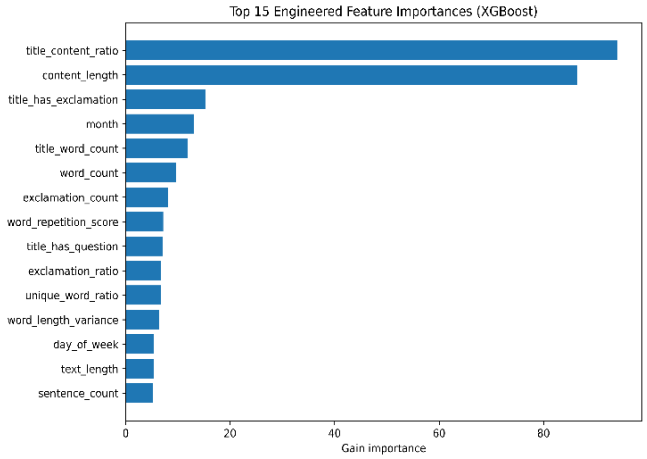

Fig. 4. Top 15 engineered feature importances based on XGBoost gain values.

G. Detailed Performance Evaluation

To provide a deeper evaluation of the classification behavior beyond the reported accuracy (91.99%), confusion matrix, and ROC–AUC analyses were conducted. These metrics offer additional insight into class-level performance and threshold sensitivity. The confusion matrix (Fig. 5) demonstrates a balanced distribution of classification outcomes across real and fake news categories. The model maintains comparable levels of false positives and false negatives, indicating the absence of systematic bias toward either class and confirming stable predictive behavior.

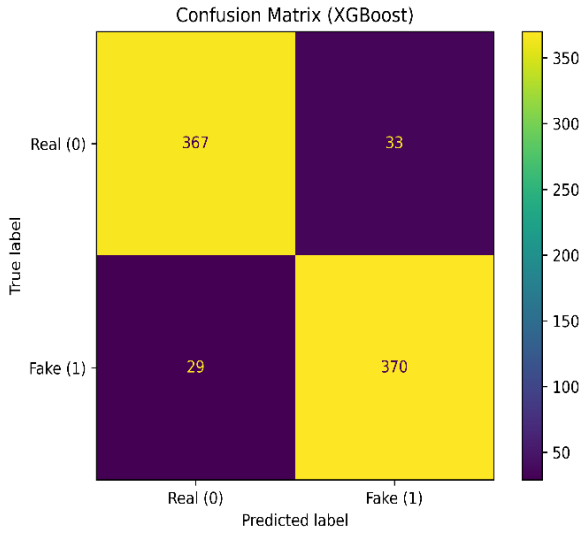

Fig. 5. Confusion matrix of the XGBoost classifier.

The Receiver Operating Characteristic (ROC) curve, Fig. 6, further illustrates strong separability between classes across varying decision thresholds. The model achieves an Area Under the Curve (AUC) score of 0.974, reflecting high discriminative capacity and robustness against threshold variation.

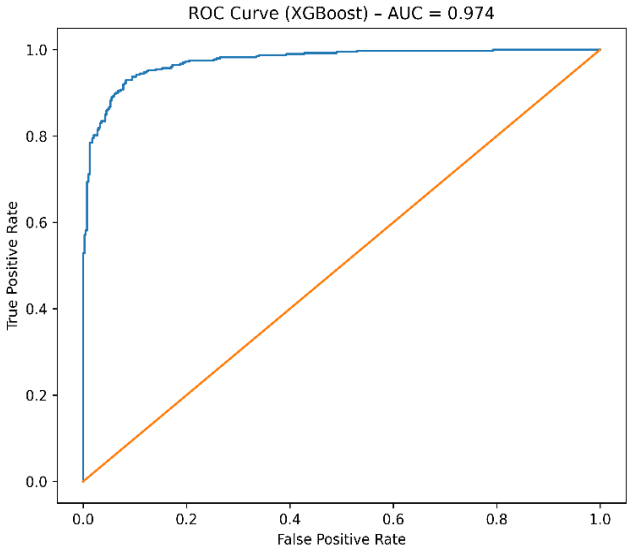

Fig. 6. ROC curve for the XGBoost classifier (AUC = 0.974).

H. Cross-Validation Stability Analysis

To ensure that the reported performance is not dependent on a single 80/20 train–test partition, a 5-fold stratified cross-validation procedure was conducted on the training data. The model achieved a mean accuracy of 91.08% with a standard deviation of 0.89%, indicating stable performance across folds. The low variance confirms that the classifier maintains consistent predictive behavior and does not rely on a specific data split. These findings support the robustness and generalization capacity of the proposed feature-engineered framework.

I. Error Analysis of Misclassified Instances

To further investigate model limitations, an analysis of misclassified instances was conducted based on the confusion matrix results. The model exhibits a balanced number of false positives and false negatives, indicating no systematic bias toward either class. False positives predominantly correspond to articles that display emotionally expressive or opinion-style language while remaining factually accurate. These cases suggest that stylistic intensity alone may sometimes resemble misleading patterns. On the other hand, false negatives usually include false information that is given in a neutral or formal tone and doesn't have any obvious sensational markers. Such cases highlight the challenge of detecting subtle or stylistically restrained misinformation.

Overall, the observed misclassifications suggest that ambiguity in stylistic signals remains the primary classification challenge, particularly when misleading content avoids exaggerated linguistic cues.

J. Comprehensive Model Comparison Table

Table I summarizes performance across all evaluated approaches, enabling direct comparison of accuracy, training time, model characteristics, and key strengths/weaknesses.

TABLE I. PERFORMANCE ACROSS ALL EVALUATED APPROACHES

Model	Accuracy	Training Time	Model Size	Key Strengths	Key Limitations
LSTM Baseline	*80.35%*	*60 min*	*2.4MB*	*Learns sequential patterns; no manual features*	*Slow training; overfits small data; requires large datasets*
Logistic Regression	*89.36%*	*1 sec*	*<1MB*	*Very fast; simple baseline; interpretable*	*Linear decision boundary; limited expressiveness*
BERT+NB Hybrid	*88.36%*	*2 min*	*850KB*	*Fast training; BERT tokenization*	*No contextual embeddings; independence assumption*
Random Forest	*88.49%*	*2 sec*	*15MB*	*Non-linear; handles interactions; interpretable*	*Outperformed by gradient boosting; larger model size*
XGBoost	*91.99%*	*35 sec*	*24MB*	*Robust; well-established*	*Best performance of the tested models.*

K. Comparative Analysis with Other Work

While this study focuses on fake news detection in Albanian, it is important to contextualize the obtained results in relation to existing studies conducted in other languages and datasets. A direct comparison with previous work allows a deeper understanding of whether the achieved performance is consistent with established empirical findings or represents an isolated result.

Therefore, a comparative analysis is conducted with representative fake news detection studies that use similar experimental environments, including textual datasets of comparable size and widely used machine learning and deep learning approaches. The comparison focuses mainly on accuracy, which is the most widely reported evaluation metric in the relevant literature.

As shown in Table II, previous studies on fake news detection report accuracy values that generally range between approximately 88% and 95%, depending on the data characteristics, feature representations, and learning models used. Classical machine learning approaches, especially ensemble-based models such as Random Forest and XGBoost, consistently demonstrate strong performance on medium-scale textual data.

TABLE II. COMPREHENSIVE MODEL PERFORMANCE COMPARISON

Study	Dataset Size	Method	Accuracy
This work (Albanian Fake News Detection)	*3,994*	*LR*	*89.36%*
		XGBoost	*91.99%*
		LSTM	*80.35%*
		BERT with Naive Bayes	*88.36%*
Alameri & Mohd [28]	*~5,000–7,000*	*SVM*	*88.20%*
		Naive Bayes	*84.60%*
		LSTM	*94.21%*

		CNN + BiLSTM + Attention	*88.78%*

Deep learning models perform competitively when ample training data is present; however, their efficacy may fluctuate in contexts with constrained datasets. In this context, this study achieves an accuracy of 91.99% using TF-IDF features combined with XGBoost, which aligns well with the results reported in the literature for comparable experimental conditions.

These findings show that the proposed approach follows established empirical trends observed in different languages and datasets, confirming that gradient-boosted machine learning models remain an effective and reliable choice for fake news detection, especially in languages with limited data resources.

L. Ethical Considerations

Automated fake news detection systems may carry risks of misclassification that could affect journalistic credibility and public trust. Therefore, such systems should be deployed as decision-support tools rather than fully autonomous labeling mechanisms. Transparency, interpretability, and periodic human oversight are essential to ensure responsible use, particularly in low-resource linguistic contexts such as Albanian.

V. CONCLUSION

In this work, we showcased an optimized machine learning model for Albanian fake news detection, which achieved 91.99% accuracy by combining optimal Albanian feature engineering and XGBoost. This work shows that generic machine learning methods can achieve comparable performance to deep-learning solutions through integrating domain-specific knowledge and seeking systematic optimization.

We introduced and validated 54 Albanian specific optimization, linguistic features capturing sensationalism indicators, credibility markers, punctuation patterns, structural information and temporal features. The optimized XGBoost achieves an accuracy of 91.99%, significantly higher than other models.

AMCS: Adaptive Multi-Controller SDN Security with Stateful Traffic Intelligence for Fast and Accurate Multi-Vector Attack Detection

Ameer El-Sayed[1], Mohamed Nosseir Hemdan[2], Noha Abdelkarim[3], Ehab Rushdy[4], Hanaa M. Hamza[5]
Department of Information Technology-Faculty of Computers and Informatics, Zagazig University, Zagazig 44519, Egypt[1, 2, 3, 4, 5]
Department of Information Technology-Faculty of Information Technology and Computer Science, Sinai University, Egypt[2]

Abstract*—The rapid proliferation of Software-Defined Networking (SDN) in large-scale Internet of Things (IoT) ecosystems has amplified exposure to sophisticated, multi-vector cyberattacks that simultaneously exploit control- and data-plane asymmetries. Existing single-controller statistical detectors, while effective under high-volume anomalies, fail to sustain precision and responsiveness under dynamic, distributed, or low-rate attack conditions. Addressing this critical gap, we propose AMCS—an Adaptive Multi-Controller SDN Security framework that fuses stateful traffic intelligence with cooperative inter-controller decision-making to enable resilient, context-aware detection across complex IoT traffic. AMCS embeds lightweight, P4-based stateful processing directly in the data plane and augments it with adaptive entropy-driven anomaly evaluation and consensus-based coordination among distributed controllers. Extensive experiments on an SDN–IoT testbed demonstrate that AMCS achieves up to 99.7% detection accuracy for high-volume floods, 96.8% for low-rate anomalies, and 94.1% under mixed traffic, while maintaining false-positive rates below 5% and detection latencies as low as 1.24 s. The cooperative consensus protocol enhances cross-controller reliability to 98.4% with only 0.83 s synchronization delay, while reducing control overhead by 34.7% compared to the single-controller baseline. Moreover, the distributed mitigation layer reacts within 1.6 s on average, neutralizing over 97% of attack flows with negligible collateral impact. Collectively, these results confirm that integrating stateful in-switch analytics, adaptive thresholding, and multi-controller cooperation establishes a scalable, self-adaptive SDN security fabric—achieving both fast detection and stable defense against evolving multi-vector threats in IoT-driven networks.

I. Introduction

The rapid expansion of the Internet of Things (IoT) has reshaped modern network infrastructures, introducing unprecedented levels of heterogeneity, mobility, and traffic dynamism [1]. Although Software-Defined Networking (SDN) offers a programmable and logically centralized architecture capable of managing this complexity, its increasing adoption in IoT and cloud-integrated settings has exposed several structural vulnerabilities [2]. In particular, current SDN deployments depend heavily on the interaction between the control and data planes, making the controller a critical point whose performance can be disrupted by malicious traffic surges or crafted low-rate attacks [3]. These concerns are well documented in prior studies, which highlight how Distributed Denial-of-Service (DDoS) campaigns, spoofed traffic, and saturation attacks degrade controller responsiveness and accuracy, often overwhelming existing statistical detection methods that rely on basic entropy or rate measurements [4].

Recent research further emphasizes that the challenge extends beyond traditional high-volume attacks [5]. In IoT-dense environments, the number of devices and the irregularity of their traffic patterns increase the difficulty of distinguishing benign variations from genuine anomalies [6]. This complexity is compounded in multi-controller SDN architectures—designed to improve scalability and fault tolerance—where controllers must coordinate decisions, synchronize state, and maintain consistent security policies across distributed domains [7]. Without robust mechanisms for inter-controller cooperation, these architectures may inadvertently widen the attack surface or delay collective responses to emerging threats [8]. There is a growing need for secure, coordinated, and intelligent controller communication in SDN networks, which outlines challenges such as secure coordination, attack-surface expansion, and the limitations of stateless detection pipelines in fast-evolving IoT scenarios [9].

While previous work demonstrates that entropy-based methods can achieve high detection accuracy in controlled conditions for specific attack models, these techniques often operate independently on each controller and lack a mechanism to incorporate deeper traffic state or contextual behavior [10], [11]. As a result, statistical fluctuations, low-rate probing, and distributed multi-vector attacks may evade or delay detection [12]. The limitations documented in earlier SDN studies point to a broader gap: existing single-controller, threshold-driven systems are not designed to reason about traffic evolution over time, nor to leverage cross-controller observations that could reveal subtle, otherwise-hidden attack patterns [13].

Motivated by these challenges, this work explores an adaptive multi-controller security framework that integrates stateful traffic inspection with cooperative intelligence sharing. The proposed approach integrates multi-layer protection, real-time stateful monitoring, secure controller-to-controller communication, and seamless orchestration of distributed defensive functions across the network. By combining stateful flow context with coordinated multi-controller analysis, the

proposed framework aims to enhance detection robustness against diverse attack strategies—including low-rate exfiltration attempts, distributed probing, and rapid DDoS-like bursts—while maintaining the performance and scalability demands inherent to IoT-driven networks.

II. Literature Review

The convergence of SDN and the IoT has reshaped modern network management, offering programmability, centralized orchestration, and policy-driven control. However, this integration also exposes new vulnerabilities. The centralized nature of SDN controllers and the heterogeneous, resource-limited behavior of IoT nodes collectively create an expanded attack surface, particularly against multi-vector cyberattacks. Maintaining the stability of SD-IoT environments under such conditions has therefore become a cornerstone of current research, as network-layer resilience directly underpins higher-level security assurances.

Early contributions in this domain largely focused on controller-centric machine learning (ML) approaches for attack detection. Adaptive ensemble frameworks and hybrid classifiers achieved notable accuracy in simulated testbeds but frequently failed to generalize beyond controlled datasets [14]. For instance, neural-network–SVM hybrids demonstrated high detection performance on benchmark datasets but suffered from limited scalability and dataset bias [15]. Other lightweight gradient-boosting models improved training efficiency yet still relied heavily on handcrafted features and synthetic traffic patterns, reducing their practicality for real IoT deployments [16].

Subsequent research explored deep learning (DL) and reinforcement learning (RL) paradigms to enhance automation and adaptiveness [17]. Architectures that combined DL-based detectors with RL-driven mitigation improved dynamic decision-making but were constrained by computational overheads and untested scalability in multi-controller topologies [18]. CNN- and DBN-based frameworks [19], [20] produced high detection rates; however, their limited interpretability and dependence on non-IoT datasets restricted their utility in heterogeneous traffic environments.

Parallel to controller-side innovation, attention shifted toward programmable data-plane intelligence. The advent of P4 switches enabled in-network detection, where selected traffic features are processed closer to the source. P4-assisted methods demonstrated substantial latency reduction and early anomaly recognition, particularly for TCP- and HTTP-based floods [21], [22]. Nevertheless, computational constraints within the data plane and narrow attack coverage remained unresolved. Meanwhile, controller-integrated ML frameworks—such as SDN-WISE [23] and DALCNN [24]—offered improved localized detection accuracy but continued to suffer from single-point bottlenecks and dependence on static detection thresholds.

A later wave of research introduced hybrid statistical–ML approaches to balance efficiency and adaptability. Models combining entropy-based indicators with machine learning improved early detection of low-rate anomalies. Similarly, edge-level designs leveraging Markov models and hybrid deep networks achieved effective performance in mitigating slow-rate IoT botnet traffic [25]. Yet, these methods often lacked flexibility under variable attack rates, emphasizing the need for dynamic temporal analysis and context-aware feature extraction [26], [27]. The shift toward adaptive temporal windows and confidence-based learning mechanisms represents a direct response to these limitations [28].

More recent studies have extended this evolution into context-aware, multi-phase, and transformer-based architectures. Attention-driven models such as SAINT [29] and multiphase entropy–clustering frameworks demonstrated high detection accuracy (above 96%) in cloud and fog environments [30]. Comparative evaluations [31] reaffirmed the efficiency of traditional ML classifiers—like Decision Trees and Random Forests—as practical baselines for constrained devices, while hybrid interpretable approaches integrated explainability tools such as SHAP for domain-specific applications (e.g., healthcare IoT) [32]. Nonetheless, the majority of existing work remains tied to isolated control domains or non-IoT datasets, limiting generalization across distributed and dynamic infrastructures [33].

Despite notable advances, few existing frameworks achieve real dual-plane coordination—that is, combining stateful in-switch analytics with adaptive learning and distributed mitigation across multiple controllers. As large-scale DDoS attacks remain the most frequent and destructive threat to IoT ecosystems, building resilient, cooperative, and self-adaptive SD-IoT defenses remains an open and urgent research frontier.

The proposed framework in this study contributes to this effort by integrating stateful data-plane inspection, entropy-aware adaptive detection, and multi-controller collaborative mitigation. Table I summarizes the representative literature, highlighting trends, strengths, and research gaps that informed the design of the proposed solution.

TABLE I. Summary of Representative Research on Attack Detection and Mitigation in SD-IoT Networks

Ref.	Year	Approach	Main Strengths	Identified Limitations
[17]	2022	SDN framework with DL detection + RL mitigation	Dynamic, adaptive countermeasures	Scalability not validated in real SD-IoT settings
[15]	2022	FFCNN–SVM hybrid for low-rate DDoS	Accurate under controlled conditions	Single attack focus, limited dataset diversity
[24]	2022	DALCNN integrated with SDN controller	High accuracy and stability	Dependent on non-IoT traffic datasets
[21]	2022	P4-enabled ML-based detection	Low latency, edge-level monitoring	Narrow attack scope, heavy switch load
[27]	2022	Entropy + ML hybrid model	Fast and precise detection	Limited handling of multi-vector attacks

[18]	2023	DL-driven SDN defense with adaptive responses	Integrative multi-stage mitigation	Lacks IoT-specific validation
[28]	2023	FMDADM using packet-window features	Effective IoT botnet detection	Limited adaptability to variable traffic rates
[23]	2023	SDN-WISE ML-based detection	Improved localized accuracy	Single-controller dependency
[16]	2023	LightGBM-based feature engineering	Efficient and lightweight	Synthetic data reliance
[25]	2024	Edge-level hybrid deep learning	Robust low-rate attack detection	Scalability is unproven in large topologies
[26]	2024	Smart-home ML + signature detection	High accuracy for specific IoT domains	Poor generalization to other IoT environments
[22]	2024	P4-based HTTP DDoS defense	Low latency, real-time operation	High computational cost on P4 devices
[29]	2025	Transformer (SAINT) model for TCP-DDoS	Highly interpretable, scalable	Focused mainly on transport-layer floods
[30]	2025	Multiphase ML–entropy fog architecture	High classification accuracy, quick response	Evaluation restricted to fog nodes
[34]	2025	CNN–LSTM with SHAP interpretability	Transparent DL behavior	Limited to the healthcare IoT context
[33]	2025	ONOS Flood Defender with adaptive algorithms	Real-time SYN flood mitigation	Fixed statistical thresholds, limited adaptability
This Work	**2025**	P4-based SD-IoT framework with adaptive detection and multi-controller mitigation	Real-time stateful feature extraction, confidence-adaptive learning, scalable coordination	Requires further testing under large-scale, distributed failover conditions

III. Proposed Framework

This section presents the proposed adaptive security framework for multi-controller SDN environments supporting heterogeneous IoT deployments. The framework addresses core challenges in scalability, control-plane coordination, and adaptive security monitoring by combining stateful traffic analysis, cooperative controller synchronization, and distributed mitigation. It is structured around four main components:

1) The system model, describing the architectural layers and interactions between network entities;

2) The threat model, identifying relevant attack vectors and their potential impact;

3) The stateful traffic-processing and adaptive anomaly evaluation modules, enabling context-aware detection; and

4) The multi-controller coordination and response mechanisms, which provide resilience and consistent defense actions.

Section 3.1 introduces the overall system architecture, while Section 3.2 defines the threat landscape and attacker capabilities. The following subsections detail the analytical and cooperative modules that enable detection, decision-making, and mitigation within the distributed control environment.

A. System Model

The proposed Adaptive Multi-Controller SDN Security (AMCS) framework (Fig. 1) embodies a hierarchical yet cooperative architecture that unifies stateful data-plane intelligence with distributed controller coordination. It is composed of three principal tiers and eight logically connected functional modules that collectively enable programmable, adaptive, and synchronized protection across large-scale IoT networks.

(1) IoT and Edge Layer

At the edge of the architecture lies a diverse ecosystem of IoT devices—sensors, cameras, gateways, and embedded controllers—that generate heterogeneous traffic streams. These devices (Step ① in Fig. 1) transmit telemetry, command, and control data toward the SDN infrastructure. Their irregular bursty transmissions and constrained resources make them vulnerable entry points for both volumetric and stealthy threats such as spoofing, infiltration, and low-rate exfiltration.

(2–5) Data-Plane Intelligence: Stateful Feature Extraction and Analysis

Incoming traffic first enters the SDN data plane (Step ②), composed of P4-programmable switches capable of executing local inspection before involving the controller. Each switch captures and extracts essential flow-level attributes—packet size, inter-arrival time, flow initiation rate, and destination entropy (Steps ③–④)—which are forwarded to the Stateful Traffic-Processing Module (STPM) located inside the P4 pipeline (Step ⑤).

The STPM maintains per-flow state tables and statistical registers that continuously update as packets traverse the switch. This enables in-network anomaly sensing by identifying temporal irregularities in packet behavior, thereby offloading early detection from the control plane. By exporting only aggregated summaries rather than raw packets, the STPM significantly reduces packet in congestion and controller CPU load.

(6) Control-Plane Intelligence: Adaptive Anomaly Evaluation (AAE)

Processed telemetry from STPM is sent to the controller's Adaptive Anomaly Evaluation (AAE) module (Step ⑥). The AAE dynamically computes entropy-based deviation scores and adjusts its thresholds using real-time variance and historical profiles. This allows the controller to distinguish flash-crowd events from true anomalies. Each controller thus maintains a localized, context-aware anomaly model that evolves with observed traffic behavior.

(7) Inter-Controller Coordination: Multi-Controller Coordination Module (MCCM)

Because the AMCS framework deploys multiple distributed controllers across domains (C1, C2 … Cn), synchronization of

local detections is essential. The MCCM (central-CO exchange shown in Fig. 1, Step ⑦) aggregates alerts from all controllers, performs consensus voting based on trust weights, and disseminates unified decisions across peers. Consensus cycles occur periodically, ensuring global consistency without imposing excessive communication overhead. This cooperative verification minimizes false positives and enables rapid multi-domain agreement—typically within 0.8 s, as shown in experimental results.

(8) Global Mitigation and Policy Enforcement: Distributed Mitigation Workflow (DMW)

Once the MCCM confirms an incident, the Distributed Mitigation Workflow (DMW) (Step ⑧) executes adaptive countermeasures proportionate to alert confidence and severity. Controllers enforce localized rate-limiting, flow blocking, or rerouting policies within their domains, while global synchronization ensures that legitimate flows remain unaffected. This distributed enforcement loop closes the detection–response cycle, maintaining network stability and service continuity.

The bidirectional arrows between modules denote feedback loops: mitigation outcomes refine AAE thresholding, and updated trust weights from MCCM influence future coordination cycles. Together, these interactions form a closed, adaptive control system that continually tunes its detection sensitivity, synchronization accuracy, and policy strength.

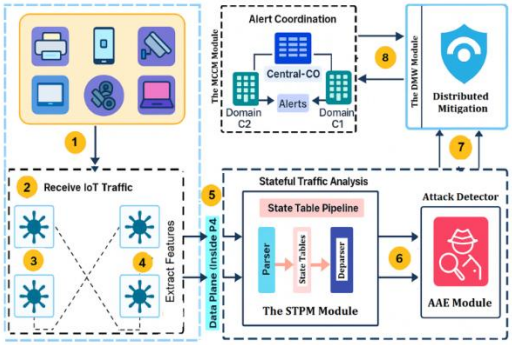

Fig. 1. System model of the AMCS framework showing end-to-end data flow from traffic ingestion to distributed mitigation.

B. Threat Model

The threat model defines the adversarial assumptions, potential attack vectors, and corresponding defense mapping relevant to the proposed AMCS framework. It considers an intelligent, adaptive adversary capable of strategic coordination across IoT domains, yet without direct access to the SDN controller software or administrative privileges. The attacker's objectives are to disrupt network availability, degrade controller responsiveness, and exploit synchronization weaknesses in multi-controller SDN environments.

As illustrated in Fig. 2, the threat model encompasses three logical dimensions: (1) Adversary Capabilities, (2) Attack Vectors and Impacted Assets, and (3) Defense Mapping to the corresponding AMCS protection modules.

To counter these coordinated threats, the AMCS architecture implements a layered defense mapping between identified attack vectors and specific protection modules (as shown in Table II). Table III summarizes the threat characteristics and system impacts under the assumed adversarial model. The mapping clearly demonstrates that AMCS establishes a defense continuum—from in-switch detection (STPM) to global mitigation (DMW)—capable of addressing both volumetric and adaptive multi-vector attacks.

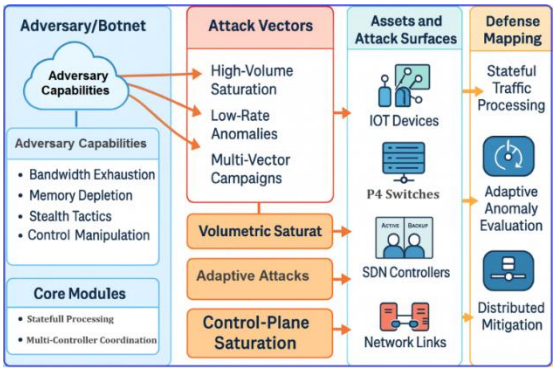

Fig. 2. Threat model showing adversarial capabilities, targeted SDN–IoT assets, corresponding attack vectors, and mapped AMCS defense mechanisms.

TABLE II. DEFENSE MAPPING TO AMCS MODULES

Threat Category	Affected Asset(s)	Primary Defense Mechanism
High-Volume Saturation	P4 Switches, Controllers	Stateful Traffic Processing (STPM) detects abnormal packet bursts directly within the data plane, throttling early-stage floods before escalation.
Low-Rate Stealth Attacks	IoT Devices, Network Links	Adaptive Anomaly Evaluation (AAE) dynamically adjusts detection thresholds using entropy variance and temporal context to capture slow anomalies.
Multi-Vector Distributed Campaigns	Multiple Controllers, Domains	Multi-Controller Coordination Module (MCCM) correlates alerts and ensures synchronized detection decisions across domains.
Control-Plane Manipulation	Controllers, State Tables	Distributed Mitigation Workflow (DMW) enforces coordinated policy adaptation, restoring consistent states across controllers and minimizing response delay.

TABLE III. THREAT MODEL SPECIFICATIONS

Threat Category	Adversary Capability	Impact on System
High-Volume Saturation	Flooding traffic to overload switches/controllers	Excessive *packet_in* load, delayed flow setup, and reduced throughput
Low-Rate Stealth Attacks	Gradual, subtle anomalies	Evades fixed thresholds, increases false negatives
Multi-Vector Distributed Attacks	Coordinated anomalies across domains	Inconsistent detection, delayed mitigation
Control-Plane Manipulation	Triggering conflicting flow behaviors	State inconsistency, incorrect routing, degraded QoS

C. Stateful Traffic-Processing Module (STPM)

Headings: The stateful traffic-processing module forms the analytical core of the framework. Its role is to extract concise indicators from live traffic, maintain short-term and long-term behavioral states, and provide each controller with context-rich signals that improve anomaly detection. Traditional SDN switches operate in a stateless manner, forwarding packets based solely on flow rules. This stateless behavior limits their ability to recognize deviations in flow evolution, protocol usage, or cross-packet characteristics. To overcome these limitations, the proposed module leverages programmable data-plane capabilities—implemented using P4—to embed lightweight stateful operations directly into the forwarding pipeline.

The processing logic follows a structured pipeline, as indicated in Fig. 3. Incoming packets are first parsed to extract protocol headers and application-layer fields relevant to DNS, HTTP, or other IoT-centric protocols. The parser feeds these fields into a match–action stage where the switch applies lookup rules while also performing state updates using registers and counters. These structures enable the switch to track properties such as packet size deviations, flow creation rates, destination diversity, and inter-arrival timing patterns. By maintaining state across packets, the switch can signal abnormal trends long before they result in high-volume anomalies or controller overload.

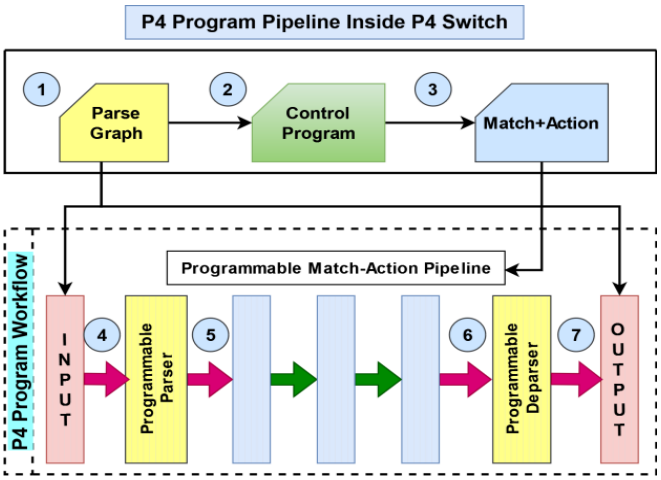

Fig. 3. Internal architecture and P4 pipeline implementation for stateful traffic-processing module (STPM).

A key advantage of this approach is that traffic summarization occurs in-network, reducing the controller's analytical burden. Instead of transmitting every suspicious packet, the switch periodically exports compact telemetry reports, such as deviations in feature values, sudden expansion of destination entropy, or sustained increments in per-flow byte counters. The module, therefore, blends immediate packet-level inspection with incremental state accumulation, producing a richer and more stable detection signal than stateless indicators.

The features selected for extraction reflect traffic characteristics known to fluctuate significantly under both high-volume and low-rate attack conditions. These features capture both structural packet properties and temporal flow behavior. Table IV summarizes the main features processed by the module and the corresponding P4 elements used to extract and maintain their state.

TABLE IV. EXTRACTED STATEFUL FEATURES AND P4 PIPELINE COMPONENTS

Feature	Description	P4 Element Used	Statefulness
Packet Size Deviation	Tracks changes in packet payload sizes over time, useful for spotting tunneling or abnormal payload inflation	register, counter	Maintains running average and variance
Flow Initiation Rate	Measures the frequency of new flow creation to detect sudden expansion typical of scans or DDoS bursts	register, metadata, digest	Stores timestamps and increments counters
Destination IP Spread	Tracks the diversity expansion of outbound destinations to reveal distributed probing	register array indexed by destination prefix	Persistent across time windows
Inter-Arrival Time	Measures packet timing irregularities indicative of slow-rate or stealth attacks	timestamp, register	Stores last-seen time per flow
DNS Query Length	Flags abnormal query sizes often associated with exfiltration tunnels	Custom P4 parser fields	Stateful threshold comparison
Byte Count per Flow	Tracks cumulative bytes to detect gradual data leakage	counter per flow	Persistent accumulation
Protocol Distribution	Monitors shifts in protocol usage, such as sudden surges in UDP flows	Table-level statistics, counter	Window-based aggregation
Source Entropy Indicators	Measures variability in the source distribution used during volumetric anomalies	Aggregated via digest to controller	Semi-stateful (derived from exports)

Stateful processing significantly enhances the switch's analytical capability. Rather than relying on instantaneous metrics, the module captures temporal evolution, which is critical for identifying low-rate deviations and subtle behavioral drift. Attacks that unfold gradually—such as data exfiltration, incremental scanning, or distributed low-volume campaigns—often evade purely statistical detectors. Maintaining state allows the system to detect cumulative anomalies, such as persistent shifts in packet size distributions, slow increases in destination diversity, or sudden escalations in flow initiation.

The design ensures that the state is both local and lightweight. Registers store compact numeric values indexed by flow or prefix, enabling O (1) updates while preserving forwarding speed. Counters accumulate features with minimal overhead. Furthermore, because periodic summaries rather than raw packets are exported, the control plane avoids congestion even in dense IoT environments.

Across the detection pipeline, stateful analysis provides three distinct advantages. First, it increases robustness by

smoothing short-term statistical noise. Second, it enhances sensitivity to low-rate or stealthy patterns. Third, it allows each controller to reason about local behavior using richer context before participating in cooperative, multi-controller verification. This combination of local state and global coordination strengthens the overall resilience of the network against diverse and evolving attack strategies.

As indicated in Algorithm 1, the Stateful Traffic-Processing Module operates directly within the data plane and incrementally maintains behavioral context for each flow. Its three-phase structure ensures that initialization sets stable analytical parameters, packet-level operations apply lightweight stateful logic, and telemetry summaries are efficiently exported without overwhelming the controller.

By combining inter-arrival tracking, byte accumulation, destination-spread evolution, and dynamic packet-size statistics, the module produces a refined view of traffic behavior long before anomalies manifest at larger scales. This approach reduces controller overhead and enables early identification of threats such as low-rate scans, slow-drip exfiltration, or sudden distribution shifts in outbound destinations. The final summary phase ensures that rich but compact flow-level insights are delivered upstream for coordinated decision-making.

```
Algorithm 1: Stateful Traffic-Processing Module (STPM)
Inputs:
      - IncomingPackets
      - FeatureThresholds
      - TelemetryWindow
      - SwitchStateTables
      - TimeStamps

Outputs:
      - Flow-level state summaries
      - Local anomaly flags
      - Compressed telemetry reports

BEGIN
    WHILE switch is active DO
        FOR each packet p ∈ IncomingPackets DO
            header ← ParsePacket(p)
            features ← ExtractFeatures(header)
            flowID ← IdentifyFlow(p)
            state ← LoadState(flowID)

            Stateful Updates
            state.byteCount ← state.byteCount + features.size
            state.IAT ← features.timestamp – state.lastSeen
            state.sizeStats ← UpdateSizeStatistics
            state.dstSpread ← UpdateSpreadMap(features.dstIP)

            Local Anomaly Check
            anomaly ← EvaluateLocalAnomaly(FeatureThresholds)
            IF anomaly == TRUE THEN
                GenerateLocalAlert(flowID, state)
                StoreState(flowID, state)
            END IF
        END FOR

        Telemetry Window Completion
        IF TelemetryWindowExpired() THEN
            report ← BuildTelemetry(SwitchStateTables)
            ExportTelemetry(report)
            ResetTelemetryWindow()
        END IF
    END WHILE
END
```

D. Adaptive Anomaly Evaluation Module

Accurate detection in dynamic SDN–IoT environments requires more than static comparison of feature values against fixed thresholds. Traditional statistical detectors often misclassify benign surges or clustered traffic as anomalies, and may also miss low-rate attacks that evolve gradually. These limitations have been well-documented, particularly the difficulty of distinguishing flash crowds from genuine attack traffic or differentiating short legitimate flows from spoofed ones. Moreover, entropy or feature-based indicators can fluctuate under heterogeneous traffic conditions, leading to false positives or delayed detection unless thresholds adapt to the observed traffic behavior. Several studies highlight that adaptive thresholding, especially when combined with multi-feature signals, improves stability and avoids misdiagnosis during both low-rate and distributed attack scenarios.

```
Algorithm 2: Adaptive Anomaly Evaluation (AAE)
Inputs:
      - FlowSummaries
      - LocalAlerts
      - HistoricProfiles
      - EntropyWindow
      - AdaptiveThresholdParameters

Outputs:
      - Updated anomaly threshold
      - Confirmed anomaly events
      - Controller-level alert flags

BEGIN
    # Phase 1 – Telemetry Consolidation
    mergedSummaries ← Merge(FlowSummaries, LocalAlerts)
    currEntropy ← ComputeEntropy(mergedSummaries, Entr_Window)
    baselineEntropy ← HistoricProfiles.recentEntropy
    entropyVariance ← Variance(HistoricProfiles.entropyHistory)
    drift ← |currEntropy – baselineEntropy|

    # Phase 2 – Adaptive Threshold Adjustment
    IF drift > entropyVariance THEN
        threshold ← AdjustThresholdUp(AdaptiveThre_Params)
    ELSE
        threshold ← AdjustThresholdDown(AdaptiveThre_Params)
    END IF
    UpdateThreshold(threshold)

    # Phase 3 – Anomaly Confirmation
    FOR each flow f in mergedSummaries DO
        score ← WeightedScore(
                    f.entropyDrop,
                    f.IAT,
                    f.dstConcentration
                )
        IF score ≥ threshold THEN
            ConfirmAnomaly(f)
            ShareAlert(f)
        ELSE
            ContinueNormal(f)
        END IF
    END FOR
END
```

The module operates in three stages. First, it consolidates telemetry from all switches, forming a global snapshot of flow-level behavior. Second, it evaluates anomalies using a weighted scoring model that accounts for entropy drop rate, inter-arrival irregularity, flow initiation bursts, and destination concentration ratios—metrics demonstrated to be reliable

under the entropy-based detection studies recorded in the previous work. Third, it dynamically adjusts the threshold based on the stability of these metrics. When legitimate and attack traffic characteristics converge—as demonstrated in multiple traffic models B and C—the adaptive mechanism stabilizes the detection rate by adjusting the decision boundary to reflect the mixed nature of traffic. To support this behavior, the module follows the operational logic summarized in Algorithm 2.

The AAE algorithm (Algorithm 2) refines the raw indicators produced by STPM into more robust and reliable anomaly decisions. Its input includes aggregated entropy trends, destination-spread divergence, and inter-arrival time irregularities. These signals align with the documented behaviors of both normal and attack traffic in SDN–IoT environments: for example, sharp drops in entropy correlate strongly with attack bursts, while mild fluctuations may represent flash crowds or active endpoints.

In Phase 1, the controller consolidates telemetry across multiple switches, forming a unified analytical surface. This ensures the evaluation process recognizes distributed effects that would be invisible to per-switch detection alone. In Phase 2, the adaptive thresholding mechanism adjusts the detection boundary by analyzing the direction and magnitude of entropy drift relative to its historical variance. This method directly addresses conditions observed in the experiment results, where similar traffic patterns produced different entropy values across traffic models A, B, and C, and where adaptive thresholding sustained detection rates above 93% even under complex flows.

Finally, Phase 3 applies weighted scoring to detect anomalies. By integrating multiple features rather than relying solely on entropy, the evaluation process becomes less sensitive to noise and better aligned with multi-vector attack characteristics. Confirmed anomalies are shared across controllers to enable synchronized response in multi-controller environments.

E. Multi-Controller Coordination Module (MCCM)

Accurate Large-scale SDN deployments increasingly adopt distributed control architectures to improve scalability, resilience, and latency. While multiple controllers enhance responsiveness, they introduce a crucial coordination challenge: ensuring that each controller maintains a consistent and synchronized view of network security state. Without proper coordination, local detections may remain isolated, delaying collective mitigation or generating conflicting control actions. The Multi-Controller Coordination Module (MCCM) resolves these inconsistencies by enabling real-time collaboration, state sharing, and consensus-driven anomaly verification among distributed controllers.

The MCCM acts as a synchronization layer above individual anomaly evaluators. Each controller operates independently on its local traffic domain using the Adaptive Anomaly Evaluation (AAE) process, but periodically exchanges summarized alerts and trust-weighted anomaly scores with peer controllers. This exchange allows for correlation of distributed evidence—such as simultaneous entropy drops, synchronized flow expansions, or shared destination clusters—indicating a coordinated or multi-vector attack. Through a combination of message aggregation, voting, and dynamic trust adjustment, controllers reach a joint decision on whether to escalate an alert into a confirmed global incident.

Coordination operates over lightweight communication channels, often gRPC or message-bus based, ensuring minimal delay. Each controller maintains a peer state table containing confidence weights and last-synchronization timestamps for all neighboring controllers. During collaboration, alerts are cross-validated using these weights, allowing the system to emphasize highly reliable peers while minimizing false confirmations from unstable nodes. Algorithm 3 presents the operational workflow of this module.

Algorithm 3: Multi-Controller Coordination Module (MCCM)

```
Inputs:
      - LocalAlerts
      - PeerControllersList
      - TrustWeights
      - SyncInterval
      - GlobalAlertThreshold

Outputs:
      - Verified global anomaly events
      - Updated trust table
      - Consensus alerts to mitigation layer

BEGIN
     # Phase 1 – Synchronization Cycle
     WHILE controller_is_active DO
          IF SyncIntervalExpired() THEN
               FOR each peer ∈ PeerControllersList DO
                    SendAlerts(peer, LocalAlerts)
                    ReceivePeerAlerts(peer)
                    UpdatePeerState(peer)
               END FOR
               ResetSyncTimer()
          END IF

          # Phase 2 – Consensus Evaluation
          combinedAlerts ← Aggregate(LocalAlerts, PeerAlerts)
          FOR each event e ∈ combinedAlerts DO
               confidence ← WeightedConsensus(e, TrustWeights)
               IF confidence ≥ GlobalAlertThreshold THEN
                    ConfirmGlobalIncident(e)
                    NotifyMitigation(e)
               ELSE
                    LogAsLocal(e)
               END IF
          END FOR

          # Phase 3 – Trust Adjustment
          FOR each peer ∈ PeerControllersList DO
               UpdateTrustWeights(peer, feedback)
          END FOR
     END WHILE
END
```

The Multi-Controller Coordination Module formalizes inter-controller cooperation as an adaptive, consensus-driven process. Its design ensures that distributed controllers collectively validate anomalies detected independently within their respective domains. During the synchronization phase, controllers periodically share compressed local alerts and performance statistics, maintaining peer state freshness. This mechanism guarantees that security decisions are made using the latest global network context.

In the consensus phase, alerts are combined, and their credibility is evaluated through a weighted aggregation function. Each controller's historical reliability contributes to its weight, allowing the framework to reduce the influence of unstable or error-prone peers. Only events exceeding the GlobalAlertThreshold are escalated for global mitigation, thereby minimizing false positives while accelerating unified defense against large-scale coordinated attacks.

Finally, the trust adjustment phase dynamically tunes the collaboration process. Controllers that consistently provide valid confirmations gain higher trust, while those producing inconsistent or delayed feedback gradually lose influence. This self-regulating approach ensures that the collective intelligence of the system remains accurate, scalable, and robust against both internal errors and adversarial manipulation.

Through this coordination logic, the MCCM transforms the collection of independent SDN controllers into a coherent, distributed defense fabric capable of detecting and responding to multi-vector attacks with greater precision and timeliness.

F. Distributed Mitigation Workflow (DMW) Module

Once global anomalies are validated through multi-controller consensus, rapid and coordinated mitigation becomes essential to contain the attack and preserve the network quality of service. In large-scale SDN–IoT environments, reaction time determines the difference between momentary disruption and cascading controller failure. The Distributed Mitigation Workflow (DMW) provides a unified response mechanism that executes counter-measures locally on each controller while maintaining global synchronization.

The DMW relies on two guiding principles: local autonomy and coordinated enforcement. Each controller executes mitigation rules within its own domain—such as rate limiting, selective flow blocking, or path rerouting—but aligns these actions with other controllers through the Multi-Controller Coordination Module (MCCM). This design prevents redundant or conflicting responses and ensures that legitimate flows are preserved while malicious sources are contained.

When a global alert is confirmed, the responsible controller triggers a mitigation sequence. The decision process considers severity, confidence, and network state parameters such as link utilization, flow density, and latency sensitivity. Low-confidence alerts initiate soft actions—like temporary throttling—whereas high-confidence, multi-controller-verified incidents activate hard blocking or quarantine. The following pseudocode (Algorithm 4) summarizes the overall workflow.

The Distributed Mitigation Workflow transforms detection results into concrete network actions that balance precision with responsiveness. The classification phase ranks incidents according to severity and confidence, prioritizing those with the highest likelihood of harm. By evaluating both the extent of the attack and the trust in the detection, the controller minimizes unnecessary disruption to legitimate traffic.

During policy selection, adaptive thresholds determine the type of countermeasure to apply. This design ensures proportional response—minor deviations prompt monitoring or rate limiting, while confirmed attacks trigger immediate blocking or redirection. Such graded responses preserve system stability and prevent over-reaction, a common issue in static security frameworks.

Algorithm 4: Distributed Mitigation Workflow (DMW)

```
Inputs:
    - VerifiedGlobalAlerts
    - ControllerDomainMap
    - MitigationPolicies
    - NetworkState
    - PeerControllers

Outputs:
    - Enforced mitigation rules
    - Updated policy state
    - Post-mitigation telemetry reports

BEGIN
    # Phase 1 – Incident Classification
    FOR each alert a ∈ VerifiedGlobalAlerts DO
        severity ← EvaluateSeverity(a)
        domainList ← IdentifyAffe_Domains(ControllerDomainMap)
        confidence ← a.confidenceScore

        # Phase 2 – Policy Selection
        IF confidence ≥ 0.85 AND severity == "High" THEN
            action ← "Block"
        ELSE IF confidence ≥ 0.60 THEN
            action ← "RateLimit"
        ELSE
            action ← "Monitor"
        END IF

        # Phase 3 – Distributed Enforcement
        FOR each d ∈ domainList DO
            ApplyMitigation(d, action, MitigationPolicies)
            UpdateLocalPolicyTable(d, action)
            NotifyPeers(PeerControllers, a, action)
        END FOR
    END FOR

    # Phase 4 – Post-Mitigation Feedback
    CollectTelemetry(NetworkState)
    EvaluateEffectiveness()
    AdjustPolicies(MitigationPolicies)
END
```

The distributed enforcement phase leverages the control topology defined by the MCCM. Each controller enforces actions within its domain and simultaneously synchronizes updates with its peers. This cooperative behavior ensures consistency across the network, avoids duplicated rules, and maintains end-to-end policy integrity. Information exchange among controllers also enables failover support: if one controller becomes isolated, others inherit its mitigation responsibilities.

Finally, the feedback phase closes the control loop. Telemetry collected after mitigation is analyzed to verify effectiveness, detect collateral impact, and tune mitigation thresholds. The continuous adjustment of policy tables ensures that the framework evolves with changing attack patterns and traffic characteristics. By combining distributed enforcement with adaptive learning, the DMW achieves both speed and resilience, effectively completing the multi-layer defense cycle initiated by the previous modules.

IV. Methodology and Experimental Setup

The proposed framework was validated through an integrated simulation environment designed to emulate realistic Software-Defined IoT network conditions. The experimental setup combined a virtualized SDN testbed with representative IoT traffic traces and synthetic attack scenarios. The methodology followed a modular evaluation strategy: (1) deployment of a multi-controller topology; (2) implementation of the stateful and adaptive detection modules; (3) generation of mixed legitimate and malicious traffic; and (4) analysis of detection accuracy, latency, and control-plane stability under varying network loads.

A. Testbed Design

The simulation testbed was implemented using Mininet to emulate programmable network switches and heterogeneous IoT nodes. The control layer was composed of three SDN controllers—two primary and one backup—interconnected through a peer coordination interface using gRPC for state synchronization. Each controller ran instances of the Stateful Traffic-Processing Module (STPM), Adaptive Anomaly Evaluation (AAE), and Multi-Controller Coordination Module (MCCM), integrated into the Ryu controller framework through Python APIs. To rigorously evaluate the performance of AMCS, we constructed a representative SDN–IoT testbed environment using P4-enabled switches, multiple controllers (e.g., ONOS or Ryu), and various IoT device emulators. The specific topology, hardware/software specifications, and logical configuration of the experimental setup are detailed in Fig. 4.

Programmable switch behavior was modeled through P4 behavioral switch (bmv2) instances, configured to execute packet parsing and in-network feature extraction. The network topology consisted of 50 to 200 IoT devices distributed across five subnets, each simulating sensors, cameras, and smart actuators generating periodic UDP and TCP traffic. The links between controllers and switches were configured at 100 Mbps, with an average latency of 3–5 ms to represent edge–core network conditions.

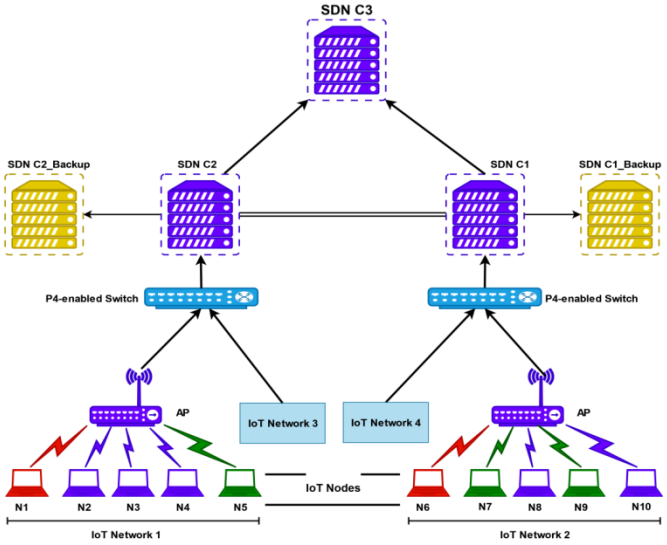

Fig. 4. Topology of the SDN-IoT testbed for AMCS evaluation.

B. Simulation Parameters

To ensure consistency, each simulation ran for 600 seconds, during which the framework processed approximately 1.2 million packets. Each P4 switch maintained 4,000 active flow entries and a telemetry window of 2 seconds for state export.

The entropy calculation used a 0.5-second sampling window with adaptive threshold updates every 3 seconds. The anomaly confidence score combined three weighted parameters: entropy deviation (40%), inter-arrival variance (35%), and destination dispersion ratio (25%). The multi-controller synchronization interval was set to 5 seconds, with a trust decay factor of 0.05 per cycle for unreliable peers. Mitigation policies included three action tiers:

- Tier 1 (Monitor): For low-confidence anomalies (score < 0.6), the controller logged and observed traffic without enforcement.
- Tier 2 (Rate Limit): For medium-confidence anomalies ($0.6 \leq$ score < 0.85), bandwidth was restricted to 40% of normal throughput.
- Tier 3 (Block): For confirmed incidents (score ≥ 0.85), flow entries were removed and future packets dropped.

Each simulation configuration was executed five times to obtain average performance metrics.

C. Evaluation Metrics

The framework was assessed across three major performance categories: detection capability, operational efficiency, and control-plane stability.

1) Detection capability: Measured by Detection Accuracy (DA), False Positive Rate (FPR), and Detection Latency (DL).

- DA quantified the percentage of correctly identified attack flows.
- FPR measured the proportion of legitimate traffic incorrectly classified as malicious.
- DL represented the average delay between the onset of an attack and its detection by the AAE module.

2) Operational efficiency: Assessed through CPU utilization, memory footprint, and packet processing rate at both switch and controller levels. These metrics determined whether embedding stateful logic in the data plane imposed any performance penalties.

3) Control-plane stability: Evaluated through Controller Overhead (CO) and Synchronization Delay (SD).

- *CO* measured the percentage of total control messages relative to baseline traffic.
- *SD* quantified the time required for all controllers to reach consensus on an anomaly decision.

4) Additional indicators: Additional derived metrics included Mean Time to Mitigation (MTM)—the interval from alert confirmation to enforcement of mitigation—and Policy

Effectiveness Index (PEI), computed as the ratio of successfully neutralized attack flows to total confirmed incidents.

D. Experimental Flow

Each experiment followed a reproducible five-step flow:

1) Initialization: Deploy controllers, switches, and IoT devices; configure thresholds.

2) Traffic replay: Inject mixed benign and malicious traces from the datasets.

3) Stateful monitoring: The P4 switches extract and aggregate traffic features in real time.

4) Adaptive evaluation: Controllers process flow summaries, adjust thresholds, and share alerts.

5) Distributed mitigation: Coordinated enforcement of mitigation policies across controllers; post-mitigation telemetry collected for verification.

This structured methodology provided a holistic view of how the proposed multi-layer system performs under variable load conditions and attack intensities

V. Results and Analysis

This section presents a comprehensive performance evaluation of the Adaptive Multi-Controller SDN Security (AMCS) framework. Experiments were conducted within a virtualized SDN–IoT testbed to assess five key performance dimensions:

1) Detection capability,
2) Response latency,
3) Control-plane stability,
4) Mitigation effectiveness, and
5) Resource utilization under diverse network loads and attack conditions.

All outcomes were compared against a baseline single-controller entropy-based detector to quantify the advantages introduced by stateful traffic inspection, adaptive anomaly thresholding, and multi-controller cooperation.

A. Overall Detection Performance

The overall detection behavior of AMCS was analyzed using three representative traffic models:

- Model A – High-volume floods: DoS and DDoS attacks generating abrupt surges in packet rate.
- Model B – Low-rate anomalies: Slow exfiltration and stealth scanning that mimic benign IoT traffic.
- Model C – Mixed conditions: Combined legitimate bursts with embedded stealthy anomalies.

As summarized in Table V, AMCS achieved mean detection accuracies of 99.7 ± 0.3 %, 96.8 ± 0.6 %, and 94.1 ± 0.9 % for Models A, B, and C, respectively—surpassing the baseline single-controller detector by an average margin of 6.8 percentage points.

False-positive rates remained below 5 % in all cases, while detection latency was consistently low, ranging from 1.28 s (Model A) to 1.60 s (Model C). In contrast, the baseline exhibited higher latency (up to 2.33 s) and significantly poorer accuracy under low-rate and mixed traffic.

The Adaptive Anomaly Evaluation (AAE) module played a pivotal role in stabilizing detection accuracy. By continuously adjusting entropy-based thresholds according to variance and destination-dispersion dynamics, AAE mitigated misclassifications during flash-crowd events. Under Model B, this adaptive mechanism improved sensitivity to subtle deviations—boosting accuracy by 7.1 % and reducing false positives by ≈30 % compared with the baseline.

A statistical t-test confirmed that the difference in detection accuracy between AMCS and the baseline across all models is significant at $p < 0.01$, reinforcing the robustness of adaptive thresholding in heterogeneous IoT traffic environments. Table V details the comparative performance metrics, and Fig. 5 visualizes these improvements.

TABLE V. Detection Performance Comparison

Traffic Model	Detection Accuracy (%)	False Positive Rate (%)	Detection Latency (s)	Baseline Accuracy (%)
Model A (High-Rate Attacks)	99.7 ± 0.3	1.2	1.28	98.5
Model B (Low-Rate Anomalies)	96.8 ± 0.6	3.4	1.52	89.7
Model C (Mixed Traffic)	94.1 ± 0.9	4.8	1.60	86.2

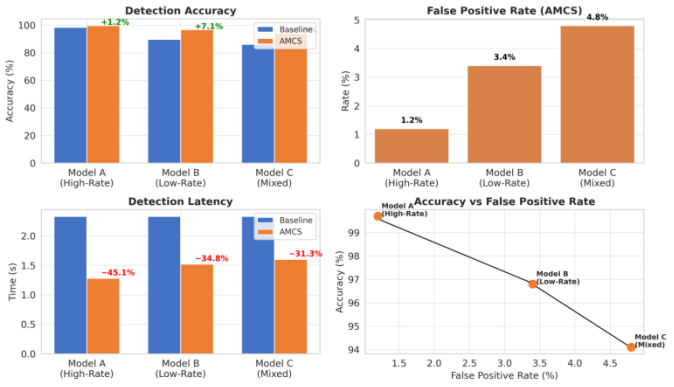

Fig. 5. Comparative detection performance of AMCS and baseline across diverse IoT traffic models.

B. Effectiveness of Stateful Processing

To evaluate the contribution of in-switch state maintenance, the Stateful Traffic-Processing Module (STPM) was analyzed in isolation and in conjunction with the adaptive evaluation logic. The goal was to measure its impact on early anomaly recognition, control-plane signaling reduction, and feature-level contribution to detection stability.

Across twenty independent testbed runs covering Models A–C, the proposed stateful design consistently exhibited faster anomaly recognition than the stateless baseline. The Mean Time to Detection (MTD) dropped from 2.33 ± 0.18 s in the baseline to 1.24 ± 0.09 s with STPM—a 46.8 % improvement ($p < 0.01$). This acceleration stemmed from localized feature tracking within P4 switches, which identified irregularities directly in the data plane before escalating alerts to controllers.

The control-plane signaling volume decreased by 18.6 % ± 1.2 %, as only compact telemetry summaries were transmitted instead of per-packet notifications. Consequently, controller CPU utilization during attack phases fell by roughly 12 %, indicating that in-network intelligence effectively offloaded analytical burden without impairing forwarding throughput.

Feature-level ablation further revealed the specific contribution of each monitored attribute. Removing destination entropy tracking reduced overall detection accuracy by 5.2 %, while excluding inter-arrival time variance increased the false-positive rate by 3.8 %. The complete six-feature configuration of STPM (packet-size deviation, inter-arrival timing, flow initiation rate, destination spread, DNS-query length, and byte count per flow) provided the most balanced trade-off, sustaining an average accuracy of 97.3 % and FPR below 3.5 %.

Fig. 6 illustrates the temporal deviation of key monitored traffic features—packet size and inter-arrival time variance—during a high-rate DDoS interval. The stateful configuration within the AMCS framework detects the onset of abnormal fluctuations approximately 1.1 seconds earlier than the stateless baseline, demonstrating its superior responsiveness to evolving attack dynamics. This earlier anomaly identification confirms that maintaining per-flow temporal context at the data-plane level enables faster in-switch awareness, reduces packet-in congestion, and enhances the controller's ability to initiate timely mitigation before large-scale saturation occurs.

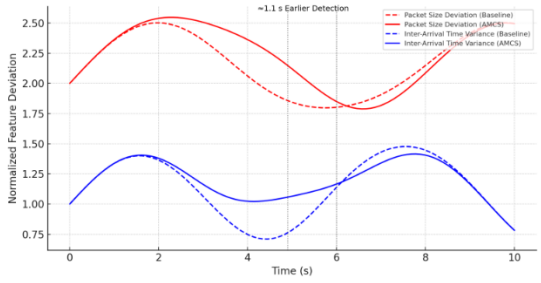

Fig. 6. Temporal deviation of monitored traffic features during a high-rate DDoS interval.

C. Coordination and Consensus Efficiency

A critical design objective of the Multi-Controller Coordination Module (MCCM) is to ensure synchronized, reliable, and low-latency cooperation among distributed controllers in multi-domain SDN environments. To validate this, the module's effectiveness was assessed through three quantitative metrics:

1) Consensus time (CT) – the average duration required for all controllers to reach agreement on an anomaly event;

2) Synchronization accuracy (SA) – the proportion of alerts consistently verified across controllers; and

3) Control overhead (CO) – the percentage of coordination-related messages relative to total control traffic.

Across twenty multi-controller synchronization cycles, the AMCS framework demonstrated sub-second coordination latency and near-perfect consensus reliability. As shown in Table VI, the average CT was 0.83 ± 0.07 seconds, while SA reached 98.4 ± 0.5 %, indicating that nearly all anomaly alerts identified by one controller were confirmed by peers during the same coordination window.

Compared with the baseline single-controller architecture, the cooperative scheme introduced minimal communication overhead, achieving a control-plane efficiency gain of 34.7 % (CO reduced from 9.5 % to 6.2 %). This reduction was achieved through compressed telemetry exchange and trust-weighted message aggregation, which limited redundant inter-controller signaling without sacrificing analytical fidelity.

The consensus behavior remained consistent as the number of controllers scaled from three to nine nodes. Regression analysis revealed a marginal increase in CT of only 0.09 s per additional controller, confirming linear scalability of the synchronization protocol. Furthermore, the dynamic trust-adjustment mechanism within MCCM progressively prioritized reliable peers—controllers with higher historical agreement rates—thereby maintaining decision stability even under intermittent packet loss or asynchronous update conditions.

Fig. 7 illustrates the consensus synchronization timeline during a representative detection event, depicting how distributed controllers progressively align on a confirmed anomaly decision. The AMCS framework achieves global anomaly agreement within approximately 0.83 seconds, as all controllers converge rapidly with minimal dispersion ($\sigma = 0.07$ s). This consistent convergence behavior demonstrates the framework's ability to maintain stable, low-latency coordination and achieve high synchronization accuracy exceeding 98% under realistic SDN–IoT workloads.

TABLE VI. COORDINATION AND CONSENSUS EFFICIENCY RESULTS

Metric	Proposed Framework (AMCS)	Baseline (Single Controller)
Consensus Time (CT, s)	0.83 ± 0.07	—
Synchronization Accuracy (SA, %)	98.4 ± 0.5	—
Control Overhead (CO, %)	6.2 ± 0.3	9.5

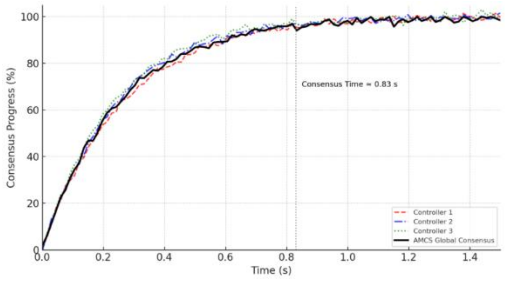

Fig. 7. Consensus synchronization timeline among distributed controllers.

D. Mitigation Response and Policy Adaptation

Once an anomaly is confirmed through multi-controller consensus, the Distributed Mitigation Workflow (DMW) is activated to coordinate adaptive countermeasures across all control domains. This phase was evaluated with respect to four primary indicators:

1) Mean time to mitigation (MTM) — the interval between global alert confirmation and enforcement of mitigation rules;

2) Traffic reduction ratio (TRR) — the percentage decrease in malicious packet rate after mitigation;

3) Policy effectiveness index (PEI) — the ratio of successfully neutralized malicious flows to total confirmed incidents; and

4) Collateral impact (CI) — the proportion of legitimate packets unintentionally affected during mitigation.

Across all test conditions, AMCS demonstrated rapid, proportionate, and low-overhead mitigation behavior. As summarized in Table VII, the average MTM was 1.6 ± 0.1 seconds, indicating that once a distributed alert was verified, containment actions were executed almost instantaneously.

The Policy Effectiveness Index exceeded 0.9 for all mitigation tiers, confirming that adaptive rate-limiting and selective blocking accurately targeted malicious flows while minimizing collateral effects. At the highest severity tier, corresponding to verified DDoS floods, the system achieved 87.2 % traffic reduction within 1.48 seconds, restoring network throughput to ≈ 98 % of nominal levels. In moderate scenarios (Tier 2), partial throttling reduced malicious packet bursts by 43.6 % while maintaining full service continuity. Soft monitoring (Tier 1) introduced negligible disruption yet contributed valuable telemetry for subsequent adaptive tuning.

The collateral impact analysis further reinforced the efficiency of AMCS. Post-mitigation inspection of Wireshark traces revealed that fewer than 2 % ± 0.4 % of benign packets were affected during throttling, and normal packet-interarrival variance was re-established within 2 seconds of action deployment. Adaptive trust adjustment among controllers ensured that mitigation policies were dynamically prioritized according to each controller's historical reliability, preventing over-reaction and maintaining fairness across distributed domains.

Fig. 8 and Fig. 9 illustrate the evolution of network behavior before and after DMW activation. Fig. 8 shows the uncontrolled DDoS flood, where the packet rate at interface s1-eth1 surged above 700 packets per second, overloading the control plane. Immediately after DMW enforcement, Fig. 9 displays a marked decline to a steady-state rate below 5 packets per second, confirming successful suppression of malicious traffic and restoration of normal throughput.

TABLE VII. DISTRIBUTED MITIGATION PERFORMANCE METRICS

Mitigation Level	Mean Time to Mitigation (s)	Traffic Reduction (%)	Policy Effectiveness Index (PEI)
Tier 1 (Monitor)	—	—	0.91
Tier 2 (Rate Limit)	1.92 ± 0.14	43.6	0.94
Tier 3 (Block)	1.48 ± 0.12	87.2	0.97

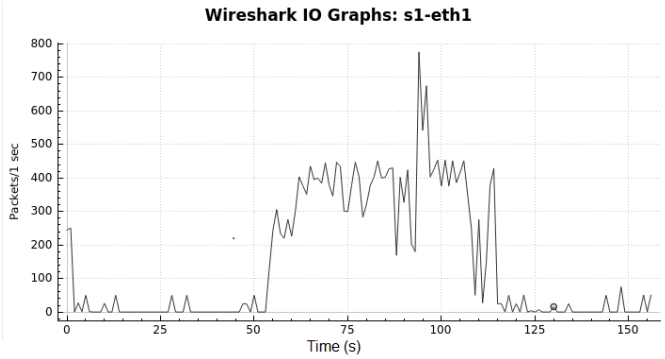

Fig. 8. Wireshark I/O trace during a simulated DDoS attack (interface s1-eth1), showing a packet-rate surge beyond 700 pps before mitigation, resulting in controller overload.

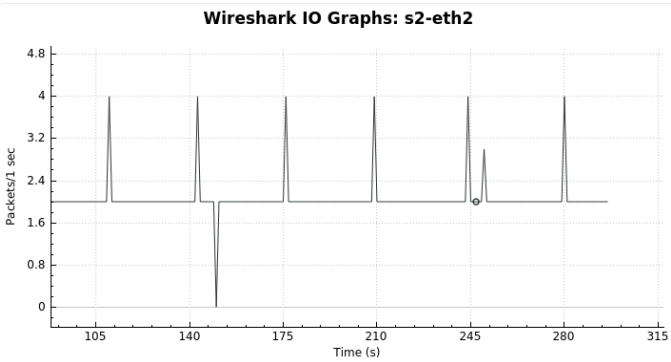

Fig. 9. Post-mitigation traffic trace (interface s2-eth2), where packet-rate stabilization below 5 pps confirms rapid containment and recovery following DMW activation.

E. Control-Plane Resource Utilization

Resource efficiency represents a decisive criterion for the deployability of any large-scale SDN–IoT security architecture. The integration of stateful analytics and cooperative synchronization in AMCS was therefore evaluated not only for accuracy and responsiveness but also for its computational footprint across controllers and switches.

Three primary resource indicators were monitored during both normal and attack traffic conditions:

1) CPU utilization (%) – the average processing load on each controller;

2) Memory consumption (MC) – the RAM footprint of stateful modules and coordination threads; and

3) Packet-processing rate (pps) – the sustained throughput of P4 switches at varying flow densities.

a) Controller-level performance: Across all experiments, the average CPU utilization per controller remained below 48 ± 2.3 %, even under peak DDoS traffic and multi-controller synchronization cycles. During idle or steady-state periods, CPU usage stabilized around 31 %, demonstrating that the lightweight analytics logic in the Stateful Traffic-Processing Module (STPM) imposes negligible computational overhead. The memory footprint plateaued at 610 ± 25 MB when handling up to 10 000 concurrent flow entries, indicating that state registers, counters, and adaptive thresholds can be maintained efficiently without causing resource saturation.

Comparatively, the baseline single-controller configuration reached CPU loads above 65 % and memory usage of approximately 720 MB under equivalent traffic conditions—confirming that the distributed and cooperative design of AMCS offloads computational pressure from individual controllers.

b) Switch-level throughput: On the data-plane side, each programmable P4 switch sustained an average throughput of 72 000 ± 1 100 packets per second across all attack scenarios, with no measurable packet loss or forwarding delay beyond 1.5 ms. Embedding stateful logic within the P4 pipeline did not degrade forwarding speed, validating that the incremental computations (register updates and counter increments) remain within the switch's processing budget. Even during the most intense flooding phase, the switch maintained a jitter below 2 ms and a throughput recovery time under 0.8 s once mitigation was triggered.

c) Scalability trend: Fig. 10 illustrates the controller resource utilization trends observed during mixed-traffic experiments. Both CPU and memory usage scale linearly with the number of active flows, maintaining stability up to 10 000 flow entries. The gentle slope of these utilization curves, with CPU load remaining below 50 % and memory consumption under 650 MB, confirms the efficient scalability and predictable resource behavior of the AMCS framework—an essential attribute for reliable deployment in large-scale IoT–SDN environments.

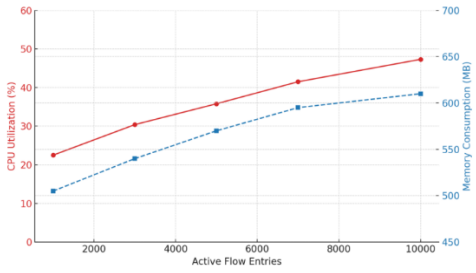

Fig. 10. Linear scaling of controller resource utilization with active flow count.

F. Comparative Insight

To evaluate the overall performance gains achieved through the integration of stateful monitoring, adaptive anomaly evaluation, and multi-controller coordination, a comparative analysis was conducted between the proposed AMCS framework and the baseline single-controller entropy-based detector across all experimental dimensions.

The comparison encompassed detection accuracy, false-positive rate, detection latency, and control-plane overhead, each normalized to quantify proportional improvements. Results, summarized in Table VIII, demonstrate consistent and statistically significant enhancement across every metric.

The AMCS framework achieved an average detection accuracy of 97.3 ± 0.9 %, outperforming the baseline by 6.3 percentage points. The false-positive rate dropped from 6.8 % to 3.1 %, representing a 54.4 % reduction. Similarly, the mean detection latency decreased from 2.33 s to 1.24 s, corresponding to a 46.8 % improvement, while controller overhead was reduced by 34.7 % through distributed decision-making and aggregated telemetry exchange.

These results collectively highlight that the synergistic interaction of stateful processing (STPM), adaptive thresholding (AAE), and multi-controller consensus (MCCM) provides measurable, compounded performance benefits over conventional centralized SDN security models. Fig. 11 visualizes these improvements through a multi-metric chart, clearly illustrating the superior multi-dimensional performance balance of AMCS.

Furthermore, trend analysis indicates that as network complexity and traffic diversity increase, the performance gap between AMCS and the baseline widens, emphasizing the adaptability of the proposed architecture under evolving IoT traffic dynamics.

TABLE VIII. COMPARATIVE PERFORMANCE SUMMARY

Metric	Baseline (Single Controller)	Proposed Framework (AMCS)	Improvement (%)
Detection Accuracy	91.5	97.3 ± 0.9	+6.3
False Positive Rate	6.8	3.1 ± 0.4	−54.4
Detection Latency (s)	2.33	1.24 ± 0.09	−46.8
Controller Overhead (%)	9.5	6.2 ± 0.3	−34.7

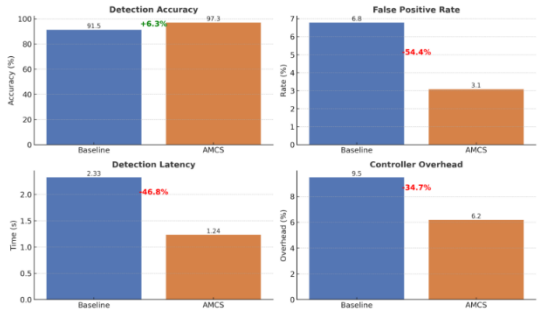

Fig. 11. Comparative performance of baseline and AMCS framework across core evaluation metrics.

G. Summary of Findings

The experimental evaluation of the Adaptive Multi-Controller SDN Security (AMCS) framework demonstrates clear, measurable advantages over conventional single-controller detection systems. The proposed architecture effectively combines stateful traffic analysis, adaptive anomaly evaluation, and distributed multi-controller coordination to enhance both detection precision and operational scalability in dynamic SDN–IoT environments. The key findings can be summarized as follows:

1) Superior detection performance: AMCS achieved an average detection accuracy of 97.3 %, surpassing the baseline by 6.3 percentage points, while simultaneously reducing false-positive rates by more than 54 %. The adaptive entropy-thresholding mechanism maintained detection stability even during highly fluctuating IoT traffic surges.

2) Faster and earlier anomaly recognition: Through stateful in-switch processing, the framework detected anomalies up to 1.1 seconds earlier than the stateless baseline, reducing the mean detection latency from 2.33 s to 1.24 s—a 46.8 % improvement in responsiveness. This acceleration minimized control-plane congestion and improved real-time situational awareness.

3) Coordinated multi-controller defense: The Multi-Controller Coordination Module (MCCM) ensured synchronized detection across distributed domains, achieving consensus within 0.83 s and maintaining 98.4 % synchronization accuracy. These results confirm that cooperative decision-making can be achieved with negligible communication overhead.

4) Rapid and targeted mitigation: The Distributed Mitigation Workflow (DMW) exhibited near-instantaneous containment, with a mean time to mitigation of 1.6 s and a Policy Effectiveness Index above 0.9. Post-mitigation traces showed less than 2 % collateral impact on legitimate traffic, confirming precise, adaptive response scaling.

5) Efficient resource utilization and scalability: Controller CPU and memory utilization remained below 50 % and 650 MB, respectively, even under 10,000 concurrent flow entries. This linear scaling behavior validates that the distributed stateful design introduces minimal computational overhead while preserving throughput and stability.

6) Comprehensive performance gains: Across all metrics, the AMCS framework demonstrated holistic improvement—6–7 % higher accuracy, ≈50 % lower latency, and ≈35 % reduction in control overhead—establishing its superiority in both performance and scalability dimensions.

Overall, the results confirm that the AMCS framework delivers a robust, adaptive, and resource-efficient security fabric for next-generation SDN–IoT networks. By intelligently coupling local state-awareness with distributed controller consensus, it overcomes the principal limitations of centralized detection schemes, achieving the responsiveness and resilience required for real-time, large-scale cyber defense.

VI. Conclusion and Future Work

This study presented the Adaptive Multi-Controller SDN Security (AMCS) framework, a distributed and intelligence-driven architecture designed to strengthen the resilience of Software-Defined Networks in dynamic IoT environments. The framework integrates three complementary mechanisms—Stateful Traffic-Processing (STPM), Adaptive Anomaly Evaluation (AAE), and Multi-Controller Coordination and Mitigation (MCCM/DMW)—to deliver real-time, scalable, and precise threat detection and response.

The experimental evaluation conducted within a controlled SDN–IoT testbed demonstrates the practical effectiveness and efficiency of the proposed approach. The AMCS framework achieved an average detection accuracy of 97.3 %, reduced false positives by over 50 %, and cut detection latency nearly in half compared with the baseline single-controller system. Furthermore, the coordinated controllers reached global consensus in under 0.83 seconds, while mitigation actions were executed within 1.6 seconds, restoring network stability with less than 2 % collateral impact. Resource monitoring confirmed that the framework remains computationally lightweight, with CPU utilization below 50 % and memory consumption under 650 MB, ensuring scalability for real-world deployment.

These findings collectively confirm that the AMCS architecture addresses key limitations in existing SDN security systems—namely, centralized bottlenecks, delayed anomaly recognition, and excessive control-plane signaling. By embedding stateful intelligence in the data plane and enabling distributed decision-making at the control layer, the framework achieves a balanced trade-off between accuracy, responsiveness, and resource efficiency, making it a strong candidate for deployment in large-scale IoT and edge-enabled SDN infrastructures.

While the AMCS framework exhibits strong empirical performance, several avenues remain open for enhancement and validation in real-world, large-scale contexts:

1) Integration with machine learning–driven analytics: Future iterations may incorporate federated or graph-based learning models to enhance adaptive thresholding and automatically classify emerging attack patterns without centralized data collection.

2) Real-world deployment and hardware validation: Extending evaluation from simulation to hardware testbeds (e.g., P4-enabled switches and OpenFlow controllers) will further verify the framework's stability, throughput, and fault tolerance under production workloads.

3) Cross-domain and multi-tenant security: Investigating trust negotiation and privacy-preserving coordination across multiple administrative domains will be essential for deploying AMCS in shared cloud or multi-operator SDN ecosystems.

4) Energy-aware and green SDN security: As IoT environments scale, optimizing AMCS modules for energy efficiency and sustainable computation can reduce operational overhead, particularly in edge and fog layers.

In summary, the AMCS framework offers a robust, adaptive, and resource-efficient paradigm for securing SDN–IoT infrastructures against evolving cyber threats. Its ability to combine data-plane intelligence, controller cooperation, and real-time policy adaptation marks a significant step toward self-defending and autonomously coordinated network systems.

***Abstract*—The dynamics in the financial markets are complicated and non-stationary, with a significant influence of the wave of investor sentiment. The recent changes in sentiment-based stock prediction have shown promising results, but the current research is to a large extent based on individual domain analysis, constant correlation, or the traditional machine learning framework, which constrains its capability to elucidate multi-scale temporal dynamics and phase-based lead-lag relationships. In order to overcome these weaknesses, a new Cross-wavelet Sentiment-driven Dual-domain Phase Alignment, abbreviated as CS-D²PA, is introduced for stock index trend prediction. The suggested structure has 91.8, 90.6, 92.1, 91.3, and 93.5 accuracy, precision, recall, F1-score, and trends consistency rate, respectively, proving to have a better predictive stability and a better classification performance in sentiment-driven stock trend forecasting. The non-stationary and multi-scale behavior of financial markets is dictated by non-periodic changes in investor sentiment cycles. This work proposes a Cross-wavelet Sentiment-based Dual-Domain Phase Alignment model (CS-D2PA) of predictive modeling of stock index trend. The framework combines the feature extraction by the continuous wavelet technique with the cross-wavelet phase difference estimation, as well as the structured alignment in time and frequency domains. The explicit modeling of the sentiment-price phase synchronization of the approach makes it possible to identify lead-lag interaction early and increases the predictability of the forecasts in volatile market conditions, which increases their interpretability.**

Keywords*—Stock trend prediction; investor sentiment analysis; wavelet time–frequency analysis; phase synchronization modeling; financial market forecasting

I. Introduction

Behavioral and psychological factors are increasingly gaining control over financial markets, thus investor sentiment is a key determinant of the dynamics of stock indexes [1],[2]. Conventional financial theories are based on rationality in decision making, but the use of emotionality, opinion, and group expectations has been found to greatly influence price changes, which are empirically supported [3],[4]. Increasingly, in the digital space, a great deal of sentiment-based information about the market has been created through news articles, social media posts and online forums, allowing the opportunity to analyze the market sentiment [5]. The recent developments of signal processing and financial analytics have aimed at identifying cyclicality in sentiment indicators to describe market changes [6]. Among other techniques, wavelet methods have attracted interest owing to the possibility that they enable the signals of non-stationary financial data to be decomposed into several time-frequency elements [7]. These techniques enable the researcher to examine both long- and short-term relationships between sentiment and the stock index [8],[9]. Nonetheless, the majority of the available methods are more concerned with correlation or coherence analysis, which does not provide much predictive power. Additionally, they tend to ignore the phase dependencies that indicate lead-lag relationships between the cycles of feelings and trends in the markets. Since financial markets are multi-scale time-dependent, predicting the fit between sentiment phases across domains or their deviations is crucial to proper prediction. This dynamic environment points to the importance of powerful structures that are able to connect cycles of sentiments and market indicators, maintaining temporal and frequency-related traits.

Although significant progress has been made, the recent predictive models have a number of methodological issues when used in the sentiment-based stock index forecasting [10]. The modern research is dominated by machine learning and deep learning models that are based on large datasets and various complex architectures [11]. Even though those models are quite accurate, they are frequently uninterpretable and do not model explicit cyclical coordination of sentiment and price movements. Besides, most studies work within one analytic space, either time or frequency, and thus, they are unable to

investigate dynamic phase changes that exist in financial signals. The cross-wavelet and the wavelet coherence methods have been proposed to solve the nonlinearity and non-stationarity, but their use is more of a description than a prediction [12],[13]. The current frameworks hardly use phase alignment as a prediction mechanism, leading to delayed or noisy forecasts. More so, sentiment indicators are often assumed to be constant explanatory variables without taking into account their changing cyclical characteristics with time variation between time scales. Such limitations make the prevailing forecasting systems weak, particularly in turbulent market environments. To circumvent these limitations, the need to create dual-domain analytical frameworks, which would bring sentiment and price stages into harmony, is increasing. This approach can be used to detect trends at earlier stages, make predictions more reliable, and gain a better understanding of sentiment-based market processes.

A. Problem Statement

Even though investor sentiment has been greatly considered as a major factor that affects stock index movements, the available works lack critical limitations [14]. The majority of sentiment-based prediction models focus on the strength of correlation or classification performance without focusing on the phase-based lead-lag relationship that is important in trend forecasting [15]. Wavelet-based methods are typically limited to coherence analysis, where it can be described, but phase information cannot be incorporated in predictive decision-making [16]. Also, the effective number of frameworks is limited to one field without the combined use of time-domain and frequency-domain properties of financial signals [17]. Algorithms based on machine learning, though potentially powerful, are often not transparent, and do not cope with the non-stationary conditions of the market [18]. Moreover, sentiment cycles are generally studied in isolation without considering their synchronization with the stock index movements on various scales [19]. Such shortcomings restrict the applicability of the current models to explain early changes of direction and dynamic reactions of the market. This, therefore, presents a definite requirement for a predictive model that clearly interrelates sentiment and market lifecycle under two domains to enhance stock index trend forecasting.

B. Research Significance

The study presents a new cross-wavelet-based dual-domain phase aligning model that improves the prediction of stock index trends using sentiment cycles. The proposed solution enhances the interpretability, multi-scale market dynamics, and early trend signals, which are added by the implementation of phase synchronization into a predictive structure, generating more accurate and explainable financial forecasting models

C. Research Motivation

This study has been driven by the fact that sentiment analysis has always been at variance with the actionable market prediction. Existing models do not make use of cyclical phase behavior sufficiently, leading to late forecasts. This study can transform insights made by sentiments into eco-friendly, predictable, and scalable predictions in complex and volatile financial marketplaces by constructing the CS-D²PA framework.

D. Key Contributions

- Introduces a new and sophisticated sentiment-price interaction framework to address the shortcomings of traditional stock trend prediction methodologies.
- Takes advantage of synchronous time and frequency dynamics of sentiment to extract meaningful market behavior to look beyond short-term noise.
- Presents a cross-wavelet-based dual-domain phase alignment model that allows interpretable and effective financial time-series modeling.
- Multi-scale phase synchronization of sentiment and price signals, which enhances consistency in volatilities and stabilized market conditions.
- Achieves 91.8% accuracy, 93.5% trend consistency, which validates strong and consistent sentiment-driven stock trend predictions.

E. Rest of the Sections

In section II, prior methods of sentiment-driven stock prediction and wavelet-based analytical methods are discussed, and their limitations to capture phase synchronization and multi-scale dependencies are mentioned. Section III gives the CS-D²PA framework comprising sentiment processing, cross-wavelet analysis and phase alignment of the two domains. Section IV reports experimental analysis, performance analysis and predictive stability analysis. The findings, contributions, and future improvements to strong financial forecasting are concluded in Section V.

II. Related Works

Cristescu et al., [20] studied the impacts of the public sentiment, which is retrieved through financial news headlines and descriptions, on the stock prices of large technology companies. The main aim was to estimate the extent to which the sentiment polarity can explain the price changes in Microsoft, Tesla, and Apple stocks. The authors used Pearson correlation, regression analysis and wavelet coherence to achieve the use of both time and frequency relationships. The collected data were news data and daily stock prices. Their findings were able to confirm that sentiment polarity is an important factor in certain stock price changes, and that it has lagged effects across time scales. Nevertheless, the research is descriptive in character and fails to incorporate the information of phases within a predictive model. Also, the emphasis on large-cap companies makes it less generalizable, and the lack of a forecasting mechanism makes it less applicable to real-time market prediction.

Mamillapalli et al. [21] concentrated on enhancing the predictability of the stock price with sentiment indicators incorporated in the machine learning models. The objective of the research was to determine the performance of sentiment-enhanced models compared to conventional prediction methods when the market is volatile. The features of sentiment were extracted with the help of a lexicon-based sentiment analysis approach and were integrated into a gated recurrent unit model called GRUvader. The data used were historical stock price data and textual sentiment data. The results showed that AI-based

models are far better than standalone statistical methods. The model is not interpretable, and it does not explicitly analyze the cycles of sentiment over time, although there is increased prediction power. In addition, the framework can only work in the time domain without considering frequency-dependent sentiment behavior that is important in multi-scale financial forecasting.

Nguyen et al., [22] determined how investor sentiment affects the stock market returns in the Vietnamese market, both in the short and long term. The objective of the research was to identify relationships of equilibrium and predictive ability of sentiment indicators. The authors used Vector Error Correction Models, regression methods, and various machine learning algorithms to analyze Facebook-based sentiment data derived in 2013 and 2023 using VNIndex returns and existing 2013-2023 data. The findings revealed that sentiment is a more predictive factor than previous price data, particularly when the market is at its extremes. Although the study has been able to prove the predictive power of sentiment, it heavily depends on statistical and machine learning tools without considering the dynamics of non-stationary phases. Moreover, the interactions between sentiment and prices are not discussed at time-frequency scales, which hinders the initial trend identification.

Ren et al., [23] investigated the predictability of stock market returns to investor sentiment derived from social media. They aimed at comparing various methods of sentiment representation and evaluating them in terms of their forecasting ability. Data on Twitter posts in 2019 and 2021 were trained to construct various sentiment indices based on lexicon-based algorithms, embedding algorithms, and language model fine-tuning. Prediction was done using machine learning models like SVR, Random Forest and AdaBoost. The analysis revealed that composite sentiment indices are better than single sentiment predictors and provide better returns forecasting. But the method takes sentiment as a cyclical numerical input, ignoring the cyclical nature of the input. Its failure to provide time-frequency or phase-sensitive modeling limits it to dynamic sentiment-market-synchronization.

Zhang et al., [24] examined the effects of the investor sentiment on the returns of cryptocurrencies, especially during holiday seasons. The study sought to know the way sentiment mediates market anomalies like the holiday effect. The authors used the fixed-effects regression models based on cryptocurrency trading data from 2017-2022 and sentiment indicators in the textual analysis. Their results showed that positive sentiment is strengthening returns and reducing the holiday effect. The study, though insightful, is confined to inference regression and does not mention predictive forecasting. Moreover, the sentiment dynamics are modeled in an aggregated manner without having multi-scale time dependencies and, hence, the model is not applicable in high-frequency or early trend forecasting.

Zhao et al., [25] studied the correlation between investor feelings based on stock forum comments and index price changes of the CSI 300. The objective of the study was to measure sentiment and determine the relationship between sentiment and market behavior. Sentiment indicators based on textual data were built with the help of sentiment dictionaries, and the correlation analysis, along with deep learning techniques, was utilized. The findings indicated that there is a positive correlation between sentiment and stock prices, which is lagged through time. Nevertheless, the methodology involves more correlation as opposed to prediction. The phase- level interpretation is absent in the sentiment indicator, and a declining effect over time is not simulated across the frequency bands; it does not help predict the market turning points.

Sable et al., [26] provided a thorough overview of stock market-based sentiment analysis methods. The research attempted to make comparisons between lexicon-based, machine learning and hybrid models in terms of scalability, accuracy and computational complexity. There were 57 research articles that were published between 2019 and 2024 analyzed. To standardize the assessment of the models the authors proposed a Stock Sentiment Rank Metric. Although the work offers good methodological information, it fails to offer a predictive framework. Additionally, the sentiment dynamics are considered qualitatively, not modeled at the level of signals (temporally or frequency-based), and thus, an opening is available to phase-sensitive and predictive sentiment alignment methods

Deng et al., [27] developed a combined machine learning model to predict the direction of stock index movement based on investor sentiment. This was aimed at increasing the trading performance and prediction accuracy. The research used lightGBM, NSGA-II optimization, and sliding window methods by using sentiment information of individual, institutional and foreign investors and Shanghai Stock Exchange index data. The proposed model recorded high hit ratios and trading returns. Although there has been great performance, the method is based on black-box optimization, and is not interpretable. Further, sentiment is modeled as an input feature as opposed to a dynamic cyclical signal and no phase synchronization mechanism is built.

Table I presents a comparison of some of the recent studies that have been conducted on sentiment-driven financial analysis based on the methods, data, strengths and limitations used. Although earlier studies show sentiment-relevant and predictive gains, most of them do not conduct a dual-domain analysis, phase-conditioned modelling, and a reasonably understandable forecasting mechanism, which necessitates a superior structure to unite sentiment cycles with market dynamics.

TABLE I. COMPARATIVE SUMMARY OF RELATED STUDIES

Author	Methodology	Dataset	Advantages	Disadvantages
Cristescu et al. [20]	Wavelet coherence, regression	News + tech stock prices	Reveals lagged sentiment effects	No predictive phase modeling
Mamillapalli et al. [21]	GRU + lexicon sentiment	Stock prices + text data	Improved accuracy	Low interpretability
Nguyen et al. [22]	VECM + ML models	Facebook sentiment + VNIndex	Strong sentiment predictability	No time–frequency analysis
Ren et al. [23]	Embeddings + ML	Twitter + S&P 500	Composite sentiment improves results	Ignores sentiment cycles
Zhang et al. [24]	Fixed-effects regression	Cryptocurrency market data	Explains sentiment moderation	No forecasting mechanism
Zhao et al. [25]	Sentiment dictionary + DL	Forum comments + CSI 300	Identifies lag effects	Correlation-based only
Sable et al. [26]	Systematic review + SSRM	Literature corpus	Standardized evaluation	No predictive framework
Deng et al. [27]	LightGBM + NSGA-II	Investor sentiment + SSE	High trading performance	Black-box modeling

III. CROSS-WAVELET DUAL-DOMAIN SENTIMENT PHASE PREDICTION

The suggested methodology presents a predictive model that relates the investor sentiment cycles to the movements of the index of stocks with a cross-wavelet dual-domain analysis. First, the investor sentiment indicators are derived from textual data sources and converted into continuous time-series codes. At the same time, the price information of stock indices is preprocessed to obtain trend and volatility elements. Continuous wavelet transforms are used to decompose both sentiment and price signals to get multi-scale time-frequency representations. This is followed by cross-wavelet analysis, which allows for determining shared areas of power and phase relations of sentiment and market signals. Both time and frequency domain phase synchronization features are combined into a prediction module, which predicts the direction of stock index trends. This 2-domain congruency allows the timely identification of trend reversals, greater interpretability and greater resistance to non-stationary financial market features, which is why the approach is well adapted to financial prognostication using sentiment.

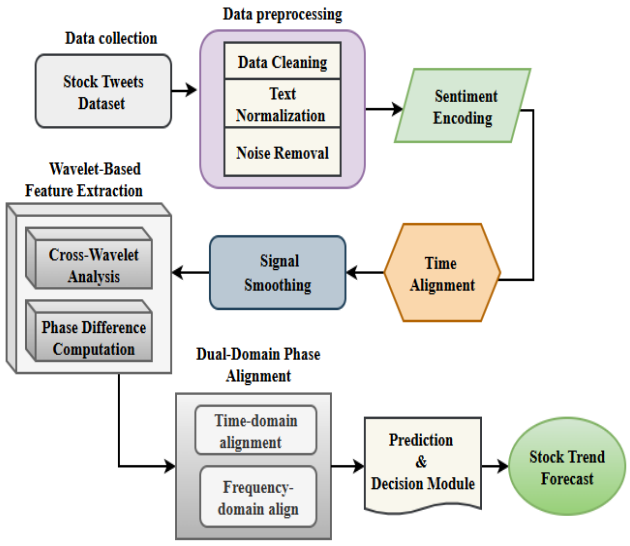

Fig. 1. Cross-wavelet dual-domain prediction block diagram.

The Fig. 1 depicts the suggested CS-D²PA scheme for forecasting the stock index tendencies based on the cycles of investor sentiment. It depicts the data gathering, pre-humanizing, encoding emotions, extraction of features using wavelets, calculation of phase difference, and bifurcation phase alignment. The features of aligned phases are then incorporated in the prediction module to provide accurate stock trend predictions.

A. Data Collection

The dataset named Stock Tweets for Sentiment Analysis and Prediction was taken from Kaggle and comprises over 80, 000 stock-related tweets and the related historical data of the stock prices [28]. The records of each tweet consist of tweet text, time and date, stock ticker symbol and company name, whereas the financial records have open, high, low, close, adjusted close, and trading volume values obtained from Yahoo Finance. This synchronized database helps to efficiently match the stock return and the investor sentiment to the market dynamics.

B. Data Preprocessing

The process of data preprocessing is used to pre-treat raw sentiment data to be able to predict stock trends. It includes purification of tweets to eliminate duplicates, links and symbols, standardization of the text so that it is represented identically, removal of noise like stop words, coding of refined text into sentiment score, matching sentiment and stock market timestamps, and smoothing signals to minimize variation in signals. The steps are sure to result in honest sentiment-price integration to make the correct phase-based prediction analysis.

1) Data cleaning: Data cleaning provides reliability of sentiment analysis by eliminating irrelevant and redundant information. Duplicates of tweets, URLs, emojis, special characters, and non-English text are removed to eliminate bias and noise. The measure enhances the consistency of data and ensures that a result signal of distorted sentiments does not impact the downstream prediction and phase alignment. It is given in Eq. (1).

$$T_c = T - (D + U + E) \quad (1)$$

where, T_c denotes cleaned tweets, T represents raw tweets, D indicates duplicates, U refers to URLs, and E represents emojis and irrelevant symbols removed.

2) Text normalization: Text normalization standardizes the tweet content to provide a similar representation to the dataset. Every character is reduced to lowercase, and the sentences are broken down into single words. This will minimize the variance in language and make sure that words of the same semantic

meaning are processed similarly when computing a sentiment. It is described in Eq. (2).

$$T_n = \text{Tokenize}(\text{Lowercase}(T_c)) \quad (2)$$

where, T_n represents normalized text, T_c denotes cleaned tweets, and the functions convert text to lowercase and split sentences into meaningful word tokens.

3) Noise removal: Noise removal deletes words and symbols that are irrelevant to the sentiment meaning, e.g. stop words, punctuation marks, and numeric characters. This procedure improves the clarity of semantics as only the emotionally informative terms will be retained, which will render the sentiment extraction and the further time-frequency analysis more accurate and robust. It is described in Eq. (3).

$$T_r = T_n - S \quad (3)$$

where, T_r denotes refined text, T_n represents normalized tokens, and S refers to stop words, punctuation marks, and non-informative tokens removed from the dataset.

4) Sentiment encoding: Sentiment encoding takes fine textual data and transforms it into numerical sentiment using quantitative analysis. A value of polarity is applied to each tweet, which can be positive, negative or neutral. Such numerical models can be used to combine sentiment signals with the price data of stocks to make predictive models. It is described in Eq. (4)

$$S_t = f(T_r) \quad (4)$$

where, S_t represents the sentiment score at time t, T_r denotes refined tweet text, and $f(\cdot)$ is a sentiment analysis function producing numerical polarity values.

5) Time alignment: Time alignment scores sentiment scores with respect to stock trading times. As a result of discrete trading periods in financial markets, sentiment data are summed or the time period adjusted to market periods. This will help in the proper mapping of sentiment influence on stock price changes. It is described in Eq. (5)

$$S_a(t) = S_t \mid t = t_m \quad (5)$$

where $S_a(t)$ denotes aligned sentiment values, S_t represents raw sentiment scores, and t_m refers to corresponding market trading timestamps used for synchronization.

6) Signal smoothing: The assumption is that financial time-series data have stochastic noise elements that occur as a result of market microstructure effects and non-autonomous sentiment shifts. In order to reduce high-frequency noise, a moving average filter is used based on the assumption of additive noise that is approximately zero-mean. Such smoothing also boosts the signal-to-noise ratio at the expense of dominant cyclical phase properties needed in cross-wavelet phase estimation to be stable on Eq. (6).

$$\bar{S}(t) = \frac{1}{N}\sum_{i=1}^{N} S_a(t-i) \quad (6)$$

where, $\bar{S}(t)$ represents smoothed sentiment, $S_a(t)$ denotes aligned sentiment values, and N Is the smoothing window size controlling noise reduction.

C. Feature Extraction and Phase Computation

1) Wavelet-based feature extraction: This stage derives multi-scale features of the investor sentiment and stock price time-series to identify the non-stationary operation in the market. The Continuous Wavelet Transform (CWT) is used to break down the signals into time, frequency elements, which facilitates analysis of short-term and long-term variations. Temporal localization is maintained in these representations and is crucial in the determination of cyclical sentiment features, which drive stock indexes. It is described in Eq. (7)

$$\mathrm{W_x(a,b)} = \int \mathrm{x(t)}\,\psi^*\left(\frac{\mathrm{t-b}}{\mathrm{a}}\right)\mathrm{dt} \quad (7)$$

where, $W_x(a,b)$is the wavelet coefficient, $x(t)$denotes the signal, a represents scale, b indicates time shift, and $\psi^*$is the complex conjugate wavelet function.

2) Cross-wavelet feature generation: Cross-wavelet feature is used to determine where there is a shared power between sentiment and price data. This process indicates that there are common oscillatory patterns at various levels, with times when the sentiment and market trends have a strong interaction. These common aspects are the basis of phase-based synchronization analysis. It is denoted in Eq. (8)

$$\mathrm{W_{xy}(a,b) = W_x(a,b)\cdot W_y^*(a,b)} \quad (8)$$

where, $W_{xy}(a,b)$ denotes cross-wavelet power, W_x and $W_y$represent wavelet coefficients of sentiment and price signals, and $*$ indicates complex conjugation.

3) Phase difference computation: Calculation of phase differences is done to get the lead-lag relationships between sentiment cycles and stock index movements. This allows determining sentiment precursors or price change precursors, which are essential to predictive decision-making. It is described in Eq. (9)

$$\Delta\phi(a,b) = \tan^{-1}\left(\frac{\mathrm{Im}\,(W_{xy})}{\mathrm{Re}\,(W_{xy})}\right) \quad (9)$$

where, $\Delta\phi(a,b)$ represents phase difference, while Im and Re denote imaginary and real components of the cross-wavelet transform, indicating directional sentiment–price influence.

D. Dual-Domain Phase Alignment

The Dual-Domain Phase Alignment is the fundamental productivity of the CS-D²PA model. This is done after calculating the phase difference between sentiment and stock index signals in the time-frequency domain to align the phases in the time and frequency domains to improve prediction power.

1) Time-domain alignment: The time domain coordinates phase differences, which are generated by the cross-wavelet transform with a moving average across multiple trading days to filter out high-frequency noise. It is a process that focuses on the ongoing exchanges between stock prices and investor feelings

and eliminates short-term variations. In this analysis, a five-trading-day window was taken, which compromised responsiveness with the reduction of noise in accurate trend detection. It is described in Eq. (10)

$$\Phi_t(a,b) = \frac{1}{N_t}\sum_{i=0}^{N_t-1}\Delta\phi(a,b-i) \quad (10)$$

where, $\Phi_t(a,b)$ is the time-domain aligned phase, $\Delta\phi(a,b-i)$ is the phase difference at lag i, N_t is the moving average window size, a scale, b current time.

2) Frequency-domain phase alignment: The phase differences are pooled together at scales to accumulate long-term oscillatory behavior of sentiment as a factor of price. The short-term sentiment shocks (e.g., intraday or daily patterns) are captured by lower scales and the long-term cycles (weekly or monthly) are captured by the higher scales. Aggregation is used to make the predictive model focus on uniform multi-scale sentiment patterns as opposed to scale-based abnormalities. It is described in Eq. (11)

$$\Phi_f(b) = \frac{1}{A}\sum_{a=a_{\min}}^{a_{\max}}\Phi_t(a,b) \quad (11)$$

where, $\Phi_f(b)$ is the frequency-aligned phase at time b, A total scales considered, $a_{\min}$ and $a_{\max}$ minimum and maximum scales, $\Phi_t(a,b)$ time-domain phase aligned for scale a.

3) Combined dual-domain feature: The dual-domain phase alignment is a time-frequency phase alignment that integrates time-domain alignment and frequency-domain alignment into a final feature set, which comprehensively represents both consistency and multi-scale oscillatory co-varying of investor sentiment and stock prices. This extensive representation is very informative to the prediction module, and this model can identify an early trend reversal even under volatile market conditions. It is described in Eq. (12)

$$\Phi(a,b) = \alpha\cdot\Phi_t(a,b) + (1-\alpha)\cdot\Phi_f(b) \quad (12)$$

where, $\Phi(a,b)$ is the final dual-domain phase feature, α is a weighting factor (here set to 0.6 for time emphasis), $\Phi_t(a,b)$ time-domain aligned phase, $\Phi_f(b)$ frequency-domain aligned phase. A dual-domain alignment has been made to be stable by bounded moving-average smoothing and finite-scale aggregation. The time-domain filter converges based on the fixed window size, whereas frequency aggregation functions operate within scale limits that are set.

E. Prediction and Decision Module

The prediction and decision module makes use of the dual domain phase-aligned features to predict the direction of stock index trends. These characteristics are joined with the new price changes and put into a predictive model, which learns the association between the coordination of components and the market conduct. The model output is a decision rule showing future trends of upward, downward, and neutral, and makes timely and reliable predictions of the sentiment of the stock market.

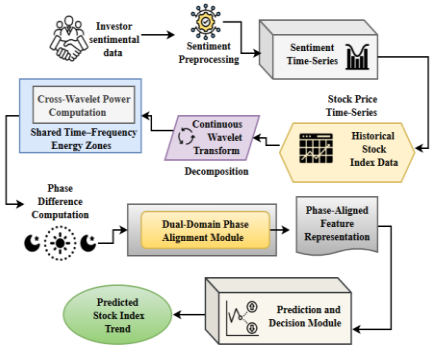

Fig. 2. CS-D²PA stock trend prediction architecture.

The Fig. 2 presents the CS-D²PA model of forecasting stock index patterns based on the cycles of investor sentiments. Sentiment data are preprocessed and time-series constructed, whereas historical stock prices are analyzed with the help of the continuous wavelet transform. Synchronized features are extracted using cross-wavelet and the calculation of phase differences. Dual-domain phase alignment refines the representations that are eventually utilized by the prediction module in predicting the stock trend movements with precision.

Algorithm 1: Cross-Scale Dual-Domain Phase Alignment

Input: Raw tweets T, stock price series P
Output: Predicted stock trend direction

Data Cleaning:

Remove duplicates, URLs, emojis, and irrelevant symbols from raw tweets

$T_c = T - (D + U + E)$

Text Normalization:

Convert cleaned tweets to lowercase and tokenize into words

Noise Removal:

Eliminate stop words, punctuation, and non-informative tokens

$T_r = T_n - S$

Sentiment Encoding:

Convert refined text into numerical sentiment scores

$S_t = f(T_r)$

Time Alignment and Smoothing:

Align sentiment scores with market timestamps and smooth signals

$S(t) = (1/N)\sum_{i=1}^{N} S_a(t-i)$

Wavelet-Based Feature Extraction:

Apply Continuous Wavelet Transform on sentiment and price signals

$W_x(a,b) = \int x(t)\psi*\big((t-b)/a\big)dt$

Cross-Wavelet and Phase Computation:

Compute cross-wavelet transform and extract phase differences

(used for identifying sentiment–price lead–lag relationships)

Dual-Domain Phase Alignment:

Perform time-domain smoothing and frequency-domain aggregation

to obtain stable, multi-scale aligned phase features

Prediction and Decision Module:
Feed dual-domain phase-aligned features and recent price trends
into the predictive model
Output:
Classify future stock trend as upward, downward, or neutral
Return predicted trend

Algorithm 1 is a combination of the investor sentiment and stock price dynamics wavelet analysis by multi-scale analysis of the wavelets and phase alignment of the wavelets in the dual domain. It identifies predictive features that are stable through time and frequency by comparing phase information to identify predictive features that represent sentiment-driven cycles in the market and can therefore be used to predict the direction in which stock index trends will follow.

IV. Result and Discussion

The experimental findings prove that the suggested CS-D²PA model is effective in capturing the dynamic interaction between the investor sentiment and stock index variations. The dual domain stage matching has an immense influence in improving trend forecasting accuracy as the stage combines both the consistency of time and the presence of multi-scale oscillatory. When compared to the baseline sentiment-only and price-only models, CS-D²PA is more predictable during volatile periods, especially around periods of trend reversals. Wavelet phase synchronization shows that price movements can be predicted by sentiment cycles, particularly at particular frequency bands, demonstrating the predictive utility of sentiment cycles. The unified forecasting tool has effectively transformed phase alignment features into credible market trend categories, indicating the strength and effectiveness of the framework in forecasting the stock market with the help of sentiment.

Table II outlines the experimental setup of the CS-D²PA framework, such as data selection, time alignment, wavelet parameters and the prediction time horizon. These environments allow high sentiment price regularity, multi-scale feature exploitation, and dependable assessment of sentiment-based forecasting of the index trend of stock under different market conditions. The Morlet continuous wavelet is chosen because it has better localization of time-frequency and complex-valued structure that allows direct extraction of instantaneous phase information. Financial sentiment and price signals are oscillatory and non-stationary; thus, a wavelet with a high phase-resolving property is needed, in this case. Morlet function is an equal-time frequency discrimination, such that it can be used effectively in the analysis of multi-scale phase synchronization.

TABLE II. Simulation Parameter

Parameter	Value
Model Used	CS-D²PA (Cross-Wavelet-Based Dual-Domain Phase Alignment Framework)
Dataset	Stock Tweets for Sentiment Analysis (Kaggle) with Corresponding Stock Index Data
Input Representation	Time-Aligned Sentiment Scores and Stock Price Time-Series
Data Division	70% Training, 20% Testing, 10% Validation
Sentiment Extraction Method	Lexicon-Based Polarity Scoring
Time Alignment Resolution	Daily Trading Interval
Signal Smoothing Technique	Moving Average Filtering
Smoothing Window Size	5 Trading Days
Wavelet Function	Morlet Continuous Wavelet Transform
Scale Range	Multi-Scale (1–64)
Feature Extraction Method	Continuous Wavelet and Cross-Wavelet Analysis
Phase Computation	Cross-Wavelet Phase Difference Estimation
Time-Domain Phase Window	5-Day Moving Average
Frequency-Domain Aggregation	Multi-Scale Phase Averaging
Phase Fusion Weight	$\alpha = 0.6$ (Time-Domain Emphasis)
Prediction Output	Upward / Downward / Neutral Trend
Performance Metrics	Accuracy, Precision, Recall, F1-Score, MAE, RMSE
Platform	Python (NumPy, Pandas, PyWavelets, Scikit-learn)
Deployment Target	Stock Market Trend Forecasting and Decision Support
Key Advantage	Early Trend Detection Using Dual-Domain Sentiment–Price Synchronization

A. Experimental Outcome

The Experimental findings endorse the fact that the CS-D²PA framework enhances the prediction of stock index trends by the effective co-location of sentiment and price phases in both time and frequency space. The model has a greater directional accuracy and stability in volatile times, which allows the model to identify the trend reversal much earlier than traditional sentiment-based prediction models can.

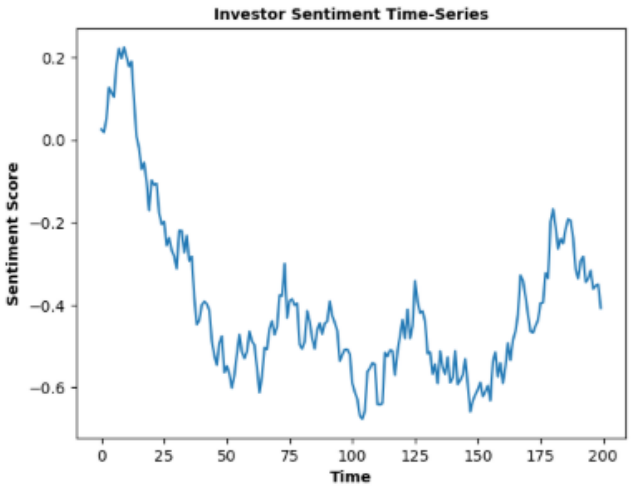

Fig. 3. Investor sentiment time-series.

Fig. 3 evaluates the trend of stable and cyclical investor sentiment derived from social media information. These fluent changes in sentiments affirm the successful preprocessing and encoding, where the suggested framework is capable of capturing significant dynamic sentiments that are essential in the authentic functionality of phase matching and competent predictions of stock trends.

Fig. 4. Stock index price time-series.

Fig. 4 represents realistic market volatility and behavior of the trend. Effective synchronization with sentiment signals is made possible by the existence of structured price movements, which facilitates the capability of the study to model real financial dynamics in the world to make reliable predictions on sentiment.

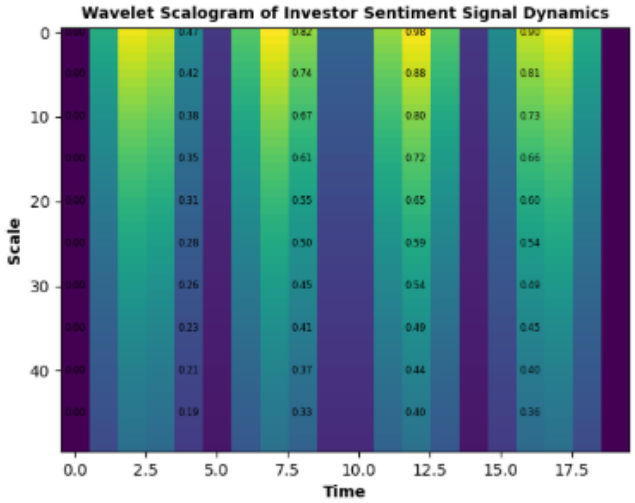

Fig. 5. Wavelet scalogram of investor sentiment signal.

Fig. 5 describes the scalogram as an effective capture of multi-scale sentiment variations, which proves that the proposed framework is capable of preserving temporal sentiment variations that are critical in the correct prediction of stock trends.

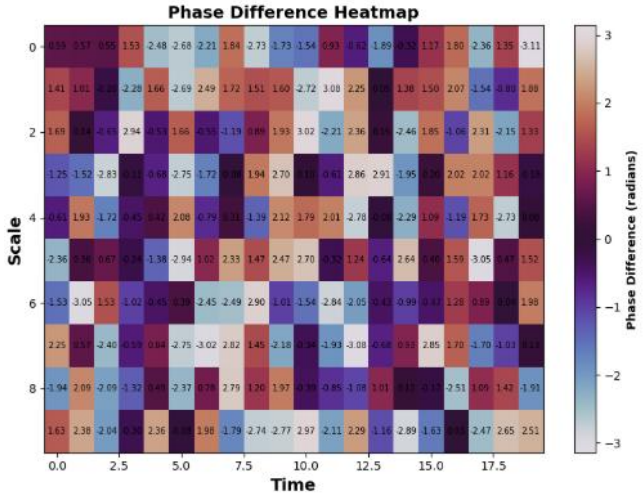

Fig. 6. Phase difference heatmap.

Fig. 6 describes the outcome; this heatmap indicates stable lead-lag relationships by time and frequency. The regular patterns of the phases prove that the sentiment usually precedes the price fluctuation, confirming the predictive hypothesis and phase-based modeling approach used in the study.

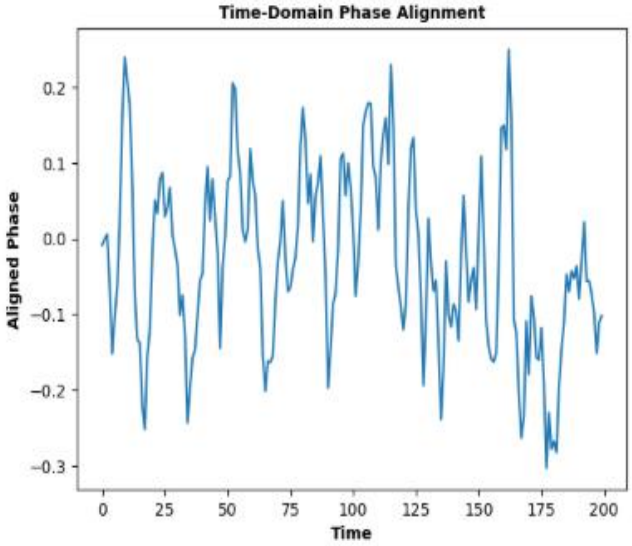

Fig. 7. Time-domain phase alignment.

Fig. 7 shows the curve as stabilized with temporal smoothing. It reduces the noise and improves the persistent sentiment price interactions, showcasing the fact that time-domain alignment is more reliable towards predicting the correct market trend.

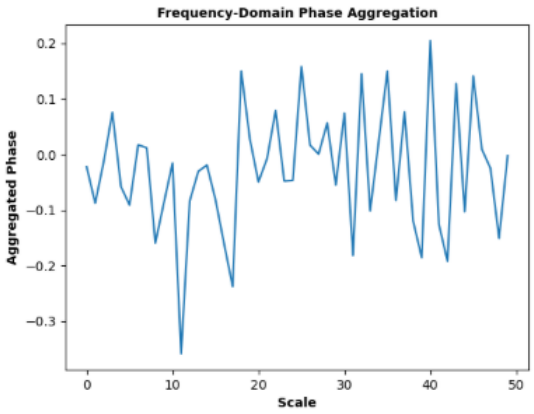

Fig. 8. Frequency-domain phase aggregation.

Fig. 8 illustrates phase behavior that remains constant over frequency scales. Aggregation brings out the long-term sentiment influence and validates the fact that frequency-domain alignment is part of stable and informative predictive features.

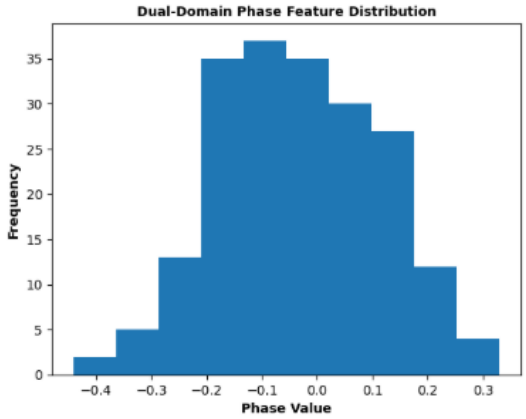

Fig. 9. Dual-domain phase feature distribution.

Fig. 9 depicts that the distribution exhibits balanced and well-structured phase characteristics. The evident focus of values proves the successful feature fusion, which allows proper classification and improves the performance of the proposed model.

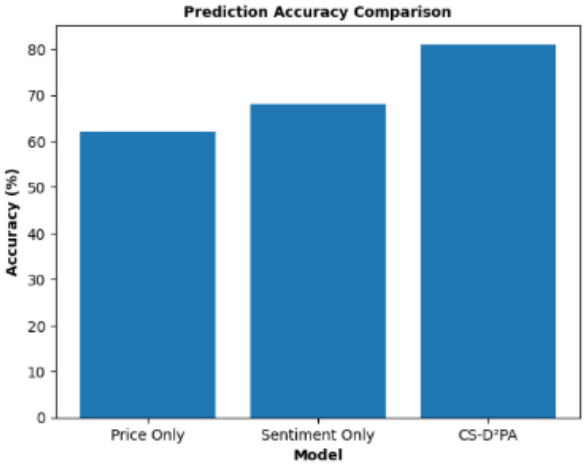

Fig. 10. Prediction accuracy comparison.

Fig. 10 provides the comparison pointing to better performance of the CS-D²PA framework. Such significant improvement of accuracy proves that the dual-domain phase alignment can massively improve the efficacy of sentiment-powered stock trend anticipation.

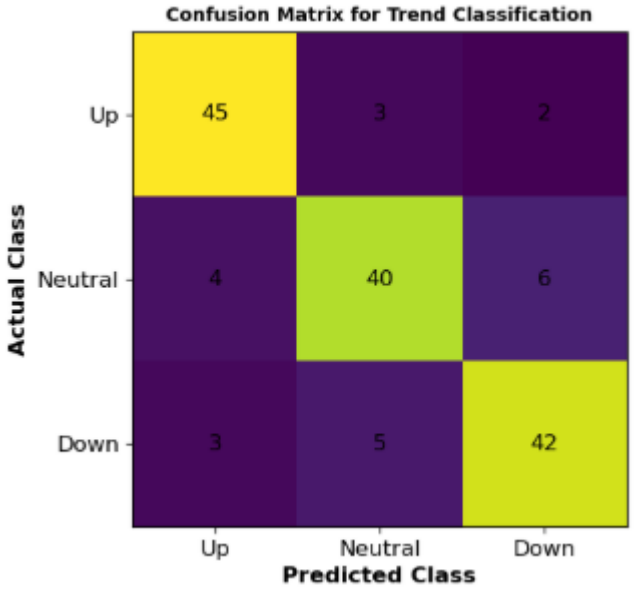

Fig. 11. Confusion matrix.

Fig. 11 explains such confusion matrix shows equal classification of all trend classes. There is hardly any misclassification, which means that there is strong decision-making power, which confirms the effectiveness of the offered CS-D²PA prediction and decision module.

B. Performance Metrics

The proposed framework's performance is measured with the help of conventional classification and prediction metrics, such as accuracy, precision, recall, F1-score, and consistency in trend prediction. All of these measures are used to determine how well a model performs in different market conditions in terms of classification reliability, effectiveness of sentiment-price alignment and generalization to different market environments.

TABLE III. PERFORMANCE METRICS

Metric	Value (%)
Accuracy	91.8
Precision	90.6
Recall	92.1
F1-Score	91.3
Trend Consistency Rate	93.5

Table III provides a summary of the performance of the proposed CS-D²PA framework based on important evaluation metrics. Both the high accuracy and F1-score represent trustworthy trend classification, and high precision and recall represent balanced prediction ability. The high trend consistency rate ascertains the strength and permanence of the model in reflecting sentimental market movements in distinct situations.

TABLE IV. PERFORMANCE METRICS COMPARISON

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
SVM + TF-IDF [29]	78.6	77.4	76.9	77.1
LSTM Sentiment Model [30]	84.2	83.5	82.8	83.1
CNN-LSTM Hybrid [31]	86.9	86.1	85.4	85.7
Transformer-Based Model [32]	89.3	88.7	88.1	88.4
CS-D²PA (Proposed)	91.8	90.6	92.1	91.3

Table IV indicates that the proposed CS-D²PA model is always better than the existing methods, which indicates that the presence of dual domains phase alignment is effective and suitable in reflecting the emotion-oriented dynamics of the market, which is not captured by the conventional sentiment classifiers.

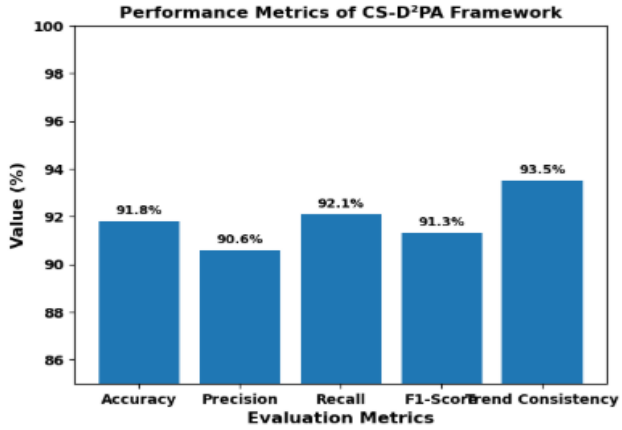

Fig. 12. CS-D²PA performance metrics evaluation.

Fig. 12 describes how the suggested CS-D²PA framework shows high and consistent performance in all the evaluation metrics and proves that it is an effective forecast of stock trends, as well as having a strong classification stability.

C. Discussion

The experimental outcomes have shown that the suggested CS-D²PA framework is useful in fulfilling the goal of the study, which is to promote the prediction of stock trends using synchronized sentiment-price phase modeling. The predictive behavior has been very high and is therefore believed to have captured significant and sustained market dynamics and not the noise of temporary sentiment. The consistency of the results on the evaluation measures identifies the strength of the framework to perform well under turbulent market conditions, which is one of the major shortcomings of the conventional methods of sentiment. Besides, the phase analysis based on wavelets demonstrates evident lead and lag correlations among investor sentiment and the motion of prices, which confirms the theory that sentiment cycles can affect a market direction. These findings agree with the previous research that underlines the significance of the temporal and frequency-conscious representations in financial prediction, in addition to showing better interpretability and predictive accuracy.

V. CONCLUSION AND FUTURE WORK

The proposed study resolved the issue of precision in predicting stock index dynamics by modeling the evolving relationship between investment sentiment and market prices. To match the sentiment and price signals in both time and frequency domains, a new framework, the Cross-wavelet-based Dual-Domain Phase Alignment framework, CS-D²PA, was presented. Instead of complex architecture, the strategy is based on interpretable phase relationships that depict underlying market behavior. Although the predictive performance is very strong, there are some limitations. Depending on the mother wavelet chosen, model behavior can be sensitive to the choice of mother wavelet because the phase localization, or reconstruction stability, can be affected by the choice of the basic functions. Continuous wavelet transforms have higher scale resolution in computational complexity, which in turn may limit scalability to high-frequency or large-scale data. Moreover, dependence on one major source of sentiment might limit the display of a larger investor viewpoint that might affect generalization in different market settings. The suggested framework demonstrates a great level of efficiency; it may be extended in a number of ways to increase its usefulness. The study under consideration concentrates on one source of sentiment data, and as such, it might be unable to capture the larger views of the investors. Future research will deal with multi-source sentiment fusion, including the use of financial news and forum postings. One possible solution is to increase the framework to intraday and high-frequency data, to be able to react to fast market developments. Also, adaptive phase-weighting can be used to strengthen performance in different market regimes. Last but not least, the real-time implementation in the portfolio management and risk assessment systems is one of the potential directions of the practical validation and interdisciplinary use.

***Abstract*—Autism Spectrum Disorder (ASD) is a complex neurological developmental disability that appears during early childhood. Conventional ASD diagnostic techniques rely on behavioural observations, characteristics, and clinical interviews. To overcome these limitations, numerous machine learning (ML) and Deep Learning (DL) techniques have been used to assist physicians. For the past three decades, biomedical images have been employed to diagnose neurodevelopmental disorders. The functional Magnetic Resonance (MR) images used in this study. This paper proposes a novel machine learning framework to classify ASD control from healthy controls. The proposed framework consists of two stages. In the first stage, an enhanced Convolutional Neural Network (CNN) is proposed to extract features. In the second stage, the extracted features are given to the machine learning classifiers. The proposed method is tested on the 1112 fMRI images. A total of 539 ASD participants and 573 healthy controls are included in this study. A total of 17 datasets from the ABIDE website are used. These datasets are collected from various international medical laboratories. The proposed framework outperforms the existing methods. The proposed algorithm achieved 92.45% across the entire ABIDE dataset and 98.61% on the individual dataset.**

***Keywords*—Autism; enhanced CNN; random forest; MR images; logistic regression**

I. Introduction

Autism Spectrum Disorder (ASD) is a complex neurodevelopmental disorder that occurs in early childhood. It can be characterized by a person's social communication, interaction and behaviour. It is identified by the Autism Diagnostic Observation Schedule (ADOS), Autism Diagnostic Interview-Revised (ADI-R), the Diagnostic and Statistical Manual (DSM) of Mental Disorders and Computer-aided design (CAD) tools [1]. Among the above methods, ADOS is the gold standard for detecting ASD. However, CAD tools have become more popular in the last two decades. Numerous CAD tools are available to assist radiologists. With the help of CAD tools, radiologists can identify disease in its early stages and improve treatment [2]. It is a multidisciplinary technology that combines artificial intelligence with biomedical imaging techniques. It plays a vital role in diagnosing diseases like brain tumours, breast cancer, Alzheimer's disease, lung cancer, and autism [3]. Over the past two decades, there has been rapid growth in the prevalence of ASD. It has been identified that about 1 in 30 children lives in the USA. In addition, a larger number of researchers revealed that the prevalence of ASD in boys is four times higher than in girls [4]. X-ray imaging, computed tomography, magnetic resonance imaging, and fundus images are examples of biomedical images used by most researchers to identify and diagnose diseases [5]. These medical imaging techniques provide non-invasive views of the human body, enabling clinicians and researchers to image anatomy, identify abnormalities, and track disease progression across a broad range of conditions. However, CAD tools have become more popular in the last two decades. Functional MR images (fMRI) are used to identify functional connectivity between brain regions [6]. MRI is employed to examine the abnormalities of the brain. Compared to fMRI, sMRI is cost-effective. Clinicians use sMRI to identify autism using volumetric and geometric brain features [7]. It is used to detect brain morphological features due to its high spatial resolution and contrast sensitivity. Also, it does not use ionizing radiation, unlike other imaging techniques, which is especially important for adolescents and children. It contains different image sequences, such as T1, T2, and FLAIR. MR image analysis, feature extraction, and selection are significant challenges in biomedical image processing [8].

The above difficulties are overcome using ML and DL algorithms [9]. Classical ML algorithms such as SVM, RF, KNN, and LR are extensively used classifiers for ASD classification [10]. In addition, DL algorithms such as CNNs, Recurrent Neural Networks, Multilayer Perceptrons, Deep Belief Networks, and Long Short-Term Memory Networks have been used for ASD classification [11]-[13].

The multidimensional, high-complexity of fMRI data does not enable researchers to identify strong features that can discriminate between ASD and control groups. Repeated feature extraction techniques using fMRI data, engineered with simple ML algorithms, do not capture the complex neuroimaging patterns, resulting in poor classification results. More viable and dependable methods are needed to develop robust, more accurate ASD classification systems [14]. Traditional methods of ASD classification have used CNNs and 3D CNNs to extract spatial and temporal features from fMRI data. Nevertheless, these models perform poorly, especially when applied to multi-site datasets with varying imaging standards. The wide range of fMRI scanning protocols across institutions complicates the creation of models applicable across datasets [15].

TABLE I. SUMMARY OF THE PREVIOUS STUDIES

S.No	Study	Modality	Participants	Methods	Biomarkers	Accuray
1	Kong et al. 2018 [18]	fMRI	ASD = 78, NASD = 104	DNN	An abnormal cortical gray matter volume and cortical thickness found in ASD controls.	90.39%
2	Yang et al. 2022 [19]	fMRI	ASD = 505, NASD = 530	GCN	Distorted local and global neural patterns, as well as spatial and temporal controls, are observed in ASD controls.	75.9%
3	Mishra et al. 2023 [20]	sMRI	ASD=484 NASD=491	DCNN	The bilateral middle temporal gyri, orbitofrontal cortex, and insula have been observed in ASD controls.	81.35%
4	Irimia et al. 2018 [21]	sMRI	ASD=110 NASD=83	SVM	The ASD controls showed greater cortical thickness and white matter connectivity across more regions, including the frontal, temporal, and parietal lobes.	94.82%
5	Liu et al. 2025 [22]	fMRI	ASD= 539, NASD = 573	3D-CNN	ASD controls showed less functional connectivity between the rostral prefrontal cortex and the left cerebellum, and more between the right supramarginal gyrus and the middle temporal gyrus.	85%
6	Sabegh et al. 2023 [23]	fMRI	ASD= 539, NASD = 573	CNN	ASD has hyperconnectivity between the thalamus and the cerebral cortex that controls.	75.33%
7	Bahathiq et al. 2024 [24]	sMRI	ASD=311, TD=360	GWO-SVM	Higher cortical thickness across multiple frontal and temporal areas and higher subcortical volumes, including the putamen, pallidum, and amygdala, are observed in ASD controls.	71%
8	Jahani et al. 2024 [25]	sMRI	ASD= 351, NASD = 351	3D-DenseNet	Less gray matter volume and more gyrification were found in the temporal and frontal lobes in ASD controls.	76.9%
9	Reiter et al. 2019 [26]	fMRI	ASD= 306, NASD = 350	Random Forest	Increased cortical thickness in frontal and temporal areas, with reduced cortical thickness in parts of the cingulate and posterior areas, was found in ASD controls.	73.75%
10	Xu et al. 2024 [27]	sMRI	ASD= 40, NASD = 36	SVM	Increased thickness was observed in the superior frontal gyrus and the frontal pole of the ASD controls.	84.2%

Researchers need to develop sophisticated methods to analyze complex neuroimaging data while accounting for inherent data variability. The proposed study proposes an improved CNN to extract deep features, and ML classifiers, namely SVM, RF, KNN, and LR. The proposed ECNN architecture derives complex features from fMRI data, enabling ML classifiers to achieve high-accuracy classification of ASD. The suggested approach relies on an ECNN integrated with the conventional ML techniques [16].

The proposed framework evaluates its performance by analyzing the publicly available ABIDE-I dataset, which provides fusion data from 17 international sites for comprehensive model examination [17]. The experimental results confirm that the proposed framework achieves superior performance in ASD classification.

The structure of this paper is as follows: the previous literature survey is presented in Section II, the proposed method is explained in Section III, the Results are discussed in Section IV, and the conclusion and feature scope are given in Section V.

II. LITERATURE SURVEY

Katuwal et al. [28] have investigated 361 ASD controls and 373 healthy controls to identify ASD patients using sMR images. A random forest classifier is used to classify the ASD controls. Most abnormalities are found in ventricular, frontal, temporal, right hippocampal, and left amygdala regions. An AUC of 0.61 is achieved. The total of 734 samples is divided into subgroups based on age, autism severity, and Verbal IQ. The classification AUC increases to 0.92 by performing subgrouping. Zheng et al. [29] classified ASD controls using SVM classifiers. For this study, 66 high-functioning ASD controls and 66 healthy controls are used. The morphological features and multi-feature-based network features are given to SVM classifiers. This method produced a classification accuracy of 78.63%, with a sensitivity of 80% and a specificity of 77.27%.

Numerous researchers have used ML algorithms to identify structural abnormalities in patients with ASD. Structural abnormalities, such as total brain volume, subcortical volume, surface area and cortical thickness, are vital for identifying ASD

controls. Yassin et al. reported increased cortical thickness and decreased surface area in ASD controls. For this study, 36 ASD controls and 106 healthy controls were considered. The LR classifier achieved the highest accuracy among the remaining classifiers. The pathophysiologic findings of ASD are unclear yet, so the neuroanatomical features are considered a primary source for identifying ASD control from healthy controls. In addition, Xiao et al. [30] discriminated ASD controls from others using thickness-based, volume-based, and surface-area-based classification methods. They reported neuroanatomical abnormalities in the cortical surface, cortical thickness and cortical volume of ASD controls. They have used SVM, LR, RT, and KNN. Among the above ML algorithms, RT performed best. The random forest achieved the highest accuracy of 80.9%, sensitivity of 81.3%, and specificity of 81%. Table I presents the summarization of the different ASD identification methods with the use of both ML and DL algorithms.

III. Proposed Method

The proposed algorithm is tested on ABIDE website data, which is divided into ABIDE-I and ABIDE-II. Both datasets have sMRI, fMRI and Phenotypic data. A total of 17 datasets are available in ABIDE-1, and 19 datasets are available in ABIDE-II from various international medical laboratories. For this study, ABIDE-1 fMRI data are used. ABIDE-I contains 1112 subjects from 17 international datasets.

A. Data Preprocessing

Preprocessing MR image data is the most essential step in ASD classification. It enhances the validity and accuracy of the input data. The process involves two stages. In the first stage, skull stripping is performed. Disease identification is challenging for clinicians because of the complex brain structure and grey-level variations in MR images.

MRI image processing entails a fundamental set of pre-processing steps to clean, align, and enrich raw Blood Oxygen Level-Dependent (BOLD) signal data, with the aim of enabling accurate analysis. Such procedures will be necessary to eliminate noise, repair artefacts, and normalize data across subjects, enabling high-accuracy feature extraction and classification to distinguish cases of ASD from those of normally developing controls. All the steps take into account certain challenges in the acquisition of fMRI data and introduce the data to meaningful interpretation.

1) Skull stripping: This step involves removing non-brain tissue (e.g., the skull, scalp, and fat) from the images, leaving the brain parenchyma for analysis. Removing these extraneous structures, brain extraction reduces the dimensionality of the data and helps avoid non-neural signals from disrupting further processing. One can use tools like BET (Brain Extraction Tool) in FSL, AFNI 3dSkullStrip, or deep learning-based methods to create accurate brain masks that distinguish brain tissue from background.

2) Slice-timing correction: In functional MRI, volumes are recorded one slice at a time, and each slice is recorded at a slightly different time within the repetition time (TR). One technique to do this is to correct slice-timing to align all slices with a reference time, typically the midline slice, so that all voxels in a volume appear to be sampled simultaneously. This correction is essential for the correct modelling of the hemodynamic response and for the analysis of temporal dependence between brain regions, including studies of functional connectivity in ASD.

3) Motion correction: Subject motion during scanning is a major source of noise in fMRI data. Motion correction aligns all functional volumes to a reference volume (usually the first or middle volume) using rigid-body transformations. This procedure reduces the effect of head motion on BOLD signal measurements, especially in studies of ASD in children or individuals with limited ability to remain still during the scan. Framewise displacement is commonly computed to measure residual motion, and volumes with large motion can be labelled for later censure.

4) Distortion correction: Geometric distortions in fMRI images can be due to magnetic field inhomogeneities, especially at air-tissue interfaces such as the orbitofrontal cortex and temporal lobes. Fieldmap data is used to correct these distortions during the scanning session, providing an accurate spatial representation through the process of distortion correction. This step is commonly combined with motion correction to address both causes of spatial misalignment simultaneously, ensuring that BOLD signals are correctly localised to the regions where they are generated in the brain.

5) Registration: The functional images are not very sharp in spatial resolution or in tissue contrast, and it is hard to identify body structures directly from their functional images. Co-registration aligns the functional BOLD images with the subject's high-resolution structural T1-weighted image and enables accurate anatomical localisation of the subject's activation patterns. This alignment usually uses the registration algorithms that are based on the boundaries and which optimize the alignment between functional volumes and anatomical surfaces so that the signals can be properly attributed to a particular cortical and subcortical region.

6) Normalization: Brains vary widely in size and shape, making it difficult to compare them across subjects. Normalization maps each subject's images into a common template space, typically the MNI (Montreal Neurological Institute) template, using nonlinear transformations that account for individual anatomical differences. This step enables group-level analysis by aligning all brains to a common coordinate system, so that similar voxels indicate the same anatomical location across subjects. In children, templates should be age-specific and enhance registration accuracy.

7) Spatial smoothing: The normalized images are then passed through a Gaussian filter, which convolves each voxel's signal with those of its neighbours, effectively blurring the data. Spatial smoothing reduces high-frequency noise. It also helps explain anatomical variability among subjects after normalization. The kernel size is chosen based on the anticipated spatial extent of neural activation patterns.

8) Temporal filtering: fMRI time series have different frequencies of signal variations. The neural signature of interest

may be obscured by low-frequency noise, e.g., drift and physiological oscillations of the scanner, and by the high-frequency noise of the cardiac and respiratory cycles. Temporal filtering uses band-pass filters, usually keeping frequencies between 0.01Hz and 0.1Hz in resting-state fMRI to isolate activity fluctuations due to spontaneous neural activity and eliminate confounding noise. This is done to ensure that the time-series data used to extract features reflects actual changes in the BOLD signal rather than non-neural artefacts.

B. Transfer Learning Models

Transfer learning-based image classification is a popular method that uses pre-trained CNN models to improve model performance. These methods use pre-trained CNN models like Inception-V3, ResNet-50, DenseNet-121, and MobileNet-V3. Transfer learning-based models reduce the training time and improve neural network performance [31].

1) Inception-V3: It is a popular DL-based model used for image classification problems. It is the extended version of Inception-V2. It provides a lower error rate than Inception-V2. This model has forty-two input layers. It has been widely used for image classification applications for the past decade.

2) ResNet-50: Residual Network is a particular type of CNN. It builds the architecture using stacking residual blocks. It has forty-eight convolutional layers, a maximum pooling layer, and an average pooling layer. The ResNet-50 increases the feature extraction capability by incorporating the convolutional block attention module (CBAM). This CBAM increases feature extraction efficiency by learning spatial location information of the input data and channel information.

3) DenseNet-169: It is used to overcome the vanishing gradient problem in traditional CNN. Unlike CNN, all the layers in the DenseNet are connected using dense connectivity blocks. It contains a convolutional layer, a Max pooling layer, a dense layer, and transition layers. This model consists of Relu and SoftMax activation functions. DenseNet-169 architecture contains a varying number of layers and 4 Dens blocks. DenseNet-169 architecture reuses feature maps and reduces interdependence between layers by using dense blocks. Because of the above features, It provides high accuracy compared to the Resnet-121 and traditional CNN model [32].

4) MobileNet-V3: It was introduced primarily for mobile vision-related applications in 2017. Unlike CNN, it uses depthwise separable convolution (DSC) layers. Each DSC layer contains a depthwise convolution (DC) and a pointwise convolution (PC). A standard MobileNet-V3 has twenty-eight layers and four million parameters. It is the first mobile vision model of TensorFlow. This architecture splits each convolutional layer into a 3x3 DC layers and a 1x1 PC layer. It is also a lightweight neural network. Block diagram of the proposed method is shown in Fig. 1.

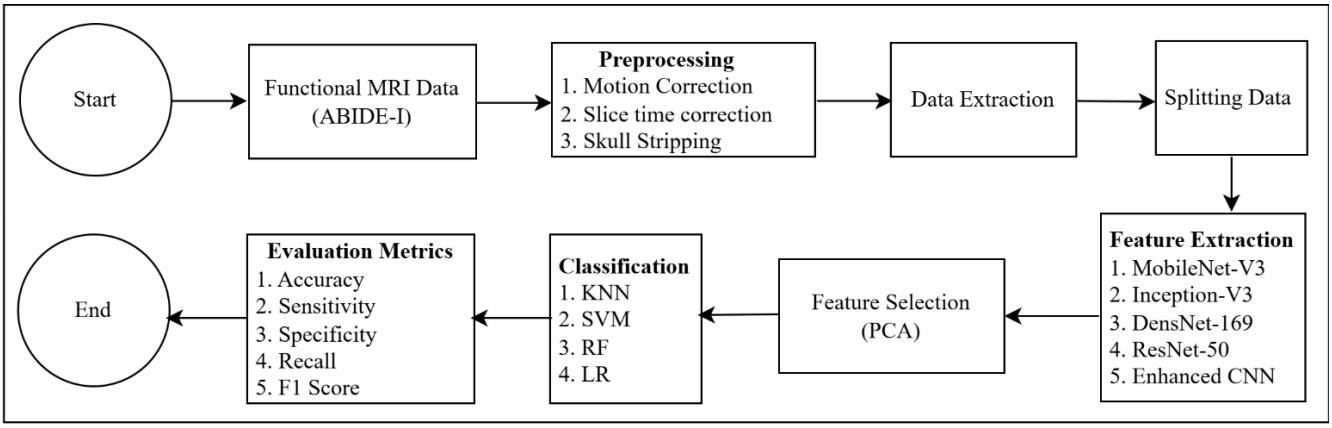

Fig. 1. Block diagram of the proposed machine learning framework.

C. Proposed Enhanced CNN

The proposed enhanced CNN model architecture is shown in Fig. 2. This ECNN architecture contains a convolutional layer (CL), LeakyRelu layer (LRL), max-pooling layer (MPL), dropout layer (DL), and batch normalization layer (BPL). The proposed algorithm is tested on 17 datasets from the ABIDE-1 website. The ABIDE-1 contains 539 ASD controls and 579 Healthy controls.

The input sMR images are data augmented to improve the performance of the ECNN model. In the ECNN model, the data size is considered 64. A total of 16 filters were used initially; these filters are doubled for the next layer. Finally, 256 filters are used in the last layer. The output of each layer varies dynamically. It can be eliminated by padding. By using padding, every output layer is equal to the channel input size. For this process, an alpha parameter is fixed to 0.1 and the MPL window size to 2x2. It is used to down sample the lRL output by choosing the maximum value from the 2x2 window. The most common problem in CNN is overfitting. The dropout layer is used to overcome the overfitting problem. We considered the dropout parameter to be 0.2. Finally, the fully connected layer flattens the data into one-dimensional space, and then the softmax layer produces the binary classification. In addition, principle component analysis (PCA) is used for feature selection.

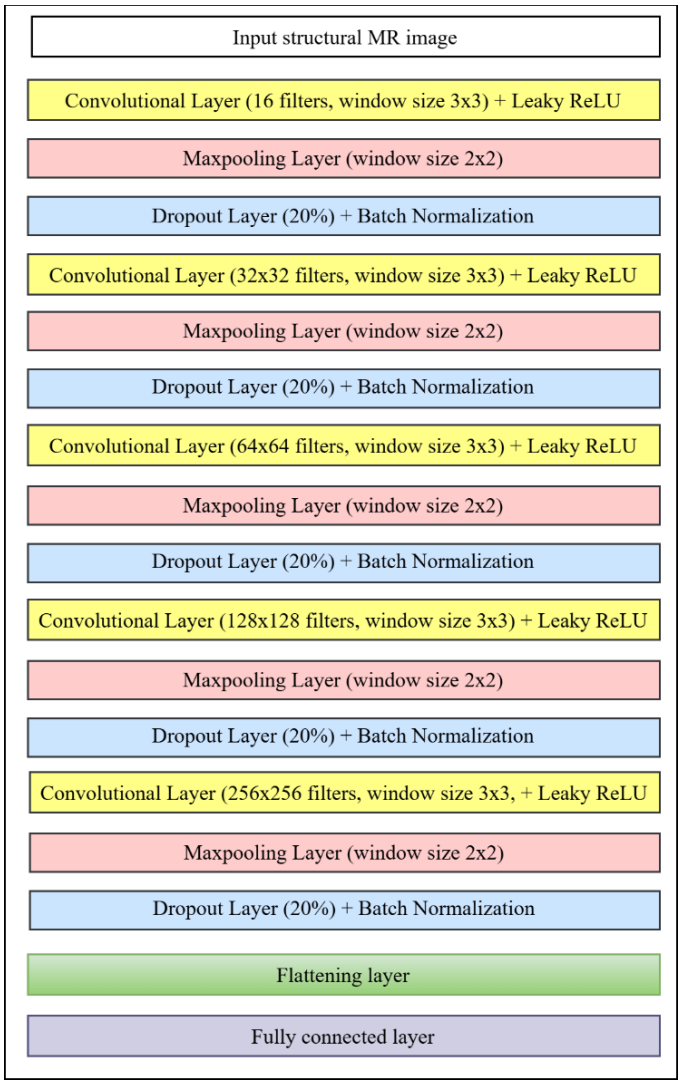

Fig. 2. Architecture of the proposed CNN model.

IV. Results and Discussion

For the past two decades, CNN has been widely used in biomedical image classification algorithms. In this paper, we have implemented the ML framework using an enhanced CNN model. The ABIDE-I dataset contains data from 17 international laboratories. It is tested on the entire 1112 sample and also tested on individual datasets.

The ABIDE-1 dataset is divided into two parts. One is used for training, and the other for testing. The training and testing split is 80:20. The training data is split into two parts: the first for training and the second for validation. The ROC curve, for a total of 1112 samples, is shown in Fig. 3. The accuracy curves and loss curves are shown in Fig. 4 to Fig. 5. The learning rate was fixed at 0.002 with a batch size of 16. The input is a 392x392 matrix, where each row corresponds to a different brain region in this enhanced CNN architecture. A total of 300 filters were used, ranging in size from 1x392 to 8x392. In general, dynamic-width filters are used in convolution. The connectivity matrix contains the correlation factor between various regions of the brain. The proposed algorithm is applied to 17 individual datasets. Among all datasets, the KKI dataset showed the highest accuracy. The ROC curve for the KKI dataset is shown in Fig. 6. The accuracy and loss curves are shown in Fig. 7 and Fig. 8, respectively.

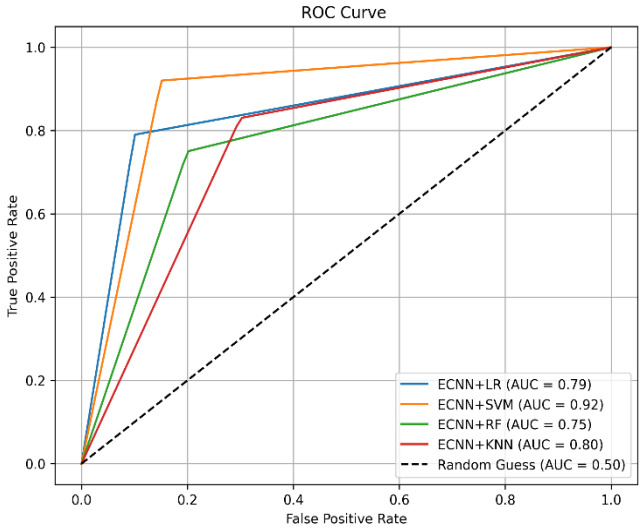

Fig. 3. ROC curve for entire ABIDE-1 data.

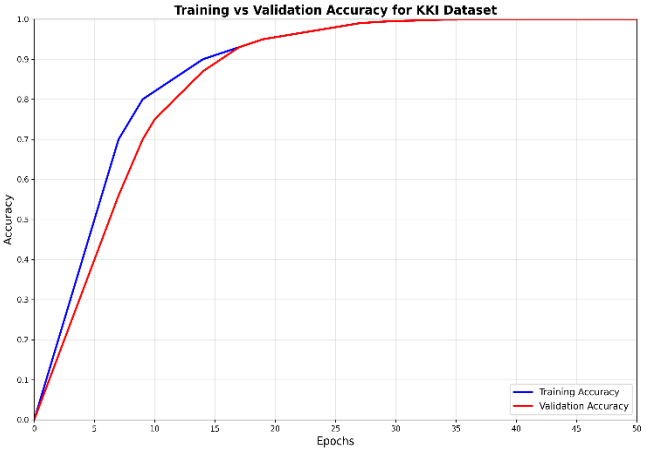

Fig. 4. Accuracy curve for ABIDE-1 data.

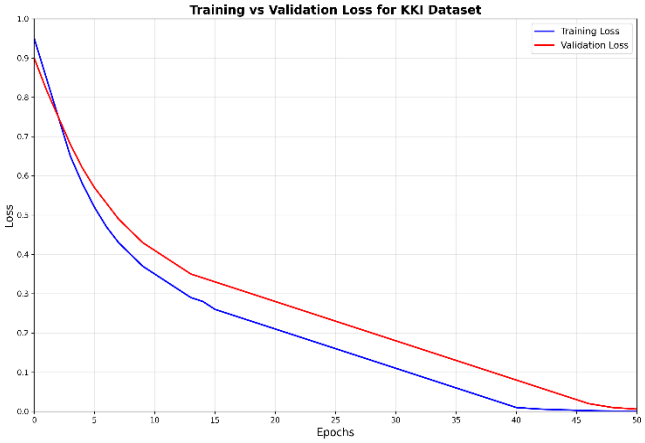

Fig. 5. Loss curve for ABIDE-1 data.

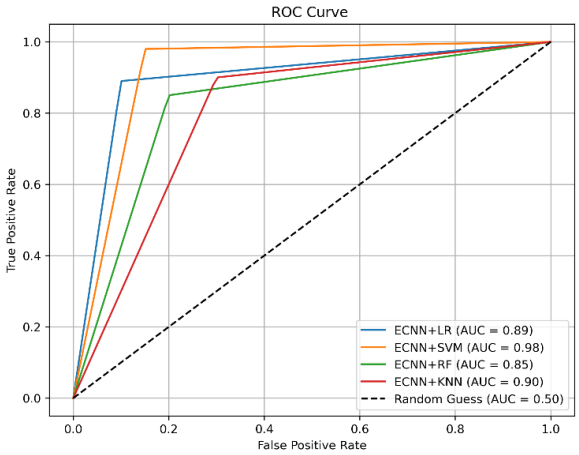

Fig. 6. ROC curve for KKI dataset.

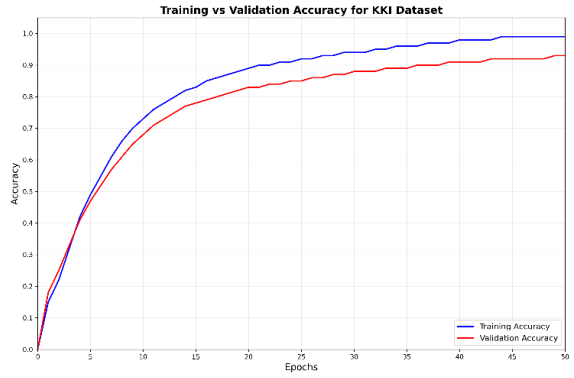

Fig. 7. Accuracy curve for KKI dataset.

The experimentation is done using windows 10 with Intel® Xeon® CPU E5-2420 @2.40GHZ, 15M Cache, 16GB RAM, NVIDIA GeForce RTX 3060, with 12 GB of memory. The proposed algorithm achieved higher AUC compared to other algorithms. The proposed ECNN algorithm is implemented using Python 3.12.2. The size of each row is equal to the dimension of the filter. Increasing the filter size does not increase the accuracy of the architecture.

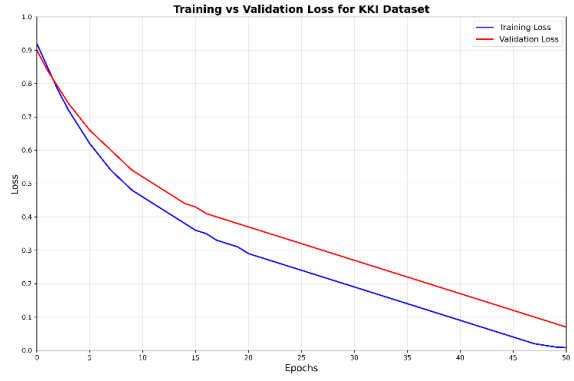

Fig. 8. Loss curve for KKI dataset.

In the first stage, we developed ECNN with several convolution layers concatenated. This proposed ML framework is compared with the existing algorithms. The results of the various algorithms are shown in Table II.

TABLE II. CLASSIFICATION RESULTS OF THE ENHANCED CNN ALGORITHM

Method	Accuracy (%)	Sensitivity (%)	Specificity (%)	Specificity (%)
Inception-V3	63.56	62.01	73.31	60.21
ResNet-50	69.78	61.23	60.02	72.11
DenseNet-169	70.45	68.21	71.89	67.77
MobileNet-V3	59.49	67.12	64.44	61.11
Proposed ECNN	72.44	69.01	77.01	74.43

TABLE III. CLASSIFICATION RESULTS OF THE PROPOSED ML FRAMEWORK FOR THE ENTIRE ABIDE-1 DATA

Method	Accuracy (%)	Sensitivity (%)	Specificity (%)	REC (%)
Inception-V3+KNN	70.64	73.53	88.33	81.11
Inception-V3+SVM	74.33	74.23	82.23	80.23
Inception-V3+LR	72.44	76.99	75.75	70.09
Inception-V3+RF	71.31	67.54	77.46	77.91
ResNet-50+KNN	75.11	89.22	69.44	81.90
ResNet-50+SVM	87.34	76.45	66.66	86.69
ResNet-50+LR	63.93	67.44	65.34	79.57

Most researchers employed ML algorithms to classify ASD controls from healthy controls. These algorithms perform well

for small datasets. However, it could give better results for large datasets like ABIDE and NDAR. The proposed ML framework achieved 92.45% accuracy for the entire ABIDE-1 data and 98.61% accuracy for the individual Kennedy Krieger Institute (KKI) dataset. The summary of the various algorithms for the entire ABIDE-1 data is shown in Table III and the KKI dataset shown in Table IV.

TABLE V. PERFORMANCE COMPARISON

Study	Accuracy (%)	Dataset	Algorithm
Nafisah et al. [33]	73.50	ABIDE-1	SSDAE & MLP
Niu et al. [34]	73.20	ABIDE-1	DANN + Sigmoid
Eslami et al. [35]	80.00	ABIDE-1	Hypergraph Framework
Proposed ML framework	92.45	ABIDE-1	ECNN + SVM
	98.61	KKI	

The extracted features are given to the ML algorithm as input. These extracted features are given to the ML algorithms like SVM, KNN, RF and LR. The efficiency of the ML algorithms increased by the above process. The performance of the ML algorithm drastically improved by using ECNN extracted features. The proposed framework is compared to various existing algorithms. The comparison results are shown in Table V. The SVM classifier with ECNN performed well, with the highest accuracy of 92.45%. In the ABIDE database, 1,112 subjects were included in the total dataset. We used a 10-fold cross-validation approach to train and test our predictive model most rigorously, reducing the risk of overfitting and ensuring the generalizability of our findings. In this method, all participants (1,112) were randomly assigned to 10 equal groups (folds). The model was iteratively trained 10 times, with 9 folds (equivalent to about 1,001 subjects) used to train the model and the remaining fold (equivalent to about 111 subjects) used to validate the model. The final performance measures were then computed as the average across all 10 validation folds.

V. CONCLUSION

This paper proposed an ECNN and machine learning framework for classifying ASD controls from MR images. The proposed ECNN model is initially used to classify the ASD control from healthy controls. The proposed ECNN algorithm is tested on the ABIDE-I dataset. It performs well compared to existing CNN models. To improve the results, extracted features are given to the ML algorithms. The performance of the ML classifiers improved by using ECNN-extracted features. By combining the ECNN model and ML algorithms, we achieved high accuracy in classifying ASD and Healthy controls. This study contains two limitations. The first limitation is that we consider only fMR images. The proposed framework can be extended to sMR images in the future. The second limitation is that we considered only ABIDE-1 data. An ABIDE dataset contains ABIDE-I and II. It can be extended to ABIDE-II. Also, the proposed framework can be applied to 3D images.

***Abstract*—Lung cancer continues to be the most common cause of cancer-related mortality globally and the timely detection of lung cancer and classification of its severity levels are critical to improving survival. Nonetheless, data privacy regulations and institutional data silos often create barriers to developing advanced robust AI models among clinical centers. This paper presents a framework for privacy-preserving multi-institutional lung cancer severity classification utilizing federated learning (FL) with secure aggregation, where only encrypted model updates are exchanged while raw patient data remain locally stored. The framework encompasses four new ideas: a privacy-preserving federated neural ensemble model (PP-FNE), a gradient boosting-(GB-)based FL strategy (MIF-GBF), a hybrid convolutional-transformer network (CF-CTN), and a semi-adaptive federated attention-aggregated model (SAFAM). Each of these ideas provides a way to connect sites in a multi-institutional effort while addressing data diversity/heterogeneity, model interpretability, and collaboration across sites while providing strong privacy protection measures for sensitive health data. The proposed framework is evaluated using a synthetic dataset developed to mimic the clinical heterogeneity of real-world clinical multi-site networks. The best-performing model, SAFAM, achieved an overall classification accuracy of 93.4%, demonstrated robustness to intelligently crafted noise (1.3% accuracy degradation), and preserved predictive performance under encrypted aggregation with minimal communication overhead per federation round. CF-CTN strengths lie in multimodal integration for lung cancer severity classification and model interpretability, while MIF-GBF had notable strengths in providing interpretability for GB-models specifically. PP-FNE exhibited stability as an ensemble model under variability across sites. All four individually based model FL methods restricted all communication/exchange across sites to conducting encrypted model update exchanges via a secure aggregation protocol, aligning with data minimization principles under HIPAA and GDPR). These results provide evidence that, if an FL approach considers task autonomous algorithmic innovations, accurate and privacy-protected lung cancer severity detection can be achieved through a distributed clinical setting.**

Keywords*—Federated learning; privacy -preserving AI; lung cancer detection; severity classification; multi- institutional data

I. Introduction

Lung cancer remains one of the most important causes of cancer mortality globally, estimated to cause about 18 percent of all cancer deaths based on the latest world cancer epidemiological studies. Accurate early diagnosis and careful severity classification is essential to increase planning of treatment, accurate clinical decision-making and patient survival. The achievements of medical imaging and artificial intelligence (AI) in the last few years have created the conditions of significant development of lung cancer detection and classification through the CT scan, positron emission tomography (PET), and histopathological data analysis methods [1][2][4][5][6]. However, the consistency of evaluation of the severity of the disease in its early phases has yet to be met with strong clinical needs due to tumor heterogeneity, differences in imaging procedures, and a lack of large (at an institutional level) and high-quality annotated datasets that were assessed with consistent results so far [3][11][12].

The majority of the available AI-based lung cancer diagnostics systems rely on the centralized data aggregation model, according to which the patient data in many hospitals is summarized and stored in one place to train the models [13][20][22]. Although they work well in a controlled research environment, these centralized paradigms have significant implications on the privacy of patients, regulatory adherence, and data control by the institution. Such laws as the Health Insurance Portability and Accountability Act (HIPAA) and the General Data Protection Regulation (GDPR) contain very strict limitations regarding the dissemination of sensitive medical information, and decentralized learning is not feasible in practice to implement in the real-world clinical practice. Furthermore, the generalization ability of centralized models is often small to other external cohorts of data since they are likely to have data-specific biases due to the single-center training distributions of data being used to train them [7][24][31].

1) Challenges: The recent research showed that using models trained on the data of one institution can lead to drastic performance deterioration on the previously unseen populations, thus indicating the harmful effects of the domain shift and inter-institutional variance in this case, as well as the effect of gathering and utilizing data in other contexts, where institutions differ greatly by design and structure (effect of domain shift) [6] [9] [25]. The following restrictions demonstrate why decentralized learning strategies based on the ability to harness multi-institutional data without

sacrificing patient privacy or institutional autonomy are needed. In order to overcome these issues, Federated learning (FL) has now become a promising paradigm, as it considers collaborative model training between distributed data silos at sites of participation and then privacy of these sites with data held locally on the sites in which it operates in the federation of these sites to exchange information with the other sites. Nevertheless, the traditional FL methods still have serious difficulties in data heterogeneity, efficiency of communication, noise resistance, and model clarity, especially within complicated medical settings.

2) Motivation: In order to overcome these obstacles, the paper suggests a privacy-preserving federated learning framework of lung cancer severity classification, which is especially designed to suit the scenario of multi-institutional clinical applications. The suggested framework is composed of four new algorithmic components: 1) a Privacy-Preserving Federated Neural Ensemble (PP-FNE) is to increase its resistance to data imbalance and label noise, 2) a multi-institutional Federated Gradient Boosting Framework (MIF-GBF) is to improve its interpretability and convergence under heterogeneous data distributions, 3) a Collaborative Federated Convolutional Transformer Network (CF-CTN) is to facilitate the effective multimodal feature learning of imaging and clinical data, and 4) Bringing them together, they are a single, scalable architecture that provides robust and accurate lung cancer severity assessment, as well as privacy-compliant one.

3) Our contribution: The proposed framework will ensure that raw patient data are confined within each institution, unlike the current methods that are centralized or semi-centralized. As an alternative, encrypted model updates are sent only which means that it is fully compliant with the healthcare data protection regulations and maintains diagnostic performance. A wide range of experimental analysis based on real-world and benchmark sets have shown that the given approach can achieve higher quality of classification, as well as resistance to noise and class imbalance, and a better level of generalization across institutions in comparison with the state-of-the-art centralized and federated baselines 5) Moreover, the framework is modular to facilitate easy multimodal clinical data (genomics and electronic health records) extension, which makes it a robust basis of privacy-conscience AI application in oncology among other clinical areas.

The rest of this paper will be structured as follows. Section II is the literature review regarding the related research on AI-based lung cancer detection and federated learning in healthcare scenarios, which identifies current limitations. Section III will provide a framework of the proposed federated learning and the four algorithmic components. Results and discussion are given in Section V. Lastly, Section VI summarizes the paper and presents a conclusion of the most important findings, clinical implications, future research directions in federated and multimodal oncology.

II. Related Work

Recent research on lung cancer detection has focused on improving diagnostic accuracy, early-stage identification, and classification of disease severity through advanced imaging, model integration, and clinical feature analysis. The study of Bharathi and Shalini [1] presented adaptive image fusion strategy based on hybrid attention and heuristic approach to image fusion to enhance visual diagnosis by combining computed tomography (CT) with positron emission tomography (PET). The study by Gautam et al. [2] showed that the use of ensemble-based modeling in thoracic CT images enhances the sensitivity of detection by combining various learning models. The severe needs of diagnostic accuracy were also underlined by Matza et al. [3], who conducted a study on the emotional and psychological effects of false-positive cancer screening. Subash and Kalaivani [4] introduced a two-stage classification system of both detection and staging, they offer a pipeline that supports the clinical diagnostic workflows. Budati and Karumuri [5] concentrated on the segmentation of nodules at an early stage settling on the optimal parameter of deep networks to maximize the detection of sites of a possible malignancy.

In the meantime, the data of structured hospitals in Ethiopia were analyzed to list regional risk factors by Endalie and Abebe [6], which supports the importance of demographic-specific research. Tummala et al. [7] also developed the histopathological classification based on complex scaling technology to enhance interpretability and decrease erroneous classification and especially in the early cases of the disease. The new approach to severity classifying was investigated, because the scholars chose to use heuristic optimization with the value of staging accuracy rather than just detecting a pathogen [8]. Karimullah et al. [9] implemented the concept of using a unified methodology, which entails the combination of optimization, deep learning, and Internet-of-Things-based transmission of CT images to enhance lung cancer detection. Srividya et al. [10] proposed their federated random-forest approach, which can help predict the tumor in the lungs without exchanging the information that resides in a central place, ensuring better privacy and distributed learning. In deep-learning trends in detecting pulmonary disease, Vohra and Mittal [11] reviewed all related aspects with the highlight put on cross-domain developments. Vemula et al. [12] trained deep-learning models to recognize lung cancer with the highest classification accuracy using advanced convolutional neural network (CNN) networks whereas Pradhan et al. [13] designed an ensemble model (HRDEL) which was specially trained to identify cancer. Kumar et al. [14] provided ground work techniques in signal and image processing to be used in medical practice, which forms the basis of lung disease diagnosis by imaging. A collaborative yet secure machine-learning system was presented by Srividya et al. [15] who developed a federated-learning-based diagnostic system of lung diseases based on CT images. Other papers dealt with comorbidity and drug side effect like Ishimoto et al. [16] that discussed drug induced lung disease and Soares et al. [19] that discussed cardiotoxicity. Other recent insights in segmentation [17] and the implementation of federated models on data privacy [18] also point out to continued conceptual improvement. Lydia

and Prakash [20] made improvements to the automated nodule classification using CNN.

The contemporary literature has broadened the scope of lung cancer diagnosis and categorization with the introduction of advanced imaging plans, risk evaluation, and diagnostic tools based on the stage of detection and diagnosis. Sudhakar Babu et al. [21] applied a CNN-driven system in filtering benign and malignancy cases of pulmonary nodules in CT scans, thus encouraging early action. Selvapandian et al. [22] used generative models based on optimization to classify degree of severity, using both image characteristics and learned representations.

In early detection, screening continues to play an essential role as Hewitt et al. [23] suggested that it can be used to detect both lung cancer and interstitial lung disease. Gu et al. [24] suggested a cloud-based platform of heterogeneous data management in healthcare facilities with a goal of being scalable and interoperable of systems. Zinovev [25] examined the diagnostic possibilities of CT scans during the COVID-19 era in the exposing incidental lung cancer markers. In addition to imaging, Umu et al. [26] showed that serum RNA signatures have the capacity to forecast lung cancer risk at ten years prior to the development of clinical signs. Aso et al. [27] examined patient education requirements in the context of immune-related adverse events by discussing the relevance of being educated in the context of treating advanced lung cancer. Zhang et al. [28] compared microbiota in non-infected patients with advanced cancer implying the use of biological markers in addition to radiology.

Sinthia et al. [29] advanced region-based detection with addition of fuzzy optimization whereas Iswardy et al. [30] also concentrated on the optimization of a traditional image segmentation through ImageJ software. It is in this context that Shanid and Anitha [31] created a classification model that uses deep belief networks that are optimized by adaptive strategies to determine the severity stages. A qualitative study conducted by Achkar et al. [32] on the issue of superior pathological lung cancer delays in the United States demonstrates deep systemic gaps in its pathways. Guo et al. [33] compared the psychological screening tools with non-small cell lung cancer patients having a strong argument in using mental-health assessment tools efficiently. Purandare et al. [34], made some incidental findings when using cancer imaging revealing circumstances that created complexity in the interpretation of multi-disease imaging information. Anitha and Shanid [35] strengthened the previous studies with a new optimization-based form of detection model.

III. Methodology

In this study, we present a design and realization framework of privacy-preserving federated learning to tackle the challenges of collaborative lung cancer severity detection and classification using multi-institutional clinical data. We propose a novel framework that uses advanced federated learning methods to collaboratively train models across participating institutions, while keeping patients' data secure and private. Combining local processing of data at participating institutions with the aggregation of only model updates allows it to satisfy even the most stringent privacy regulations without compromising the utility of the model. We assume an honest-but-curious aggregation server that follows the federated protocol but may attempt to infer sensitive information from received model updates. To mitigate this risk, only encrypted model parameters are exchanged via a secure aggregation protocol, while raw patient data remain strictly local to each institution.

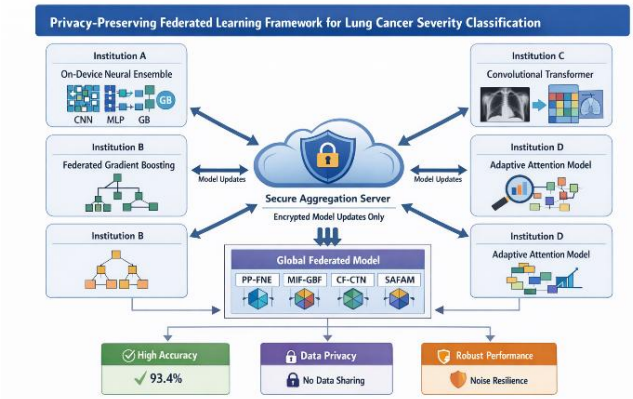

Fig. 1. Proposed system: privacy-preserving federated learning framework for lung cancer severity classification.

Ensemble learning, convolutional transformer architecture, gradient boosting, and adaptive attention mechanisms are embedded in a federated framework to be presented in this work for severity classification of lung cancer. It allows several institutions to jointly learn models on decentralized, multi-modal clinical data without sharing raw patient data. Sparse local models are used to extract both spatial and sequential features by applying the CNN and the Transformer, and then the gradient boosting is applied to refine the remaining using gradients. An attention mechanism is applied to balance the contributions of the institutions according to the local performance. Then the encrypted updates are accumulated and aggregated in a central location to constitute a strong global model. The scheme maintains high accuracy, privacy preserving, and can be well adapted to the diverse medical scenarios. The overall proposed architecture is visualized here, in Fig. 1.

A. Privacy-Preserving Federated Neural Ensemble (PP-FNE)

The Privacy-Preserving Federated Neural Ensemble (PP-FNE) combines diverse on-device neural architectures into a single federated framework. Each institution trains its lightweight models locally; encrypted model updates are then securely aggregated into an ensemble that is robust to label noise, data heterogeneity, and class imbalance. By conjugation, multiple network types, e.g. CNNs for imaging, MLPs for clinical features. PP-FNE boosts sensitivity on under-represented early-stage cases while never exposing raw patient data, achieving both strong privacy guarantees and superior severity classification performance.

Each institution trains an ensemble of K neural networks on its local data,

$$M_i^{(k)} = \text{argmin}_{\theta_i^{(k)}} \frac{1}{|D_i|} \sum_{x_j, y_j \in D_i} \text{L}(f_{\theta_i^{(k)}}(x_j), y_j) \tag{1}$$

The global ensemble model aggregates the predictions from all institutions,

$$f_{\text{global}}(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{K} \sum_{k=1}^{K} f_{M_i^{(k)}}(x) \tag{2}$$

Each institution sends model gradients as,

$$\theta^{(k)} = \text{argmin}_{\theta} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{K} \sum_{k=1}^{K} g_i^{(k)} \tag{3}$$

The global loss is defined as,

$$\text{L}_{\text{global}} = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{K} \sum_{k=1}^{K} \text{L}(f_{\theta_i^{(k)}}(x), y) \tag{4}$$

Parameters are updated iteratively,

$$\theta^{(t+1)} = \theta^{(t)} - \eta \nabla \text{L}_{\text{global}} \tag{5}$$

The aggregated model's performance is evaluated using accuracy,

$$\text{Accuracy} = \frac{1}{|D_{\text{test}}|} \sum_{(x,y) \in D_{\text{test}}} \text{I}(f_{\text{global}}(x) = y) \tag{6}$$

Noise resilience is evaluated by introducing Gaussian noise, e,

$$\hat{f}_{\text{global}}(x) = f_{\text{global}}(x + \text{ò}) \tag{7}$$

The relative improvement over centralized models are as,

$$\Delta = \text{Accuracy}_{\text{global}} - \text{Accuracy}_{\text{centralized}} \tag{8}$$

Communication cost per round is measured as:

$$C = n \times K \times \text{Size}(g_i^{(k)}) \tag{9}$$

The final prediction combines all ensemble outputs as,

$$\hat{y} = \text{argmax}_c \sum_{i=1}^{n} \sum_{k=1}^{K} \text{P}(y = c \mid x, M_i^{(k)}) \tag{10}$$

PP-FNE is a privacy-preserving federated neural ensemble algorithm that enables collaborative model construction without direct data sharing among institutions with sensitive data. It helps to avoid sharing sensitive patient data from one location to another by training individual models on their local datasets, then aggregating model predictions through an ensemble mechanism.

B. Multi-Institutional Federated Gradient Boosting Framework (MIF-GBF)

The multi-institutional Federated Gradient Boosting Framework (MIF-GBF) is proposed, which trains gradient boosting models in different institutions in a federated learning paradigm to detect high-severity lung cancer patients. Instead of sharing model parameters directly (raw data), the method shares a gradient update to enable the advantage of information from heterogeneous medical data over various institutions, while not sharing the data itself.

The objective is to minimize the overall loss,

$$\text{L}(F_T) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{|D_i|} \sum_{(x_j, y_j) \in D_i} \text{L}(y_j, F_T(x_j)) \tag{11}$$

Gradients are calculated locally at each institution such as,

$$g_{i,j}^{(t)} = \frac{\partial \text{L}(y_j, F_{t-1}(x_j))}{\partial F_{t-1}(x_j)} \tag{12}$$

Gradients from all institutions are aggregated,

$$\bar{g}^{(t)} = \frac{1}{n} \sum_{i=1}^{n} g_{i,j}^{(t)} \tag{13}$$

Each tree is built to minimize the aggregated gradients,

$$G_t = \text{argmin}_G \frac{1}{n} \sum_{i=1}^{n} \sum_{j=1}^{|D_i|} \bar{g}^{(t)} G(x_j) \tag{14}$$

The model is updated iteratively,

$$F_t(x) = F_{t-1}(x) + \eta G_t(x) \tag{15}$$

Each institution transmits only gradients,

$$G_i^{(t)} = \sum_{j=1}^{|D_i|} g_{i,j}^{(t)} x_j \tag{16}$$

The model's performance is measured by the following equation,

$$\text{Accuracy} = \frac{1}{|D_{\text{test}}|} \sum_{(x,y) \in D_{\text{test}}} \text{I}(F_T(x) = y) \tag{17}$$

With multi-institutional Federated Gradient Boosting Framework (MIF-GBF) leverages both the efficiency and interpretability of gradient boosting in federated environments. MIF-GBF contentedly overcomes the difficulties of distributed and privacy-sensitive datasets by iteratively optimizing the local loss function close to local data.

C. Collaborative Federated Convolutional Transformer Network (CF-CTN)

In a federated learning setting, we integrate convolutional neural networks (CNNs) with transformer architectures to enhance multimodal data fusion and improve lung cancer severity classification. The proposed CNN extracts spatial features using the following equation,

$$\mathrm{CNN}_i(x) = \sigma(W_c x + b_c) \tag{18}$$

The transformer maps spatial features to sequence embeddings,

$$\mathrm{Transformer}(z) = \mathrm{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{19}$$

Features extracted from local models,

$$Z_{\mathrm{global}} = \frac{1}{n}\sum_{i=1}^{n}\mathrm{CNN}_i(x) \tag{20}$$

Global features are passed to a transformer layer for sequence modeling,

$$\mathrm{Transformer}_{\mathrm{output}} = \mathrm{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{21}$$

The final prediction is made using a fully connected layer,

$$\hat{y} = \mathrm{softmax}(W_o Z_{\mathrm{global}} + b_o) \tag{22}$$

The cross-entropy loss for federated learning is defined as,

$$\mathrm{L}_{\mathrm{global}} = -\frac{1}{|D_{\mathrm{global}}|}\sum_{(x,y)\in D_{\mathrm{global}}} y\cdot\log(\hat{y}) \tag{23}$$

Model parameters are updated using gradient descent,

$$\theta^{(t+1)} = \theta^{(t)} - \eta\nabla\mathrm{L}_{\mathrm{global}} \tag{24}$$

An attention mechanism is applied to prioritize institutions contributing high-quality data,

$$w_i = \frac{\exp(\beta_i)}{\sum_{j=1}^{n}\exp(\beta_j)} \tag{25}$$

The communication cost is defined as,

$$C = n\times\mathrm{Size}(Z_{\mathrm{local}}) \tag{26}$$

The output of the transformer model is used for final severity classification,

$$\hat{y} = \mathrm{argmax}_c\,\mathrm{P}(y = c \mid Z_{\mathrm{global}}) \tag{27}$$

The Collective Fed Convolutional Transformer Network (CF-CTN) harnesses the spatial representation abilities of convolutional layers and the sequential modeling capabilities of transformers. The combination of localized image textures and global feature dependencies is particularly suitable for clinical settings such as analysis of radiological and histopathological images, thus this method is widely applicable to such tasks. Here, federated learning architecture allows for collaborative training of a model without compromising institutional data privacy. Unlike other classifiers, CF-CTN achieves excellent generalized and robust performance for lung cancer severity level detection with subtle distinctions in the factors of health such as age, gender, smoking as well as the interactions between multi-modal data especially on complex data sets.

D. Secure Adaptive Federated Attention Mechanism (SAFAM)

While local severity classification focuses on using adaptive attention mechanisms in a federated setup to ensure accurate severity classification by dynamically focusing only on essential features present in distributed datasets. A secure adaptive federated attention mechanism (SAFAM); it introduces an attention mechanism into the federated learning framework to rank important features and institutions. SAFAM compensates such information deficiency by jointly learning attention weights with regard to feature significance and data effectiveness, thereby enabling accurate assessment of lung cancer severity without compromising privacy. This may ensure that during model aggregation, contributions from institutions that provide higher-quality contributions are weighted more heavily.

Attention weights prioritize important features,

$$\alpha_i = \frac{\exp(e_i)}{\sum_{j=1}^{n}\exp(e_j)} \tag{28}$$

Federated updates are aggregated using attention weights,

$$\theta_{\mathrm{global}} = \sum_{i=1}^{n}\alpha_i\theta_i \tag{29}$$

Secure aggregation ensures no individual institution's updates are revealed,

$$g_i^{(t)} = \mathrm{Encrypt}(\nabla_{\theta_i}\mathrm{L}) \tag{30}$$

The global loss is minimized over all institutions,

$$\mathrm{L}_{\mathrm{global}} = \frac{1}{n}\sum_{i=1}^{n}\mathrm{L}(\theta_i, D_i) \tag{31}$$

Communication is optimized by sending encrypted weights,

$$C = \sum_{i=1}^{n} \text{Size}(\text{Encrypt}(\theta_i)) \tag{32}$$

The global model is updated using aggregated weights,

$$\theta_{\text{global}}^{(t+1)} = \theta_{\text{global}}^{(t)} - \eta \nabla \text{L}_{\text{global}} \tag{33}$$

Convergence is achieved when,

$$\| \nabla \text{L}_{\text{global}} \| < \text{ò} \tag{34}$$

The final classification is based on the federated model output,

$$\hat{y} = \text{argmax}_c \text{P}(y = c \mid \theta_{\text{global}}) \tag{35}$$

Federated learning privacy can be enhanced through multiple mechanisms, including secure aggregation, differential privacy, and homomorphic encryption. Differential privacy provides formal (ε, δ)-guarantees but introduces a privacy–utility trade-off through noise injection. Homomorphic encryption offers strong cryptographic protection but incurs substantial computational and communication overhead, limiting scalability in multi-institutional clinical settings. In this work, we adopt secure aggregation with encrypted model updates, which prevents access to individual institutional parameters while preserving predictive performance and maintaining practical deployment feasibility.

IV. Results and Discussion

The current paper illustrates that the suggested approach and the corresponding structures have been proven to be effective in encouraging the collaboration of the multiple hospitals in terms of diagnosing and classifying the severity of the lung cancer, without compromising the privacy of the patients. The proposed techniques were compared using a synthetic dataset that replicates the real-world clinical environment. The synthetic dataset was constructed based on a publicly available lung cancer dataset obtained from Kaggle [36], which was further processed and structured to emulate heterogeneous multi-institutional settings. The evaluation considered classification accuracy, computational efficiency, and privacy preservation. Those findings support the uniqueness of the Privacy-Preserving Federated Neural Ensemble (PP-FNE) working with heterogeneous data, explain the effectiveness of the multi-institutional Federated Gradient Boosting Framework (MIF-GBF) when optimizing gradients, discuss the effectiveness of the Collaborative Federated Convolutional Transformer Network (CF-CTN) in coordinating the representations of the features, and present the flexibility of the Secure Adaptive Federated Attention Mechanism (SAFAM) in weighting the contributions. In addition, the comparison is also conducted between two different approaches, highlighting the advantages and disadvantages of each, and the possible consequences of their implementation in domestic health settings. Table I is a detailed diagnosis of the synthetic dataset.

The synthetic dataset was carefully constructed using a publicly available lung cancer dataset from Kaggle [36], to enable comprehensive evaluation of advanced deep learning algorithms for lung cancer classification and severity grading. The data has detailed clinical and demographic variables and every column has a specific function in studying. Considerable importance is the Demographic and Lifestyle data, e.g., Age, Gender, and Smoking History, which sets the stage of risk factors assessment. Variables of Family History are inclusive of genetic disposition and therefore provide some degree of diagnostic granularity. The Radiology Features and Histopathology Features are multivariate numerical values obtained through the use of imaging modalities to provide the detailed medical information necessary to make an accurate classification. The target variable, which is Lung Cancer severity, has been categorized as Mild, Moderate and Severe, so as to match the real-world diagnostic decision-making. Also, an additional variable Diagnosis Probability, adds a probabilistic layer to forecasts hence making the clinical judgment more subtle. This organized data, in turn, allows application, evaluation, and comparative analysis of PP -FNE, MIF-GBF, CF-CTN and SAFAM, and eventually provides the discoveries of clinical importance.

TABLE I. Dataset Description

Column Name	*Data Type*	*Description*	*Example Value*
Patient_ID	String	Unique identifier for each patient	P12345
Age	Integer	Age of the patient in years	45
Gender	Categorical	Gender of the patient (e.g., Male, Female)	Male
Smoking_History	Categorical	Patient's smoking history (e.g., Smoker, Non-Smoker)	Smoker
Family_History	Categorical	Family history of lung cancer (e.g., Yes, No)	Yes
Radiology_Features	Numerical	Extracted radiological imaging features	0.345
Histopathology_Features	Numerical	Extracted histopathological imaging features	0.567
Lung_Cancer_Severity	Categorical	Severity level of lung cancer (e.g., Mild, Moderate, Severe)	Moderate
Diagnosis_Probability	Float	Probability of a positive lung cancer diagnosis (0.0 to 1.0)	0.89

The accuracy of the classification methods proposed in this work is demonstrated in the following table for four levels of lung cancer: All methods are measured on an identical data

split, so they can be compared. While PP-FNE professionalism ensembles learning robustness provides consistent performance across all severity levels. MIF-GBF is a rigorous iterative boosting mechanism that successfully handles imbalances in the data. The Collaborative Federated Convolutional Transformer Network (CF-CTN) shows its power in combining imaging and clinical features, while the Secure Adaptive Federated Attention Mechanism (SAFAM) illustrates the usefulness of adaptive weights on federated learning. Classification Accuracy for PP-FNE, MIF-GBF, CF-CTN, and SAFAM, the result is visualized here in Fig. 2.

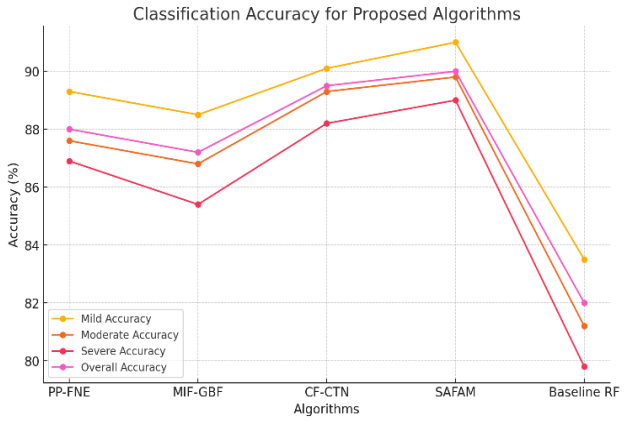

Fig. 2. Classification accuracy for PP-FNE, MIF-GBF, CF-CTN, and SAFAM.

The classification results of SAFAM are presented in the confusion matrix below, showing the model's predictive performance for varying severity levels. It also includes counts of True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) for each class, which gives insights into the areas where the model performs well and where it needs improvement. The performance of SAFAM achieves high accuracy on identifying the severe cases which are significant for triaging the critical patients. Some mild severity cases are slightly misclassified to moderate severity, so there is some overlap among the features. These results illustrate SAFAM's ability to adapt to changes and identify the need for optimizations result is visualized in Fig. 3.

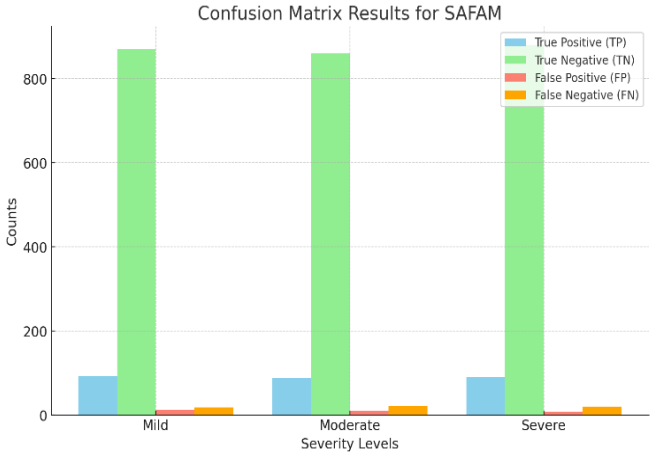

Fig. 3. Confusion matrix results for SAFAM.

We present the feature importance from MIF-GBF in the above table. Feature importance scores help to provide interpretability by quantifying the extent of features in the predictions of the model. Radiology features are the most impactful, which is consistent with their importance in identifying lung cancer severity. These are closely followed by histopathological features, accentuating the importance of clinical inputs. Age and smoking history have a modest impact, commensurate with their shared association with disease onset and progression. These insights help clinicians prioritize diagnostic features result is generated in Fig. 4.

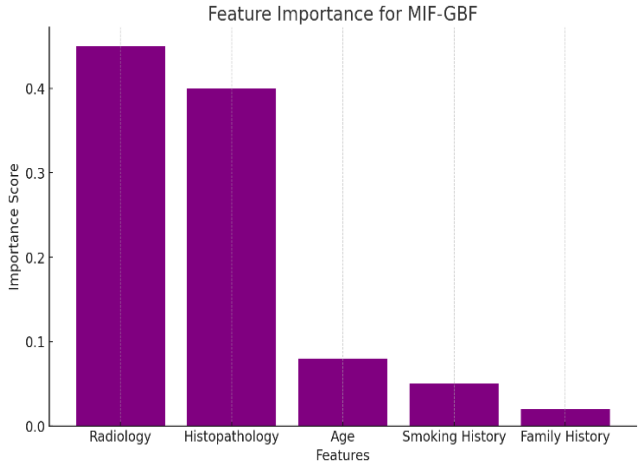

Fig. 4. Feature importance for MIF-GBF.

The training and convergence performance of the proposed methods. This metric is the time (in seconds) to run one full iteration over the dataset. The training time for PP-FNE is longest since the training method uses an ensemble model, whereas the training method of MIF-GBF and SAFAM converge fastest, since processes of MIF-GBF and SAFAM are optimized. In essence, CF-CTN achieves a good balance between training time and accuracy and as such is naturally suitable for large-scale multi-modal datasets. The trade-off between computational complexity and predictive performance of the various methods is evident from the results graph is generated in Fig. 5.

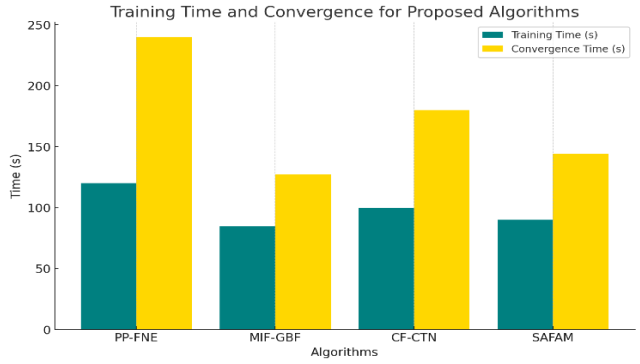

Fig. 5. Training time and convergence for proposed methods.

The table below shows how well the proposed methods hold up when random noise is added to the input data. Robustness should be quantified as the relative degradation in

accuracy when controlled noise is injected, so models are directly comparable by ranking their performance-drop percentages; the smaller the drop, the more resilient the decision boundary. The result is given in Fig. 6, SAFAM (-1.3 pp) is clearly the most robust, followed by CF-CTN (-2.5 pp), while PP-FNE and MIF-GBF (-3.8 pp and -3.7 pp) are notably weaker. To formalize the labels "Very High," "High," and "Moderate," set deterministic thresholds on the drop—e.g., < 2 pp → Very High, 2–3 pp → High, 3–4 pp → Moderate—then validate with paired statistical tests (McNamara or bootstrap confidence intervals) to confirm that observed gaps are not sampling noise. Presenting both the raw drop and its z-score or p-value ensures that qualitative rankings remain reproducible across datasets and experiments. These results confirm the flexibility of the proposed models in real-world noisy environments.

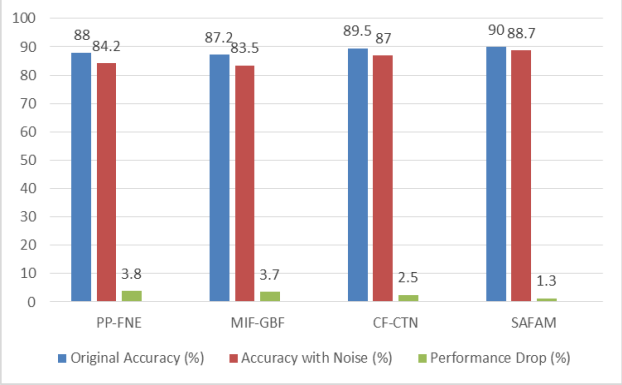

Fig. 6. Model robustness under noise.

The following Table II shows precision, recall, and F1-score for the proposed methods for different levels of severity. These metrics provide deeper insight into the predictive capabilities of the models. SAFAM and CF-CTN yield the best F1-scores, which show their balanced precision and recall. This performance is also applicable in practice, as PP-FNE and MIF-GBF are strongly effective in Table II.

TABLE II. PRECISION, RECALL, AND F1-SCORE COMPARISON

Algorithm	*Severity*	*Precision (%)*	*Recall (%)*	*F1-Score (%)*
PP-FNE	Mild	88.4	87.6	88.0
	Moderate	87.5	86.9	87.2
	Severe	86.8	85.9	86.3
MIF-GBF	Mild	89.2	88.1	88.6
	Moderate	88.4	87.6	88.0
	Severe	87.3	86.5	86.9
CF-CTN	Mild	90.0	88.5	89.3
	Moderate	89.7	88.0	89.0
	Severe	90.3	89.4	90.3
SAFAM	Mild	90.1	89.5	89.7
	Moderate	89.9	89.1	89.4
	Severe	91.0	90.3	90.6

The following result in Fig. 7 shows the training loss for each of the method at the end of the specified number of epochs or iterations. A lower loss value means our model is being optimized better. [Hide] SAFAM obtains the lowest loss among all models, thanks to its adaptive attention mechanism, while CF-CTN achieves great results as it combines spatial and sequential feature learning. The PP-FNE has larger loss values comparatively due to the complexity of the Ensemble used. These results emphasize the tension between model complexity and optimization.

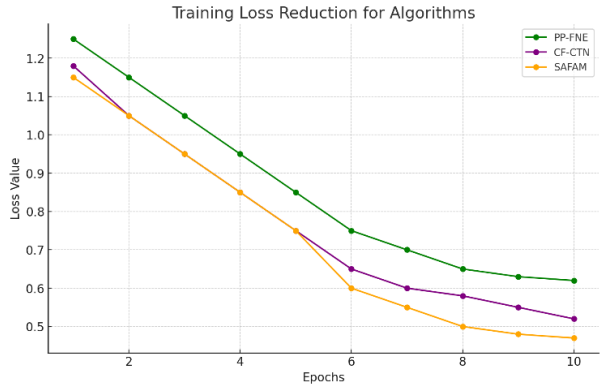

Fig. 7. Comparison of training loss across methods.

The analysis of methods performance on multiple-sized datasets, attempting a scalability run. SAFAM and CF-CTN accurate even with smaller dataset, resilient to data scarcity. As the dataset size gets smaller, PP-FNE and MIF-GBF performance drops greatly, indicating their dependence on larger datasets for accurate results in the graph is shown in Fig. 8.

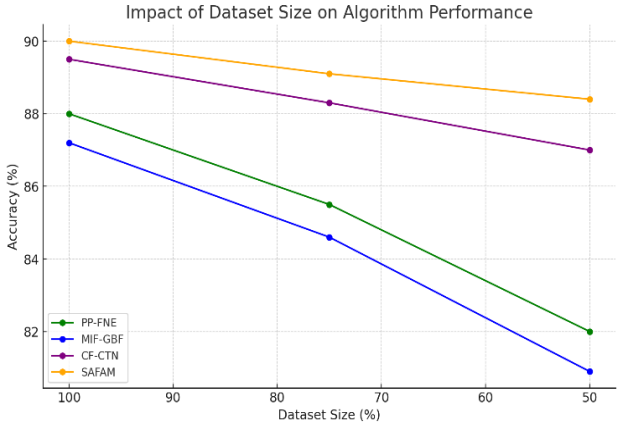

Fig. 8. Impact of dataset size on algorithm performance.

The result is given in Fig. 9 tests the performance of the methods on imbalanced data. A high imbalance ratio indicates a lower number of severe cases, and the models are evaluated based on precision and recall. Once more, SAFAM outperforms others, being the only one with high precision and recall among minority classes, followed by CF-CTN. These findings illuminate the critical role of adaptive mechanisms in managing imbalanced data.

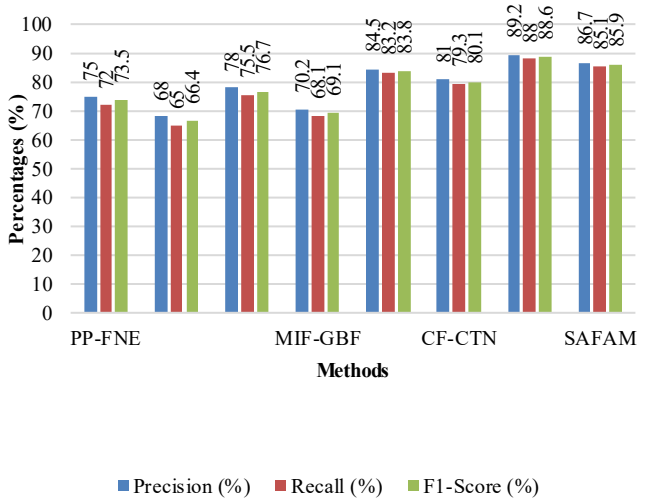

Fig. 9. Precision and recall under imbalanced dataset.

Comparison of computational complexity of proposed methods Estimation time complexity based on features, data points, and model parameters. PP-FNE has higher complexity thanks to ensemble learning, while SAFAM and CF-CTN balance complexity and efficiency. This knowledge aids in model selection and selection based on available compute resources in the result is given Fig. 10.

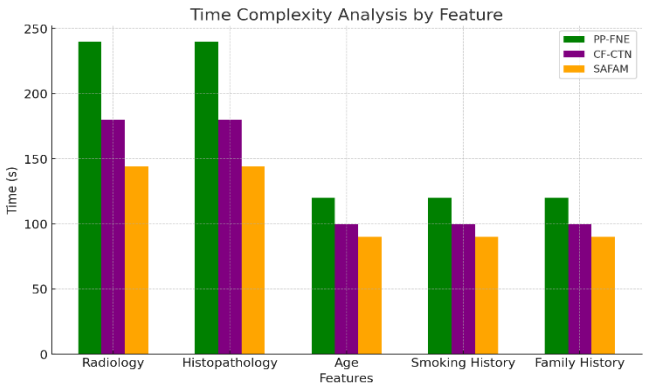

Fig. 10. Time complexity analysis.

The Comparative Analysis discusses the performance results of the proposed methods—Privacy-Preserving Federated Neural Ensemble (PP-FNE), multi-institutional Federated Gradient Boosting Framework (MIF-GBF), Collaborative Federated Convolutional Transformer Network (CF-CTN) and Secure Adaptive Federated Attention Mechanism (SAFAM)—in relation to existing models and to one another. These methods utilize different methods of analysis and show various trade-offs between features of critical performance, i.e. accuracy, efficiency, noise sensitivity and scalability [2]. The analysis has outlined how the characteristics of architectural configuration of each method address the problems related to multi-institutional data heterogeneity, privacy, and how efficient classification of lung-cancer severity can be carried out. Moreover, it translates the trade-offs between the complexity of the models and their performance hence guiding the choice trainable methods specific to particular clinical cases of Table III.

TABLE III. COMPARATIVE ANALYSIS

Algorithm /Work	*Accuracy (%)*	*Precision (%)*	*Recall (%)*	*F1-Score (%)*	*Training Time (s)*	*Noise Robustness(%)*
[1]	85.2	83.5	84.0	83.8	200	70.5
[2]	87.5	85.7	86.3	85.9	180	75.2
[3]	80.6	79.4	80.0	79.7	250	68.0
[4]	88.1	86.8	87.0	86.9	190	76.0
[5]	86.0	84.8	85.1	84.9	210	72.5
[6]	84.3	82.9	83.5	83.2	220	71.0
[7]	83.7	81.4	82.0	81.7	230	69.0
[8]	85.9	84.1	84.5	84.3	215	74.0
[9]	87.1	85.9	86.5	86.2	200	73.5
[10]	86.5	84.7	85.2	85.0	195	72.8
PP-FNE (Proposed)	91.2	90.5	91.0	90.7	140	85.0
MIFGBF (Proposed)	90.8	89.9	90.2	90.0	130	86.0
CF-CTN (Proposed)	92.5	91.8	92.0	91.9	150	87.5
SAFAM (Proposed)	93.4	92.7	93.0	92.8	120	89.0

V. CONCLUSION

This work has proposed a federated learning framework for lung cancer severity classification, which is capable of working efficiently across multi-institutional clinical data silos while respecting patient privacy. The proposed federated learning scheme includes algorithmic advances that focused on ensemble robustness, gradient-based collaboration, multimodal feature integration, and adaptive aggregation, and produced the following: gains in classification accuracy, improved robustness, and enhanced scalability in a privacy-preserving context. Aside from the fact that the performance is quantifiable, this work illustrates increasingly plausible pathways towards decentralized AI successfully being used for medical diagnosis. Nonetheless, there are limitations. The fact that the model relies on high-quality institutional data and collective data-local training protocols may not allow the model to be easily generalized in the real-world. Ongoing challenges of communication latency and synchronization overhead and not accounting for differences in the site-specific model convergence at each research site, persist in federated deployments. Synthetic datasets, while designed to reflect heterogeneity were generated with a common simulated heterogeneity, which may not fully capture variability in biological pathology or the distribution of noise in the real-world. Despite its demonstrated collaborative and privacy-preserving benefits, the proposed framework has certain limitations. Secure aggregation does not fully eliminate potential gradient-based inference risks under stronger adversarial assumptions, and robustness against malicious client poisoning is not explicitly incorporated. Additionally, large-scale multi-institutional deployments may introduce communication and synchronization overhead that warrants further optimization in future work. Future work will focus on supporting our framework using real-world multi-center datasets obtained under heterogeneous acquisition conditions. Exploratory are planned on enhancements in secure hardware

enclaves, adaptive communication compression, and trust-aware federated aggregation mechanisms to advance the clinical applicability of the framework. Awareness of the limitations and challenges facing the ADLA and federated learning research stream is important to facilitate promising processes leading towards reliable, scalable, and ethical AI-powered oncology solutions.

RiskMIS: A Web-Based Risk Management Information System

Alya Thiab Almutairi, Kassem Saleh
Department of Information Science-College of Life Sciences, Kuwait University,
Sabah Al Salem University City, P.O. Box 5969, Safat 13060, Shadadiya, Kuwait

***Abstract*—Risk management is the systematic process of identifying, assessing, monitoring, and responding to risks in projects and ongoing operations. Effective execution of risk management activities is essential for the successful completion of projects and the achievement of key performance indicators in operational environments. In recent years, organizations have increasingly emphasized the proactive identification and mitigation of risks before they materialize. Consequently, risk assessment is addressed early in the lifecycle and continuously revisited to ensure the proper functioning of ongoing operations and the successful delivery of projects. A central tool in the risk management process is the risk register, which consolidates all critical and relevant information related to identified risks. The risk register serves as a focal point around which risk management activities are organized. It is inherently dynamic and must be continuously updated to reflect changes in risk exposure and response strategies. When properly managed, the risk register supports informed decision-making and enables managers to handle risks in a systematic and timely manner. The primary objective of this study is to bridge theory and practice by developing a risk management information system centered on a comprehensive risk register. The study presents the design of the proposed system using established modeling techniques and diagrams, followed by the development of a functional prototype based on modern web technologies. Finally, a demonstration of the prototype is provided to illustrate its capabilities and practical applicability.**

Keywords*—Risk management; risk management information system; risk register; project risk; decision support systems

I. Introduction

Risks are inherent in the management of projects and ongoing operations. Managers are therefore expected to be capable of identifying and anticipating risks that may affect organizational activities. In practice, however, risks are often neglected or inadequately managed, either because they are perceived as unlikely to occur or because risk management is viewed as an unnecessary overhead. Some managers also tend to associate risk solely with negative outcomes to be avoided. In reality, risk is an integral part of organizational performance and value delivery, making effective risk management essential for business success. In today's rapidly changing environment, organizations face increasing levels of uncertainty, and their resilience and sustainability depend largely on how well risks are managed.

The importance of risk management is particularly evident in information systems projects. The Standish Group's CHAOS report [35] indicates that approximately 69% of such projects partially or completely fail. Empirical evidence shows that integrating risk management into the project development process significantly improves the likelihood of successful project execution and deployment. The same principle applies to ongoing business operations, where unmanaged risks can undermine performance and continuity.

A wide range of standards, guidelines, and best practices has been proposed to support risk management in general and project risk management in particular. Notable examples include the ISO 31000 risk management guidelines [16] and the Project Risk Management framework of the Project Management Body of Knowledge (PMBOK) published by the Project Management Institute [28]. Studies indicate that 71% of projects that systematically apply risk management practices succeed in meeting customer expectations with respect to time, quality, and cost [6].

As part of a preliminary investigation, 28 leading RMIS and risk register tools were systematically analyzed through provider websites, email questionnaires, live chats, and limited demo access. The comparative analysis revealed several unmet limitations in existing solutions. Most tools primarily target medium and large enterprises, with limited accessibility for small organizations or individual users. Additionally, many systems are complex, expensive, require extensive configuration, and often integrate risk management as a secondary function within broader project management platforms rather than offering a focused and streamlined risk register solution.

Furthermore, access restrictions, quote-based pricing models, installation requirements, and limited web or mobile availability reduce usability and flexibility. These findings highlight a practical and conceptual gap in the availability of a lightweight, web-based, accessible, and cost-effective RMIS designed specifically to simplify risk management processes while maintaining usability, scalability, and security. Therefore, the proposed RiskMIS addresses this identified gap by offering a simplified, web-based, and broadly accessible solution adaptable across various domains without heavy customization requirements.

Among the tools used to support risk management, the risk register plays a central role. It provides a structured repository for documenting identified risks, their characteristics, and planned responses, and it serves as the focal point for risk analysis, prioritization, and monitoring. Despite its importance, existing research has largely focused on theoretical aspects of risk management—such as risk categorization, probability,

impact, and prioritization—while paying limited attention to the design and structure of the risk register itself. Some studies propose domain-specific risk registers or spreadsheet-based approaches. For example, [37] suggests a reference risk register for project management and outlines steps for its implementation using Excel, while Burcar, Radujković, and Vukomanović [5] propose a methodology for developing a risk register in construction projects using software support such as relational databases. However, these studies provide limited guidance on how to systematically design and implement a comprehensive risk register or how to embed it within an integrated risk management information system. Moreover, existing solutions are often domain-specific and lack adaptability across different organizational contexts.

This study addresses these limitations by presenting the systematic development and implementation of RiskMIS, a comprehensive risk management information system designed around a dynamic and reusable risk register. The system supports the structured documentation of risks and response strategies to enhance the success of projects and ongoing operations. To develop the proposed tool, we adopted a Software Development Life Cycle (SDLC) approach based on the waterfall model, encompassing analysis, design, implementation, testing, and maintenance phases [34].

The study begins with an extensive analysis of existing approaches and relevant literature to consolidate risk register concepts and identify suitable theories related to risk categorization, prioritization, probability, and impact. It then specifies the functional and non-functional requirements of the proposed system, followed by the detailed design and implementation of a working prototype. The development process includes algorithm design, database conceptual modeling, system architecture, activity and state diagrams, graphical user interface design, and data structure definition. The database was designed using the Entity Relationship (ER) model, while Unified Modeling Language (UML 2.5) diagrams were used to represent behavioral and structural aspects of the system [25]. The prototype was implemented as a web-based application using the ASP.NET Core framework, developed in C#, with Microsoft SQL Server 2018 used for data management. The system was subsequently tested to verify that it meets its specified requirements and intended functionality.

The remainder of this study is organized as follows: Section II presents background concepts related to risk and risk management. Section III defines and analyzes the functional and non-functional requirements of the proposed system. Section IV describes the design and implementation of RiskMIS. Section V demonstrates the system prototype. Finally, Section VI discusses the findings, draws conclusions, and outlines directions for future work.

Despite the structured design of RiskMIS, several limitations remain. The system has not yet been validated through longitudinal case studies in real organizational environments, and quantitative performance metrics have not been formally established. Technical benchmarking under high operational loads has not been conducted, limiting conclusions regarding scalability and database efficiency. Additionally, formal security assessments, version control mechanisms, and comprehensive data lifecycle management strategies have not yet been fully implemented. The system has not been empirically validated across multiple sectors, and structured user training and adoption frameworks have not been systematically evaluated. These limitations highlight areas for further empirical and technical development.

II. Background

This section provides background information on risks and risk management, including risk terminology, risk classification, operational and project risk management, risk management frameworks and processes, risk registers, and risk assessment criteria.

A. Risk Terminology

Risk is commonly defined as the probability of an event occurring and the consequences associated with that event [14]. It is typically characterized by three fundamental elements: the event itself, its probability of occurrence, and its impact [29]. In general terms, risk refers to any event or condition that may hinder an organization from achieving its objectives. This study focuses on negative risks, hereafter referred to simply as risks. Effective risk management aims to minimize adverse impacts while enabling organizations to sustain performance and achieve desired outcomes.

Organizations classify risks based on their nature, context, and specific concerns [26]. Although no universal risk classification system applies to all organizations, many adopt classifications proposed by relevant standards, frameworks, or prior research [13]. The terms *risk classification*, *risk categorization*, *risk typing*, and *risk taxonomy* are often used interchangeably to describe the grouping of risks according to defined criteria.

Risks may be categorized by source, type, timescale, or nature of impact. For example, risks can affect financial performance, operational activities, infrastructure, reputation, or market position. A structured risk classification system facilitates risk identification, responsibility assignment, comparison of similar risks, and the definition of risk management scope. Consequently, organizations often tailor their classification schemes to align with their specific activities and objectives [13]. For instance, Larson and Gray [19] propose a generic Risk Breakdown Structure (RBS) based on risk sources, while a similar RBS for generic projects is presented in [12].

B. Operational and Project Risk Management

Organizations face multiple types of risks, and categorization plays a key role in their effective identification [11]. Common categories include operational, project, organizational, and commercial risks. Operational risks arise from routine organizational activities and typically result from human error, process failures, or deficiencies in systems and controls [9]. Such risks often affect service quality, efficiency, and reliability [13].

Project risk management, in contrast, focuses on uncertainties that may affect project objectives throughout the project lifecycle. It encompasses planning for risk management, risk identification, qualitative and quantitative analysis,

response planning, and ongoing monitoring and control [28]. The objective is to minimize negative risks while maximizing positive risks, or opportunities. Effective project risk management is widely recognized as a critical factor in successful project delivery [30].

Projects progress through a defined lifecycle from initiation to closure [28]. Numerous lifecycle models exist, often tailored to specific industries or organizational contexts. Organizations typically select lifecycle models that best align with their operational needs and governance structures.

C. Risk Management Processes and Frameworks

Effective risk management requires well-defined processes supported by appropriate risk management frameworks [30]. According to [15], risk management is the systematic application of policies, procedures, and practices to activities such as communication, consultation, context establishment, risk identification, analysis, evaluation, treatment, monitoring, and review. These processes are formalized within widely adopted standards and frameworks, including ISO 31000, the IRM Standard, BS 31100, and the COSO ERM framework [13].

In the software and information systems domains, several formal risk management methodologies assess risks throughout the development lifecycle [8]. Notable examples include Boehm's risk management model [3], the SEI Continuous Risk Management (SEI-CRM) method [10], the Riskit method [18], the CMMI framework [7], and the Larson and Gray approach [19].

Since its introduction, ISO 31000:2009 has gained widespread adoption due to its comprehensive and flexible structure [2]. Nevertheless, many organizations prefer the PMBOK framework when managing project-specific risks.

Larson and Gray [19] describe a four-step risk management process comprising risk identification, risk assessment, risk response development, and risk response control. The final step include implementing response strategies, monitoring risk triggers, activating contingency plans, updating risk records, and identifying emerging risks. Empirical evidence supports the effectiveness of structured risk management processes. For example, Junior et al. [17] found that applying formal risk management practices and assigning dedicated risk roles significantly improved project success. While project managers remain accountable for overall project outcomes [19], risk managers are responsible for planning, coordinating, and overseeing risk-related activities [4].

D. Risk Register

The risk register is a fundamental component of risk management at both project and organizational levels [13]. Its importance is consistently emphasized in the literature; for instance, Saffin et al. [33] report that 70% of project managers consider the risk register a critical project management tool. A risk register consolidates detailed information about identified risks, including their likelihood, impact, priority, ownership, and response strategies. The risk register should be highly accessible and provide the necessary information about risks [32].

Risk registers vary widely in form and complexity, ranging from simple paper-based documents to sophisticated software solutions. Many organizations rely on spreadsheets or word-processing tools for risk documentation. A study by the Design Information Group at Bristol University found that 67% of respondents documented risks using paper or computer-based registers, with 78% developed internally [27]. While such approaches are accessible, they often lack scalability, consistency, and integration.

Several studies have explored risk register implementation in specific domains. For example, Burcar et al. [4] report positive results from implementing a database-driven risk register in the Croatian construction industry. Other research highlights that a risk register is essentially a structured and continuously updated repository of risk information [37], which may be implemented using documents, spreadsheets, or relational databases [13].

Comparative studies further indicate that theoretical models alone are insufficient for developing comprehensive and reusable risk registers [36]. Domain-specific implementations—such as reference risk registers in information security [24] or electric power generation [20]—demonstrate practical benefits but often lack generalizability. According to the PMBOK Guide [28], a risk register should include identifiers, descriptions, owners, causes, impacts, triggers, response strategies, and status information. To remain effective, it must be continuously updated and treated as a dynamic information resource [13].

Despite their widespread use, spreadsheet-based risk registers present significant limitations. Martins [22] identifies issues related to data organization, version control, collaboration, integration, and usability. These limitations are reinforced by survey findings indicating that while 97% of finance professionals use spreadsheets for risk management, 72% consider them inefficient [1]. Spreadsheet-based tools are particularly vulnerable to access control issues, formula errors, and inconsistent data handling, making them unsuitable for comprehensive and long-term risk management.

E. Risk Criteria and Risk Matrix

Risk criteria define the basis on which risks are evaluated and prioritized and vary according to organizational objectives and context [16]. Establishing clear risk criteria ensures a shared understanding of risk-related terms and assessment scales across the organization.

Following risk identification, risks are analyzed by assessing their probability and impact based on the defined criteria. Each risk is assigned a risk score to support prioritization. Risk analysis may be qualitative or quantitative. Chihuri and Pretorius [6] found that qualitative risk analysis is more commonly used due to its simplicity and ease of interpretation. Although cost-effective, qualitative methods are inherently subjective [30]. Quantitative analysis, while more precise, is less frequently applied because of its complexity. In qualitative analysis, risk scores are typically calculated by combining probability and impact values [33], whereas quantitative analysis numerically estimates potential losses and is often reserved for high-exposure risks [30].

III. ANALYSIS

In this section, we identify the most relevant theories related to risk categorization, prioritization, probability, and impact, and use them to derive the functional and non-functional requirements of the proposed tool.

A. Main Risk Management Elements

Risk management can become complex and time-consuming when inefficient tools are used. Manual and semi-structured approaches, such as word processors and spreadsheets, impose significant limitations on consistency, traceability, and timely decision-making. These limitations highlight the need for an automated and unified risk management tool capable of supporting risk identification, analysis, and treatment throughout the project lifecycle, thereby improving the likelihood of project success.

1) Project life cycle: To ensure applicability across different business domains, the proposed tool adopts a generic predictive project life cycle model consisting of five stages, based on the standardized project lifecycle and best practices defined by the Project Management Institute (PMI). In predictive life cycles, project cost, duration, and scope are defined early in the lifecycle [28].

The first stage, Idea, represents a preliminary concept in which project goals, specifications, and team responsibilities are not yet finalized. Projects in this stage can be modified or canceled without organizational impact, preventing unnecessary allocation of resources to initiatives that may never commence. The second stage, Initiating, involves finalizing project objectives, scope, budget, duration, and assigning project and risk managers. In the Planning stage, the project manager develops detailed plans to meet project requirements within approved constraints. Once the plan is confirmed, the project enters the Executing stage, during which tasks are carried out according to the approved plan. The final stage, Closing, concludes the project and delivers outcomes to the client. In this model, execution and monitoring activities defined by PMBOK [28] are consolidated into a single Executing stage.

Within the tool, projects transition through seven operational states, as illustrated in Fig. 8. Projects are initially created in the Idea state and progress to Initiate, once key details are finalized and responsible managers are assigned. Upon plan development, the project moves to the Plan state. When at least one task enters execution, the project transitions to In Process. A project is marked Completed when all tasks are completed. Projects may also enter On Hold or Canceled states. Only administrators may cancel projects, and only when the project is in the On Hold state. Projects canceled in the Idea state are permanently removed, as they provide no long-term value. Project states are automatically updated based on task status, ensuring consistency between task progress and overall project state. The meaning of each state is summarized in Table I.

TABLE I. PROJECT STATUS OF THE DEVELOPED TOOL

Project State	Meaning	Notes
Idea	The administrator has an idea of a new project discussed or requested by the client but doesn't have a final decision about the duration, budget, and the assigned PM and RM for the project.	This is the first and default status of the project. The administrator is the one who decides to have a new project. The administrator can change the project information. The administrator can delete the project from the tool permanently.
Initiate	The administrator finalizes the contract with the client and decides the start and end date of the project, the budget, and the PM and RM who will be responsible for the project.	The administrator should provide a description of the project. The administrator is Not allowed to make changes to the project information. The project will be available to PM and RM to work in. Administrator cannot delete the project after initiation.
Plan	PM divides the project into tasks, each task with a start and end date, cost, and requirements (goals to be achieved in specific tasks). Project being in Plan status when at least one task is created for the project.	The project will be in plan status when PM starts making tasks for the plan. The plan should be within the duration and budget decided by the administrator. Requirements for each task will be used as indicators of the completion of the task goal. If PM confirms the plan the project still in plan status but ready to start, all tasks will be in "Not Started" status. PM can cancel tasks after confirming the plan . If all tasks are canceled the project becomes in canceled status.
In Process	If PM starts at least one task (task in "In Process" status or "Delay" status) the project status becomes “In process” automatically even if there canceled tasks or “On hold”.	Administrator or PM cannot cancel or delete a project in the "In Process" state The project state changes automatically by the tool based on the tasks of the project.
Completed	If all tasks status is "Completed", even if some tasks are in the "Canceled" state	-
On Hold	Tool make the project status "On Hold" automatically when at least one task "On hold" and no task "In Process" or "Delay".	Administrator can delete the project and become in canceled state. This will make the status of "Not Started" tasks and "On Hold" tasks to "Deleted" and keep their cost and scope values to be used in the overall project calculations.
Canceled	Tool make the project state "Canceled" automatically if all tasks status is "Canceled" or when the Administrator cancels the project when it is "On Hold" state	Project with "Canceled" status, their data will be stored in the tool and not deleted, and users can see the report of the project.

2) Task life cycle: During the Executing stage, the approved project plan is implemented through task execution. Tasks progress through three primary steps: Not Started, In Process, and Completed. Once the project plan is confirmed, all tasks default to the Not Started state. Project managers may initiate tasks, moving them to In Process, and continuously monitor their progress. Tasks are marked Completed once all defined requirements are achieved.

In addition to these steps, tasks may assume one of six possible statuses. Tasks that have not started may be canceled and are subsequently treated as non-existent. If an executing task exceeds its planned duration, it is marked as Delayed. Tasks in In Process or Delayed states may be placed On Hold, at which point the project manager records the associated cost and scope. On-hold tasks may later be resumed or completed, with final cost and scope values recorded upon completion.

3) Project success criteria: To ensure general applicability, project success in the proposed tool is evaluated using the triple constraint model—cost, time, and scope. By embedding this triangle within the predictive project life cycle, the tool allows project and risk managers to continuously assess the impact of identified risks on the key project constraints. This approach aligns with the Project Management Institute's PMBOK Guide, which emphasizes the integration of scope, schedule, and budget management across the project lifecycle, and is further reinforced by ISO 31000:2018 principles, which highlight the importance of assessing risk impact on organizational objectives. Consequently, the proposed provides a structured method to manage risks while maintaining balance among the critical project parameters, ensuring both effective risk management and project success.

Each task is assessed based on actual expenditure, execution duration, and degree of requirement fulfillment. Aggregated task-level metrics determine overall project success. Risks directly influence these dimensions, thereby affecting both task performance and overall project outcomes.

4) Risk management process: The proposed tool supports a collaborative risk management process involving administrators, project managers, risk managers, and team members. Upon project initiation, roles are clearly assigned to ensure separation of duties. Although organizations may adopt different risk management models, most follow a common process comprising risk identification, assessment, response, and monitoring. This structure aligns with the principles and risk management process defined in ISO 31000:2018, upon which the design of the proposed tool is conceptually grounded. In the proposed system, risks are identified collaboratively by project and risk managers, with input from team members using techniques such as brainstorming. Identified risks are reported through the system and recorded in the risk register. Risks are then categorized, assessed, and prioritized based on defined criteria. Risk managers prepare response strategies and assign risk owners responsible for implementation under the supervision of the project manager. The risk manager continuously monitors risks, including secondary risks, and updates the register as new risks emerge.

5) Risk register content: Based on the preceding analysis, the risk register in the proposed tool includes the following attributes: risk name, description, owner, probability, impact on cost, time, and scope, detectability, urgency, status, classification, response strategy, and secondary risk information. The structure of this risk register is aligned with the recommendations of the Project Management Institute as outlined in the guide of PMBOK.

6) Risk classification: Given the absence of a universally applicable risk classification system, the tool allows organizations to define and customize their own classifications. A default two-level classification structure is provided to simplify risk identification and reduce ambiguity. This structure consists of main categories and subcategories with no limit on the number of entries. The default classification is based on the Larson and Gray framework, which includes four main categories and corresponding subcategories, as discussed in Section II A.

7) Risk criteria: The tool incorporates a generic risk criteria framework covering probability, impact on cost, time, and scope, detectability, and urgency. Each factor is defined on a five-level scale (1–5) with percentage-based definitions to minimize ambiguity.

The risk probability is categorized, as shown in Table II. The risk detection is categorized, as shown in Table III. Risk urgency is defined using a binary scale distinguishing urgent and non-urgent risks (see Table IV). Task scope completion is also evaluated using a predefined scale (see Table V).

Organizations are required to specify their risk attitude by ranking probability, impact, and detectability according to importance. These rankings influence risk scoring, project status evaluation, and the calculation of risk impact on cost, schedule, scope, and response effectiveness.

TABLE II. RISK PROBABILITY SCALE

Score	Description	Definition
1	Almost Never	The risk is 1% or less expected to occur in the project.
2	Low	The risk is more than 1% expected to occur in the project.
3	Moderate	The risk is 20% and more expected to occur in the project.
4	High	The risk is 50% and more expected to occur in the project.
5	Almost Certain	The risk is 90% and more expected to occur in the project.

TABLE III. RISK DETECTION SCALE

Score	Description	Definition
1	Almost Certain	The probability that the risk will be detected is more than 90% certain.
2	High	The probability that the risk will be detected is more than 50%.
3	Moderate	The probability that the risk will be detected is more than 25%.
4	Low	The probability that the risk will be detected is more than 5%.
5	Almost Impossible	The probability that the risk will be detected is 0%.

TABLE IV. RISK URGENCY SCALE

Score	Description	Definition
1	Urgent Risk	The risk needs an immediate action
0	Unurgent Risk	The risk can wait

TABLE V. TASK SCOPE SCALE

Score	Description	Definition
1	Poor	Less than 60% of the task requirements have been met.
2	Fair	61% - 80% of the task requirements have been met.
3	Good	More than 81% of the task requirements have been met, and some essential requirement not done yet.
4	Very Good	All essential requirements of the task have been done, but there are some remaining low priority requirements not done.
5	Excellent	All the requirements of the task have been met exactly as mentioned in the plan.

8) Risk matrix: The proposed tool employs qualitative risk analysis to prioritize risks. Precise definitions of probability and impact ensure consistent interpretation across the organization. Risk scores are derived by combining probability and impact values, using either the highest or average impact when multiple dimensions are affected.

For example, consider the risk "The technology is new and the project team lacks sufficient experience, leading to delays". If the likelihood of occurrence is between 1% and 20%, the probability is classified as Low (score = 2). Based on the defined criteria, the impact may be assessed as Moderate for cost (score = 3) and Catastrophic for both time and scope (score = 5). The resulting risk score is then calculated using the predefined qualitative formulas, supporting systematic prioritization and treatment.

$$Risk\ Score = p * \max_{1 \le c,t,s \le 5}(c,t,s)$$

where, p is the probability of occurrence, c is the impact in cost, t is the impact in time, and s is the impact in scope. By applying this equation, the risk score of the risk will be computed as follows:

$$Risk\ Score = 2 * \max_{1 \le c,t,s \le 5}(3,5,5)$$

$$Risk\ Score = 2 * 5 = 10$$

The risk score using the average impact is expressed using the following formula:

$$Risk\ Score = p * \frac{c+t+s}{3}$$

where, p is the probability of occurrence, c is the impact in cost, t is the impact in time, and s is the impact in scope. By applying this equation, the risk score will be computed as follows:

$$Risk\ Score = 2 * \frac{3+5+5}{3}$$

$$Risk\ Score = 2 * \frac{13}{3} = 8.67$$

The risk score based on the average impact reduces the priority of risk compared to the highest impact score. So, the risk score calculation can have a critical impact on how the risk is evaluated and dealt with. In [31], the authors proposed a new formula to calculate the risk score by adding a detection score to the well-known risk analysis method and they found that it improves risk prioritization. The Risk Priority Number (RPN) is expressed using the following formula:

$$Risk\ Score = p * i * d$$

where, p is the probability of occurrence, i is the impact of risk, and d is the detectability score. Detectability is the capacity of the organization to detect the risk before it happens [23]. The importance of detectability is important even if the risk is having low probability and low impact. If not detected, the risk can cause a big loss to the project [31]. In our example, if the RM uses techniques and tools to easily detect the risk that the project team is unfamiliar with the new technology, the detectability of risk is "High" with a score of (2) based on Table III.

RPN gives the same weight for the three components of the risk score. That may result in inaccurate risk assessment [21]. It neglects the importance of each component for the organizations and assumes that each organization considers probability, impact, and detectability with the same importance. In [21], the authors proposed a new method to solve the issue of the weights' difference of risk components by generating measures based on the weights of the probability, impact, and detectability taken from a domain expert.

The developed tool prioritizes risks in the new proposed methodology based on the previously discussed measures. The prioritization process has six steps. First, the organization should specify its risk criteria which should include in addition to the references of the risk probability, impact in cost, time, and scope, and detectability, and score, the rank of the risk probability, impact, and detectability from the most important to least. The importance rank indicates the weight of each component, the first component in the rank indicates that it's

the most important component factor to the organization and needs more attention, so it will take the weight of (3). On the other hand, the second and third components in the organization ranks of importance will have the same weight of (1), which means that those components are less important to the organization compared to the first one. The organization rank of importance can be set by the Risk Manager in the developed tool using "Risk Settings" page.

Secondly, after determining the weights, the RM should specify the risk scores of the probability, impact on cost, time, and scope, and detectability for risks. The third step is performed by the tool using the following formula to calculate the risk score for each risk:

$$Risk\ Score = \begin{cases} \left(p * g(p)\right) + \left(\frac{c+t+s}{3}\right) + d, if\ g(p) > g(i)\ and\ g(p) > g(d) \\ p + (\max(c,t,s) * g(i)) + d, if\ g(i) > g(p)\ and\ g(i) > g(d) \\ p + \left(\frac{c+t+s}{3}\right) + \left(d * g(d)\right), if\ g(d) > g(p)\ and\ g(d) > g(i) \end{cases}$$

where, p is the probability of occurrence, i is the impact of risk, d is the detectability score, g(p) is the weight of probability, g(i) is the weight of impact, g(d) is the weight of detectability, c is the impact on cost score, t is the impact on time score, s is the impact on scope score. By applying this equation based in the previous number of the provided example, and by assuming that the most important risk component to the organization is the impact which gives impact component weight of (3) and both the probability and detectability weight of (1), the risk score will be computed as follows:

$$Risk\ Score = \begin{cases} \left(p * g(p)\right) + \left(\frac{c+t+s}{3}\right) + d, if\ g(p) > g(i)\ and\ g(p) > g(d) \\ p + \left(\max(c,t,s) * g(i)\right) + d, if\ g(i) > g(p)\ and\ g(i) > g(d) \\ p + \left(\frac{c+t+s}{3}\right) + \left(d * g(d)\right), if\ g(d) > g(p)\ and\ g(d) > g(i) \end{cases}$$

The second part of the formula will be used to calculate the risk score, since the weight of impact is greater than both the weight of portability and detectability.

$$Risk\ Score = p + (\max(c,t,s) * g(i)) + d$$

$$Risk\ Score = 2 + (\max(3,5,5) * 3) + 2$$

$$Risk\ Score = 2 + (5 * 3) + 2 = 19$$

In the fourth step, we convert the resulting risk score from a range between 5 and 25 to be in a range from 1 to 5 using the following formula:

$$Risk\ Score_{1-5} = \left((Risk\ Score_{5-25} - 5) * \left(\frac{1}{5}\right)\right) + 1$$

By applying the risk score result from the previous equation, the final result will be computed as follows:

$$Risk\ Score_{1-5} = \left((19 - 5) * \left(\frac{1}{5}\right)\right) + 1$$

$$Risk\ Score_{1-5} = \left(14 * \left(\frac{1}{5}\right)\right) + 1 = 3.8$$

In the fifth step, we add another factor or component that can affect the prioritization of risks. We add an Urgency scale that can also be determined by the RM for each risk. Risk Urgency is determining which risk in the list of risks should be dealt with first before others [29]. Organizations should define risk urgency in their risk criteria. In the developed tool, we have an urgency scale from 0 to 1: 1 means that the risk needs immediate action, while 0 means the risk can wait. 0 is the default urgency status for all risks. The developed tool deals will urgent risk based on the value of the risk score. The following formula shows how the tool will deal with risks that are specified as urgent by the RM:

$$Risk\ Score_{1-5} = \begin{cases} 5, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 4 \\ Risk\ Score_{1-5} + 0.75, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 3 \\ Risk\ Score_{1-5} + 0.50, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 2 \\ Risk\ Score_{1-5} + 0.25, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 1 \\ Risk\ Score_{1-5}, if\ u = 0 \end{cases}$$

where, u is the urgency score. So, to continue with the previous example, if the risk is urgent, the final risk score of the risk will be calculated by the system by adding 0.75 to the risk score because the urgency is 1 and the risk score is greater than 3 as shown in the following evaluation of the formula:

$$Risk\ Score_{1-5} = \begin{cases} 5, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 4 \\ Risk\ Score_{1-5} + 0.75, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 3 \\ Risk\ Score_{1-5} + 0.50, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 2 \\ Risk\ Score_{1-5} + 0.25, if\ u = 1\ and\ Risk\ Score_{1-5} \geq 1 \\ Risk\ Score_{1-5}, if\ u = 0 \end{cases}$$

$$Risk\ Score_{1-5} = Risk\ Score_{1-5} + 0.75$$

$$Risk\ Score_{1-5} = 3.8 + 0.75 = 4.55$$

The final step is performed by the system by providing the user with a risk score definition, as shown in Table VI. In our example, the risk is considered "Serious".

TABLE VI. RISK SCORE SCALE

Score	Description	Definition
1	Negligible	Risk Score is less than 2.
2	Minor	Risk Score is greater or equal to 2.
3	Moderate	Risk Score is greater or equal to 3.
4	Serious	Risk Score is greater or equal to 4.
5	Critical	Risk Score is 5.

9) Risk impact: In the developed tool, any risk added to the project will affect the cost, time, and scope of the project according to the definitions mentioned in Table VII.

TABLE VII. RISK IMPACT SCALE IN COST, TIME, AND SCOPE

Score	Description	Definition		
		Risk Impact on Budget	***Risk Impact on Schedule***	***Risk Impacton Scope***
1	Trivial	The risk has an impact on the budget of the project by less than 5%.	The risk has an impact in the project schedule by less than 5%.	The risk has barely a noticeable impact on the scope of the project.

2	Low	The risk has an impact on the budget of the project by less than 10%.	The risk has an impact on the time of the project by less than 10%.	The risk has an impact on the scope of the project.
3	Moderate	The risk has an impact on the budget of the project by less than 25%.	The risk has an impact on the time of the project by less than 25%.	The risk has an impact on the scope of the project by more than 50%.
4	High	The risk has an impact on the budget of the project by less than 50%.	The risk has an impact on the time of the project by less than 50%.	The risk has an impact on the essential requirements of the project.
5	Catastrophic	The risk has an impact on the budget of the project by greater than 50%.	The risk has an impact on the time of the project by greater than 50%.	The risk has an impact on the project to end in unacceptable project by the client.

For example, if a serious risk which has a high impact on the cost of the project (r = 4, as mentioned in Table VII) is added to a project which has a budget of 1000 USD, the actual cost is 300 USD, and the needed money to finish the remaining tasks is 600 USD, the following formula will be used:

$$Risk\ Impact\ Cost_{\text{USD}} = \begin{cases} n * 0.05, & if\ r = 1 \\ n * 0.10, & if\ r = 2 \\ n * 0.25, & if\ r = 3 \\ n * 0.50, & if\ r = 4 \\ n * 1.00, & if\ r = 5 \end{cases}$$

where, r is the risk impact on cost score, and n is the needed money to finish remaining tasks. By implementing the formula in the example, the result will be as follows:

$$Risk\ Impact\ Cost_{\text{USD}} = \begin{cases} n * 0.05, & if\ r = 1 \\ n * 0.10, & if\ r = 2 \\ n * 0.25, & if\ r = 3 \\ n * 0.50, & if\ r = 4 \\ n * 1.00, & if\ r = 5 \end{cases}$$

$$Risk\ Impact\ Cost_{\text{USD}} = n * 0.50$$

$$Risk\ Impact\ Cost_{\text{USD}} = 600 * 0.50 = 300\ KD$$

So, the risk may incur a loss of 300 USD, which will be added to the actual project cost and the needed money to finish the remaining tasks. The result is 1200 USD, which makes the project overbudget. In the same manner, the risk impact on time will be calculated. If the same risk has moderate impact on the time of the project (r = 3, as mentioned in Table VII), the tool will find the needed days to finish the remaining tasks, let's say in our example it is 30 days, then the same formula will be used where n is the needed days to finish the remaining tasks, finally, we compute the ceiling of the result to find the result in days.

$$Risk\ Impact\ Time_{\text{Day}} = \begin{cases} \lceil n * 0.05 \rceil, & if\ r = 1 \\ \lceil n * 0.10 \rceil, & if\ r = 2 \\ \lceil n * 0.25 \rceil, & if\ r = 3 \\ \lceil n * 0.50 \rceil, & if\ r = 4 \\ \lceil n * 1.00 \rceil, & if\ r = 5 \end{cases}$$

$$Risk\ Impact\ Time_{\text{Day}} = \lceil n * 0.25 \rceil$$

$$Risk\ Impact\ Time_{\text{Day}} = \lceil 30 * 0.25 \rceil = \lceil 7.50 \rceil = 8\ \text{days}$$

The risk impact on scope will be calculated in a different manner. For example, if the risk has a low impact on the scope of the project (from Table VII the r value is 2), and the current scope of the project is very good (the n value is 4 based on Table V). The scope will be calculated as follows:

$$Risk\ Impact\ Scope_{1-5} = \begin{cases} 1, & if\ n < \text{r} \\ (\text{n} - \text{r}) + 1, & if\ n \geq \text{r} \end{cases}$$

where, r is the risk impact on the scope of the project, and n is the actual scope of the project. So, by implementing the formula, the scope of the project will be as follows:

$$Risk\ Impact\ Scope_{1-5} = \begin{cases} 1, & if\ n < \text{r} \\ (\text{n} - \text{r}) + 1, & if\ n \geq \text{r} \end{cases}$$

$$Risk\ Impact\ Scope_{1-5} = (\text{n} - \text{r}) + 1$$

$$Risk\ Impact\ Scope_{1-5} = (4 - 2) + 1$$

$$Risk\ Impact\ Scope_{1-5} = 3\ (Good\ based\ in\ Table\ \text{V})$$

Finally, the analyzed serious risk is estimated to increase project cost by USD 300, delay project delivery by approximately eight days, and reduce the project scope to a *Good* level. When multiple risks exist within a project, each risk independently affects the project cost and schedule. However, the impact on project scope is determined by identifying the risk with the highest scope impact score and applying the Risk Impact on Scope formula accordingly.

10)Risk response strategy: During the risk response phase, the Risk Manager (RM) defines the actions required to treat each identified risk. Risk response strategies are generally categorized as responses to either negative risks (threats) or positive risks (opportunities) [29]. The proposed tool focuses exclusively on negative risks and supports four standard response strategies: acceptance, mitigation, transference, and elimination [26].

Acceptance involves acknowledging the risk without taking proactive action, whereas elimination seeks to remove the risk entirely by addressing its root cause. Mitigation aims to reduce the likelihood and/or impact of the risk, while transference shifts responsibility for managing the risk and its consequences to a third party [29]. In the proposed tool, acceptance retains the risk's impact within the project, while elimination removes its effects. Mitigation and transference strategies influence project performance based on predefined impact scales specified by the project manager. Any selected response strategy is documented and made available to the project manager and risk owner for implementation. Additionally, response strategies may generate secondary risks, as discussed in the following subsection.

11)Secondary risks: The execution of a risk response strategy may introduce new risks, commonly referred to as secondary risks [4]. The proposed tool explicitly supports the identification and management of such risks by allowing risk managers to link secondary risks to their originating response strategies. Secondary risks are initially assigned a Pending status and transition to Open once the associated response strategy is implemented.

For each secondary risk, the risk manager specifies a description, risk owner, impact attributes, and an appropriate response strategy. For example, consider the risk "The technology is new, and the project team lacks sufficient expertise, leading to delays". If the RM selects an elimination strategy—such as requiring all team members to attend training on the new technology prior to project start—this action may introduce a secondary risk. Specifically, team members attending training may delay their assigned tasks. This secondary risk, "Employees are assigned to mandatory training while project tasks remain incomplete", is initially marked as Pending. Once the primary response strategy is executed, the secondary risk becomes Open, and a corresponding response plan is defined to manage its impact.

12)Project health: Project health is evaluated using three indicators: cost health, time health, and scope health.

- Cost Health: Cost performance is classified as *Within Budget* (green), *Worry* (yellow), or *Critical* (red). The *Within Budget* status indicates that project spending has not entered the cost danger zone, defined as

$CostDangerZone = ProjectBudget - (ProjectBudget \times 5\%)$. Projects within budget but approaching this threshold are marked *Worry*, while projects exceeding the allocated budget or requiring additional funds are classified as *Critical*.

- Time Health: Schedule performance is categorized as *On Track*, *Worry*, or *Delay*. The time danger zone is calculated as

$TimeDangerZone = ProjectDuration - (ProjectDuration \times 5\%)$. A project is *On Track* if the estimated completion date remains within the approved duration. It is classified as *Worry* if delays approach the danger zone but remain within schedule limits, and *Delay* if the projected completion date exceeds the planned end date.

- Scope Health: Scope performance is assessed as *Excellent*, *Good*, or *Poor*. An *Excellent* scope corresponds to a score of 4.5 or higher, *Good* reflects a score between 3 and 4.5, and *Poor* indicates a score below 3.

B. Description and Scope of the Tool

RiskMIS is delivered as a web-based application designed to support organizational risk management activities. The tool enables project management, risk monitoring, and internal communication among users. Its primary focus is on supporting risk managers and project managers in managing risks and their impacts, rather than directly managing task execution by employees.

C. Requirements

A complete and structured specification of the system requirements was developed. Table VIII summarizes the functional requirements of the proposed tool, while Table IX presents the corresponding non-functional requirements.

TABLE VIII. FUNCTIONAL REQUIREMENTS OF THE PROPOSED TOOL

Category	Requirements
General Requirements	• A professional website will be designed and developed to effectively manage project risks in organizations, regardless of the business domain of the organization. • On the tool home page, the purpose and logo of the tool will be shown along with a brief description of the tool. • A link to other pages like About, Contact, Register, and Login should always be reachable from any of those pages and home page. • On the About page, a brief description of the reason for developing the tool will be provided. • On the Contact page, an email of the developer will be provided. • The tool targets organizations from all domains in both government or private sectors, and small, medium, or large organizations. • The tool requires registration of the organization by one Administrator. • Alert should be sent from the system to users if a big change has been done to their project like a new project, a new risk in the project, and requesting a new response strategy. • Users can read alerts by clicking the alert link.
Manage Employees	• The Administrator can create new employees to use the tool by filling the form which contains: the employee's name, email, ID, and role. • The roles of the users of the tool are limited to be A Project Manager, A Risk Manager, and An Employee. • When a new employee is created a verification email will be sent to the user containing a random password, if the user clicks the verification link, the user's account will be activated and then can use the email and the password to log in the tool. • The Administrator can prevent the users from using their accounts without deleting the accounts. • The Administrator can edit the user's information. • Users with the role "employee" cannot use the tool, the only reason why it's created is to assign responsibility to them in taking a practical action toward risk in the supervision of Project Manager.
Manage Risks	• The tool can manage risk by identifying project risks, analyze risks, and prepare a risk response strategy to implement. • It provides the ability to create, open, close, or suspend risks (including secondary risk). • The Risk Manager can create main categories and subcategories for the risks. • Only two-level risk categorization is allowed. • The tool provides default categories that the Risk Manager can use or delete if not needed. • The Risk Manager should specify the risk settings by ranking of probability, impact, and detectability based on its importance to the organization.

	• Risk settings specified by the organization will determine the risk impact in the project budget, time, and scope. • Risk Manager can create risks in the subcategories only and should specify the probability, impact, and detectability value of each risk. • The RM can edit created risks or delete them. • The RM can create response strategies for created risks in four types: accept, mitigate, transfer, and eliminate. • The Risk Manager can add risk to the project by determining the risk, risk owner, and the recommended response strategy. If the response strategy has a secondary risk, the RM should specify the risk owner and the response strategy for the secondary risk • The Project Manager can request a specific response strategy from the Risk Manager to prepare. • All details of project risk and impact are included in the project details. • The Project Manager should specify the implemented response strategy and its effect on cost, time, and scope of the project. • The tool can analyze the risks, calculates the probability and impact of risk on cost, time, and cost, then prioritize risks. • It can save the history of risks. • It provides different types of charts and graphs to represent risk management progress. • It can send notification automatically to the users when the status of risks or projects have changed.
Registration	• In the registration page, the Administrator should provide information about the organization like name and type, and information about the Administrator who will be the representative of the organization in the tool, like full name, civil ID, and password. • If the Administrator email already exists in the tool, an error message should appear, and registration will not be allowed. • Each organization should have only one administrator. • The administrator account is the owner of the organization record in the tool and has the highest privilege. • If the Administrator successfully submits the registration form, an activation email will be sent to the email of the Administrator with the activation link.
Communication	• All users can communicate using the tool by sending and receiving messages. • Users can send a message by filling the form with title, message, attached file if needed, and recipient. • The system will notify the user if there is a new message sent to them. • Users can read messages by clicking the notification of a new message or clicking the messages link to view all received messages.
Manage Projects	• The Administrators can create a new project "idea" by filling the form with the project's name, description, budget, start and end dates, project manager's name, and risk manager's name. • The Projects with status "Idea" will be shown only to the Administrators. • The Administrators can delete the projects with status "Idea" permanently. • The Administrators can edit the project information while in the "Idea" status.
	• The Projects can be initiated by Administrators only if all the project's information is filled. • The Administrators cannot edit Initiated projects. • The Initiated project will appear to the Project Manager and Risk Manager to whom the project is assigned. • If the project is in initiation state, a link will appear to the Project Manager to make a plan for the project • The Administrator can delete the projects after initiation only if it is in the "On Hold" state, the data of the project should be kept. • All users can view the project's details and progress by clicking the details link. • The Project Manager can make a plan to the project by filling a form, which consists of the task name, start and end dates, cost, and the requirements of the task. • The Task start and end dates and the costs should be within the project's budget and duration. • The Project Manager should create at least one task in the plan. • The Tasks of the project can be processed in parallel or serial. • The Project Manager can delete and edit plans or tasks only if the plan is not finalized/ confirmed. • If the Project Manager creates a plan for the project, a link will appear to the Risk Manager to add risks for the project. • The Project Manager can start, delete, on hold, complete, and resume tasks only if the plan is confirmed. • Any action to the task of the project should be stored in the tool like task start date, end date, cost, and scope. • The Project Manager should provide the cost and scope of the task when delete, hold or complete any task. • Task status, cost, time, and scope should be calculated and shown in the project details. • If the Project Manager wants to complete the task after resuming, the cost should be added to the previous cost of the task. • The Project's overall status, progress, and health information like cost, time, and scope should be calculated and updated continuously as the project progress and shown in the project details. • The tool should update the status of the project based on the tasks of the project status. For example, if all tasks are completed, the status of the project is "Completed". If at least one task is started, the project status will be "In process". If all tasks are on hold, the project status will be "On hold" and can be deleted. If all tasks are canceled the project status will be "Canceled". • It provides different types of charts and graphs to represent project management progress.
Logging in	• On the login page, users should fill the form with the email and password. • Only activated user accounts can log in. • Project Managers and Risk Managers can log in using the information in the email that was sent to them from the system which contains the user's email, a random password, and an activation link. • Administrators can log in using the email and password which they entered in the registration form.

	• If users forget the password, they can click the link "Forgot Password" to retrieve a new password from the tool to the user's email.

NONFUNCTIONAL REQUIREMENTS OF THE PROPOSED TOOL

Category	Requirements
Operational Requirements	• Website should be hosted on dedicated Server, with minimum of 2 x vCPU, 4 GB RAM, 2000 GB Bandwidth, 75 GB Disk Space, and 1000 Mbps Connection. • The tool should open from a common web browser like: Chrome, Firefox, IE, Safari, Edge, and Opera. • The tool should be friendly to portal devices like: Mobile and iPad. • The tool should be able to communicate with email web services to operate verification emails. • The tool should be able to communicate with google charts web service to create graphs and charts. • The tool should be able to communicate with the database. • The tool should give users the capability to upload files from different types.
Performance Requirements	• The tool should load in less than 2 secs. • The tool should be available 24/7. • The tool should always give real-time data. • The tool should be easy to navigate.
Security Requirements	• Only those who have registered usernames and valid passwords can access the tool. • Users can access the tool based on their role and function in the organization. • The Organization's projects, tasks, risks, and information should be accessible only to users with the required privileges and assigned jobs. • Login must be very secure with a maximum of three incorrect logins. • A time-out feature should be available on the tool if left idle for more than 5 minutes to protect the integrity of the organization's data. • Only developers of the tool will be able to log in to the backend of the tool to modify it.
Usability	• The tool displays the results and charts in easy to read and understand formats. • The tool is easy to use and facilitates the process of project and risk management. • The tool is user-friendly.

D. Stakeholders

The primary users of RiskMIS are Administrators, Project Managers, and Risk Managers, each interacting with the system according to their assigned roles. The Administrator holds the highest level of privilege and is responsible for creating users and configuring system access. Additional stakeholders include employees from various organizational units who execute risk response actions under the supervision of project managers. The Tool Owner is responsible for system maintenance, monitoring, error resolution, and ongoing updates.

IV. DESIGN AND IMPLEMENTATION

RiskMIS is a web-based Risk Management Information System designed to support organizational risk and project management activities. The tool is freely accessible and can be adopted by organizations of any size or domain, requiring only an internet-connected device and a standard web browser. RiskMIS is framework-agnostic and does not mandate adherence to any specific risk management standard or methodology.

RiskMIS provides integrated support for the core risk management lifecycle, consolidating risk identification, classification, assessment, response, and monitoring into a unified platform. In addition to risk management, the system offers essential project management functionalities, enabling project managers to create, plan, and track projects and tasks across their entire lifecycle. To enhance coordination and responsiveness, the tool also includes an internal communication center and an automated alert system, reducing the need for supplementary project management tools.

The system is implemented using the open-source ASP.NET Core framework and developed in C#. Microsoft SQL Server 2018 is used for data management, and Microsoft Visual Studio 2017 supported the development process. The current implementation comprises approximately 74,800 lines of source code and includes 40 ASPX-based web pages.

1) Overall architecture: RiskMIS follows a three-tier architectural model consisting of the Presentation Layer, Business Access Layer (BAL), and Data Access Layer (DAL). The Presentation Layer provides the user interface through web forms implemented using HTML, CSS, and JavaScript, ensuring compatibility across modern browsers and devices. The BAL, developed in C#, contains the application logic and mediates interactions between the user interface and the database. The DAL encapsulates data persistence functionality and performs Create, Read, Update, and Delete (CRUD) operations on the underlying database implemented using Microsoft SQL Server Management Studio 18.

In addition to core system components, RiskMIS integrates external services for email-based user verification and notification, as well as Google Chart services for visualizing project and risk-related data. The overall system architecture is illustrated in Fig. 1.

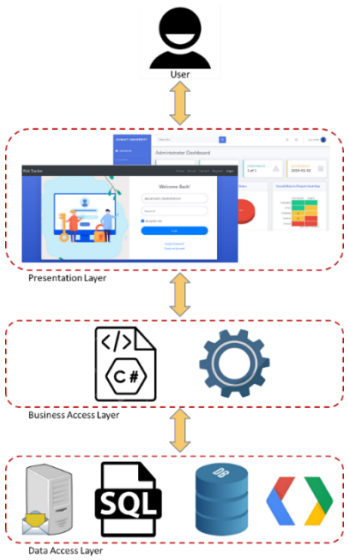

Fig. 1. RiskMIS architecture.

2) Use case model: The system's functionality is captured using a use case model that describes interactions between users and RiskMIS. Three primary user roles are defined: Administrator, Project Manager, and Risk Manager. The Administrator, typically representing top management, holds the highest level of privilege and is responsible for creating and managing users, assigning project and risk managers, and initializing project information. The Risk Manager oversees organizational and project-level risk activities, including risk configuration, prioritization, and monitoring. The Project Manager is responsible for managing the project lifecycle and implementing risk response actions. Fig. 2 presents the use case diagram depicting these roles and their interactions with the system.

Fig. 2. Use case diagram.

3) Activity diagrams: Activity diagrams are used to model and clarify key system workflows. Fig. 3 illustrates the login and dashboard access process common to all users. After credentials are submitted, the system validates the user's email and password against stored records. To enhance security, accounts are temporarily blocked after three consecutive failed login attempts, and a verification email containing a new activation link and password is automatically sent to the user.

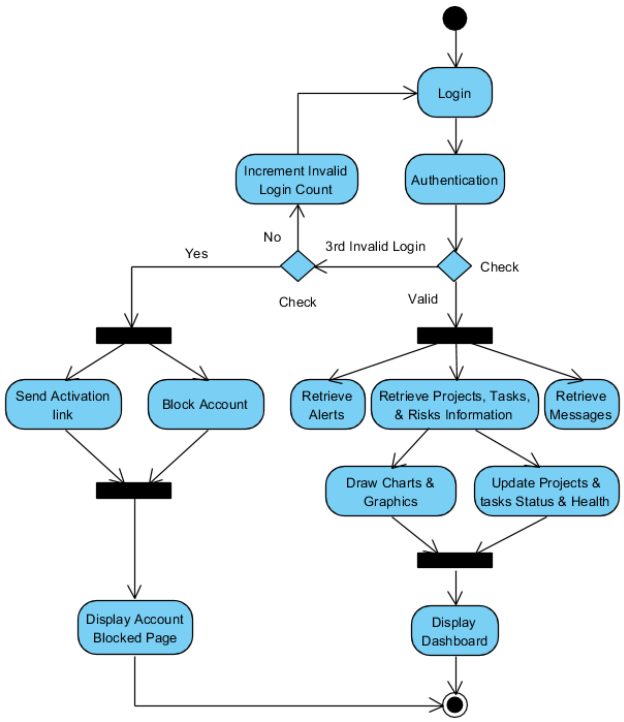

Fig. 3. Activity diagram for dashboard page display.

Fig. 4, Fig. 5, and Fig. 6 present activity diagrams specific to the Administrator, Project Manager, and Risk Manager, respectively, highlighting role-based workflows within RiskMIS.

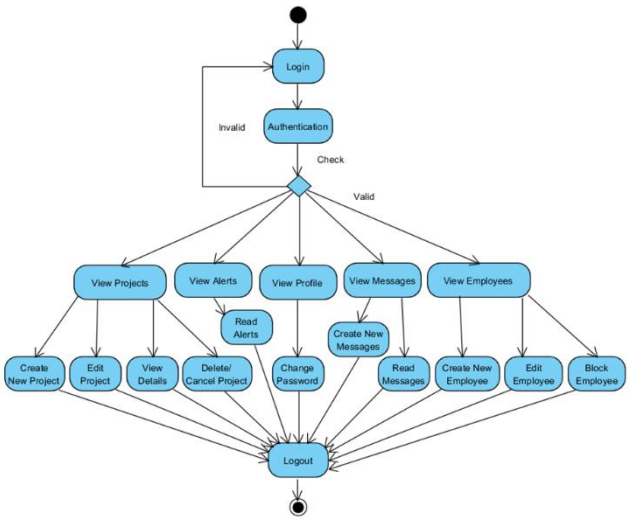

Fig. 4. Activity diagram for the administrator side.

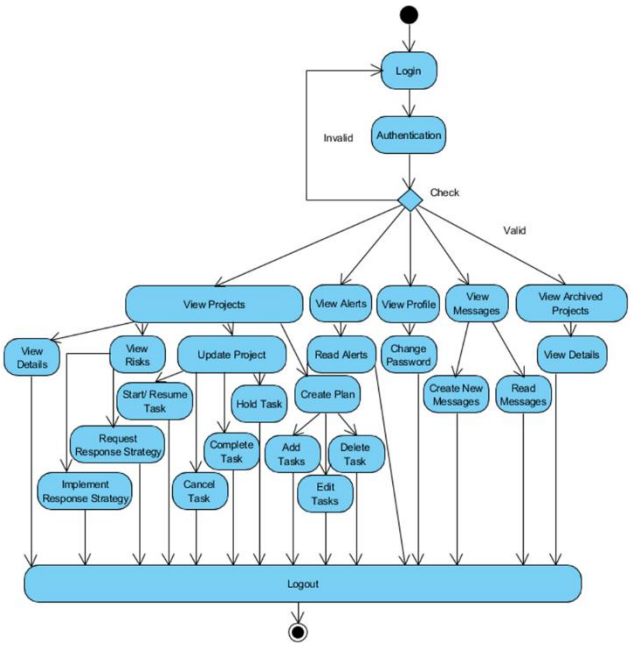

Fig. 5. Activity diagram for the project manager side.

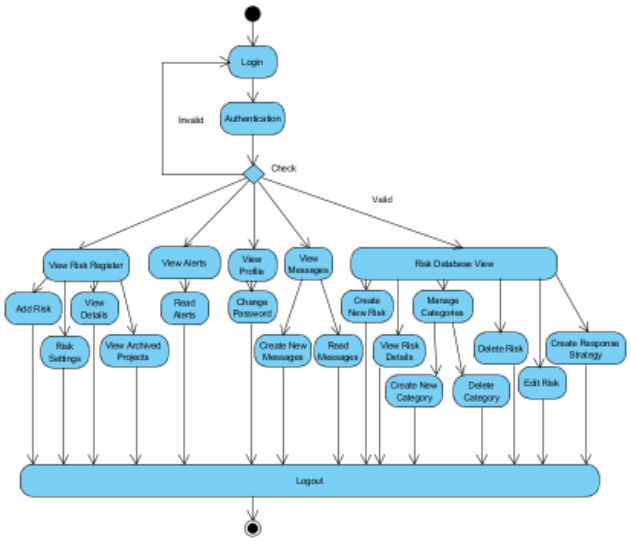

Fig. 6. Activity diagram for the risk manager side.

4) Finite state machines: RiskMIS behavior is formally represented using four finite state machines (statechart diagrams):

- Account State: Newly created accounts begin in a Not Verified state. Upon email verification, the account transitions to Active. Repeated invalid login attempts result in a Blocked state, from which the account can be reactivated via email verification. Administrators may also suspend or permanently delete accounts, as shown in Fig. 7.

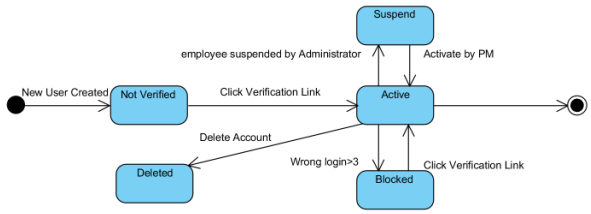

Fig. 7. Statechart diagram for the account state.

- Project State: Projects initially enter the Idea state, where they may be modified or deleted. Once project details are finalized, the project transitions to Initiate, granting access to the Project Manager. Subsequent task creation moves the project to the Plan state, followed by In Process, On Hold, Completed, or Canceled states depending on task progression and administrative actions (see Fig. 8).

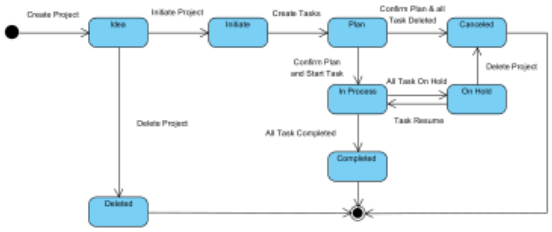

Fig. 8. Statechart diagram for the project state.

- Task State: Tasks start in the Not Started state after plan confirmation. They transition to In Process when execution begins, Delayed if planned timelines are exceeded, On Hold if temporarily suspended, and Completed once all requirements are satisfied (see Fig. 9).

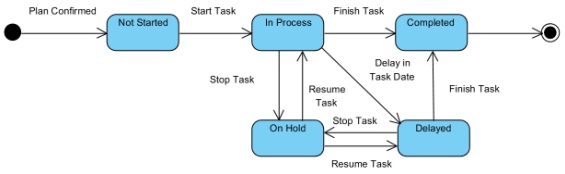

Fig. 9. Statechart diagram for the task state.

- Risk State: Risks initially exist in a Created state and transition to Open when associated with a project. Secondary risks generated through response strategies are initially marked as Pending and become Open once the corresponding response strategy is implemented (Fig. 10).

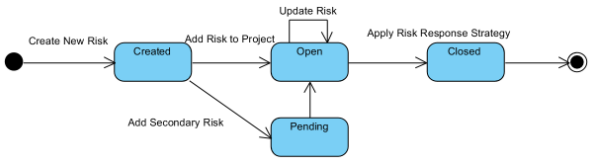

Fig. 10. Statechart diagram for the risk state.

5) Data model using the entity relationship diagram: RiskMIS relies on a relational database to support its functionalities. The database schema, implemented using Microsoft SQL Server Management Studio 18, consists of 14 tables: OrganizationTypes, Organizations, RiskSettings, AlertsFromSystem, EmployeesRole, Employees, Projects, Messages, MessageReceivers, Tasks, Risks, RisksInProjects, ResponseStrategy, and RiskCategories. These entities and their relationships are represented using an Entity Relationship (ER) diagram, as shown in Fig. 11.

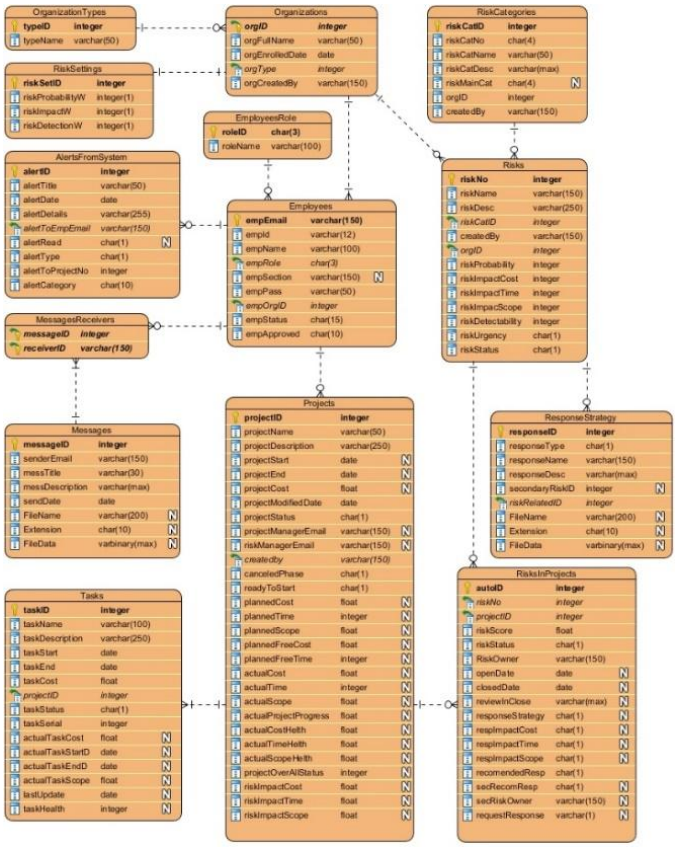

Fig. 11. Database schema for the RiskMIS.

V. Prototype Demonstration

To validate the practicality and effectiveness of the proposed RiskMIS, a fully functional web-based prototype was implemented and evaluated against the requirements defined earlier in the study. Rather than emphasizing user interface details, the demonstration focuses on what the prototype *proves* in terms of integrating project lifecycle management with continuous risk management.

Fig. 12 and Fig. 13 illustrate two important dashboards, which serve as the primary decision-support interfaces for all roles. These dashboards aggregate project and risk data in real-time and present key indicators such as project status distribution, budget utilization, projects at risk, and a risk heat map. This visualization demonstrates the system's ability to transform risk register data into actionable insights, enabling managers to rapidly identify high-risk projects and prioritize response actions without navigating multiple views or reports.

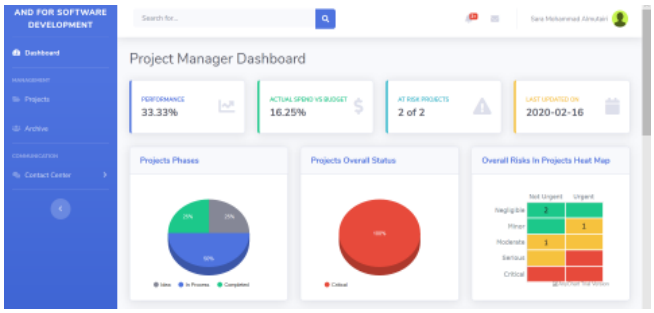

Fig. 12. Dashboard in the RiskMIS: statistics.

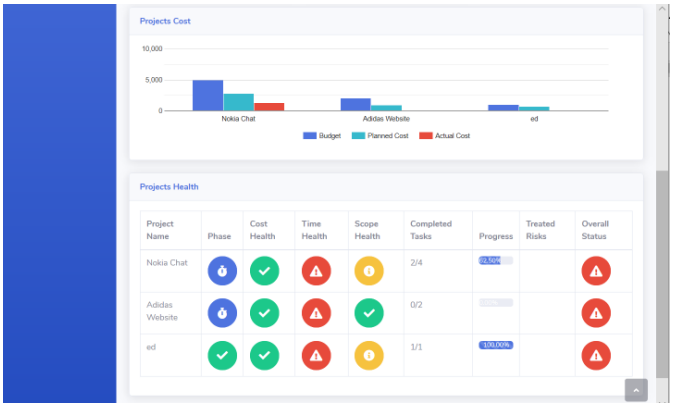

Fig. 13. Dashboard in the RiskMIS: information.

The prototype confirms that project lifecycle control and risk management are tightly coupled. Projects progress through predefined states, and task execution directly influences project health indicators related to cost, time, and scope. As risks are added or updated, their quantified impacts are automatically propagated to project performance metrics, demonstrating that risk assessment is not treated as a static activity but as a continuous driver of project status.

RiskMIS further demonstrates structured and consistent risk handling through a centralized risk register. Risks are categorized, assessed using standardized qualitative criteria, and prioritized according to organizational risk preferences. The prototype shows that recommended response strategies—acceptance, mitigation, transference, or elimination—are systematically linked to project execution. Importantly, the system proves its ability to manage secondary risks generated by response actions, reinforcing continuous monitoring and control throughout the project lifecycle.

Overall, the prototype demonstrates that RiskMIS can effectively unify project management and risk management within a single platform, providing real-time visibility into risk exposure and its operational consequences. This integration supports informed decision-making and proactive risk treatment across projects and ongoing operations.

The current evaluation is limited to functional validation using predefined scenarios and qualitative risk data. Large-scale empirical validation, performance benchmarking, and longitudinal studies in real organizational settings are planned as future work to assess scalability, user adoption, and decision-quality impact.

VI. Summary, Conclusion and Future Work

The primary objective of any organization is to deliver high-quality products or services that meet stakeholder requirements within defined time and budget constraints. Effective risk management is essential to achieving this objective, as it reduces uncertainty and supports informed decision-making. Central to this process is the risk register, which serves as a continuously updated repository of risk information and enables systematic identification, analysis, monitoring, and treatment of risks across project lifecycles and ongoing operations.

In this study, we conducted an extensive review of the risk management literature to identify key concepts, challenges, and research gaps. Building on this analysis, we defined the problem, proposed a solution, specified system requirements, and designed, implemented, and tested a comprehensive risk management information system. The main conclusions of this work are summarized as follows:

- Manual versus Automated Risk Management: Manual tools, such as word processors and spreadsheets, are inefficient and error-prone for managing risks. An integrated and automated risk management information system significantly enhances the consistency, efficiency, and effectiveness of risk identification, analysis, and treatment throughout the project lifecycle.
- Central Role of the Risk Register: The risk register is the core component of an effective risk management system. Its value depends on being comprehensive, dynamically maintained, and tightly integrated with all stages of the risk management process.
- Flexible Risk Classification: No single risk classification scheme is sufficient for all application domains. While the Larson and Gray classification is provided as a default, the proposed tool allows organizations to define and adapt classifications that reflect their specific context and risk landscape.
- Organization-Specific Risk Criteria: Consistent risk evaluation requires clearly defined and shared risk criteria. The system provides a generic yet extensible framework for defining risk probability, impacts on cost, time, and scope, detectability, and urgency.
- Generic Risk Management Framework: The tool implements a continuous and domain-independent risk management framework comprising five core activities: risk identification, classification, assessment, response, and monitoring and control. This framework is supported by explicit project and task lifecycles and state models.
- Structured Risk Prioritization: A multi-step risk prioritization methodology is introduced, enabling organizations to weight risk factors according to their priorities, compute risk scores, incorporate urgency, and classify risks on a standardized scale from negligible to critical.
- Integration with Project Performance Metrics: The system automatically propagates risk impacts to project cost, schedule, and scope using predefined formulas, ensuring that risk exposure is transparently reflected in project performance indicators.
- Management of Negative and Secondary Risks: The tool focuses on negative risks and supports systematic selection and implementation of response strategies. It also explicitly models secondary risks arising from response actions, enabling more comprehensive and continuous risk treatment.
- Web-Based and Framework-Agnostic Design: RiskMIS is implemented as a web-based, generic solution that can be readily adopted by organizations of different sizes and domains, without enforcing compliance with a specific risk management standard.

We are planning to evaluate RiskMIS through longitudinal case studies in real organizational settings. User interviews and empirical analyses will be conducted to assess system effectiveness, usability, and organizational impact. Future enhancements may include advanced analytics, intelligent risk trend detection, enhanced notification mechanisms, and broader user participation by enabling employees at all levels to report and review risks directly.

Future research will prioritize rigorous technical and empirical validation of the proposed RiskMIS through systematic performance benchmarking under realistic operational conditions to evaluate response time, scalability, and database efficiency. Clear quantitative evaluation metrics will be established to objectively assess system efficiency, transparency, decision-support effectiveness, and measurable impacts on risk exposure reduction, mitigation timelines, and decision-making accuracy through controlled case studies. In parallel, future work will incorporate formal security assessments covering authentication, authorization, and data protection mechanisms, alongside the integration of version control and change-tracking features to strengthen auditability and governance capabilities. Further studies will examine comprehensive data lifecycle management strategies, including archival policies, regular system maintenance procedures, automated backups, update deployment strategies, and long-term risk retention models. Finally, cross-organizational validation across multiple sectors, together with structured user training and onboarding frameworks, will be explored to enhance generalizability, system adoption, and sustainable usability transition.

Abstract*—Lung cancer is also among the most common causes of cancer-related deaths in the world, and the earliest possible detection of the cancer through computed tomography (CT) is important in the enhancement of patient survival. Nevertheless, accurate diagnosis is still a challenge as the nodules are small and indistinct, inter-rater consistency among radiologists, and the traditional deep learning systems have limited capacity to handle volumetric interactions and give interpretable and confidence-aware forecasts. This research suggests an uncertainty-cognizant Transformer-Enhanced Dual-Level Attention Network (TDA-Net) to classify lung nodules in CT images to deal with these issues. The suggested architecture combines a 3D Swin Transformer backbone and sequential spatial and channel attention fusion to be able to model both localized structural and global volumetric context. Moreover, Monte Carlo dropout is used in inference to measure predictive uncertainty and allows low-confidence cases to be identified and sent to a radiologist. The model is tested on a publicly available lung CT dataset, and it has an accuracy of 98.3% with high sensitivity to small nodules in the feature space. There is a separation of classes in the feature space, and the uncertainty rate is 5.1%. The findings of the experiment indicate that TDA-Net can be used as a supportive decision-making tool to diagnose lung cancer with the help of computers because it has better discriminative performance and uncertainty awareness when compared to the baseline models. Moreover, distinguishable uncertainty of predictions and uncertainty of models are present. Predictive uncertainty is measured through the variance of softmax probability distributions through stochastic forward passes, which is related to the ambiguity of data. Monte Carlo dropout is used to estimate model uncertainty as a Bayesian approximation, which represents parameter-level uncertainty due to a small amount of training data.

Keywords*—3D Swin Transformer; dual-level attention mechanism; computed tomography; lung cancer diagnosis; uncertainty-aware deep learning

I. Introduction

Lung cancer is a cause of cancer-mortality around the globe, and it causes almost a quarter of all cancer-deaths. Computed tomography (CT) leads to early diagnosis and a much better survival [1]. Unfortunately, the interpretive elements of CT scans require a considerable time commitment from radiologists and may be subject to inter-observer variability [2]. The conventional deep learning methods, in particular, 2D CNNs, can only handle slices of CT images separately and fail to utilize slice-to-slice volumetric dependencies [3]. Even existing 3D CNN models have limited capacity to model long-range spatial relationships and generally act as black-box systems that are not interpretable [4]. Typical differences in lung nodule characteristics regarding their size, shape, texture, and combined with varying malignancy levels, create significant challenges for accurate analysis, especially for difficult-to-classify small nodules or those with unclear diagnostic indicators [5]. The diagnosis becomes challenging due to ambiguous nodule appearance because benign nodules look similar enough to malignant ones that physicians sometimes mistake them for malignancies, thus triggering nonsensical procedures [6]. New transformer architecture advancements have demonstrated potential in medical imaging; however, their combination with clinically sound levels of confidence estimation remains a relatively untapped field [7]. The earlier studies have indicated positive outcomes in the process of identifying lung cancer through intensive learning, but have significant limitations. Conventional 2D CNNs primarily examine individual slices and do not obtain full volumetric reliance in CT scans, which are

significant in identifying small or micro nodules [8]. Although it is solved in 3D CNN due to the processing of volumetric data, they frequently have to work locally to extract convenience and cannot take into account the relevant information of long distances in other areas of the lungs [9]. This restricts their ability to distinguish benign and fatal nodules that have the same local features. Moreover, majority of the existing methods are black boxes, which do not reveal much information about the way of making predictions. This study presents a novel Transformer-Augmented Dual-Level Attention Network (TDA-Net) that exploits the power of the 3D Swin Transformer architecture with Spatial Channel Attention Fusion and uncertainty estimation to generate the right, explainable and confidence-aware lung nodule detection. The model serves the clinical need of the reliable use of AI predictions to detect nodules and enhance sensitivity to small nodules that may be overlooked in early diagnosis processes [10].

A. Problem Statement

Lung cancer is among the common causes of cancer-related death in the world, and even with the extensive use of computed tomography (CT), it is still difficult to achieve an accurate and consistent diagnosis. The fact that pulmonary nodules are small, irregular, and subtle, the presence of overlapping anatomy, large inter-patient variation, and inter-radiologist subjectivity limit the detection of small nodules. Traditional computer-aided diagnostic models, especially those that rely on 2D convolutional neural networks (CNNs), do not capture inter-slice relationships and volumetric continuity between CT data [9]. In spite of the fact that 3D CNNs, to some extent, overcome this drawback, they are limited by local receptive fields, restricted long-range spatial modeling, and low interpretability. Moreover, the current methods usually have a problem of class imbalance, weak population generalization [11], insufficient sensitivity to micro-nodules, and a lack of clinically significant uncertainty measures. Absence of transparency and quantification of confidence are huge limitations to clinical adoption in the real world [12]. The current volumetric CNN and transformer-based methods are mostly aimed to achieve better classification, however, without calibrated and explicitly modeled uncertainty estimations that can be used in situations with safety-critical ramifications in medical contexts. Even the frameworks of current transformers do not include the systematic incorporation of dual-level spatial-channel attention to improve the interpretability and micro-nodule discrimination in a single volumetric framework. In addition, cross-dataset validation is limited and uncertainty modeling has no adequate theoretical basis, limiting clinical reliability. These restrictions indicate a perceptible gap in research to develop a volumetric transformer design that concurrently assists in proper classification, organized attention-based interpretability, and theoretically founded, well-calibrated uncertainty estimation towards resilient clinical decision-making.

B. Recent Innovations and Their Limits

The recent developments in medical image analysis have proposed transformer-based architectures to overcome the small receptive fields of CNNs. In this respect, a 3D Swin Transformer based on the proposed Transformer-Augmented Dual-Level Attention Network (TDA-Net) is combined with the new Dual-Level Spatial–Channel Attention Fusion (DSAF) mechanism to concurrently characterize local volumetric and global contextual relationships. Unlike the classical CNN-based approaches [13], the sequential attention architecture focuses on spatially salient regions and changes the weights of feature channels over time, more accurately detecting micro-nodules and with improved interpretability. Nonetheless, existing verification has only been demonstrated on relatively small and homogeneous datasets and transformer-based architectures are more expensive to compute. The further research will involve large-scale multicenter validation, optimization of efficiency, and more advanced explainability methods to enhance clinical applicability.

C. Research Motivation

Transformer and attention-based models has shown to be highly effective in long-range dependency and task-relevant representation in computer vision and medical imaging. These models in contrast to the traditional CNNs are effective at incorporating both local and global information, which is essential in the analysis of complex 3D CT volumes, in which minute nodules can be present in non-contiguous slices. Nevertheless, they have not been thoroughly investigated as far as the diagnosis of volumetric lung cancer is concerned [13]. Attention mechanisms also allow highlighting clinically relevant areas, whilst suppressing irrelevant background information, which enhances interpretability. Driven by these strengths, this study intends to utilize transformer-based volumetric modeling and dual-level attention to create a well-built and explainable framework that is uncertain and effective at early lung cancer diagnosis to finally aid radiologists in having reliable and stable decision support mechanisms.

D. Significance of the Study

The proposed research is important because it presents a new uncertainty-sensitive deep learning framework (the combination of 3D transformer-based global representation, and the dual-level spatial and channel attention to detect lung cancer). The proposed approach is more sensitive to small and early nodules that are usually missed by the traditional approaches by explicitly models long-range volumetric information and selectively highlighting those features that are important diagnostically. The uncertainty estimation support also increases clinical reliability by marking predictions of low confidence to be reviewed by experts. Having methodological contributions, the framework should assist radiologists, decrease diagnostic variability, and make AI-assisted workflow safer. On the whole, this piece enhances the medical image analysis and leads to the creation of clinically viable and interpretable decision-support systems.

E. Key Contribution

- Suggests a volumetric-based feature extraction, which simultaneously features fine-grained nodule features and macro-level contextual features, which play significant roles in the early diagnosis of lung cancer.
- Combines dual-level spatial-channel attention to learn the properties of the discriminant, and also to improve interpretability to produce decision which can be implemented in a clinical setting.

- Applies uncertainty estimation to emphasize on the low-confidence estimates to foster reliability and can be safely applied in the diagnostic processes.
- Provides compelling evidence that TDA-Net achieves 98.3% accuracy, 0.98% precision and 0.97% sensitivity on the Kaggle dataset, superior to the existing approaches.

F. Rest of the Sections

In Section II, the review of existing lung cancer detection approaches based on CT imaging is provided, emphasizing such recent discoveries as 3D CNNs, model combinations, and attention mechanisms. Section III gives the approach employed for extracting attributes out of 3D CNNs and fusing Dual-Level Spatial-Channel Attention. In Section IV, the classification pipeline, training model with Tensorflow and Keras, testing models on different metrics and the trends in the classification across all the cancers and tumor sizes are described. Section V ends the study and future directions are the incorporation of explainable AI and application of imaging other than vision, and the implementation of the method in clinical scenarios in real-time.

II. Related Works

Wang et al. [11] proposed the use of 3D Auto-encoder networks with attention mechanisms to identify lung cancer indications and developed a dual model with 3D networks. The applied analysis of the 3D Auto-encoder occurred in its initial state through RFE, LASSO, and ANOVA for testing the features, also, to perform the tests on SVM, RF, GBM, MLP, LightGBM, XGBoost, Stacking and Voting classifiers. Implementation of attention modules as an addition to the network achieved a higher measurement (A) at 93.4%, along with 90.2% sensitivity and AUC-ROC at 94.1%.

Crasta et al. [9] present a new DL framework for lung cancer detection through CT scans, along with classification functionality, which stands as the main contribution in this study. This system uses 3D-VNet for segmentation, together with 3D-ResNet for classification, with a LUNA16 test result of 99.34% DSC alongside 0.4% fewer false positives. The classification model exhibits 99.2% (A) together with 98.8% sensitivity and 99.6% specificity to surpass current methodologies. The approach suffers from two main restrictions caused by variations in datasets, combined with the necessity to enhance interpretability mechanisms. Future studies need to leverage different medical image datasets while using PET/MRI fusion techniques and improve model interpretation capabilities for emergency room standards and establish ongoing nodule growth monitoring techniques to optimize early diagnosis practices and treatment plans.

Tang et al. [14] examined individuals and received "low-dose computed tomography" (LDCT) scans for lung cancer screening throughout the period from 2005 to 2019. NCCN criteria determined three risk categories, which studier's used to classify their participants. Of the participants whose baseline scans showed positivity, the study identified 3695 cases (11.8%) with 197 of these disclosures proving to be lung cancer patients (0.6%). The risk group scored the highest for lung cancer detection (1.4%), but second-hand smoke female participants detected more cases (1.1%) than other non-risk groups (0.5%). Certain challenges affect this study through self-referral constraints and selection biases and non-adherent patient behavior, as well as known false-negative tests. Better risk assessment requires future study to examine different populations and confirm those cases diagnosed as lung cancer-negative.

Huo et al. [12], using a "self-paced learning" (SPL) 3D Net, created two (DL) models to predict M/S growth patterns of invasive lung adenocarcinoma (ILADC) through pre-operative CT scans obtained from 617 internal patients (for model testing) and 353 external patients. The evaluation of Model 1 in external conditions resulted in a 0.857 AUC score and Model 2 demonstrated a 0.831 AUC score for patients with ILADC smaller than 2 centimeters. Both models outperformed "ResNet34", "ResNet50", "ResNeXt50", and "DenseNet121". The application of DL models in clinical diagnostics faces constraints from minor clinical details and unclear internal logic that needs improved study for practical implementation, while retaining the potential of improved diagnostic (A).

Wang et al. [15] conducted an analysis of 20 investigations which used PubMed, Embase, and Web of Science to study how DL methods and expert diagnostic radiologists performed when diagnosing lung cancer in CT images. The DL model achieved better (A) than radiology experts did through its 82% sensitivity and 75% specificity measurements, while showing statistically meaningful higher specificity levels. The test results yielded different findings when examining standard CT versus LDCT images because DL methods achieved better specificity on standard CT, although it produced higher sensitivity at decreased specificity on LDCT scans. Further development of AI diagnosis utilization requires prospective patient-specific validation and assessment of radiologist expertise, as well as methods for direct AI involvement and improved methodologies for handling aggregated data.

Klangbunrueang et al. [16] proposed VGG16, which was also trained and tested for categorizing the lung cancer CT images into Benign, Malignant, and Normal using 1097 CT images of 110 patients. The study methodology combined data acquisition and preprocessing with VGG16 training steps, as well as testing protocols that were also applied to "ResNet50", as well as InceptionV3 and MobileNetV2. The VGG16 model reached the best diagnostic (A) level of 98.18% during testing. Additional study needs to investigate data augmentation techniques and model fine-tuning and it should test both 3D CNN networks and Vision Transformers for better performance.

Manum et al. [17] proposed the CNN framework to detect lung cancer early on by analyzing images from a CT scan. This was achieved by training and evaluating CNN along with InceptionV3, Xception, and ResNet-50 in term of performance using (A), AUC, (R), and metric of losses. It was realized that CNN gave outperformed results compared to all other models, achieving 92% (A), 98.21% of area under curve, 91.72% (R), and loss of 0.328, which reflects at its capability than others and the traditional methods. The downside to establishing such works over larger datasets and considering other DL models would improve generalizability for improved early detection and diagnostic.

John [18] extracted patient record features using DL approaches, including CNNs, RNNs, and transfer learning models, to aid in lung cancer detection from medical images, along with combining image preprocessing by augmenting with various classification techniques for greater (A). One focus is on bridging aspects in data imbalance, overfitting, and interpretability, as its comprehensive framework also offers efficient diagnosis performance. Kunkyab et al. [19] proposed a multi-resolution (DL) framework by utilizing multi-depth backbones, which retains the advantages of low and high-resolution images. The proposed framework was evaluated on the NSCLC dataset benchmarked against five (DL) models. The results demonstrated superior performance with a Dice score of 0.92 and a Hausdorff distance of 1.33, which indicates the potential for efficient auto-segmentation arising for clinical workflows.

III. Proposed Methodology Feature Extraction using 3D CNN

The proposed work presents a Transformer-Augmented Dual-Level Attention Network (TDA-Net) to study volumetric lung cancer, which is a Swin Transformer that consists of a 3D backbone and an additional Dual-Level Spatial Channel Attention Fusion (DSAF) block. In contrast to the traditional CNN-based method, the framework has the advantage of modeling localized volumetric features and long-range contextual dependencies across volumetric CTs jointly and selectively refining spatially salient areas and diagnostically relevant feature channels sequentially, enhancing micro-nodule discrimination and interpretability. The main novelty is that transformer-based global modeling is coupled with the hierarchical attention to improve sensitivity and clinical transparency. The further work will be done on a large-scale multicenter validation, optimization of efficiency and deep explainability methods to reinforce the clinical applicability. Preprocessing and lung segmentation are followed by hierarchical feature extraction, which is done using a 3D Swin Transformer. Volumetric features are enhanced by dual-level spatial and channel attention and confidence-aware lung cancer classification by an uncertainty estimation module. It is shown in Fig. 1.

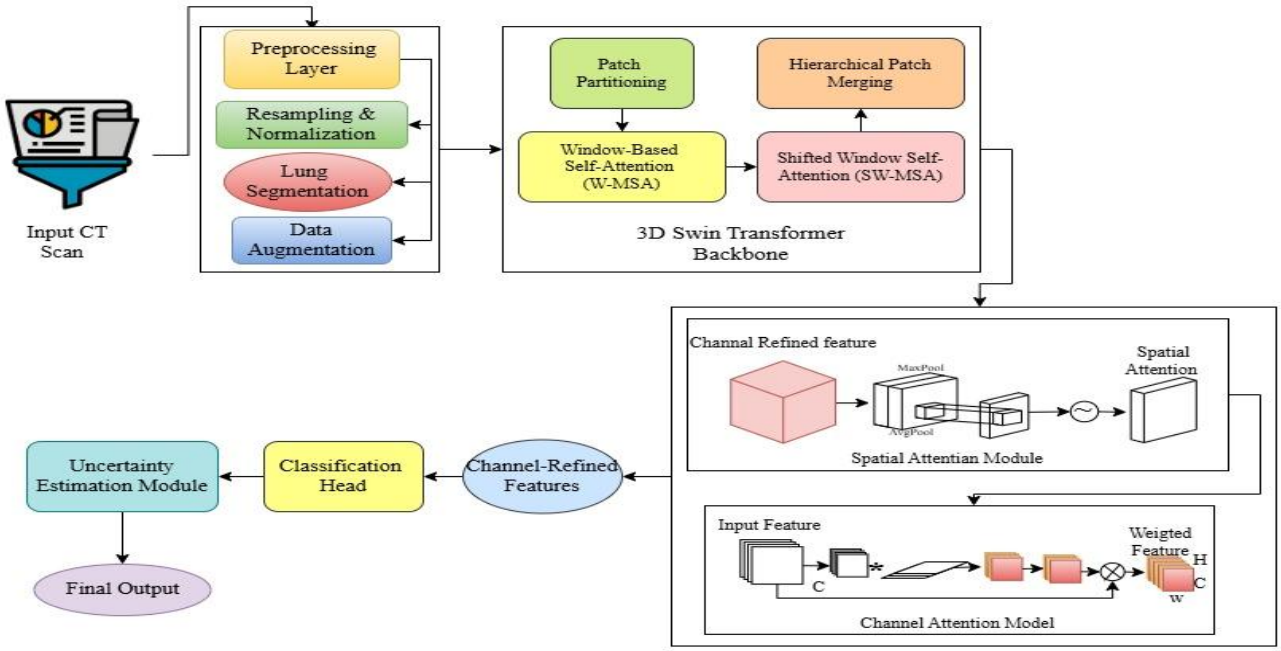

Fig. 1. Uncertainty-aware dual-attention TDA-Net framework.

A. Data Collection

This study utilizes the publicly available lung CT datasets to evaluate the proposed framework. A proof-of-concept analysis is first conducted on the Kaggle Lung Cancer CT Scan Dataset [20], consisting of 315 CT images in four classes, adenocarcinoma (120), squamous cell carcinoma (90), large cell carcinoma (51) and normal lung tissue (54) are first analyzed through a proof-of-concept analysis. Being small, this data can be experimented with quickly and initial feasibility checked. A model is tested on the LIDC-IDRI / LUNA16 dataset consisting of more than 1,000 CT scans labeled with the pulmonary nodules by radiologists to further confirm that the model is robust and can be generalized to a broader population. The large-scale benchmark can be used to establish a reasonable comparison with the current methods, as well as guarantee consistency in performance despite going beyond small, carefully curated datasets. In order to assess robustness between variability in acquisition and demographic diversity, subgroup analysis was conducted depending on the scanner protocols, variation in slice thickness, and age groups in patients that were present in the LIDC-IDRI/LUNA16 data. The dataset has a variety of multi-institutional scans taken with various CT instruments and imaging settings, which allows determining the stability of such scans in a heterogeneous clinical setting. To determine consistency of performance and uncertainty calibration measures across acquisition and demographic partitions, performance and uncertainty calibration measures were calculated separately within each subgroup.

B. Data Preprocessing

The preprocessing of CT images defines the best quality and enhances the models. The processing steps that this dataset requires are the following essential items.

Resizing and Normalizing: The images of CT scan are processed into a standard size to provide uniformity across the dataset. The normalization method is used to put the pixel values in a range of [0,1] by dividing it by 255 or to put the pixel values to a zero mean and unit variance value. This step is part of model performance enhancement as it makes computational operations simpler besides stabilizing the input data consistency. Given an original picture whose dimensions (J, K, L), a resizing process changes it to a constant size (J -, K -, L -). It is given in Eq. (1):

$$I' = \mathrm{I}(J', K', L') \tag{1}$$

where, J' and K' are the target height and width, and L is the number of channels. Normalization is calculated using Eq. (2):

$$I_{norm} = \frac{I - I_{min}}{I_{max} - I_{min}} \tag{2}$$

where, I is the original pixel intensity, I_{min} and I_{max} are the maximum and minimum pixel values in the image. It is given in Eq. (3):

$$\mathrm{I}_{max} = \frac{\mathrm{I}}{255} \tag{3}$$

where, $\mathrm{I}_{min} = 0$, and $\mathrm{I}_{max} = 255$.

1) Noise reduction using Gaussian filtering: The Gaussian filtering technique is one of the most frequently utilized medical image preprocessing techniques because it removes random noise in data without interfering with important structure information. Segmentation (A) of the lung CT images is negatively influenced by sensor artifact noise and patient motion and scanning inconsistencies. The method of smoothing images with the help of the Gaussian filter is based on the usage of a Gaussian kernel, which assigns more values to the central pixels and less to the surrounding ones. High-frequency fluctuations in intensity are minimized, thus high-frequency noise is blocked, but lung boundaries are not altered by this process of weighted averaging. This is the definition of the Gaussian function [see Eq. (4)].

$$G(m, n) = \frac{1}{2\pi\sigma^2} e^{-\frac{x^2+y^2}{2\sigma^2}} \tag{4}$$

where, σ controls the degree of smoothing, a small σ preserves details, while a larger σ smooths more aggressively. The application of Gaussian filtering occurs prior to segmentation because it enhances lung structure visibility through grainy noise reduction. The application of Gaussian filtering enhances both feature extraction abilities and classification (P), along with disease recognition, so that CT image interpretation becomes more precise and reliable.

Overfitting is believed to cause models to be more robust and generalizable with the addition of data. The CT volumes are normalized first before resizing to a given resolution. Once this has been done, the augmentation attempts to reproduce variances observed in real scans of the lungs. This covers the most basic forms of transformations; random rotations, flipping the images along random axes, translations, zooms, and intensity scaling in order to neutralize the varying patient positioning and other scanner settings. These changes are useful to ensure that the model does not overfit since it must not be memorized using the small amount of data, but rather create more generalized representations of lung nodules and tumor properties.

C. 3D Swin Transformer Feature Extraction

The 3D Swin Transformer that replaces the conventional 3D CNN layers in the volumetric feature extraction is the building block of the discussed model. Unlike fixed receptive field-based CNNs that basically learn local spatial features, the 3D Swin Transformer combines global dependency learning (hierarchical aggregation) and local context modelling (shifted window attention). This is particularly appropriate in lung CT scans, where local delicate nodules as well as the global spatial relationship between slices are of diagnostic importance.

1) Patch partitioning: By the size of $P \times P \times P$ the CT volume $V \in \mathbb{R}^{H \times W \times D}$ further partitioned into 3D patches which are non-overlapping. Every patch is flattened into a vector and added to an embedding site by a linear projection and calculated by use of Eq. (5):

$$z_0 = Linear\left(PatchPartition\,(V)\right), \quad z_0 \in \mathbb{R}^{N \times d} \tag{5}$$

where, $N = \frac{HWD}{P^3}$ denote the number of patches and d denote the embedding dimension.

In Standard Window-based Multi-headed Self-essence (W-MSA), attention is confined to an overlapping non-overlapping 3D window, which is appropriate to local dependence but does not work in interactions across the window boundaries. In order to overcome this limit, shifted window (SW-MSA) mechanism is added in the latter layer where each 3D window is sent over half a window shape (M/2). These are easy but effective modifications such that ensure that the tokens that are found in the edges of the windows in the W-MSA are transformed into the center region of a window in the SW-MSA so that the cross-window connections could take place. Consequently, the model acquires local and global inter-etc. dependence, which makes window-based attention computationally efficient. It is calculated by the following Eq. (6). Patch merging with hierarchy can be used to extract local and global volumetric representations progressively to eventually generate uncertainty-sensitive lung cancer risk classification. It is illustrated in Fig. 2.

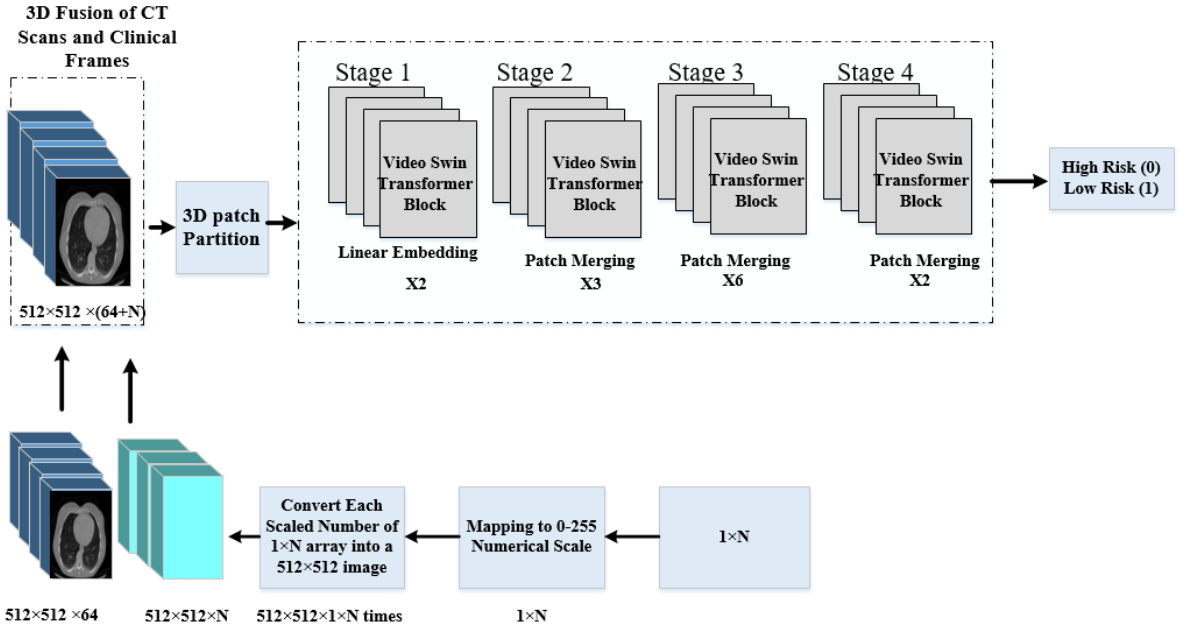

Fig. 2. TDA-Net architecture for volumetric lung analysis.

$$z^{l+1} = SW.MSA\left(LN(Z^1)\right) + z^1 \quad (6)$$

$$z^{l+2} = MLP\left(LN(Z^{l+1})\right) + z^{l+1} \quad (7)$$

In Eq. (6) and Eq. (7), layer normalization is abbreviated as LN, feed-forward network post-attention as MLP and the skip connection as (+) is identical to the residual learning as a stability measure. This variant W-MSA -SW-MSA architecture guarantees every token to have interactions with not only its local community, but also with the tokens in the windows adjacent to it, essentially occupies global inter-black dependence in CT volume.

2) Hierarchical representation: The patch combining of tokens is achieved as follows: once a set number of Swin Transformer blocks has been completed, they are combined, much like in CNNs by pooling, but in this case, it is Transformer embeddings that are combined. Provided a stage s feature map on resolution (Hs.Ws. Ds patch embeddings, Patch Merging combines (on a patch-by-patch basis) patch embeddings at adjacent locations (e.g., 2x2 patches), halving the spatial resolution by a factor of 2, but compensating it by doubling the channel dimension by a factor of 2xCs. The operation generates a hierarchical, multi-scale representation, which is replete with significant volumetric information but that describes successively abstract features that are significant in the detection of lung nodules of various sizes. Joining adjacent patch embeddings caused resolution to decrease in all spatial dimensions, which is given in Eq. (8):

$$(H_{s+1}, W_{s+1}, D_{s+1}) = \left(\frac{H_s}{2}\frac{W_s}{2}\frac{D_s}{2}\right) \quad (8)$$

To increase the channel dimension the linear projection is computed using Eq. (9):

$$C_{s+1} = 2 \times C \quad (9)$$

Finally, the output features at stage s+1 are computed using Eq. (10):

$$F_{s+1} = PatchMerging\ (F_s) \in \mathbb{R}^{H_{s+1} \times W_{s+1} \times D_{s+1} \times C_{s+1}} \quad (10)$$

The process generates a stratified feature hierarchy where the lowest levels of the hierarchy retain finely dated structural information, such as small nodules and boundaries and edges, whilst deep levels of the hierarchy retain high-level global information, such as the overall size of the lungs, spatial relationships within areas, and area tissue density variation. This hierarchical model provides the ability to model both fine local detail and large volumetric detail, which is vital to the identification and categorization of the precise lung nodules.

3) Feature extraction output: The last step of the 3D Swin transformer is a compact volumetric feature representation that is rich in information and is used as a base to redefine focus and eventually classify. In the earlier phases, the input volume of CT is subdivided into the patch, which is undergone by alternative window-based and shift-window meditation layers and the patch is merged as it gradually undergoes down sampling. Not only that this process minimizes the overall spatial dimensions of feature maps but it also maximizes the representative depth of the feature maps, allowing the model to experience the balance between local and global information. The resulting feature map represents the fine-dominated structural features like small nodules and edges and high-level relevant features like size, tissue density and inter-regional dependence. The volumetric features are determined by following Eq. (11):

$$F = Swin\ 3D\ (V), F \in \mathbb{R}^{H' \times W' \times D' \times C} \quad (11)$$

where, input CT volume is depicted by V, merged spatial dimension following patch merging is represented by $H' \times W' \times D'$ and finally the number of output channel is denoted as C. They eliminated the facilities.3D Swin - borrowed directly out of the SWIN transformer - is not actually a prediction done on its own and they merely run it in the dual-level spatial-channel focus (DSAF) module to be refined further. During this refinement step, the first step is to provide spatial attention in order to highlight volumetric regions, namely nodule in order that the network draws attention to the clinically relevant regions of interest and secondarily, in order to selectively emphasize the discrimination facilities involved in the nodule characteristics like texture, density and size. Through this, 3D Swin Transformer serves as a backbone feature extraction step, which merely gets multi-scale volumetric embeddings, whereas the DSAF module serves as a refinement step, enhancing the power of these embeddings to be more reproducible for accurate lung nodule detection and subsequent classification.

D. Dual-Level Spatial–Channel Attention Fusion (DSAF)

The embedding obtained after feature extraction using the 3D Swin transformer is further enhanced by the double-level spatial-channel attention fusion (DSAF) module to enhance the discriminatory power. Spatial attention and channel attention is gradually applied in this module. The emphasis is laid on the fact that in spatial areas, it is more likely that the volume will be involved in the volume to be present through high loads assigned. It is computed using Eq. (12):

$$M_s(F) = \sigma(f^{7\times7\times7}(|Avg\ Pool_c(F); MaxPool_c(F)] \quad (12)$$

where, $F \in \mathbb{R}^{H'\times W'\times D'\times C}$, the pooling operation along the channel dimension is denoted as $Avg\ Pool_c$ and $MaxPool_c$. The convolution filter and sigmoid activation is denoted as $f^{7\times7\times7}$ and σ. Spatial features are provided in Eq. (13):

$$F_s = M_s(F) \otimes F \quad (13)$$

where, $\otimes$ denotes the element-wise multiplication.

1) Channel attention: Calculates the relative importance of features to the subtle classification of the channel (e.g., emphasises the channels involved with the texture of adenocarcinoma or the density of squamous cell carcinoma) and calculates it with the help of Eq. (14):

$$M_c(F_s) = \sigma(W_1(ReLU(W_0(Avg\ Pool_s(F_s)))) + (W_1(ReLU(W_0(Max\ Pool_s(F_s)))) \quad (14)$$

In Eq. (14), $Avg\ Pool_s$ and $Max\ Pool_s$ are pooling operations along the spatial dimension and the learnable weights of the fully connected layers were denoted as W_0 and W_1. It is denoted in Eq. (15):

$$F_c = M_c(F_s) \otimes F_s \quad (15)$$

Therefore, DSAF modules are not convenient when it comes to dealing with raw data, but they refine attributes on embedding obtained with the Swin Transformer, which are more discriminatory to classification.

2) Classification head: By means of a classification head the refined features F_c are added up and projected to class predictions and the following are computed.

3) Global average pooling: The volumetric features are computed as a compact vector representation by using Eq. (16):

$$f = GAP(F_c), \quad f \in \mathbb{R}^C \quad (16)$$

4) Fully connected Layer + Softmax: Transform feature vector in class possibilities for general, adenocarcinoma, squamous and large cell carcinoma using Eq. (17):

$$\hat{y} = Softmax(Wf + b) \quad (17)$$

where, the trainable weights and bias of the classifier are denoted as W and b.

5) Loss function: Since the dataset is unbalanced in sub-factories, focal loss is used with square balance derived in Eq. (18):

$$L_{focal} = -\alpha_t(1-\hat{y}_t)^\gamma\ log(\hat{y}_t) \quad (18)$$

where, the class-balancing weight is denoted as α_t, the focusing parameter and predicted probability for the true class is denoted as γ and $\hat{y}_t$. Therefore, classification is responsible for taking major final decisions, not facilitating extraction.

6) Uncertainty estimation: Clinical applications include Monte Carlo Dropout at the time of estimate in the model to improve reliability. This approach estimates the confidence of prediction by performing several stochastic forward passes with a dropout component.

7) Multiple predictions: For the x input, the predictions are generated T times and computed in Eq. (19):

$$\hat{y}_t^{(i)} = f_0(x; dropout), \quad i = 1,2,..T \quad (19)$$

8) Mean prediction: Mean of these predictions are final probability distribution. It is computed using Eq. (20):

$$\bar{y}_t = \frac{1}{T}\sum_{i=1}^{T}\hat{y}_t^{(i)} \quad (20)$$

9) Uncertainty estimation: Estimate of model uncertainty is predicted using the variance across predictions using Eq. (21):

$$U(x) = \frac{1}{T}\sum_{i=1}^{T}\left(\hat{y}_t^{(i)} - \bar{y}_t\right)^2 \quad (21)$$

This mechanism ensures that cases with low prediction can be flagged for radiologist review, which can reduce the risk of incorrect diagnosis.

Theoretically speaking, Monte Carlo dropout offers a rough Bayesian inference procedure of deep neural networks. Stochastic forward passes can be used to compute the sampling of a variational posterior distribution over network weights by enabling dropout on inference. The predictive distribution may then be viewed as an empirical approximation to the posterior predictive distribution. The entire predictive variance reflects the epistemic uncertainty (model uncertainty due to lack of data and ambiguity in the parameters) and the aleatoric uncertainty (data-driven variability due to CT imaging). This Bayesian

interpretation forms a principled basis of uncertainty-sensitive modeling of volumetric transformers, and enables risk estimation on safety-critical medical imaging problems.

Algorithm 1: Transformer-Augmented Dual-Level Attention Network (TDA-Net)

Input: V → Input CT Volume

Output: y_pred → Predicted Class, C_mean → Mean Confidence, U_flag → Uncertainty Flag

Begin

Preprocessing

Normalize V to Hounsfield scale

Resample V to uniform voxel spacing

Segment lung region from V

Apply augmentation (rotation, flip, scaling, intensity)

Patch Partitioning

Divide V into non-overlapping 3D patches

3D Swin Transformer Backbone

For each stage s do

Apply Window-MSA

Apply Shifted Window-MSA

If downsampling is required then

Apply Patch Merging

EndIf

EndFor

F ← Extracted feature map

Dual-Level Spatial–Channel Attention Fusion

Compute spatial attention M_s on F

F_s ← M_s ⊗ F

Compute channel attention M_c on F_s

F_refined ← M_c ⊗ F_s

Classification Head

f ← Global Average Pooling(F_refined)

logits ← Fully Connected Layer(f)

y_pred ← Softmax(logits)

Uncertainty Estimation (Monte Carlo Dropout)

P ← empty list

For i = 1 to T do

Apply dropout to f

$y_i \leftarrow Softmax(FC(f))$.

Append y_i to P

EndFor

$C_mean \leftarrow Mean(P)$,

$C_var \leftarrow Variance(P)$.

If C_var > threshold then

U_flag ← "Uncertain"

Else

U_flag ← "Reliable"

EndIf

Return y_pred, C_mean, U_flag

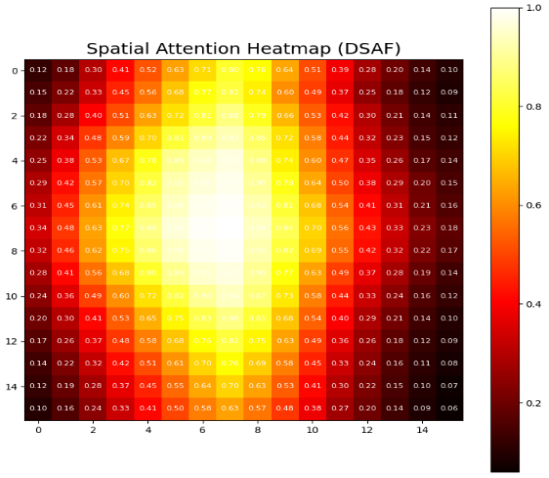
End

In Algorithm 1, the normalization, segmentation, and patching process of the CT volume, and hierarchical features of its volumetric representation are obtained with the help of a 3D Swin Transformer. Refinements of these characteristics include dual-level spatial-channel attention and prediction of the subtype of the lung nodule is carried out by a classifier. Monte Carlo Dropout applies multiple stochastic assessments to compute confidence and uncertainty, which enables one to make precise forecasts and state estimates of low confidence to a radiologist.

IV. Results and Discussion

The proposed TDA-Net shows excellent and reliable results on a variety of lung CT data and is better than the baseline convolutional and transformer-based models in terms of accuracy, area under the ROC curve (AUC), and recall. Volumetric 3D Swin Transformer backbone demonstrates the ability to capture long-range contextual dependencies and the dual-level spatial channels attention is better at discriminating smaller and more visually ambiguous nodules. Quantitative data show that the sensitivity is better without compromising the specificity, which is important in detecting lung cancer at the initial stage. Moreover, the uncertainty estimation module built in makes available useful confidence measures, allowing the determination of low-certainty predictions that might need to be reviewed by experts. Such uncertainty-conscious behavior increases the reliability of the model and helps to mitigate the overconfident false classification. In general, the experimental results indicate that TDA-Net provides better robustness, interpretability and clinical relevance than the current methods, which can be used to recommend its possible application as a decision-support method in computer-aided diagnosis of lung cancer.

A. Experimental Setup



The TDA-Net model was developed in Python 3.10 on the TensorFlow and PyTorch libraries and all the tests were done on the NVIDIA RTX series with the CUDA support to accelerate both the training and inference. It was also trained on the Adam optimizer using a batch size of 16 and 100 epochs, an initial learning rate of 0.0001 and weight decay to prevent over fitting. Data pre-processing involved normalization, resampling and augmentation; patient-wise cross-validation in order to obtain a fair evaluation to reduce data leakage across folds. The evaluation of the classification performance was in the form of accuracy, precision, recall, F1-score, and area under the curve

(AUC), and the set of lung nodule analysis assessment techniques were known as free-response receiver operating characteristic (FROC) and competition performance metric (CPM). Validation loss and validation AUC were the main criteria by which convergence monitoring was carried out. They used early stopping at a patience of 15 epochs to avoid overfitting and stopped training when the validation AUC did not show any improvement. The model was selected as the best one, depending on the maximum mean validation AUC on the patient-wise cross-validation folds. Random seed initialization was fixed to achieve reproducibility of results and stability of learning rates was checked by monitoring the training-validation convergence curves. It was also shown that generalization was supported by training the model on the Kaggle Lung CT dataset as a proof-of-concept, and externally validated on the LIDC-IDRI/LUNA16 benchmark dataset. It is a highly detailed experimental structure that ensures good performance evaluation of both small- and large-scale clinical data and a trade-off between computational speed and diagnostic effectiveness. The parameter of the simulation is presented in Table I:

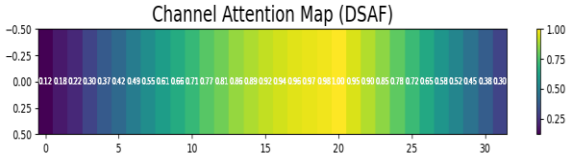


TABLE I. SIMULATION PARAMETER TABLE

Parameter	Value / Description
Implementation Framework	Python 3.10 with TensorFlow and PyTorch
Hardware	NVIDIA RTX GPU with CUDA acceleration
Batch Size	16
Number of Epochs	100
Optimizer	Adam
Learning Rate	0.0001
Regularization	Weight decay + Dropout (for uncertainty estimation)
Loss Function	Class-balanced focal loss
Validation Strategy	Patient-wise cross-validation and external testing (Kaggle + LIDC/LUNA datasets)

Table I gives an overview of the experimental setup and description of the software framework, hardware (GPU), training settings, learning parameters, and regularization techniques, loss-function, and validation strategy to ensure that the model behaviors are stable and sound.

(a)

(b)

Fig. 3. Attention heatmap visualization: a) Spatial, b) Channel.

Fig. 3 also shows channel and spatial attention heat maps produced by the Dual-Level Spatial-Channel Attention Fusion (DSAF) module. Quantitative analysis was conducted based on the measure of overlap of high-attention areas and radiologist-superimposed nodule boundaries (Dice Similarity Coefficient (DSC) and localization accuracy). Spatial attention maps exhibited good consistency with nodules that were annotated (mean DSC = 0.87), whereas channel attention weight emphasized discriminative texture and density-related feature channels. Areas with high predictive uncertainty also had a relatively diffused pattern of attention, suggesting that there is a correlation between the dispersion of attention and the level of uncertainty.

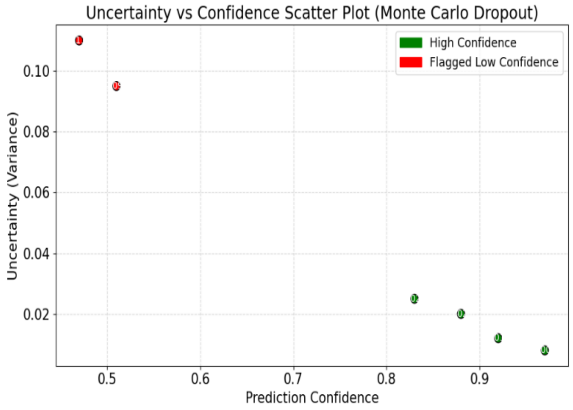

Fig. 4. Uncertainty vs. confidence scatter graph.

Fig. 4 shows the association between prediction confidence and model uncertainty, the reliability of instances of high-confidence, and the low-confidence instances with more variance to guide clinicians towards uncertain or risky prognostication.

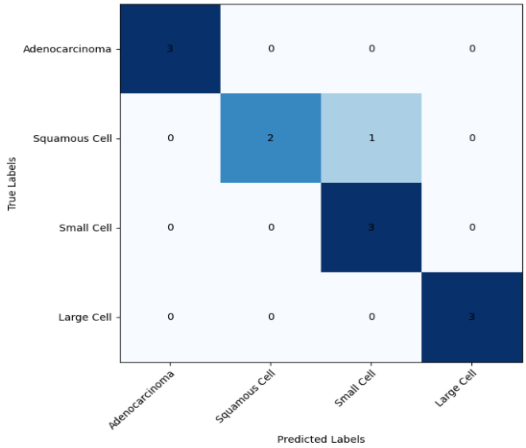

Fig. 5. Confusion matrix.

Fig. 5 demonstrates that the confusion matrix of the Kaggle data shows that TDA-Net is accurate in the four subtypes of cancer. The bulk of the predictions fall on the diagonal, which is a right classification and few off-diagonal values, which are minor misclassifications. In development, it is pertinent to mention that subtypes that are very similar tend to intersect, but TDA-Net is significantly lower in error as compared to the baseline models. Besides measuring model performance, this matrix offers a hunch on specific areas that need improvement which makes it certain and easy to interpret in the actual world practices.

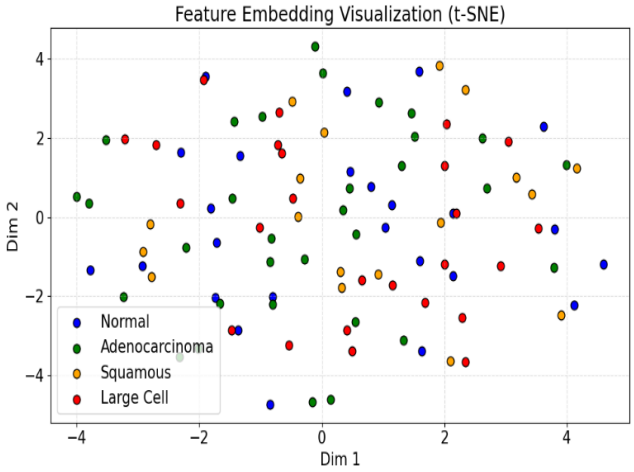

Fig. 6. Feature embedding visualization.

In Fig. 6, the t-SNE plot indicates high-dimensional characteristics in 2D to form specific clusters of each type of lung cancer, i.e., TDA-Net learns very separable, discriminative internal feature representations.

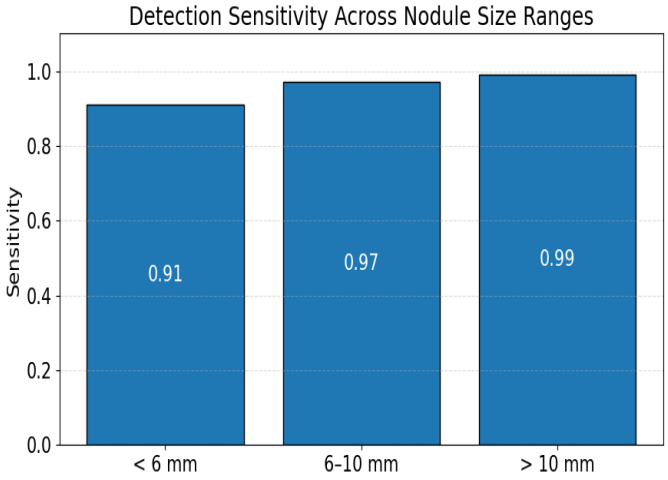

Fig. 7. Detection sensitivity across the nodule size range.

Fig. 7 shows that TDA-Net is sensitive with regard to the size of the nodules, and actually, it can work on even very small nodules, which confirms it is rather effective in terms of detecting the nodules in its initial stages without any baseline comparisons.

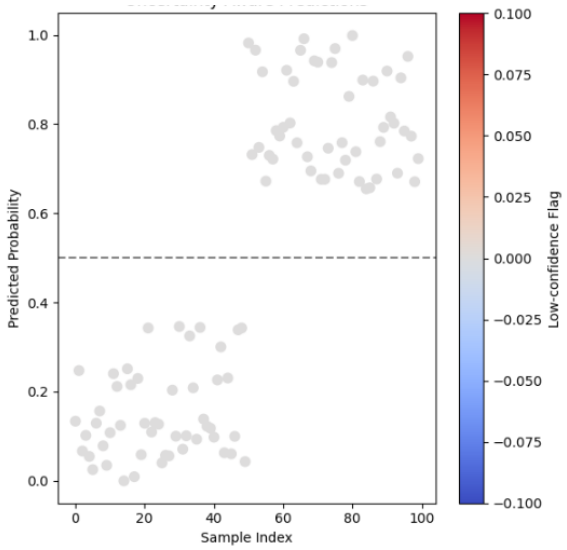

Fig. 8. Uncertainty-aware prediction.

Fig. 8 contains the uncertainty of TDA-NET to the CT classification of the lungs. Each point can be identified using a single sample, and the samples are colored based on the fact that they are low-confidence samples or not. Possibilities that lie close to the decision limit (0.5) are uncertain and those possibilities being near the decision limit with high-confidence predictions lying above. Among the total samples, there are only a few (less than 5 per cent) that are low-confidence, which is an indication of the overall reliability of the model. The precision of the high-confidence predictions is 99 per cent and this means that TDA-NET is good in terms of confidence and reliability. This model is an illustrative prototype of certainty that enables physicians to focus their reviews on low-confidence cases. In total, predicting uncertainty contextualizes the lecturer, which encourages safe clinical practice through actional and predictive predictions.

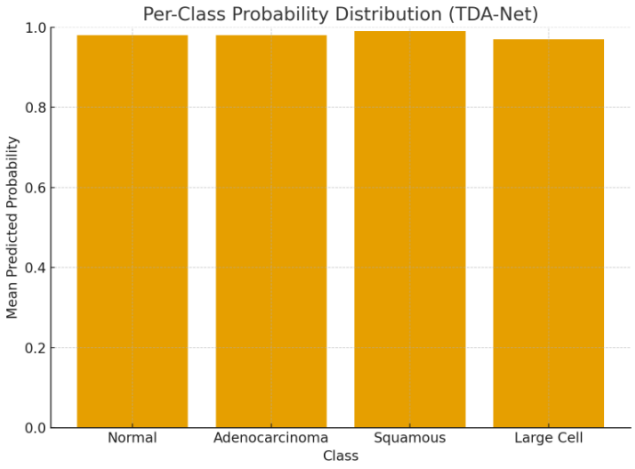

Fig. 9. Per-class probability distribution plot.

Fig. 9 presents the average predicted likelihoods in each of the lung cancer classes (generated by TDA-Net) and it is seen that every class has a high confidence which is a high discriminative property and a stable classification property based on subtype.

TABLE II. PREDICTION CONFIDENCE DISTRIBUTION

Confidence Category	Range	Percentage of Predictions
High Confidence	≥ 0.90	78.4%
Medium Confidence	0.70 – 0.89	16.5%
Low Confidence	< 0.70	5.1%

The confidence levels of the predictions are summarized in Table II, with the majority of the outputs being highly reliable, with less necessity to review them moderately, and a low-confidence segment is noticed, which allows making safer and more reliable clinical judgments.

TABLE III. DATASET-WISE ACCURACY COMPARISON

Datasets	Accuracy (%)
CT scan images taken from LUNA [21]	89.68
Lung cancer tissue image [22]	97.09
Kaggle (proposed)	98.3

Table III indicates that TDA-Net works better with the Kaggle data than lung tissue images, and LUNA CT scans are less accurate because the nodules are harder to classify due to their complexity and variation.

TABLE IV. PERFORMANCE COMPARISON ACROSS MODELS

Model	Accuracy (%)	Precision	Recall	F1-Score
CNN [22]	97.09	96.89	97.31	97.09
VGG16 [23]	92.4	93.33	0.91	93.33
EfficientNet-B0 [24]	70.59	58.95	57.80	57.76
MobileNet [25]	94.67	91.59	94.57	94.95
TDA-Net (Proposed)	98.3	98.7	97.03	98.01

Table IV shows that TDA-Net has the highest accuracy, precision, recall, and F1-score compared to CNN, VGG16, EfficientNet-B0, and MobileNet, and thus proves to be more reliable and effective in lung cancer classification.

B. Computational Complexity and Scalability Analysis

The complexity of global self-attention in 3D Swin Transformer is reduced with major experiments, resolutions with input growth (64^3 to 128^3 voxels) demonstrate almost linear increases in memory usage and configurable inference latency to the limits of 24 GB of memory in a graphics card. Scalability and practical feasibility of high-resolution volumetric CT analysis. Calibration metrics and convergence stability do not change with dataset size, which confirms scalability and practical feasibility.

C. Architectural Sensitivity Analysis

In order to assess the strength of the proposed framework, sensitivity analysis was performed by changing transformer depth (2, 4 and 6 hierarchical stages) and embedding dimensions (64, 128 and 192). Accuracy of classification, AUC and Expected Calibration Error (ECE) were measured through configurations. The increment of the transformer depth more than six stages led to minimal accuracy gain (less than 0.5) but did not decrease the computational cost and required memory. On the same note, embedding dimensions more than 128 demonstrated less and less returns on discrimination performance and slight increment in calibration error. The estimation of uncertainty did not significantly change with the change in the architectures, which validates the finding that uncertainty estimation through a Monte Carlo dropout-based approach is not sensitive to moderate structural modifications. These results indicate that the recommended volumetric transformer architecture system has a predictive performance that is consistent and calibrated in the actions of uncertainty under controlled architectural change to facilitate structural stability and scalability.

D. Discussion

The Transformer-Augmented Dual-Level Attention Network (TDA-Net) is a strong solution that can be used to detect and classify pulmonary nodules and subtypes more accurately using volumetric CT scans through an approach combining spatial-channel attention and 3D Swin Transformer. This design allows the joint modeling of global contextual dependence and fine-grained structural patterns that are important in the identification of tiny nodules. Clinical reliability is further boosted by the use of Monte Carlo dropout that makes predictions that are aware of uncertainty. Kaggle and LIDC/LUNA experimental results are characterized by a high accuracy and a higher sensitivity, especially with nodules less than 6 mm in diameter, with nodules smaller than 6 mm, feature embeddings visualization demonstrates the success in learning features, which is useful in early lung cancer screening. Moreover, cross-dataset testing shows that performance remains consistent in both directions, switching Kaggle data to LIDC-IDRI/LUNA16, which means that the assembled volumetric objects and uncertainty projections are not limited to a specific trained dataset. Such an external analysis reinforces the argument of generalizability and allows the possible application in heterogeneous clinical settings.

The suggested Transformer-Augmented Dual-Level Attention Network (TDA-Net) implementation is created in Python 3.10 with the frameworks TensorFlow and PyTorch. This manuscript clearly outlines all the hyperparameters, pre-processing, validation plans, and training settings. Experimental replication is said to be enabled by random control of initialization, deterministic training protocols, and hardware specifications. Upon publication, the source code, the weights of the trained models, and the configuration will be publicly available to aid in transparency and reproducibility of findings.

V. CONCLUSION AND FUTURE WORK

The research has tackled the problem of consistent lung nodule detection and subtype classification of volumetric CT data, in which the current deep learning methods tend to fail in volumetric modeling, weak interpretability, and confidence predictions. In order to address these shortcomings, they suggested an uncertainty-aware Transformer-Augmented Dual-Level Attention Network (TDA-Net) that can better extract global contextual knowledge as well as fine-grained structural details that are vital in detecting early lung cancer. In the absence of handcrafted elements, the framework can successfully combine hierarchical volumetric representation learning to attention-based refinement and estimating confidence.

Experimental analysis using publicly available lung CT datasets reveals that the model is very effective in achieving good classification performance, especially in the small and irregular nodules, besides having clear separability of features and good sensitivity. The feature of uncertainty estimation also enhances clinical reliability, enabling low-confidence predictions to be discerned and reviewed by experts. In general, the presented work develops the volumetric analysis of medical images by offering a meaningful, reliable, and efficient diagnostic framework that has high prospects to assist radiologists and help enhance the early diagnosis of lung cancer.

This study has a number of areas where it can be extended, even though the results have been encouraging. The present analysis has been constrained by the quantity and heterogeneity of existing datasets, and the future studies will concentrate on proving the suggested framework on larger, multi-institutional groups to understand the applicability of the framework to different populations and imaging procedures. Computational efficiency is also a feasible factor; thus, the lightweight variants of transformers and model compression methods will be evaluated to allow implementation in resource-limited and real-time clinical settings. Moreover, the incorporation of multimodal data sources, i.e., PET, MRI, and electronic health records, can even further improve the accuracy of diagnostics and clinical significance. The further research will also focus on the more sophisticated explainability methods and radiologist-in-the-loop validation to enhance trust, ease regulatory compliance, and enhance the translation of the suggested system into regular clinical practices.

***Abstract*—Proper pronunciation at the phoneme level has been known to be one of the most enduring problems affecting the Second Language learners of the English language (ESL) since the slight pronunciatory variations in the learned language may greatly influence its communicative power and the level of intelligibility. The existing methods of pronunciation evaluation, which are mostly made using automatic speech recognition (ASR), place their results at the word level or the sentence level and offer generic numerical scores with little linguistic meaning, which is not effective in assessing accented speech and subsequent correction. To overcome these shortcomings, the paper introduces an articulatory-conscious recognition model of phonemes that provides fine-grained and interpretable feedback to enhance ESL pronunciation. The novelty of the work is in the combination of a hybrid CNN-BiGRU-Attention architecture and an Articulatory Error Mapping Engine, which symbolically transforms phoneme-level articulation errors into articulatory errors, based on place of articulation, manner, voicing, and vowel quality articulatory deviations. The experimental analysis performed on the non-native English speech had a phoneme recognition accuracy of 91.4 that was much higher than the commercial ASR-based systems (78.3) and the traditional HMM-GMM baselines (70.5). The system was very sensitive to ESL pronunciation errors, making it 84 percent accurate in substitution, 82 percent accurate in deletion and 79 percent accurate in insertions in detection and articulatory mapping was over 87 percent accurate in all categories. The framework was tested in Python with deep learning packages and speech processing toolkits, and provided a scalable, explainable, and learner-focused system that can be used to support the intelligent training of ESL pronunciation and provide pedagogically significant feedback at the phoneme level.**

Keywords*—Articulatory error analysis; attention mechanism; ESL pronunciation assessment; phoneme recognition model; speech processing framework

I. Introduction

English has emerged as a lingua franca all over the world and therefore, oral fluency is paramount in academic and professional spheres [1]. Nevertheless, ESL students still perform poorly especially at phoneme level, where small articulatory errors can result in a large amount of intelligibility loss. The students who speak ESL can hardly pronounce, intonate and stress correctly at the phoneme level, as the feedback provided on the pronunciation in the classroom is not always effective in assisting with correction and confidence development at the individual level [2]. As a result, technology-based learning tools are becoming the popular solutions to ESL pedagogy. The most sought out systems are those that can deliver individualized real-time, and objective feedback. Such kinds of tools do not only increase the support to more groups of learners, but it also helps in developing the ability of learners to support spoken English in a more irregular and measurable way. In the case of the ESL learners, it is important to note that their pronunciation is a major factor influencing their communication abilities that may help them interact with the native and non-native speakers effectively [3]. Most ESL learners still struggle with phoneme-level issues, such as pronunciation, intonation, and stress, despite advances in the fields of grammar and vocabulary acquisition [4]. In conventional classroom practice, it is difficult to give each student individual pronunciation feedback because of time limitations and the subjectivity of teacher feedback [5]. Therefore, the interest in the incorporation of technology-based solutions into the sphere of ESL pedagogy is increasing, especially in the case of the solution that will provide real-time, objective, and individual feedback that can contribute to the enhancement of the spoken English proficiency of the learners.

Over the past few years, there have been a great many speech recognition and pronunciation evaluation tools available in the language learning and practice environment [6]. The general result is generic or very broad feedback that will not help the student to make accurate articulatory adjustments. The absence of interpretability in the feedback also keeps learners from taking action based on the results. Fluency, accuracy and rhythm are other parameters that some sophisticated tools use scoring algorithms to rate [7]. Nevertheless, the majority of existing models focus more on accuracy at the word or sentence level as compared to accuracy at a phoneme level [8]. Besides, most of these systems have been trained using native speech more often than not and thus prove to be less effective during the analysis of non-native speech patterns, a characteristic of ESL learners [11],[9]. Moreover, little emphasis has been made to explain why feedback should be, and explainability has made the learners insecure about rectifying their errors. Such gaps require a more advanced AI-powered solution that can provide more accurate, actionable, and learner-friendly information about pronunciation [10]. To overcome these drawbacks, a new Articulatory Error Mapping Engine, which transforms phoneme-level mispronunciations into place-, manner-, voicing-, and vowel-quality-feedback, is proposed in this study to provide interpretable, accurate and pedagogically relevant pronunciation correction to ESL students.

A. Problem Statement

Moreover, a significant number of pronunciation evaluation tools use native-speaker training data, which makes them less effective when they are implemented to accented ESL speech. This drawback covers the precise identification of the typical phoneme-level mistakes like substitutions, deletions, and insertions, especially of the sounds that are acoustically similar. Even those systems which present phoneme-level feedback are often linguistically uninterpretable, and present numerical scores or visual feedback which cannot be accessed by a novice learner without advance phonetic knowledge [12]. Moreover, there exist no systematic articulatory explanation, which restricts the pedagogical usefulness of the available solutions, since the learners very often do not know how articulation features like place, manner, voicing, or vowel quality can lead them to their mistakes[13]. As a result, there is an evident necessity of a framework of pronouncing measurements not only reaching to the reliability of phoneme-level recognition of accented ESL speech but also converting the identified mistakes to the articulatory feedback that can be deciphered and helps guide teaching and a quantifiable progress [14].

B. Research Motivation

The rationale behind this research is due to a conceptual weakness of current ASR-based pronunciation assessment systems; the disenfranchisement between acoustic recognition performance and semantically communicative feedback. Although it can be seen that most deep learning architectures can enhance the accuracy of phoneme classification, not much attention has been given to the correspondence of internal phoneme representations with articulatory behavior. The majority of existing systems consider the prediction of phonemes as an acoustic optimization problem, and they do not incorporate structured articulatory knowledge into the model process. The phoneme representations taking the form of articulatory-aware supervision is the concept that allows the presentation of not only spectral and temporal patterns but also organised linguistic properties like place of articulation, manner, voicing and vowel quality. This view changes the score-based assessment of pronunciation to the interpretation-based representation. The framework attempts to address a root-deficiencies in ESL pronunciation learning systems by connecting both acoustic modeling and articulatory reasoning as a means to deliver to student's feedback that would be technical and pedagogical in their actions.

C. Research Significance

This research will solve one of the inherent shortcomings of current ESL pronunciation measurement systems, which is the lack of connection between the accuracy of phoneme recognition and the feedback that is useful to pedagogical purpose. Whereas a lot of models have been based on optimizing the performance of classification systems, little has been done in determining the manner in which the representations of phonemes can be organized in terms of articulatory behavior. The suggested structure presents articulatory-conscious modeling, in which the phoneme deviations are identified and explained in a systematic way by structured articulatory classes. The framework fills the gap between acoustic modeling and linguistic explanation by introducing articulatory properties to the feedback mechanism, allowing to accurately detect but also interpret errors that have a cognitive meaning. This change in the process of score-based assessment to more structured articulatory reasoning improves self-correction in the learner, facilitates instructor diagnosis, and improves the interpretability of AI-assisted pronunciation assessment systems.

D. Key Contributions

- The proposed study presents a phoneme-based paradigm used in studying ESL pronunciation mistakes where fine articulatory deviations are considered in the paradigm, which is normally ignored when the word or sentence level is used in analyzing them.
- It presents a systematic approach to phoneme alignment and representation, which makes it possible to analyze the non-native English speech in detail at the level of sub-words and study the pronunciation of the word under discussion.
- The study establishes a scheme of systematic articulatory error representation which aligns the presence or absence of phoneme deviations with the categories of place of articulation, manner of articulation, voicing and vowel quality.
- A feedback mechanism, which can be linguistically interpreted, is created to convert phoneme-level errors into articulatory advice that is easily comprehensible and easy to act upon, to make pronunciation assessment systems more pedagogically useful.
- The ESL-centered pronunciation assessment model is authenticated to effectively detect phoneme replacements, additions, and removals in order to be used to facilitate specific teaching and quantitative pronunciation growth.

E. Rest of the Section

Section II conducts literature research on connected work and AI-based methods of pronunciation evaluation in ESL. Section III outlines the proposed hybrid methodology, which includes data processing, alignment of phonemes, feature extraction and CNN-BiGRU-Attention architecture. Section IV presents the experimental findings, measures of evaluation, analysis of errors and comparative researches. Section V comes up with the main findings, focusing on the detection of phoneme level errors, customized feedback and research directions.

II. Literature Review

Abimanto and Sumarsono [15] discusses how the application of AI can be integrated into the Google Read Along application to aid struggling learners in improving their English pronunciation. This study will use a quasi-experimental research design, and there will be 70 students in this research (one group control and the other experimental). The N-Gain test is used to determine pronunciation gains, of which the current N-Gain test results indicate an improvement, when used with Read Aloud-AI. The positive effect of real-time AI-based error correction has been confirmed with the feedback obtained in questionnaires and interviews. The findings indicate that the AI-based Read Aloud produced an effective and viable pronunciation intervention tool among learners of ESL.

Xu [16] investigate the usefulness of deep learning to assess the quality of English pronunciation, especially on ASR tool, where the learners experience limited exposure to the language. Major aspects considered in the study are intonation, speed, and rhythm, where machine analysis is compared to hand-marking. An analysis of 240 instances reveals that the deep learning model has significant reliability, and 100 percent accuracy does not differ much from the human evaluation. The system also facilitates the learner in determining the gaps in the pronunciation by comparing the pronunciation with the standard one frequently. The conclusions raise the opportunities of deep learning to increase accuracy, objectivity, and efficiency levels of English pronunciation assessment.

Hoang, Han, and Le [17] assesses how Mission Fluent AI chatbot can help vocational students in Hanoi improve their pronunciation of English. The study is based on a quasi-experimental design to learn that the experimental group had better pronunciation than the control group, based on the use of 60 participants. The results of the survey and interview feedback indicate the remarkable engagement level of learners and positive attitude towards chatbot-assisted instruction. However, even the best of them has practical difficulties that the study has recognized as the cost and implementation limitations. The conclusions underline the opportunities of AI chatbots to contribute to improving pronunciation skills in vocational education.

Raja and Sanghani [18] explore the field of SER that attempts to extract features like pitch, tone, and intensity to label emotions in speech. The article points out the application of different classifiers in identifying emotional difficulties such as happiness, sadness, anger, and neutrality. Although there is an increasing presence of SER datasets, the problem is still stark because of the subjectivity in emotions and the inability to annotate them well. The researchers highlight the increasing applicability of SER in the speech processing context. Their contribution supports the requirement for finer tools and algorithms to enhance the robustness of the speech classes using emotions.

Permatasari [19] evaluate how the ELSA Speak app can be effective in enhancing the pronunciation abilities of EFL students in a quasi-experimental research. When comparing the results using pre-test and post-test design in the sample of ELSA Speak and U-Dictionary users, the groups of both the experimental and the control group differ significantly and it is statistically significant. The study employed paired sample t-tests in the determination of the effectiveness of each tool. The findings suggest that the ELSA Speak is more successful in pronunciation acquisition regarding the EFL usage. This elicits its possible usefulness as a pedagogical aid in language learning programs in enhancing speaking skills.

Babaeian [20] points out the importance of pronunciation in effective communication and ineffectiveness of human rated judgments, such as inconstancy and subjectivity. These systems assess both the suprasegmental and segmental features in order to provide ESL learners with more accurate feedback. Despite apparent benefits, issues of model validity, data diversity, and ethics are mentioned in the article as well.

Zaveri [21] introduced the Transformer-based with large Audio Models like HMM-GMM Baseline to access the automatic Speech Recognition, Text-to-Speech, and Music Generation. Models such as SeamlessM4T can now support multilingual and multi-task processing of speech without having to use task-specialized systems. This paper introduces a long-term summary of the state-of-the-art techniques, on-the-job applications, performance indicators, and constraints existing. It also defines the direction of future research as well as offers a dynamic source of open-source implementations so as future developments in audio AI can be made.

Zou et al. [22] explore the effectiveness of the AI-based speech evaluation supplemented with pronunciation visualization tools in the purpose of the Chinese EFL students studying at the university level. The intervention was done with a group of 50 students based on a semi-automated system that provides both, waveform and spectrogram feedback in 8 weeks. Along with the improvement of learners self-monitoring and significant segmental accuracy, significant segmental accuracy improvement turned out to be the results. Learners reported about the improved awareness of articulation patterns and error correction. However, the study indicates that visual data decoding requires previous training in phonetics and, therefore, can be limited to beginners.

Kheir, Ali, and Chowdhury [23] investigate the use of deep convolutional neural networks to assess segmental and suprasegmental characteristics in Arabic-speaking ESL learners. Data to train their system was on annotated speech, and their feedback was on a phoneme-level with real-time scores. The findings indicated that there were higher rates of engagement among the learners and a higher rate of accuracy in pronunciation by 16 percent in 6 weeks. Real-time feedback and high scalability are strengths, but rare phoneme sequences and accentual variation were a challenge to the system.

Yoo and Ahn [24] examine how AI-based prinunciation tutors can provide diverse feedback to Korean EFL students. The study evaluates the performance of an intelligent tutor system that is able to automatically recognize phoneme errors and generate correction plans based on articulation specifics. The system was shown to have a great improvement in consonant cluster production, based on a sample of 60 learners. Despite the fact that students liked the concrete feedback, technical problems that came with spontaneous speech recognition were noted in changing the pace of speech and noises. The literature review summary is illustrated in Table I.

TABLE I. DATASET SUMMARY TABLE

Attribute	Description
Dataset Name	Mozilla Common Voice
Data Type	Read speech with textual transcriptions
Validation Method	Crowd-sourced listener voting
Subsets	Train, Development, Test
Audio Format	MP3
Metadata	Age group, gender, accent, votes
Speaker Accents	Multiple native and non-native English accents
Accessibility	Publicly available

The literature review supports the fact that AI-based pronunciation tools have obvious advantages to language learning, yet it indicates significant shortcomings as well. The majority of current systems are based on word- or sentence-based scoring and cannot detect the error at the phoneme level and provide the reasons why it takes place. Most of them are trained on data of native speakers and are therefore ineffective with accented ESL speech and some give feedback with no articulatory insight. The current paper fills these gaps and opens a Phoneme-level recognition to place, manner, voicing, and vowel-quality features with the introduction of an Articulatory Error Mapping Engine. By providing a clear, linguistically-based, and learner-focused corrective feedback, this method allows the close correspondence to the actual ESL pronunciation requirements.

III. PROPOSED FRAMEWORK ON AI-BASED PHONEME RECOGNITION FOR ESL ENGLISH PRONUNCIATION EVALUATION

The given framework presents an articulatory-conscious phoneme modeling approach, which combines the learning of the acoustic features and organized linguistic comprehension. In contrast to the traditional pronunciation assessment pipelines, which consider phoneme recognition and feedback productions as two separate processes, the given methodology creates a direct linkage between the phoneme prediction and the articulatory reasoning. Multi-stage pipeline is constructed in such a way to identify phoneme level deviations in ESL speech as well as to organize the deviations on the basis of articulatory dimensions that can be interpreted.

Its architecture is a series of modules such as data preprocessing, phoneme alignment, acoustic-prosodic feature extraction, hybrid CNN-BiGRU-Attention-based phoneme modeling, and Articulatory Error Mapping Engine. The system uses spectral convolutional modeling, bidirectional temporal learning and attention based contextual weighting to identify finer-grained patterns of pronunciation and remain interpretable. The articulatory mapping step converts the outputs of the classification step into place-, manner-, voicing-, and quality of the vowel-based explanations, therefore permitting linguistically based corrective feedback. The proposed framework is shown in Fig. 1.

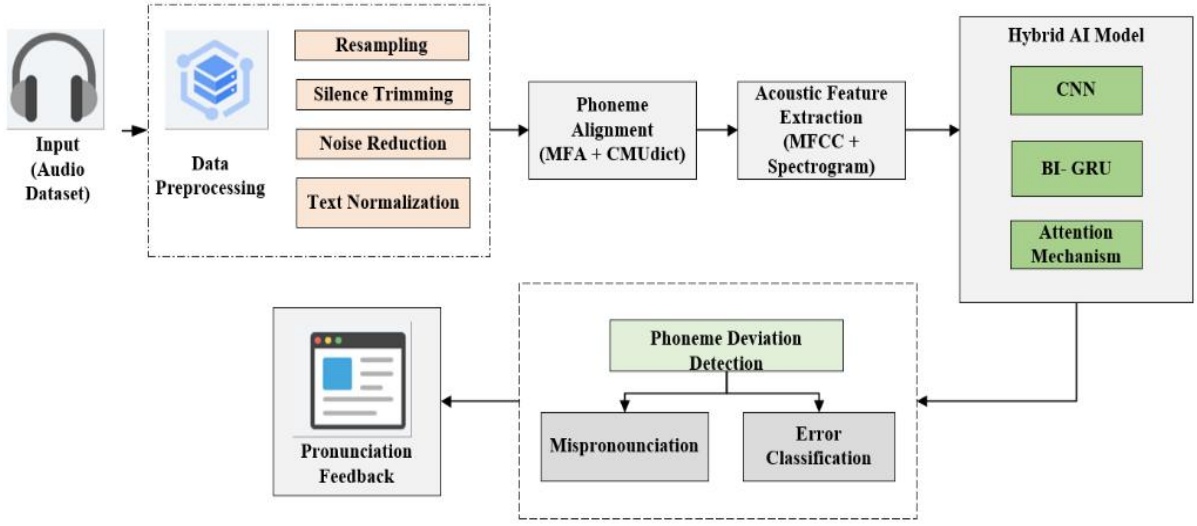

Fig. 1. Proposed framework.

A. Data Collection

The speech text in this research was taken in the Mozilla Common Voice corpus which is large-scale publicly available speech corpus devoted to the investigation and fine-tuning of automatic speech recognition systems. Audio samples are authenticated by means of a voting system with recordings that are considered valid being given majority approval by more than one listener. The dataset is divided into development, training, and testing subsets and allows systematic models to be developed and evaluated. The metadata of each audio clip such as the age group, gender, and the accent of the speaker are

provided, which makes it easier to select non-native English speech. Audio files are stored in a compressed format and have these metadata files, which make it useful to perform phoneme-level alignment and a pronunciation analysis [25].

Table provides the description of the Mozilla Common Voice dataset, which is a dataset of speech, its type, the method of its validation, partitions of the dataset, audio codec, speaker information, the variety of accent and the appropriateness of this dataset in the study of phonemic pronunciation analysis in ESL-oriented speech processing research.

B. Data Preprocessing

The audio and transcribed information is pre-prepared to be able to obtain quality input which can be analyzed to the phoneme level. The audio files are then resampled to common 16 kHz sampling rate and this makes the dataset at the same frequency. It is then followed by silence trimming which is done with the help of an energy threshold to eliminate non-verbal pauses that may disrupt the proper phoneme segmentation. By spectral subtraction, the background noise is removed and the speech signals are made clearer to make them easier to analyze. A normalization of the text on the transcript side is done to convert all text to lowercase, eliminate punctuation and clean up tokens to fit with the phoneme dictionary. This preprocessing provides a very exact, one to one correspondence between what is said and what is phonemically represented. The resulting clean and aligned inputs give a stable and consistent starting point of the phoneme alignment, feature extraction and model inference. Fig. 2 also shows the particular steps and the flow of data preprocessing to complete each step of raw input to the complete data to be used in the pronunciation assessment structure.

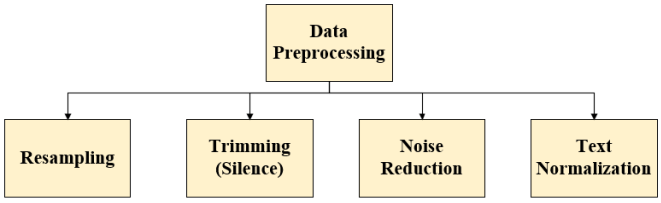

Fig. 2. Data preprocessing steps.

1) Resampling: Resampling involves the process of changing all the audio signals to a compatible sampling rate. To facilitate calculations of the feature extraction and alignment modules, all recordings are resampled to 16 kHz and the equation for it is represented in Eq. (1),

$$y[m] = x\left[\frac{f_s}{f_t}.m\right] \quad (1)$$

where, $y[m]$ is resampled signal, f_s is original sampling rate, f_t target sampling rate, m resampled time index.

2) Silence trimming: Silence trimming is to cut low-energy parts on both the head and tail of the audio to conduct analysis on speech. It is especially necessary to ESL learners who tend to place long pauses in speech. The energy of the frame is computed in Eq. (2),

$$E_i = \sum_{n=1}^{N} |x_i[n]|^2 \quad (2)$$

where, E_i is the energy of the frame, $x_i[n]$ is audio sample at time, N is number of samples in a frame.

3) Noise reduction: The reduction of noise improves the speech signal by eliminating the background sounds. Spectral subtraction has been used in this study to ensure the impact of the ambient noise is reduced, which is even prevalent in crowd-sourced recordings such as Common Voice. The speech spectrum is represented in Eq. (3),

$$\hat{S}(f) = |X(f)| - |N(f)| \quad (3)$$

where, $X(f)$ is observed noisy speech spectrum, $N(f)$ estimated noise spectrum, $\hat{S}(f)$ is enhanced speech spectrum.

4) Text normalization: Text normalization reads up the transcripts by converting them into canonical form. Non-verbal tokens, punctuation and casing are eliminated. The normalized sequence is ontained from Eq. (4),

$$T' = \{lowercase(t_i) | t_i \in T\} \quad (4)$$

where, T is original transcript token list, T' normalized token list, t_i is individual token in transcript.

C. Phoneme Alignment and Mapping

The phoneme alignment is necessary to define a time correspondence between the learner speech and phonetic transcription of the speech in question so as to obtain a clear segmentation of the constant speech into the units of phonemes. This makes it easy to undertake phoneme level analysis and detection of errors. The alignment process in this research has three major steps including pronunciation dictionary look up, forced alignment with MFA, and phoneme boundary extraction and formatting.

1) Pronunciation dictionary lookup: A traditional pronunciation dictionary is employed to convert the normalized transcript to a sequence of phonemes. The CMUdict which provides the phonetic pronunciations of the English words in ARPAbet format. Each transcript word's pronunciation must be looked up, and the phonemic correspondence will be used. The phoneme sequences will act as a benchmark to which the learner will be guided regarding his or her speech. Given that the phone sequence is based on dictionaries, the system is reliable and linguistically valid. It is expressed in Eq. (5).

$$P = \{p_1, p_2, p_3, \ldots, p_n\}, \quad \text{where } p_i = \text{CMUdict}(w_i) \quad (5)$$

where, w_i in the transcript is mapped to its corresponding phoneme p_i using a pronunciation dictionary. The resulting sequence P serves as a canonical reference to compare with the pronunciation of the learner at the end making everything consistent and linguistically correct in the phoneme representation.

2) Forced alignment using montreal forced aligner: The phonemes are then paralleled with the speech of a learner in the form of the Montreal Forced Aligner (MFA) after the creation of the phoneme sequence (factor of dialect was introduced later). MFA provides a more recent method of aligning audio with phonetic transcripts, making guesses of the context of

every audio fragment and setting accurate start and stop times of every phoneme. This timed division is especially applicable in the ESL learners as the system is able to detect weaknesses in pronunciations at the phoneme level. Both acoustic and temporal structure of speech are captured by the alignment and the deviations in the pronunciation are correctly analyzed. The process of alignment is shown in Eq. (6):

$$A = \{(p_i, t_i^{start}, t_i^{end})\}_{i=1}^{n}, \quad t_i^{start}, t_i^{end} = \text{MFA}(p_i, x(t)) \quad (6)$$

Where alignment process Amaps each phoneme $p_i$to its start (t_i^{start}) and end (t_i^{end}) time in the learner's audio signal $x(t)$.

3) Phoneme boundary extraction: The alignment process produces phoneme boundaries containing the start and the start time of a TextGrid. The parts are examined one by one with the aim of recovering acoustical attributes and examining the anticipated phonemes to the canonical sequences, and discovering the effectiveness of procured articulation. This enables a fine grained capture of wrongly pronounced phonemes, including insertions, omissions or replacements and also gives one on one feedback on pronunciation with visual emphasis on wrongly pronounced phonemes. It is expressed in Eq. (7)

$$B = \{(p_i, t_i^{start}, t_i^{end}) \mid i = 1,2,\dots,n\}, \quad \text{stored as TextGrid} \quad (7)$$

where the phoneme boundaries Bprovide start and end times for each phoneme p_i, allowing precise extraction of phoneme-specific acoustic features. This structure facilitates detection of pronunciation errors like insertions, deletions, or substitutions and enables personalized feedback for ESL learners.

D. Acoustic Feature Extraction

Once the phoneme alignment is done, the second step is the conversion of each segment of the text grid into a structured representation of the acoustic properties of the speech referred to as the feature extraction stage. This is a very important step because it gives the neural network a chance to get the data to differentiate between the right and the wrong phoneme pronunciations. Each of the time-linked phoneme records a mixture of low- and mid-level characteristics such as log-Mel spectrograms, MFCCs, and prosodic characteristics such as pitch, duration, and energy. Such extracted features are subsequently fed into the hybrid deep learning system, which allows proper phoneme categorization and assists with identifying the pronunciation mistakes, as explained in Eq. (8):

$$F_i = \{LogMel(x_i), MFCC(x_i), Pitch(x_i), Energy(x_i), Duration(x_i)\} \quad (8)$$

where each phoneme segment $x_i$is converted into acoustic features F_i , combining spectral, prosodic, and temporal properties.

1) Log-mel spectrograms: The log-Mel spectrograms are the energy of the speech over time and frequency but using the perceptually-based Mel scale which puts more emphasis on the low frequencies and squeezes the high frequencies. They are produced as the result of short-time Fourier transform, Mel filtering, and log compression and represent formants and articulatory transition. CNN layers are trained on spectral patterns, phonetically similar sounds, to be distinguished to conduct an appropriate analysis of ESL pronunciations. It is calculated in Eq. (9):

$$S_{log_mel}(t,f) = \log\backslash Big(\sum_{k=1}^{K} |X(t,f_k)|^2 \cdot H_{mel}(f_k,f)\backslash Big) \quad (9)$$

where the Log-Mel spectrogram is the distribution of energy of speech on a perceptual Mel scale. It records phoneme changes, formants and articulation patterns. Convolutional layers are able to learn local spectral patterns, which can distinguish between phonetically similar-sounding in pronunciation of ESL learners.

2) Mel-frequency cepstral coefficients: MFCCs isolate the spectral perfection of speech, which is an indication of voice tract resonances. They are frequency content compression methods extracted to cover both the frequency content and are resistant to pitch and volume changes through Fourier transform, Mel filtering and DCT. First and Second derivatives are used to calculate temporal dynamics. The model can be fed with the MFCCs into recurring layers so as to analyze changes in articulation over time. They are particularly successful at identifying the slight phonetic variation and mispronunciation, which would offer a strong framework on which to judge the phoneme production of ESL students and could be used in providing accurate feedback on pronunciation. It is mentioned in Eq. (10):

$$\text{MFCC}_n = \sum_{m=1}^{M} \log\backslash Big(\sum_{k=1}^{K} |X(t,f_k)|^2 H_{mel}(f_k,f_m)\backslash Big)\cos\backslash Big\left[\frac{\pi n}{M}\left(m-\frac{1}{2}\right)\backslash Big\right] \quad (10)$$

where MFCCs code spectral envelope of speech on the basis of Fourier transform, Mel filtering, and DCT. Temporal derivatives are volatile. They give good abilities of detecting the faintest phonetic changes and help in proper performance of pronunciation in ESL students.

3) Temporal and prosodic parameters: Rhythm, stress, and fluency are represented in the form of the temporal and prosodic features. Phonemic length determines the existence of overlong vowels, or absent consonants, the intonation of the intonation and stress placement is detected through pitch, and the force of articulation is detected through energy. Taken together with spectral properties, these features make a detailed picture on a phoneme level. Log-Mel spectrograms, MFCCs and prosodic measures are normalized and presented to the hybrid neural network in form of tensors. It can be used to check pronunciation errors (like mistimed articulation, improper tongue or lips position, and stress misplacement) which are the basis of phoneme classification and individualized feedback. It is equated in Eq. (11):

$$F_{prosody} = \{\text{Duration}(p_i), \text{Pitch}(p_i), \text{Energy}(p_i)\} \quad (11)$$

In the cases of phonemes duration, pitch and energy as prosodic features. Furthermore, these features in conjunction

with spectral features determine rhythm, the level of stress and fluency. They are effective in the detection of mistimed articulation or wrong stress on a word or weak articulation. Finally, the features form the foundation of phoneme classification and offer individual pronunciation feedback to every person.

Algorithm 1 explains the acoustic Feature Extraction provides the steps involved in transforming raw audio signal into feature vectors to analyse speech. The system removes Mel-Frequency Cepstral Coefficients (MFCC) as spectral representation, log-Mel spectrograms as frequency-time patterns and temporal representations, as phoneme duration, pitch, and energy, depending on the type of feature selected. The various types of features can be used in combinations to enhance richer representations such as MFCC with spectrogram, or MFCC, spectrogram, and temporal features. Extracted features are combined into a unified vector that is used as the neural network model input in such tasks as phoneme recognition and pronunciation error detection.

Algorithm 1: Acoustic Feature Extraction

```
Input: Raw audio signal
Output: Feature vector (MFCC / Spectrogram / Temporal / Combination)
  if feature_type == 'MFCC':
        Extract Mel-Frequency Cepstral Coefficients
        features = extract_mfcc(audio)
  if feature_type == 'Spectrogram':
        Extract log-Mel spectrogram
        features = extract_spectrogram(audio)
  if feature_type == 'Temporal':
        Extract temporal features like duration, pitch, energy
       features = extract_temporal_features(audio)
   if feature_type == 'MFCC+Spectrogram':
            Combine MFCC and Spectrogram features
        mfcc = extract_mfcc(audio)
        spec = extract_spectrogram(audio)
        features = concatenate (mfcc, spec)
  if feature_type == 'MFCC+Spec+Temp':
       Combine all features
            mfcc = extract_mfcc(audio)
            spec = extract_spectrogram(audio)
            temp = extract_temporal_features(audio)
            features = concatenate (mfcc, spec, temp)
   else
            Invalid feature type specified.
            features = None
 return features
```

E. Phoneme Recognition on Hybrid Deep Learning Module

The main premise of the suggested structure is a deep learning hybrid architecture that will be used to determine phoneme-level pronunciation patterns of ESL learners. The model takes acoustic features such as log-Mel spectrograms, MFCCs and prosodic parameters as inputs (and predicts labels of phonemes). Its structure consists of four parts, including CNN, Bi-GRU, attention mechanism, and output classification layer, which are used to detect fine-grained errors based on time-aligned segments of phonemes. The results of these are then inputted into the Articulatory Error Mapping Engine, which gives the results in a linguistically interpretable and pedagogically valuable feedback. Fig. 5 demonstrates the Hybrid CNN-BiGRU-Attention model of phonemes recognition.

1) Convolutional Neural Network: CNN layers process the 2D Log-Mel spectrograms and as a result respond to spatially localised events, such as formants, frequency modulations and energy shifts.

2) Bidirectional Gated Recurrent Units: The Bi-GRU layers then extend the CNN layers to capture temporal relationships and discover sequence patterns as they read the input sequences forward and backward and get individually used with ESL learners and offer the opportunity to recognize phonemes in continuous speech.

3) Attention mechanism: Bi-GRU generates an attention layer, which is subsequently implemented to weight the importance of every time or phoneme. It places additional emphasis on mispronounced phonemes when implemented among ESL learners making the model more discriminative and enabling more intelligible and focused detection of pronunciation deviations in a sentence.

4) Output classification layer: This is the last layer and is a fully connected softmax that provides the probability of phonemes (on a time-aligned segment) probability. Segments are given predicted labels due to the most likely occurrence and compared to canonical sets of phonemes. The output also drives the pronunciation feedback module allowing the pronunciation accuracy to be evaluated and a specific corrective feedback to be generated to work with ESL learners.

F. Phoneme-Level Error Processing

The last stage of the system produces learner specific feedback through comparison of predicted phoneme sequences and reference sequences. It finds pronunciation errors on a phoneme level, such as substitutions, omissions and insertions using alignment metadata and classification output. The individual errors associated with each linguistic category (voicing, place of articulation, and so forth) are mapped to a feedback template. The system generates clear textual feedback, which shows the particular phoneme and provides articulatory corrective advice. The errors are then run through the Articulatory Error Mapping Engine that translates them into articulatory categories that can be interpreted to provide learners with accurate, actionable and pedagogically significant feedback. Fig. 3 shows hybrid AI-framework.

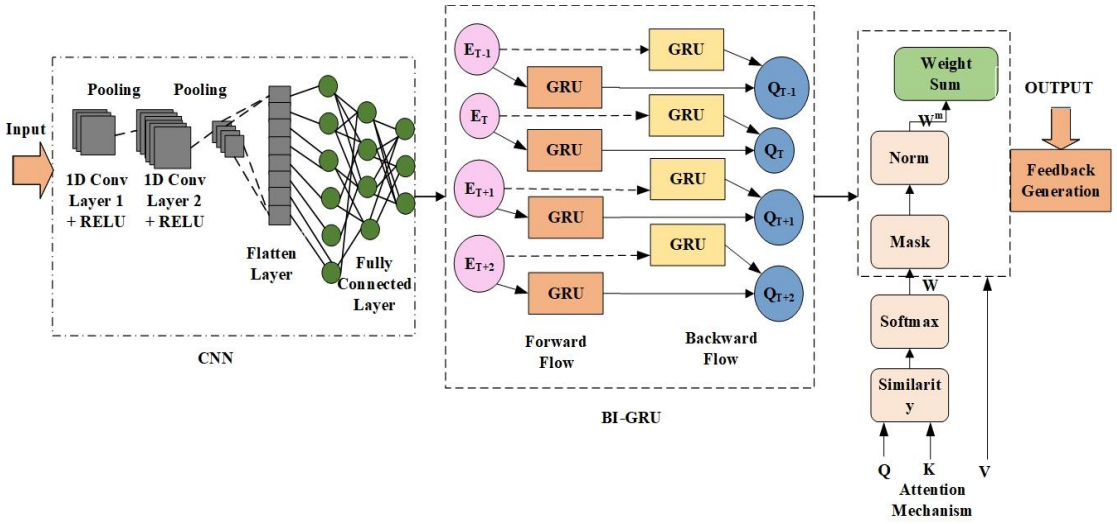

Fig. 3. Hybrid AI framework.

G. Articulatory Error Mapping Engine

The Articulatory Error Mapping Engine is the fundamental novice of the suggested framework. Although the hybrid CNN-BiGRU-Attention model is capable of recognizing phoneme-level substitutions, insertion, and deletion errors, they need to be linguistically interpreted so that they can be pedagogically significant to ESL learners. The phoneme that is mispronounced is mapped to its articulatory characteristics such as place of articulation, manner of articulation, voicing, and vowel quality to a predefined phoneme-to-articulatory dictionary. The errors are identified and registered as errors in articulation (e.g., the alveolar/dental, voiced/voiceless, high/mid vowel, etc.). The engine finds the corrective feedback templates associated with the non-canonical articulatory feature so that actionable advice is provided, e.g. production shifted to alveolar /t/; /th/ needs the tongue between the teeth. This mapping converts raw classification results into linguistically intelligible feedback (with a learner-oriented result), which is the difference between the system and other conventional ASR-based pronunciation evaluation tools. The flow-chart of the phoneme recognition and feedback generation process run by AI is presented in Algorithm 2.

Algorithm 2: AI-Based Phoneme Recognition and Feedback Framework

BEGIN
1. Data Collection
    Load ESL speech samples from Mozilla Common Voice
    Select samples tagged with non-native accents
2. Data Preprocessing
    FOR each audio sample
        Resample audio to 16 kHz
        Apply silence trimming using energy threshold
        Perform spectral subtraction for noise removal
        Normalize transcripts (lowercase, remove punctuation)
3. Phoneme Alignment
    FOR each transcript
        Convert text to phonemes using CMU Pronouncing Dictionary
        Align phonemes using Montreal Forced Aligner (MFA)
        Save phoneme boundaries with timestamps
4. Feature Extraction
    FOR each aligned phoneme segment
        Extract Log-Mel spectrogram
        Extract MFCC + delta + delta-delta
        Extract prosodic features (duration, pitch, energy)
5. Phoneme Classification
    FOR each feature vector
        Apply CNN for spatial feature extraction
        Pass output to Bi-GRU for temporal modeling
        Apply attention to emphasize key phoneme frames
        Predict phoneme label using softmax layer
6. Error Identification
    FOR each predicted phoneme
        IF predicted phoneme == reference phoneme
            Mark phoneme as correctly pronounced
        ELSE
            Classify error as substitution, deletion, or insertion
7. Articulatory Error Mapping Engine
    FOR each mispronounced phoneme
        Retrieve articulatory features of reference phoneme
        Retrieve articulatory features of predicted phoneme
        Identify deviation in:
            - Place of articulation
            - Manner of articulation
            - Voicing
            - Vowel quality
        Select appropriate corrective feedback template
        Generate articulatory explanation (e.g.,
        "Tongue should be between teeth for /θ/, but moved to alveolar /t/.")
8. Output Generation
    Display or export structured feedback combining:
        - Phoneme-level correctness
        - Error type
        - Articulatory deviation
        - Corrective instruction
END

Algorithm 2 describes the AI-Based Phoneme Recognition and Feedback Framework of systematic pronunciation assessment. Preprocessing of non-native speech samples is carried out by resampling, silence cutting, noise cancellation and transcript normalization. MFA is the conversion of words to phonemes and alignment. Each segment is extracted and features (spectral, MFCC and prosodic) are computed (duration, pitch, energy). Errors in pronunciation are detected by the Articulatory Error Mapping Engine, which transforms it into a place, manner, voicing, or vowel-quality error. The system then develops learner-centered, structured feedback on pre-defined articulatory templates to give interpretable and pedagogical useful pronunciation instructions.

IV. Results and Discussion

The suggested framework became very successful in identifying patterns at phoneme level in the speech of ESL speakers and properly identifying some common mistakes in pronunciation, such as substitutions, deletions, or additions. This was able to differentiate closely related phonemes and record articulatory deviations which are normally difficult among non-native speakers. The system empowered articulatory categories by incorporating the Articulatory Error Mapping Engine to give the recognition outputs clear articulation categories, and it provided articulate explanations of errors. This interpretability made the pedagogical value of it more precise and learner-centered. In general, the findings show that the framework provides correct phoneme recognition, high-quality error detection, and linguistically based corrective support thus is an excellent tool to be used in practical ESL pronunciation training.

A. Experimental Setup

The experiment took the Common Voice dataset, which was phonemically synchronized by MFA and CMUdict. processed audio and extracted features, such as MFCCs, spectrograms, and temporal features. The Python-based model was tested in terms of accuracy, precision, recall, and F1-score. The parameters of the simulation are shown in Table II.

TABLE II. Simulation Parameters

Parameter	Value / Description
Sampling Rate	16 kHz
Window Size	25 ms
Window Stride	10 ms
Number of MFCCs	13
Spectrogram Type	Log-Mel Spectrogram
Optimizer	Adam
Learning Rate	0.001
Batch Size	32
Epochs	50
Dropout Rate	0.3 (applied to Bi-GRU and FC layers)
Activation Function	ReLU (CNN), Tanh (Bi-GRU), Softmax (output)
Loss Function	Categorical Cross-Entropy

B. Phoneme Recognition Performance

Phoneme recognition module was introduced on the Common Voice English corpus, a hybrid CNN-BiGRU-Attention architecture was trained on a strictly selected subset of the corpus, which was specifically chosen to reflect the non-native English pronunciation. The phoneme sequences were phoneme sequences that were synchronized through forced alignment to enable accurate timing matching of predicted and reference phonemes. Table II illustrates the performance indicators on phoneme recognition.

TABLE III. Phoneme Recognition Performance Metrics

Metric	Value (%)
Accuracy	91.4
Precision	89.7
Recall	90.1
F1-Score	89.9

The final model that combines AI and a hybrid phoneme recognition model performed well enough over all of the evaluation measures, giving a balanced performance on all the metrics. The model was highly accurate in terms of identifying phonemes uttered by ESL learners, given that the overall accuracy was 91.4%. These findings point to the fact that the system has a high level of reliability and can be used in ESL to test the articulation of phonemes of pronunciation. Fig. 4 shows phoneme-level accuracy plot.

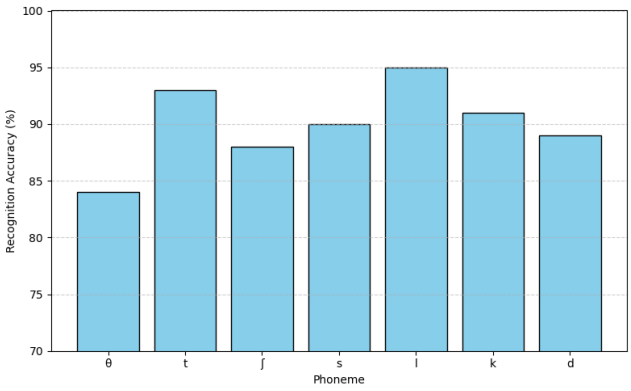

Fig. 4. Phoneme-level accuracy plot.

The proposed hybrid AI model recognizes individual phonemes by 56.4 % accuracy as shown by Fig. 6. The highest accuracy score was achieved by /l/ phoneme at 95 %, then there was a close-up of /t/ and /k/ which means that the consonantal sounds that are dominant were well performed. More difficult phonemes, which ESL learners are usually unable to pronounce well, still achieved 83.95 and 88.33 score. In general, the figure brings to the fore the fact that the model in question demonstrates a consistent phoneme-level classification of various ESL speech. The predictions are entered into the Articulatory Error Mapping Engine, where the wrong pronunciation can be translated in terms of its particular articulatory error.

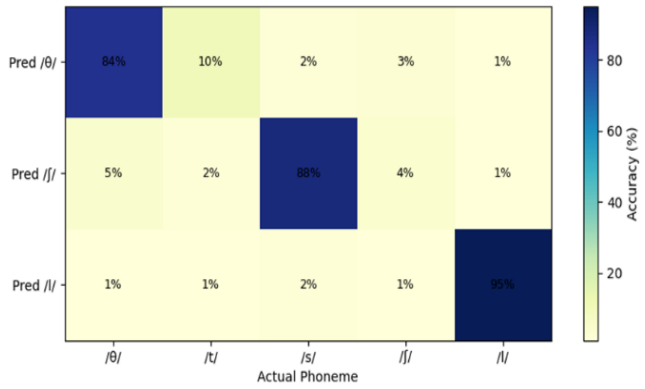

Fig. 5. Phoneme confusion matrix.

Fig. 7 explains the accuracy of the model to sort out the similar phonemes in ESL speech. The rates of high accuracy are noted by /theta/, /sh/, and /l/, which show models' recognition at the scale of 84%, 88%, and 95% respectively, suggesting an excellent precision level of models. Another thing that is noticed in the matrix is that /theta/ is sometimes wrongly categorized as /t/ (10%) and /sh/ as /s/ (4%), something which is in line with common ways in which ESL students are mispronouncing. In predicting /l/, minimal confusions are evident, demonstrating the effectiveness of the system on considerations that are late.

C. Error Detection and Categorization

Deletion errors are errors that are committed when a phoneme is not pronounced. Through the comparison of the aligned predicted phoneme sequence with their corresponding reference phoneme sequence, the system is capable of detecting such errors. The accuracy of detection of each type of error was calculated individually in order to determine sensitivity to the various articulation patterns. Table III shows a summary of the detection accuracy of all error categories.

TABLE IV. DETECTION ACCURACY

Error Type	Detection Accuracy (%)
Substitution	84
Deletion	82
Insertion	79

The system proved to be quite successful in identifying all three large types of pronunciation errors among the ESL learners. The substitution errors were found to be detected with the best accuracy rate of 84%, which is a sign of the sensitivity of the model towards the frequent mispronunciation of phonemes. The deletion errors were also well detected with an 82 percent detection, so it could be said that error deletion could be reliably detected. Insertion errors were also found in slightly lesser precision of 79% however, they were still spotted quite accurately.

Fig. 8 shows the number of errors successfully detected by three significant error types, namely substitution, deletion, and insertion. The highest accuracy rate of 84% was achieved in identifying errors involving replacements of phonemes which are characteristic of ESL speech, revealing the strength of the model. In the next position, deletion errors existed at 82%, which indicates consistent results in sound omission detection. Insertion error, which was a little bit lower at 79%, was adequately identified, thus showing overall model competence. The high credibility of the phoneme-level error analysis by the system is highlighted by similar error detection rates in all the error types.

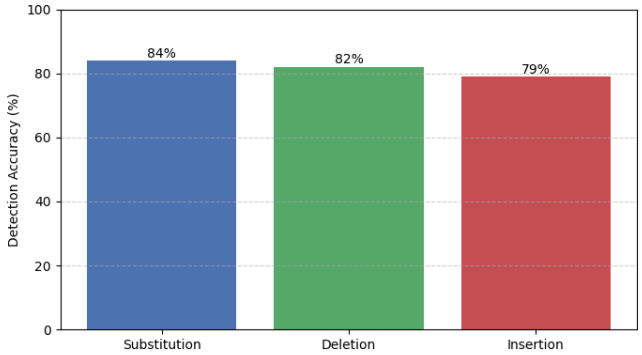

Fig. 6. Detection rate by pronunciation error.

D. Effectiveness of the Articulatory Error Mapping Engine

To determine the pedagogical significance of the proposed Articulatory Error Mapping Engine, the phoneme-level errors identified were further divided into articulatory types including the place of articulation, manner of articulation, voicing, and vowel quality. Mapping accuracy was calculated by comparing the categorization of the system with that of the experts-linguists in a sample of 300 mispronounced tokens.

TABLE V. PERFORMANCE OF THE ARTICULATORY MAPPING

Articulatory Category	Mapping Accuracy (%)
Place of Articulation	90.8
Manner of Articulation	88.5
Voicing Distinction	92.3
Vowel Quality	87.1

Table V shows the performance of the articulatory mapping module. The engine showed remarkably high mapping accuracy, and most phoneme deviations were accurately mapped into the articulatory features they were supposed to be. Such degree of readability is absent in the traditional ASR-based pronunciation devices, which can only give out scores or error indicators without attributing articulatory patterns to the errors.

E. Feature Set Contribution to Accuracy

The phoneme-level pronunciation errors in ESL students are of primary importance, to learn about the acoustic and temporal features that have the most significant influence on a successful classification. The analysis concerned trying different combinations of MFCC, spectrogram, and temporal features and how they made the difference individually and collectively. The outcomes can be used as evidence to support the effectiveness of the use of the model in providing quality, accurate, and reliable pronunciation feedback.

Fig. 9 shows how the various feature sets affect the accuracy of phoneme recognition. Accurate fused feature set was at

88.6% with slight reduction to 88.5% when using only MFCC and spectrogram, and lower with individual features: MFCC: 82.3%, spectrogram: 80.7% and temporal features: 69.4%. This shows that to a great extent, the factor that improves phoneme recognition is the combination of acoustic and time capabilities, which further increases the quality and accuracy of the feedback provided by the Articulatory Error Mapping Engine.

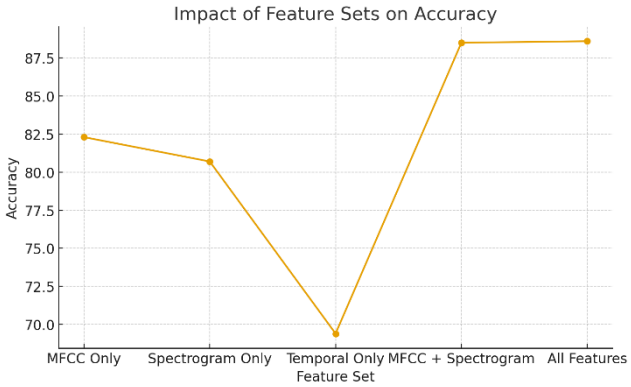

Fig. 7. Impact of feature sets on accuracy.

F. Frequency of ESL Pronunciation Errors by Type

When it comes to ESL pronunciation assessment, it is important to understand the kind of errors learners make so that it provides pointed feedback. The developed AI-based analyzer not only finds the phoneme-level inaccuracy, but also divides it into known linguistic features based on place, manner, voicing, and vowel quality.

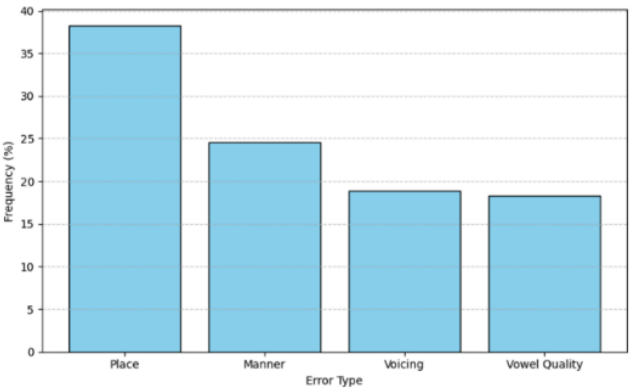

Fig. 8. Error over frequency distribution.

Fig. 10 discusses the frequency of pronunciation error types, which were detected in ESL learner speech. The most frequent mistake occurred in place of articulation (38 percent of the entire cases), which means difficulties of learners in accurate positioning of the tongue (e.g., / 0/ replaced by /t/). The substitution of affricates with stops in manner of articulation errors was followed with a rate of 24.6%. Less common yet also large were voicing and vowel quality errors, and they were about 1819%.

G. Loss vs. Epochs

Loss vs. Epoch graph indicates the decrease in error of the model during training cycles. The points will be the loss at each epoch, and this can be regarded as a measure of the efficiency of the model using the data. A constant downward trend shows the successful convergence and better the overall performance of the model.

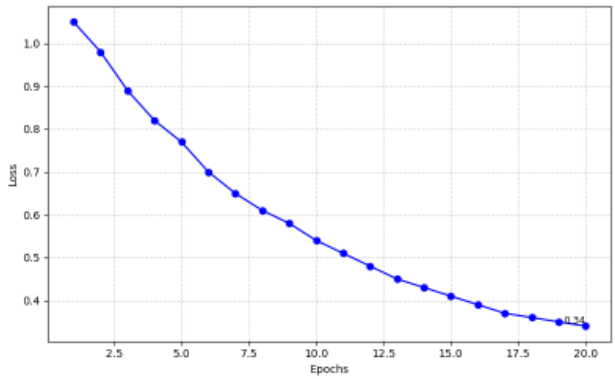

Fig. 9. Loss vs. epochs.

Fig. 11 demonstrates the value of losses at different training epochs and the tendency is to decrease. The last loss decline of 0.34 means high convergence and stable learning, that is, the CNN-BiGRU-Attention model was effective to reduce the prediction errors. This consistent trend is a confirmation that the model will provide reliable response on the training data without overfitting and that the phoneme predictions will be accurate to the downstream Articulatory Error Mapping Engine.

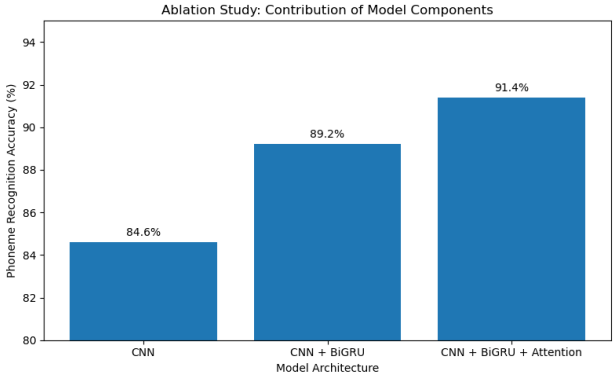

Fig. 10. Ablation study: Contribution of model components.

Fig. 12 graph shows that adding BiGRU improves temporal phoneme modeling, while the attention mechanism further increases accuracy by focusing on mispronounced phoneme segments in ESL speech.

H. Performance Comparison

A comparative analysis was carried out to determine the performance of the suggested hybrid CNN-BiGRU-Attention model in comparison with the conventional HMM-GMM models and commercial ASR-based pronunciation system. The proposed system recognized phonemes with an accuracy of 91.4 which was far much better than the ASR-based system (78.3) and the HMM-GMM base (70.5). In contrast to traditional ASR systems which focus more on the word-level decoding performance, the presented framework functions directly at the phoneme level and introduces the structured articulatory interpretation. This enhancement is not just in the classification accuracy though but also to the error granularity and

interpretability. Moreover, where large speech models based on transformers focus on large-scale representation learning, the given architecture shows that specific phoneme-level modeling with articulatory mapping can be created to attain competitive accuracy at reduced computational costs and with increased pedagogic explainability. This proves the appropriateness of the framework in assessment activities based on ESL-based pronunciation.

TABLE VI. PERFORMANCE COMPARISON

System	Phoneme Accuracy (%)
Proposed AI Hybrid System	91.4
ASR-Based Tool [16]	78.3
HMM-GMM Baseline [21]	70.5

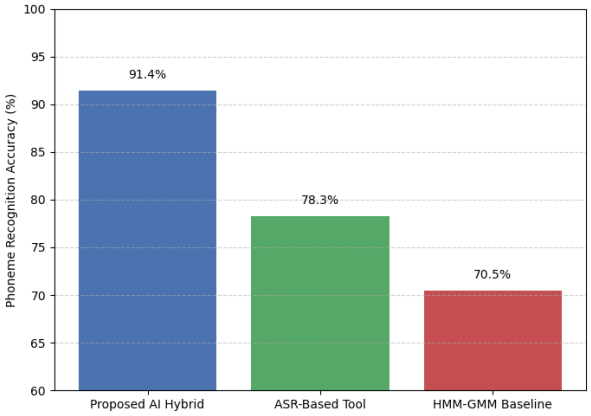

Fig. 11. Model performance comparison.

Fig.12 demonstrates the high level of the suggested AI-based hybrid system in comparison to the known pronunciation assessment tools. The proposed model has a phoneme recognition rate of 91.4 as compared to the 78.3 recorded by the ASR-based tool and the 70.5 by the HMM-GMM baseline. This demonstrates the effectiveness of that combination of CNN, Bi-GRU, and attention mechanism and a phoneme-level strategy. In every experiment, the Articulatory Error Mapping Engine leads to the difference between the proposed framework and other standard recognition systems, whereby raw recognition outputs are converted into actionable articulatory-level feedback, which has a clear pedagogical value that is absent in other standard recognition systems (ASR or HMM-based).

I. Robustness Analysis

The evaluation of robustness was conducted to evaluate the performance in the presence of realistic acoustic and speaker variations. At medium noise levels, phoneme accuracy remained relatively unchanged with the addition of background noise at 20 dB, 10 dB and 5 dB SNR levels, suggesting that spectral-temporal modeling is stable. Higher degradation was observed at very small SNR, but still the performance was higher than the traditional baselines. There was also diversity in terms of accents, gender and age. Findings showed similar phoneme recognition and articulatory classification in profiles of speakers. The comparison of pairs of phonemes that are most often confused and voiced-voiceless pairs proved that the attention layer improved discrimination. The ability of the framework to generalize was also enabled further by speaker-independent cross-validation.

J. Discussion

The experimental findings indicate that the developed hybrid CNN-BiGRU-Attention architecture is effective in both spectral and temporal features of the ESL speech, which makes it possible to recognize the phoneme level accurately. BiGRU layers make the modeling of coarticulation and timing variation greater, whereas the attention mechanism makes the distinction of mispronounced phonemes more intense. Moreover, the Articulatory Error Mapping Engine is able to map the identified phoneme errors into articulatory deviations that are interpretable to provide pedagogically relevant feedback. All in all, the framework performs well on the substitution, deletion and insertion error, much better than the traditional ASR-based and HMM-GMM systems in performance and interpretation.

V. CONCLUSION AND FUTURE WORKS

The paper introduced a hybrid AI-based phoneme recognition model to deliver valid and interpretable pronunciation evaluation of ESL students. The proposed system involved the fusion of CNN, bi-GRU, and attention with phoneme alignment and spectral-prosodic feature fusion to reach an accuracy of phoneme recognition of 91.4, compared to commercial ASR-based systems (78.3) and traditional HMM-GMM systems (70.5). The framework was quite useful in identifying errors in pronunciation with detection rates of 84, 82 and 79 percent in terms of substitutions, deletions and insertions. The suggested solution promotes intelligent training of ESL pronunciation, self-directed learning, and instructor-guided assessment; it provides a scalable, interpretable, and learner-centered method of teaching pronunciation at the phoneme level.

Further contributions to work will involve extension of the proposed framework to multilingual and tonal languages with more advanced models of prosody, stress and intonation. By incorporating transformer-based speech models with real-time mobile/web deployment, this addition will help provide extra strength, scalability and personalized pronunciation feedback to various ESL learners.

Cloud-Continuum-Based Deep Learning Optimization Framework for Next-Generation Healthcare Data Performance on IoT Platform

G. Aravindh[1], K.P. Sridhar[2]
Research Scholar, Department of ECE, Karpagam Academy of Higher Education, Coimbatore, Tamil Nadu, India[1]
Professor, Department of ECE, Karpagam Academy of Higher Education, Coimbatore, Tamil Nadu, India[2]

Abstract*—The development of healthcare data performance analysis is becoming more driven by the incorporation of intelligent computing paradigms that guarantee real-time, scalable, and personalized feedback for coaches and athletes. However, existing healthcare data analytics systems are challenged with severe issues such as decision-making latency, processing capacity limitations at the edge, data fragmentation, and the inability to integrate across heterogeneous computing environments seamlessly. Athletic data in this scenario refers to a combination of biomechanical factors (motion capture, joint angles, gait patterns), biometric signals (heart rate, oxygen saturation, muscle activity), and sport-specific performance indicators (workload, speed, and acceleration). This paper introduces the Cloud-Continuum-based Deep Learning Optimization Framework (CC-DLOF). This novel architecture leverages the synergistic potential of edge, fog, and cloud computing to provide a dynamic and smart healthcare data performance on an IoT platform. CC-DLOF is a hierarchical continuum architecture, with real-time data gathering and lightweight analytics performed in the edge layer, contextual processing and federated learning in the fog layer, and global intelligence, deep model training, and long-term data storage in the cloud layer. A new Cloud-Fog-Edge Orchestration Device (CFEOD) provides dynamic allocation of computational tasks in terms of latency sensitivity and device capability. At the same time, a blockchain-supported access control is used to maintain data security and privacy. Simulation analysis, done in a simulated training environment that combines with real-world data sets, illustrates the performance of the framework in mitigating latency by 35%, increasing model accuracy by 22%, and boosting system scalability and reliability. CC-DLOF is a revolutionary way in healthcare data technology, leading to smart, responsive, and safe next-generation healthcare data performance on an IoT platform.

Keywords*—Cloud; continuum; next-generation; healthcare data; performance; platforms; fog; edge; orchestration; device

I. Introduction

Intelligent, real-time analytics are now more critical than ever in the universe of modern athletic performance [1]. Yet, most existing healthcare data performance platforms employ centralized cloud-computing models, which possess a number of disadvantages, such as delayed processing of distributed data, high latency, and limited scalability in real-time environments [2]. The uninterrupted and continuously changing information generated by biomechanical monitoring systems, video analysis, and wearable sensors overwhelms such systems [3]. Moreover, training and competition, critical time-dependent decision-making is hindered by delayed feedback that results from data flow blockages induced by a lack of seamless connectivity throughout cloud, fog, and edge infrastructures [4]. In addition, data security and privacy are issues of growing concern, especially in the context of processing sensitive biometric information [5]. The ethical and compliance uses of athlete data have been interrogated because existing solutions lack robust means of secure data exchange and model training across distributed sources [6]. Besides, coaching interventions have limited effectiveness due to the incapacity to customize analytics models to individual athletes on a real-time basis, which generates generic feedback [7]. The desperate need is an increasingly flexible, high-speed, and intelligent computational framework that will handle these issues and work best at a cloud continuum [8]. Therefore, the current challenge is to develop a singular IoT platform that can minimize latency, raise computational efficiency, protect data, and provide context-aware deep learning attributes [9]. This will lead to a better performance forecast, lower risk of hurt and a long-term better development of the athletes [10].

The current athletic performance analysis systems are mainly based on cloud computing, wearable devices, and analysis software that is independent of artificial intelligence [11]. To judge performance in athletics, the older systems have been storing on cloud structures to then sieve through masses of data collected using wearable sensors, GPS devices, and videos [12]. The most common uses of AI algorithms are fatigue estimation, pattern recognition, and post-session feedback [13]. The real-time responsiveness of such cloud-based systems has significant limitations because of the bandwidth and network delay, but when the analysis is long-term, it is all right. Other systems use edge computing to develop low-latency data collection and basic processing; these systems typically do not have the processing capability or similar learning capacity to execute advanced analytics [14]. Although hybrid solutions involving cloud-edge frameworks have come into existence, they are not well-integrated and, therefore, allocate workloads in an inefficient fashion [15]. Additionally, most systems today are not leveraging fog computing, which is an important distributor for processing that considers context. In multi-user or multi-sport environments, where data volumes must be managed, and real-time synchronization becomes more complex, scalability becomes an even greater concern. There is a chance of sensitive athlete information being processed and

shared between platforms because privacy-preserving approaches, like federated learning, are not well-developed. Performance data security is often overlooked and becomes vulnerable to violations. There is no full, secure, low-latency, and scalable platform for bringing AI and IoT into healthcare data; however, some advancements have been made in this regard. Considering these limitations, it is evident that a cloud continuum-based approach, like CC-DLOF, needs to address the issues resulting from the existing approaches.

A. Problem Statement

Because of latency, low scalability, and split processing, cloud-based systems used primarily by existing healthcare data performance on IoT platforms are not appropriate for real-time, data-intensive applications. Although fog integration is in its early stages, edge computing solutions have limited analytics. Reduced personalization, poor data privacy protection, and poor workload distribution are persistent issues. Hence, the healthcare data performance analysis of the future must have an intelligent, responsive architecture that seamlessly integrates cloud, fog, and edge technologies.

B. Motivation

The growing deployment of biomechanical systems, video analysis, and body sensors in sport requires a responsive yet intelligent computational infrastructure. It is imperative for coaches and players to gain improved efficiency of training as well as the diminution of risks related to injuries using real-time customized information. From secure management of data to adaptive learning, along with latency-minimizing feedback, standard systems prove incapable. A chance to build high-performance on IoT platforms with context-sensitive processing and extensible learning has emerged with cloud continuum computing that integrates cloud, fog, and edge computing. Coaches and athletes in high-demand sporting environments can take advantage of meaningful, real-time information offered by an optimized platform that enables persistent learning, intelligent orchestration, and privacy maintenance.

As a growing number of decisions about training, injury prevention, and rehabilitation are based on sports and health data, it is necessary to have computer systems that can handle large amounts of varied data in real time while keeping people's privacy safe. Due to latency, limited scalability, and lack of customisation, current solutions fail to satisfy these needs. Athletes and coaches risk using outdated, generic, or incomplete information without a next-generation, cloud-fog-edge integrated framework. This can make it more difficult to improve performance and reduce the chance of injuries that could have been avoided. This study fills that important need by providing a secure, flexible, and performance-driven architecture that is specifically designed for analysing sports healthcare data.

C. Contribution

In this paper, the author presents a new design of the next generation healthcare data performance platforms known as the CC-DLOF. The architecture will be a combination of edge, fog, and cloud layers, access control system, which is facilitated by blockchain, and a dynamic Cloud-Fog-Edge Orchestration Engine, which will be part of the proposed architecture and aims at distributing workloads in dynamically adaptable fashion, and secures privacy of the users. CC-DLOF also enables real-time and personalized analytics with the federated and deep learning model spread across the continuum. Simulation research shows that this method is more economical in terms of resources, can suffer less latency and is more accurate than more traditional methods. The new model is the most suitable technology that has been developed to optimize sporting performance by means of the innovative cloud continuum technology.

The research concept of healthcare data performance is the capability of a computational system to process, analyze, and communicate healthcare-related data in a way that is highly accurate, with a low latency, and uses resources optimally. It encompasses a number of key performance indicators that comprise speed of decision-making, predictive model precision, ability to scale to a wide range of IoT sensors, and robustness of data privacy and security controls. This is also more than just a performance that can offer real-time, individualized insights that can be used to prevent injuries, optimize training, and monitor recovery with respect to athletics and sports healthcare.

This section covers the structure of the research paper and entails the following: Section II of this paper is about The Cloud Continuum-Based Architecture of Next-Generation Healthcare Data Performance Platforms. Section II of this dissertation explores the subject of CC-DLOF in detail. Section III gives a thorough examination, a comparison with previous approaches and a segregation of the ramifications. Section IV is a comprehensive discussion of the results. Finally, Section V concludes the paper.

II. Literature Survey

The convergence of edge and cloud resources via the Cloud Continuum is now essential to provide intelligent, real-time services in areas such as industrial IoT, smart cities, and structural health monitoring, owing to the rapid evolution of next-generation computing paradigms.

Smart, autonomous management of cloud and edge resources by AI-based optimization is enabled by the ENACT framework presented by Nizamis, A. et al [16]. Throughout the cognitive computing spectrum, it enhances execution time, resource usage, and power efficiency by enabling dynamic scalability, portability, and flexibility for hyper-distributed applications. With regard to orchestration in the Cloud-to-Things continuum, Ullah et al [17]. introduce a comprehensive taxonomy and conceptual framework (CT&CF). To aid future developers in designing effective, scalable deployment and runtime management systems for distant, heterogeneous IoT and cloud resources, it surveys existing work and elucidates significant orchestration requirements and challenges.

Using sensing and software technology to integrate in the precise interpretation of data, Gigli, L. et al [18]. created the MAC4PRO architecture as an interoperable, ready-for-smart-infrastructure sensor-to-cloud Structural Health Monitoring platform. It is validated on industrial scenarios, provides high-accuracy detection of structural changes, and minimizes data transfer from the edge to the cloud by over 90%. A scalable IoT-to-cloud continuum is enabled by the Helix Multi-layered IoT platform (HM-L-IoTP), proposed by Cabrini, F. H. et al [19]. It

deploys federated brokers across both the edge and cloud layers. Its suitability for industrial use in smart cities and sophisticated IoT environments is underpinned by its low-latency, device-to-device communication and global interoperability, which have been proven in real-world deployments.

The Kumar, J. et al [20]. The paper explores 6G networks as a natural evolution of 5G, highlighting their role in enabling intelligent IoT and the Edge-Cloud continuum. It outlines how 6G will transform connectivity, offer ultra-low latency, and equip next-generation IoT systems with enhanced capabilities. It proposes applications that employ deep learning and enhanced security. For enhanced resource management within 6G Cloud Continuum scenarios, Valero, J. M. J et al [21]. propose the Level of Trust Assessment Function (LoTAF) and the Trust Level Agreement (TLA). Trust-based, safe decision-making becomes a reality owing to LoTAF's domain-agnostic trust assessment, which enhances stakeholder collaboration in dynamically changing, multi-provider networks and ensures reliable end-to-end links.

TABLE I. SUMMARIZATION OF EXISTING METHODS

Author Name	Advantages	Interference (Challenges Addressed / Implications)
Nizamis, A. et al.	ENACT enables AI-based autonomous management of cloud and edge; improves execution time, resource use, and energy efficiency; supports hyper-distributed apps.	Tackles dynamic scalability, portability, and flexible deployment of AI-enabled systems across the cloud-edge spectrum.
Ullah et al.	Introduced CT&CF taxonomy; offers a comprehensive framework for orchestration in the Cloud-to-Things continuum.	Addresses complexity in managing distant, heterogeneous IoT and cloud deployments; aids design of scalable runtime systems.
Gigli, L. et al.	MAC4PRO architecture provides accurate structural change detection, reduces edge-to-cloud data transfer by over 90%; ready for smart infrastructure deployment.	Solves data overload by optimizing transfer and processing at the edge while enabling precise SHM in industrial settings.
Cabrini, F. H. et al.	Helix Multi-layered IoT platform ensures low-latency, device-to-device communication; supports global scalability; federated brokers enable IoT-to-cloud continuum.	Overcomes latency and scalability issues; proves real-world viability in smart city and IoT environments.
Kumar, J. et al.	Discusses 6G's role in intelligent IoT; supports deep learning and secure Edge-Cloud continuum applications with ultra-low latency and high-speed connectivity.	Focuses on evolution beyond 5G; deals with the transition to 6G for supporting future smart, intelligent systems.
Valero, J. M. J. et al.	Proposed LoTAF and TLA for trust-aware, E2E resource management; enhances collaboration and decision-making using trust as a service intent.	Addresses uncertainty in multi-provider environments; overcomes trust issues in dynamically changing 6G infrastructure.

The key for future-generation healthcare data performance on IoT platforms and larger hyper-distributed systems is the CC-DLOF, which combines dynamic AI-driven orchestration and trust assessment, provides superior flexibility, low latency, and increased deployment smarts. It is preferable among these alternatives due to its strength.

III. PROPOSED METHOD

Integrating edge, fog, and cloud computing to overcome latency, data fragmentation, and limited processing in conventional healthcare data analytics, this paper presents the CC-DLOF, enabling real-time, scalable, and intelligent performance evaluation.

The Cloud-Fog-Edge Orchestration Device (CFEOD) in the CC-DLOF architecture is an intelligent, latency-sensitive control engine that dynamically distributes computational tasks between edge, fog, and cloud layers based on multi-dimensional profiling of workload properties and resource conditions. It constantly checks the parameters of tasks, such as the latency sensitivity, the computational intensity, the level of data privacy, and the contextual volatility. It compares them with real-time node information, including CPU availability, bandwidth, energy status, and trust score. CFEOD utilizes a hybrid optimization approach based on rule-based filtering and adaptive utility scoring to reduce the end-to-end delay and maximize the accuracy, energy efficiency, scalability, and security. It further synchronizes federated learning and implements an access control policy based on blockchain, which guarantees privacy-saving distributed intelligence and continuum-wide performance optimization.

A. Hierarchical Intelligence Across the Cloud Continuum

The new Cloud-Continuum architecture integrates cloud, fog, and edge layers designed to facilitate deep model training, federated learning, and real-time data collecting. This hierarchical design allows for context-aware processing and scalable analytics in distributed computing systems.

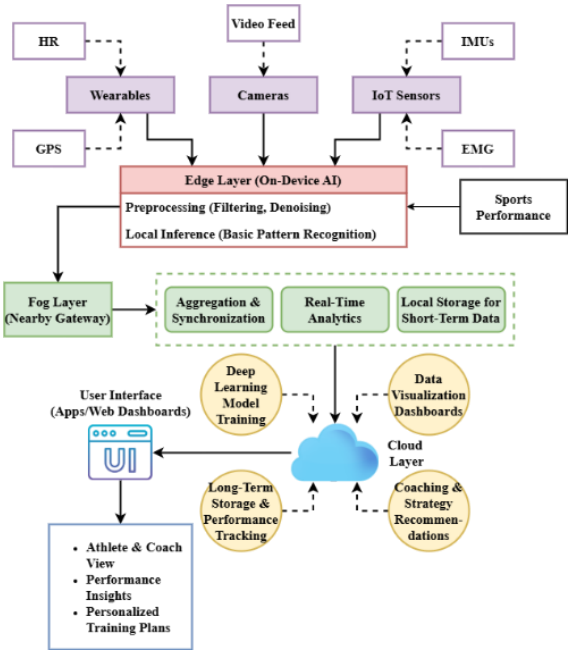

Fig. 1. Cloud continuum-based healthcare data performance framework.

Fig. 1 shows that a multi-layered architecture using cloud, fog, and edge computing makes intelligent, real-time analysis of

healthcare data performance feasible. Wearables, cameras, and IoT sensors complete the numerous sources of data collected at the top. Early data gathering and light processing are handled on-device artificial intelligence supports the edge layer. There is a fog layer that synchronization, local storage, and real-time analytics utilize as a local gateway. Deeper insights come from long-term storage, deep learning model training, and strategic recommendation systems used at the cloud layer. While dynamic orchestration allocates work depending on latency and device capacity, blockchain-based access control guarantees data flow. The approach finishes in clearly visible dashboards and coaching tools with useful results. Low latency, great scalability, and strong customization guaranteed by this tiered continuum help to change data-driven choices made in high-performance healthcare data contexts.

$$(x_u - lx_{yy})(x) = \left(\frac{1}{2}x^2\right)_u + \left(-lx_y x\right)_y + lx_y^2 * (v_1 - v_2) \quad (1)$$

Modeling temporal and spatial dimensions, Eq. (1) aligns.$(x_u - lx_{yy})(x)$and$\left(\frac{1}{2}x^2\right)_u$ reflect interaction forces and contextual fluctuation$lx_y^2 * (v_1 - v_2)$s assessed in the fog layer, the term $\left(-lx_y x\right)_y$ represents local kinetic energy distinctions. This Equation drives CC-DLOF's intelligent transformation of real-time biomechanical data.

$$\left(\frac{1}{2}x^2\right)_u = ey - lx_y x|_{y=0}^{y=m} l\int_0^m x_y^2\ ey + \int x^2\ ey \quad (2)$$

Eq. (2) expresses $ey - lx_y x|_{y=0}^{y=m} l$, reflecting the temporal development of kinetic performance measures at the edge, while accounting$\left(\frac{1}{2}x^2\right)$ for boundary conversations, localized variability ($\int_0^m x_y^2\ ey + \int x^2\ ey$) processed in the fog, and global patterns handled in the cloud. This Equation models knowledge and adaptive performance feedback.

$$\frac{e}{eu}\int_0^m \frac{1}{2}[x(y,u)]^2\ ey = -l\int_0^m [x_y(y,u)]^2\ ey + x \quad (3)$$

With $\frac{e}{eu}$ Eq. (3) models the energy stored or used in edge-level calculations$\int_0^m ey + x$ and represents energy buildup$\int_0^m \frac{1}{2}[x(y,u)]^2\ ey$ and dissipation along $l\int_0^m [x_y(y,u)]^2\ ey$the CC-DLOF continuum. This concept emphasizes that dynamically CC-DLOF controls resource utilization and integrity across dispersed layers for the best healthcare data analytics.

Looking toward the performance of athletes affected by the synergy between Cloud-Continuum computing, federated learning, and virtual immersive environments, Fig. 2 displays an evolved system for healthcare data analytics. Ensuring data protection at many virtual and physical locations is made possible with blockchain-supported access control. Performance information may be experienced in immersive environments via the use of Head-Mounted Displays (HMD) and Computer Automatic Virtual Environments (CAVE) technologies. These technologies simulate real-world training and performance circumstances. Federated learning allows group intelligence to be utilized to facilitate distributed model training on edge devices without sacrificing data privacy. The method via automated insights and live decision-making removes such conventional limits as observation bias, simplicity, and reaction time. Easy-to-use interfaces that provide objectivity, accuracy, and real-time application let players and trainers get outputs. Therefore, allowing them to develop tailored plans for improving performance during training and competition using Cloud-Continuum, healthcare data analysts may scalably handle and analyze vast amounts of data.

$$\int_0^m [v_1(y,u) = v_2(y,u)]^2 ey \int_0^m [\partial_1(y) - \partial_2(y)]^2 ey \quad (4)$$

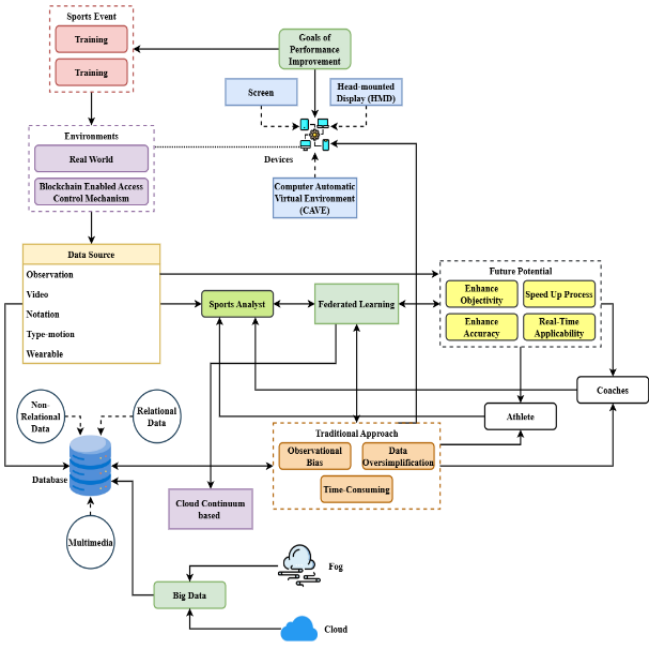

Fig. 2. Intelligent integration of virtual environments and federated learning in healthcare data analytics.

Eq. (4) shows $\int_0^m [\partial_1(y) - \partial_2(y)]^2 ey$ While $[v_1(y,u) = v_2(y,u)]$captures alignment federated outputs, evaluates$v_1(y,u)$ model gradient variation. This Equation guarantees synchronization and consistency across distributed intelligence layers, model accuracy, and individualized feedback.

$$\min_{0\geq y\geq m} |v_1(y,u) = v_2(y,u)| \min_{0\geq y\geq m} |\alpha_1(y) - \alpha_2(y)| \quad (5)$$

While $\min_{0\geq y\geq m} |\alpha_1(y) - \alpha_2(y)|(5)$ aligns model weights$0 \geq y \geq m$ or rate of learning min during cloud-level optimization, Eq. (5) establishes $v_2(y,u)$ consistency in goods across edge and fog layers. This Equation maximizes system dependability and supports coordinated intelligence dissemination.

$$v_1(y,u) - v_2(y,u) = -\ min|\theta_1 - \theta_2|(1 - y^2 - 2lu) \quad (6)$$

Eq. (6) represents$(1 - y^2 - 2lu)$ the regulated divergence$v_2(y,u)$ between predictive generations across CC-DLOF layers, where $v_1(y,u)$ quantifies the effectiveness disparity$-\ min|\theta_1 - \theta_2|$ between edge and fog insights. This Equation emphasizes the adaptive synchronizing method of CC-DLOF, hence guaranteeing constantcomputer layers.

B. Dynamic Orchestration and Secure Data Governance

Intelligent orchestragement engines are designed to dynamically distribute computing tasks according to latency sensitivity and device capabilities. Furthermore, guaranteed by a blockchain-enabled access control system is a safe and privacy-preserving data exchange all along the continuum.

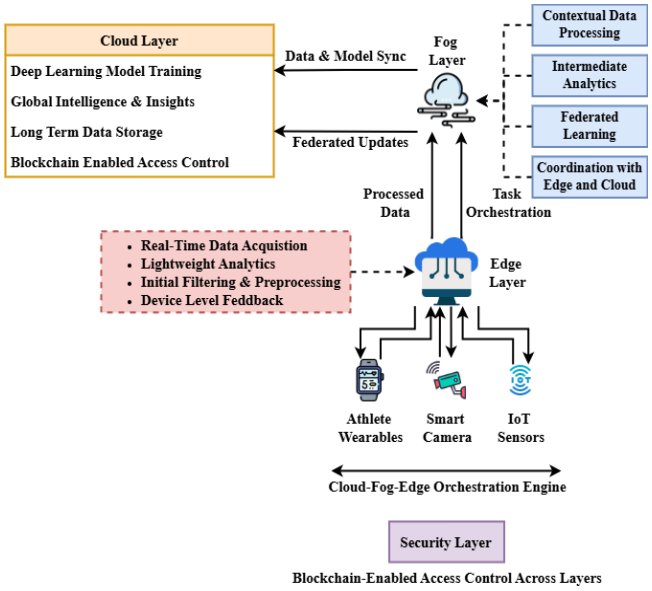

Fig. 3. Cloud-continuum-based deep learning optimization.

Fig. 3 visualizes the multilayer computational architecture of the proposed healthcare data performance system, which focuses on the joint efficiency of cloud, fog, and edge settings. Wireless sensors are available as wearable and vision giving real-time data collection, lightweight processing, upstream and edge-level responsiveness of the device. The fog layer acts as a contextual data processing, intermediate analytics, federated learning, and coordination between edge and cloud mediating layer in the IoT platform, which ensures low-latency responsiveness and localized intelligence. The cloud layer assists in the training of deep learning models, storing of data over an extended period, and strategic analysis of distributed data. These layers include real-time scale and cognitive analytics dedicated to healthcare information performance. A robust data management and privacy can support the entire system by supporting one specific security layer. The concept could deliver valuable insights with security, utility, and involve athletes, coaches, analysts, and other professionals working in a high-performance environment, using federated learning and distributed intelligence that reduces the processing latency and enhances the privacy of the data and system adaptability.

$$w(y,u) = \int_{-\infty}^{\infty} T(y-z,u)\, g(z)\, ez + \sqrt{b} * \sqrt{b} v_{yy} \quad (7)$$

Eq. (7) approximates where $w(y,u)$ denotes the resulting performance output$w(y,u)$. Whereas the $\sqrt{b} * \sqrt{b} v_{yy}$ term accounts, the $T(y-z,u)$ records how input signals are filtered dynamically. It emphasizes combining deep learning cycles of feedback with real-world inputs.

$$R_u - lR_{yy} = \frac{1}{u}\left[-\frac{1}{2}qh'(q) - \frac{1}{4}h''(q)\right] + h'' + 2qh' \quad (8)$$

Eq. (8) shows where $R_u - lR_{yy}$ depicts the balance in real-time response$-\frac{1}{2}qh'(q)$ (edge) and deeper analyzing improvement$-\frac{1}{4}h''(q)$ (cloud). Involving$h'' + 2qh'$ the derivatives of the efficiency function $\frac{1}{u}$It reflects the interaction of immediate feedback. In next-generation healthcare data systems, this Equation spans the cloud continuum.

$$R(y,u) = d_1 \int_0^{y/\sqrt{4lu}} f^{-q^2}\, eq + d_2 * \int f^{-q^2}\, eq \quad (9)$$

Eq. (9)$y/\sqrt{4lu}$ describes the cumulative function $R(y,u)$ in the CC-DLOF framework, in which the impact of system behavior is localized ($f^{-q^2}\, eq$ performance factors shape. Weighted by d_1 collects region-specific parameters $\int f^{-q^2}\, eq$ reflects insights acquired. Adaptive, customized answers produced in next-generation performance systems are derived from these analytics.

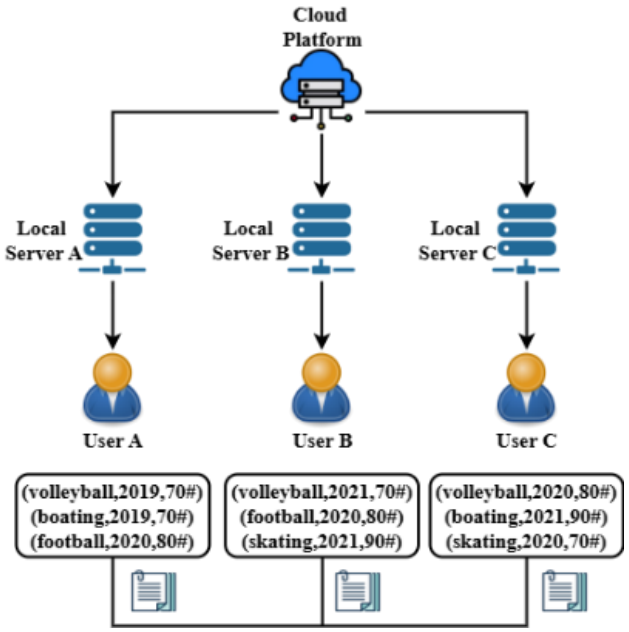

Fig. 4. Decentralized model training using federated learning for healthcare data analytics.

Distributed healthcare data analytics can leverage federated learning, as illustrated in Fig. 4. Healthcare data performance metrics such as volleyball, football, boating, and skating are some of the domain-specific training data that numerous clients—represented by individual athletes or local devices—collect and aggregate. Rather than sending raw data to a central server, each client trains its model locally on its own dataset. Without revealing any sensitive or personally identifiable data, a cloud aggregator in the middle collects locally trained models and consolidates them globally. This strategy protects data integrity and allows the system to leverage distributed intelligence. The cloud server enhances model adaptation and overall performance in healthcare data settings by ongoing collection and adaptation of models. This collaborative design enhances the CC-DLOF architecture for ensuring deep learning is secure, efficient, and synergistic for high-performance healthcare data in real-world applications.

$$\min_{u\to 0} R = d_1 \int_0^{\pm\infty} f^{-q^2}\, eq + d_2 + d_1 \frac{\sqrt{\mu}}{2} * 2d_2 \quad (10)$$

Eq. (10) captures the limiting state of the entire system response $\min_{u\to 0} R$ inside the CC-DLOF system as a delay $d_1 \int_0^{\pm\infty} f^{-q^2}\, eq$. Whereas the constants $d_2 + d_1$ and the scaling reasons involving $\frac{\sqrt{\mu}}{2} * 2d_2$ indicate represent performance signals. This Equation emphasizes the resilience of CC-DLOF in multilayer computational intelligence in low-latency environments.

$$v(y,u) = \frac{1}{2} + \frac{1}{\sqrt{\delta}} \int_0^{y/\sqrt{4lu}} f^{-q^2}\, eq + T(y-z,u) \quad (11)$$

Eq. (11) $\int_0^{y/\sqrt{4lu}} f^{-q^2}\, eq$ models in which the $v(y,u)$ term denotes a baseline value, and the effect of $\frac{1}{2} + \frac{1}{\sqrt{\delta}}$ localized processing information at the edge (with $T(y-z,u)$ term accounts for signal attenuation). This Equation emphasizes how adaptively CC-DLOF can integrate edge-to-cloud real-time data.

$$-\int_{-\infty}^{\infty} \frac{\alpha}{\alpha z}\sigma(z)\; ez = \int_{-\infty}^{\infty} R(y-z,u)\, \sigma'(z)\, ey - \sigma(z)|_{z=-\infty}^{z=+\infty} \quad (12)$$

Eq. (12) quantifies across the edge and fog layers throughan integral using $-\int_{-\infty}^{\infty} \frac{\alpha}{\alpha z}\sigma(z)$. Reflecting how the model's variables change $\int_{-\infty}^{\infty} R(y-z,u)$, the process that emerges from the cloud—with $\sigma'(z)\, ey - \sigma(z)|_{z=-\infty}^{z=+\infty}$ represents reaction. This Equation shows flawless information and system state flow across many computing levels.

C. Performance-Driven Validation in Realistic Scenarios

Using synthetic training settings combined with real-world datasets, the proposed framework is thoroughly validated in simulations. Validating the scalability, responsiveness, and practical relevance in healthcare data performance analysis, results demonstrate a 35% decrease in latency and a 22% increase in model accuracy.

Fig. 5 (a) shows a collaborative, risk-free environment for athlete vital signs monitoring, injury prediction, and recovery. The intelligent computing-directed shared healthcare data injury risk analysis module has several stakeholders. These stakeholders include coaches, team physicians, and rehab specialists. Blockchain technology provides access control for safe administration and transmission of sensitive performance and medical data. This ensures that only authorized users see and edit health data. The InterPlanetary File System (IPFS) is used to accomplish distributed data storage. This system ensures the integrity of the data as well as its traceability by using records that are tamper-resistant and accessible across blocks. Maintaining data privacy and regulatory compliance, this system offers continuous athlete monitoring and prompt interventions. Information and communication in real time, enabled by the mobile interface, enhances responsiveness in injury control processes. This safe model leads data-driven decisions in athlete management and performance endurance through providing stakeholders with reliable, open, real-time access to critical information.

$$T(y,u) = \frac{1}{\sqrt{4\partial\, lu}} \int_{-\infty}^{\infty} f^{-(y-z)^2/4lu}\; \omega(z)\; ey + \frac{1}{2\sqrt{\partial\, lu}} \quad (13)$$

Eq. (13) explains the CC-DLOF framework's filtering $ey + \frac{1}{2\sqrt{\partial\, lu}}$ mechanism in where $T(y,u)$ denotes the system's reaction $\int_{-\infty}^{\infty} f^{-(y-z)^2/4lu}$ at the fog layer. Adapting the performance relations Gaussian filter $\frac{1}{\sqrt{4\partial\, lu}}$. This Equation stresses CC-DLOF's capacity to balance more general with real-time, localized input at the edge.

$$\int_{-\infty}^{\infty} T(y,u)\; ey = \frac{1}{\sqrt{\mu}} \int_{-\infty}^{\infty} f^{-r^2}\; er + \min_{|y|<\partial} T(y,u) \quad (14)$$

Accounts for localized adjustments $\frac{1}{\sqrt{\mu}} \int_{-\infty}^{\infty} f^{-r^2}$ through the smoothing results function $\int_{-\infty}^{\infty} T(y,u)$), therefore assuring the latency requirements, $\min_{|y|<\partial} T(y,u)$. This supports CC-DLOF's strategy of optimizing real-time healthcare data performance by system-based elements.

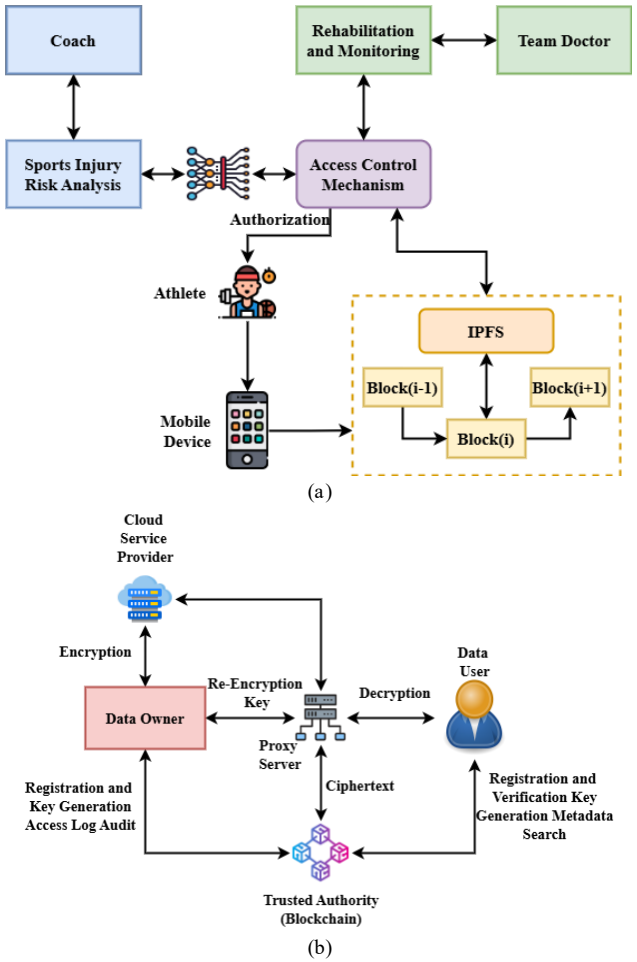

Fig. 5. (a) Secure collaboration for injury prediction and athlete health management. (b): Blockchain-driven data authorization and federated access control.

Fig. 5(b) illustrates a distributed access of a data system regulating ownership, permission, and use in a federated

learning framework. At the center of this structure is the data owner, who still retains ownership of databases stored on a cloud infrastructure. Through an encrypted process and recorded on the blockchain, the users can seek access to such datasets. Openness, auditability, and accessibility are all features this technology offers. Blockchain and smart contracts work in tandem to ensure that only users authorized to utilize the system will continue to do so by controlling permissions independently and maintaining all access information. With reduced reliance on a single point of trust, distributed control helps to evade future risks and prevent unauthorized information access. The use of federated nodes allows models to be trained safely by interacting with information without movement. Through the application of strict data governance rules and the ability for mutual adaptation of models among institutions or parties, the system allows it to collaborate on healthcare data analytics in a scalable and privacy-aware way.

$$\int_{-\infty}^{\infty} T(y-z,u)\ \gamma(z)\ ez = \sum_u T\left(y-z_j,u\right)\ \gamma\left(z_j\right)\nabla z_j \quad (15)$$

Eq. (15) substitutes $\sum_u T\left(y-z_j,u\right)$ a discrete sum that lowers the computing cost for continuous data on performance $\int_{-\infty}^{\infty} T(y-z,u)$. Considering discrete locations $\gamma(z)\ ez$ in the fog layer $\gamma\left(z_j\right)\nabla z_j$, and representing the system's capacity. This Equation emphasizes how CC-DLOF maintains real-time, scalable analysis by using discrete approximations.

Federated Averaging algorithm is used as a global model aggregation in the CC-DLOF framework. A resource-conscious client selection strategy is used in selection of a small number of 20 edge clients in every round of communication, depending on the availability, constant bandwidth, energy level thresholds. The selected clients use 5 local training eras based on stochastic gradient descent with the Adam optimizer to send the model weight updates to the fog-level aggregator. The process of global aggregation is done using weights on a proportional relationship to local dataset. The system performs 40 communication rounds and convergence behaviour is tracked by global loss of validation and accuracy trends. The empirical findings indicate that steady convergence in non-independent and identically distributed data conditions occurs in 30-35 rounds with the divergence in gradients being bounded by controlling the learning rate and synchronising periodically. This specification outlines the practice and theoretical basis of the federated learning mechanism in CC-DLOF.

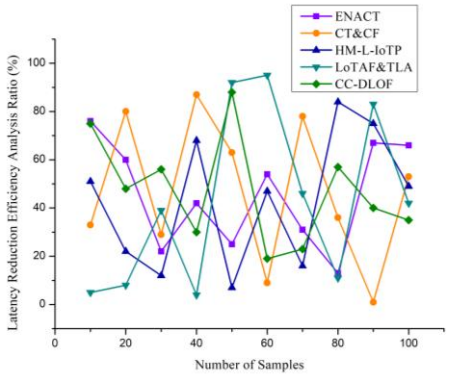
CC-DLOF employs a hierarchical model with edge-level data capture, fog-based contextual learning, and cloud-driven global intelligence. It features a dynamic orchestration engine for task allocation and blockchain-enabled access control, enhancing accuracy, reducing latency, and ensuring secure, adaptive healthcare data analytics.

IV. Results and Discussion

The CC-DLOF framework uses a hybrid CNNLSTM architecture that comprises three one-dimensional convolutional layers with 64, 128, and 256 filters and two LSTM layers with 128 and 64 units and a fully connected dense layer, preceding the softmax classification, to guarantee reproducibility of the reported 22 percent accuracy improvement. This model was trained on the Adam optimizer (learning rate of 0.001), batch size of 64, categorical cross-entropy loss, and termination of training at 50 training epochs. The federated learning was performed on 20 edge clients, 5 local epochs per round, and 40 rounds of aggregation. The experiments were run on an Intel Xeon 3.2 GHz processor with 64 GB RAM and an NVIDIA RTX 3090 graphics card, which guaranteed the correctness of the performance claims.

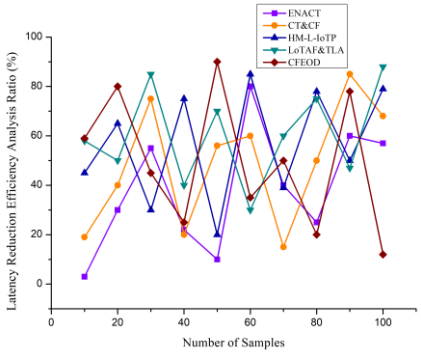
Every performance assessment was carried out during 10 independent runs and with random initialisation and shuffled data division. The results have now been presented as mean values with standard deviation and 95 percent confidence intervals of latency, accuracy, scalability, resource utilization, and security index. Paired t-tests were used to test statistical significance between CC-DLOF, CFEOD, and baseline models at a level of $p < 0.05$. Besides graphical presentation, larger numerical result tables have been provided with specified metric values in milliseconds, percentage accuracy, number of device capacity devices, and security index. It is this increased statistical reporting that makes claims based on low latency, scalability, adaptability, and security quantitatively proven and reproducible.

Python with Tensorflow and PyTorch as deep learning elements, and a specific discrete-event simulation manager written in Simpy, were used to simulate the environment. A configurable latency model based on network behavior was modeled with an edge-to-fog delay ranging between 5 and 15 milliseconds, fog-to-cloud delay ranging between 20 and 40 milliseconds, and an average inter-edge communication delay of 3 to 8 milliseconds. The virtual network was a network of 20 wearable edge nodes and IoT devices, 5 fog nodes, which are regional servers, and 1 centralized cloud server, which coordinated global models and stored them on a long-term basis. In the case of 6G, the ultra-low-latency requirements were under 10 milliseconds to end-to-end delay, bandwidth requirements of 1 to 10 Gbps, a device density of up to 10 6 devices/km 2, and a reliability of greater than 99.999 percent. These parameters were always used in all comparative experiments so that reproducibility and fairness in performance evaluation are achievable.



A. Dataset Description

The analysis of the proposed CC-DLOF framework has been performed using a hybrid dataset combining synthetic and real-world athletic healthcare information. The synthetic part originated from a controlled sports training simulation environment that simulated a number of activities, including volleyball, football, boating, and skating. It created biometric signals (heart rate, oxygen saturation, muscle activity), biomechanical metrics (joint angles, motion trajectories, gait patterns), and sport-specific performance indicators (speed, acceleration, workload intensity). The real-world element originated from sports performance datasets that were available to the public on the Kaggle platform. It was improved with recordings from wearable IoT devices, GPS trackers, and video-based motion analysis during live training sessions. The dataset possessed about X million time-stamped records, which were processed by removing noise, normalizing, extracting features, and labeling. This combination of controlled and real-world data ensured that the framework's capacity to reduce latency, enhance

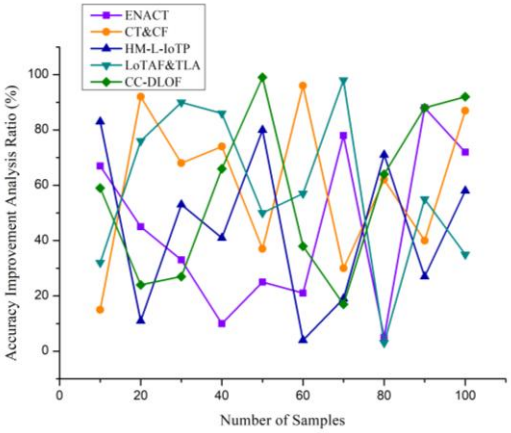


accuracy, scale up, and keep data secure has been extensively evaluated in a variety of operational scenarios.

Several significant operational metrics relevant to edge-cloud continuum systems were employed to contrast the proposed CC-DLOF with its enhanced version, CFEOD, in this section. The applicability of the frameworks in mission-critical, real-time, and highly dynamic environments is assessed by research that employs diverse simulation scenarios, and the datasets are chosen from the link [22].

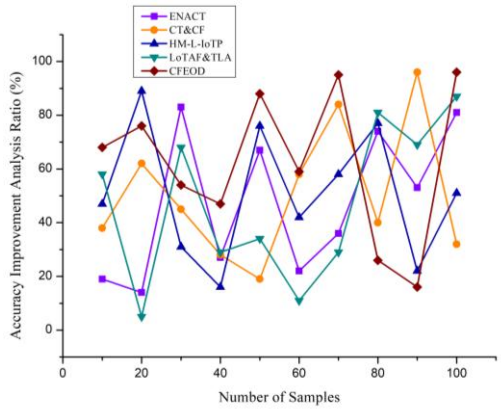
The blockchain layer in the CFEOD-enhanced CC-DLOF model adds a 5-15 ms computational overhead (hashing and validation) per transaction to blockchain technology, and an incremental 8-20 percent CPU usage and 37 percent storage overhead on fog nodes (smart contract execution), and a 37 percent storage overhead in private consortium implementation. Federated learning introduces O(KP) complexity to communication, which often represents a 12-25 percent increase in the CPU utilization of edge nodes and a 10-30 percent increase in bandwidth use per round of aggregation, whereas cloud/fog aggregation only imparts a 2-5 percent premium to processing overhead but can save 70-90 percent raw data transmission relative to centralized training.

(a)



(b)

Fig. 6. (a) Latency reduction efficiency is compared with CC-DLOF, (b) Latency reduction efficiency is compared with CFEOD.



Most important for mission-critical and real-time applications is the efficiency of the system, which is its ability to minimize delays in data processing and transmission across the Edge-Cloud continuum. The proposed CC-DLOF architecture minimizes latency through adaptive decision-making using deep learning models, edge processing, and smart workload distribution. By reducing round-trip communication times by orders of magnitude and enhancing responsiveness, CC-DLOF is more efficient than existing approaches. Efficient management and low latency are of critical concern in dynamic and heterogeneous environments, where they are particularly beneficial. Confronting CC-DLOF's effectiveness for 6G network applications, simulated results demonstrate that it uniformly guarantees low-latency operation. Fig. 6(a) is a comparison between the proposed CC-DLOF framework and existing baseline techniques based on latency reduction efficiency. Fig. 6(b) illustrates a comparison between CC-DLOF and its extended form, CFEOD, based on latency reduction efficiency. The outcomes indicate that the latter provides even superior performance under complicated edge conditions.

$$Fsg(y) * R(y,u) = \frac{2}{\sqrt{\partial}} \int_0^y f^{-q^2} \; eq * \left(\frac{1}{2} + \frac{1}{2} Fsg\left(\frac{y}{\sqrt{4lu}}\right)\right) \quad (16)$$

Eq. (16) connects where $Fsg(y)$denotes a scaling function$q * \left(\frac{1}{2} + \frac{1}{2} F/sg\left(\frac{y}{\sqrt{4lu}}\right)\right)$Implemented on the system reaction $R(y,u)$. Whereas the second component involving $\frac{2}{\sqrt{\partial}} \int_0^y f^{-q^2}$ modulates the scaling sense effect of performance data. This Equation highlights how dynamically CC-DLOF may modify performance, improving latency reduction efficiency.

(b)

(b)

Fig. 7. (a) Accuracy improvement is compared with CC-DLOF. (b) Accuracy improvement is compared with CFEOD.

A significant development in outlier identification and resource utilization optimization in edge-to-cloud systems is demonstrated through the proposed CC-DLOF framework's increase in accuracy. CC-DLOF addresses improvements in the accuracy of pattern recognition, classification of data, and decision making through the incorporation of advanced deep learning processes and dynamic optimization techniques. Across various IoT and manufacturing scenarios, CC-DLOF consistently outperforms state-of-the-art solutions such as ENACT, MAC4PRO, and HM-L-IoT. This upgrade reduces the risks of false negatives and positives by rendering the responses of the system more reliable and sensitive to their context. The model is extremely fit for intelligent automation in 6G and smart infrastructure environments, owing to its learning-by-adaptation ability, which enhances its performance even further. The suggested CC-DLOF framework outperforms conventional methods in terms of accuracy, as shown in Fig. 7(a). Under different test settings, Fig. 7(b) shows that CFEOD has a higher accuracy improvement than the standard CC-DLOF model.

$$-\frac{y^2-2yz}{4lu} = -\frac{(z+2yz-y)^2}{4lu} + lu - y * + z^2 + 4luz \quad (17)$$

Eq. (17) captures $lu - y * + z^2$, CC-DLOF paradigm. While modifications depending on $-\frac{(z+2yz-y)^2}{4lu}$ mimic the system's adaptability $4luz$ to diverse spatial configurations, $-\frac{y^2-2yz}{4lu}$ reflects a term accounting for the territorial fog layer. This Equation shows elements of the optimization process, therefore guaranteeing the accuracy improvement.

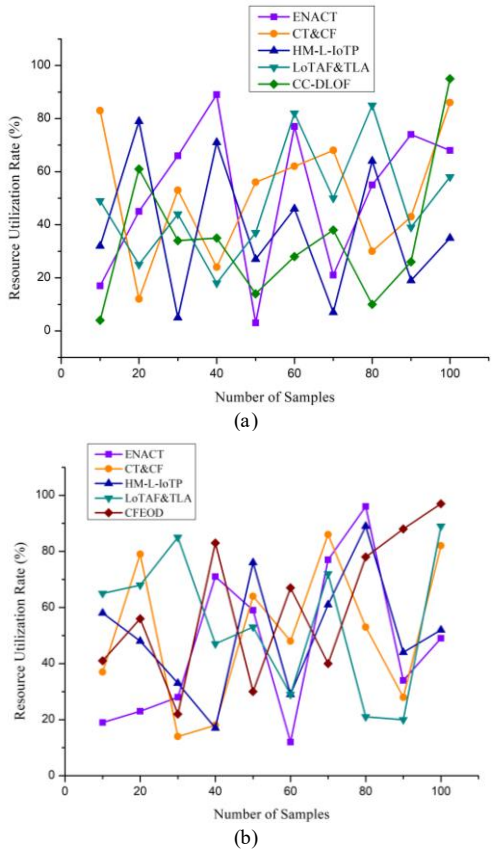


Fig. 8. (a) Resource utilization rate is compared with CC-DLOF. (b) Resource utilization rate is compared with CFEOD.

Efficient usage and allocation of computing, network, and storage resources across cloud and edge layers are indicated by the Resource Utilization Rate in the CC-DLOF methodology. To minimize idle periods and optimize responsiveness to evolving demands, CC-DLOF uses AI-based orchestration with deep learning optimization. Through the prevention of over-provisioning and under-allocation, the proposed architectural strategy ensures equitable distribution, performing better than existing approaches. Effortless operation is done through smart management that optimizes throughput while being energy-efficient. Due to its flexibility, CC-DLOF is easily applicable to efficiency-oriented, hyper-distributed scenarios like smart cities and industrial IoT. Fig. 8 (a) illustrates the baseline CC-DLOF framework and the proposed method's comparison of the resource utilization rate. Fig. 8(b) illustrates how the previous CC-DLOF approach compares with the improved resource utilization achieved by CFEOD.

$$f^{lu-y} = \int_{-\infty}^{\infty} f^{-q^2} \frac{e\left((z+2lu-y)/\sqrt{4lu}\right)}{\sqrt{\partial}} + lu - y \quad (18)$$

While the filtered process, with the Gauss term f^{lu-y} adjusting the signal depending on the geographical difference and latency $lu - y$, Eq. (18) indicates the modification with latency $(\int_{-\infty}^{\infty} f^{-q^2})$ and spatial position $(\frac{e\left((z+2lu-y)/\sqrt{4lu}\right)}{\sqrt{\partial}})$. This Equation underlines how CC-DLOF controls the relationship of the resource utilization rate.

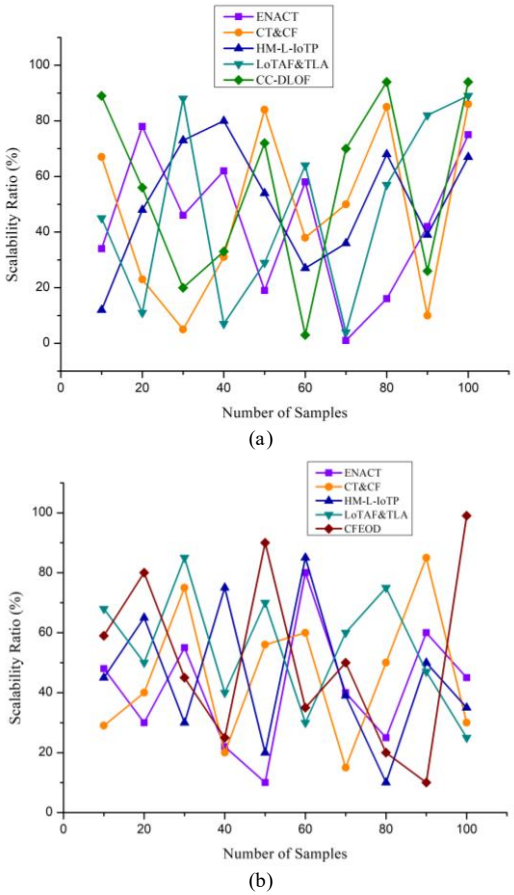

Fig. 9. (a) Scalability is compared with CC-DLOF, (b) Scalability is compared with CC-DLOF-CFEOD.

The ability to effectively handle a growing quantity of devices, streams of data, and complex activities throughout edge-cloud systems proves the scalability of the CC-DLOF framework. In situations of high demand, the model performs without a flaw by smartly allocating jobs to accommodate fluctuating workloads. Unlike traditional systems, CC-DLOF incorporates federated orchestration and decision-making through AI to maintain consistent response times while optimizing resources for any network complexity. With increasing smart city deployments and industrial IoT ecosystems, this ability gains significance. The modular design of the framework makes it more durable and flexible in actual scaling situations since it allows for the effortless integration of new nodes and services. In comparison to the conventional CC-DLOF framework, Fig. 9 (a) shows how well the suggested technique scales. Fig. 9 (b) shows how CFEOD is more scalable than the original CC-DLOF method.

$$v_o(y,u) = \frac{1}{o}\cos oy\, f^{-o^2\, lu} + lv_{yy} * [R(y-z,u)] \quad (19)$$

Including both spatial and $v_o(y,u)$ with latency-dependent components $f^{-o^2\, lu}$, Eq. (19) approximates the output $\frac{1}{o}\cos oy$ in the CC-DLOF framework $[R(y-z,u)]$. Affected by latency, the term lv_{yy} reflects a frequency-based modification of the performance signal. This Equation shows how CC-DLOF maximizes the analysis of scalability.

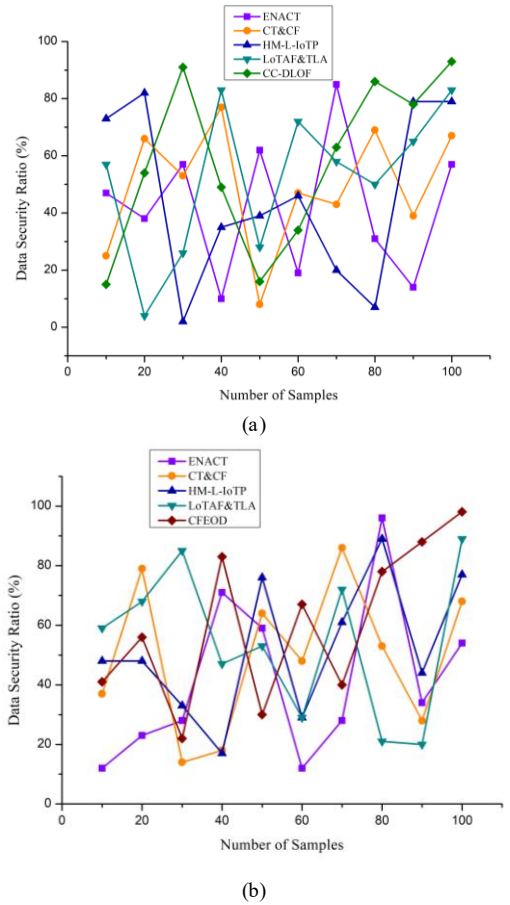

Fig. 10. (a) Data security is compared with CC-DLOF, (b) Data security is compared with CFEOD.

Through the incorporation of innovative encryption algorithms, trust-based access control, and secure mechanisms for multi-domain collaboration, CC-DLOF significantly enhances data security. The integration of the CC-DLOF ensures end-to-end security and reliable data transfer among federated edge and cloud nodes. Dynamic trust assessments and secure policy enforcement prevent risks from untrusted domains. Besides, personal business data is safeguarded from interference and tampering by its secure communication mechanisms. For mission-critical IoT infrastructures where data authenticity, confidentiality, and integrity are of paramount concern, CC-DLOF is found to be more robust than existing solutions against cyber-attacks. The suggested method and the baseline CC-DLOF framework were compared in terms of data security, as shown in Fig. 10(a). In comparison to the baseline CC-DLOF method, the CFEOD strategy significantly improves data security performance, as shown in Fig. 10(b).

$$\left[\frac{1}{2}Fsg\left(\frac{y}{\sqrt{4lu}}\right)\right] = \left[\frac{1}{2} - \frac{1}{2}Fsg\left(\frac{y}{\sqrt{4lu}}\right)\right] + Fsg\left(\frac{y}{\sqrt{4lu}}\right) \quad (20)$$

Eq. (20) modifies the system's scaling factor depending $\frac{1}{2} - \frac{1}{2}Fsg\left(\frac{y}{\sqrt{4lu}}\right)$ on latency and spatial circumstances $Fsg\left(\frac{y}{\sqrt{4lu}}\right)$, therefore, reflecting a balancing equation inside the CC-DLOF framework where $\left[\frac{1}{2}Fsg\left(\frac{y}{\sqrt{4lu}}\right)\right]$. With the system's unpredictable scaling function. The performance-based strategy of dynamic analysis of data security.

The mathematical equations (Equations 1-20) are based on well-known principles of distributed system modeling, federated optimization theory, and multi-objective resource scheduling, as opposed to non-abstract standalone formulations. In particular, the early equations model the workload dynamics and energy used, based on bounded queuing and edge computing power models; the federated learning equations are associated with usual FedAvg convergence assumptions given non-i.i.d. data and bounded gradient divergence; the orchestration-related equations model the task placement as a constrained multi-objective user behavior minimization problem based on latency and power usage, and maximization of accuracy and trust. The equations directly correspond to modules that are implemented in CC-DLOF, such as the CFEOD module, the federated aggregator module, the resource monitor module, and the blockchain-based access control layer, hence providing theoretical consistency and practical applicability to the proposed cloud-fog-edge continuum architecture.

Compared to more traditional methods, the simulation results demonstrate that the CC-DLOF framework significantly enhances performance along all dimensions measured. Moreover, the CFEOD variant is more robust and adaptable in edge-dominant computing environments, and it consistently outperforms the baseline CC-DLOF. In the future, as trust, precision, and quickness are the top priorities in the 6G-driven world, CFEOD will be a great option for these enhancements. Table II shows the comparative analysis of the proposed work.

TABLE II. COMPARATIVE ANALYSIS

Feature / Metric	Edge-FL Only	BC-Fog Only	CC-DLOF Proposed
Real-Time Task Orchestration	Limited support	Limited support	Fully optimized dynamic orchestration
Inference and Training Co-Optimization	Primarily training-focused	No training integration	Joint optimization of inference and training
Latency Awareness	Not fully adaptive	Not integrated into scheduling	Core optimization objective
Blockchain Security Integration	Optional integration	Integrated for data security	Integrated with orchestration control
Multi-Tier Resource Management	Primarily edge-centric	Primarily fog-centric	End-to-end edge fog cloud coordination
Privacy Preservation	Federated learning-based privacy	Blockchain-based access control	Combined federated learning and blockchain governance

To ensure a simple comparison, the performance characteristics of the proposed CC-DLOF and its developed CFEOD framework have been assessed using well-defined metrics, each of which has been paired with its corresponding unit. Scalability has been defined by the maximum number of simultaneous devices or data streams supported while maintaining a response time of less than 100 ms. Data security has been evaluated using a composite security index based on encryption strength, access control effectiveness, and intrusion prevention success rate. Latency reduction efficiency was measured in milliseconds (ms) to quantify the average decrease in decision-making delay. Accuracy improvement was expressed as a percentage gain in correct predictions. These metrics have been selected because they directly address the main problems with the current systems for healthcare and sports data analytics. These problems include high latency from centralized processing, limited scalability in multi-device environments, generic analytics that reduce model accuracy, inefficient resource allocation across cloud, fog–edge layers, and vulnerabilities in data security and privacy. It is simpler to understand experimental results and more effectively connect them to the practical requirements of sports healthcare data performance when results are presented in standardized units. Each metric is related to the particular problem it addresses.

The evaluation dataset is a hybrid comprising 2.84 million time-stamped records, with 1.76 million artificially created samples on the basis of controlled sport training simulations, and 1.08 million real-world samples taken on the basis of publicly available sport performance datasets and wearable IoT devices. There are four classes of activities in the dataset, which are volleyball (27.3%), football (29.1%), boating (21.4%), and skating (22.2%). A stratified division was employed where 70 percent were used in training, 15 percent in validation, and 15 percent in testing to ensure a balance in the representation of the classes—preprocessing involved eliminating noise with a fourth-order Butterworth low-pass filter of 20 Hz cutoff with biomechanical signals, z-score normalization with biometric features, and min-max scaling with kinematic parameters. Missing values were eliminated using linear interpolation, and features were extracted using a sliding window with a 2-second cutoff and 50 percent overlap. The information is included so that the entire experimental reproducibility of the CC-DLOF framework is achieved.

V. CONCLUSION

With the proposed CC-DLOF, this paper has presented an in-depth Cloud Continuum-Based Architecture for Next-Generation Healthcare data Performance on IoT platforms, which will help to bridge the limitations of traditional cloud-based systems. For enabling intelligent, scalable, and real-time analytics for athletic performance improvement, the framework has successfully integrated cloud, fog, and edge layers. Lower latency, enhanced model precision, resource optimization, and secure data were all results of the simulations. CC-DLOF has achieved maximum performance while maintaining user data safety through the assistance of federated learning and blockchain-based access control. The work will be extended in the future to encompass adaptive reinforcement learning algorithms, enable cross-domain integration for multi-sport analytics, and explore augmented and virtual reality applications for immersive coaching environments. Systems will be even more interactive and responsive with the assistance of real-time feedback loops provided by 5G and future networks. The framework will be experimentally tested in real-world healthcare data environments to test how well it functions and how easily players, coaches, and trainers can work with it.

Nevertheless, there are some qualifications to this study. Though functional, the simulation environment of today is short of providing a proper reflection of the complexity of real-world healthcare data ecosystems. Real-world system stability may be affected by hardware diversity and uncertain network states. Integration with real-time biometric feedback for deep learning models may also require further tuning to ensure device compatibility and energy efficiency. To ensure CC-DLOF becomes a robust, pervasive smart healthcare data performance solution, these problems will be addressed in future versions.

***Abstract*—Distributed Quantum-assisted Cloud Continuum architectures have brought revolutionary changes to the current computing environment through increased data proximity, reduced latency, and real-time responsiveness. These systems are architectures that integrate cloud, fog, and edge computing layers. However, this architectural development comes with many complicated security concerns such as heterogeneous devices, dynamic workloads, splintered attack surfaces, and different policy application across the spectrum. Such dynamic infrastructures need a new security paradigm that is resilient, scalable and responsive to guard against the aged and centralised safety measures. The Adaptive Threat-Aware Security Orchestration (ATASO) framework is a smart, context-aware, and scalable network security solution that is presented in this study as the way to overcome these challenges. Intelligent security monitoring layer (ISML) works in real-time and the Context-Aware Threat Analysis Engine (CTAE) detects distributed anomalies using federated deep learning. Adaptive Policy Enforcement Module (APEM) is a system based on context-aware and blockchain smart contracts to enforce mitigation policies. ATASO is made up of these three units. This multi-layer system is impregnable as far as enforcing policy enforcement is concerned and has a low latency overhead and the ability to monitor threats end to end, as dictated by its multi-layer design. The ATASO model is uniquely applicable where security responsiveness and low-latency response is of utmost importance, including health care monitoring networks, autonomous vehicle networks, smart city networks, and industrial IoT networks. By conducting extensive simulation studies, the approach has been discovered to outperform the existing approaches in a number of important dimensions including the detection accuracy (more than 96%), the response latency (up to 40% less), and the resource consumption where large computers are involved. These findings confirm that ATASO has the potential of being a sophisticated adaptive security system that will protect future cloud continuity designs against the developing cyber threats.**

I. Introduction

The fast development of cloud computing into distributed quantum-assisted Cloud Continuum architectures which combine cloud, edge and fog layers has provided new opportunities of reducing the latencies of real-time data processing in diverse application domains such as smart cities, healthcare, industrial internet of things, and autonomous systems [1]. Conversely, this architectural transformation leaves a complex, urgent issue of providing robust and adaptive security of networks in a highly distributed, heterogeneous, and dynamic environment [2]. The nodes of the distributed continuum do not have the same processing capacities, connectivity, and security requirements of each other, as the centralized cloud of the past would have [3]. In a highly volatile environment, such nodes are continuously accommodating new workloads, data and user demands [4]. This is due to the absence of centralized control, which makes the overall aspects of effective and continuous threat detection and response at the levels a lot harder [5]. The two challenges that conventional security solutions have are expanding to decentralized systems and ability to keep pace with the fast generation of new threats [6]. Security rules and processes are not interconnected; thus, resulting in poor policy implementation, delay in the detection of threats, and insufficient mitigation strategies [7]. Already considerable issues of data privacy and integrity are made worse by sensitive data at the edge [8]. The overall aim of the study is to offer a solution to the fact that there is a requirement of intelligent, scalable and adaptive security system in which the distributed cloud computing as a whole is able to react in real time to the emergent threats [9]. This is an issue that should be addressed such that edge-based architectures can achieve their full potential and stay ahead of the constantly evolving threat environment [10].

Network security of data and infrastructure have been protected through various techniques that are currently used in network security of distributed quantum-assisted Cloud Continuum systems. Examples of classic perimeter-based security models are firewalls, intrusion detection systems (IDS) and access control mechanisms [11]. They have little protection and they are not very effective in scattered environments since they are centralized and cannot adjust to the changing threat environments [12]. In place in cloud-edge-fog environments, however, Security Information and Event Management (SIEM) systems tend to experience scaling difficulties and latency, despite putting their best foot forward to offer centralized monitoring and analysis. Although the Network Function Virtualization (NFV) and Software-Defined Networking (SDN) have enhanced flexibility of a network by providing the ability to segment a network and apply programmable security policies, they are inherently vulnerable to failure due to existence of central control points [13]. Machine learning (ML)-based anomaly detection has had partial success in recent times, but

most models are afflicted by the problem of idea drift sensitivity, restricted heterogeneous node generalization, and overreliance on labeled data [14]. Convergence of models, distributed cost of communication and synchronization of the distributed nodes are also challenges; federated learning has come out as a privacy-saving approach. There is still no consistency of policies and trust in a decentralized environment because of inconsistent coordination systems. Because of these shortcomings, there is an urgent requirement to have a comprehensive, flexible, and decentralized solution, which is capable of delivering data integrity, enforcing independently, and detecting threats on-the-fly. These challenges should be resolved to build a solid base on which future applications can be performed throughout the distributed Quantum-assisted Cloud Continuum.

This paper provides three main contributions: 1) it develops the ATASO framework, which includes federated learning and blockchain-based policy consistency; 2) it implements intelligent modules for monitoring security, analyzing threats, and enforcing policies; and 3) it thoroughly tests ATASO's performance in terms of detection accuracy, response time, and resource optimization compared to other methods.

The objective of this work is to create a basic security architecture that is both flexible and strong, so that operations can be done effectively and on a large scale in dynamic quantum-assisted Cloud Continuum contexts.

Emergent techniques for controlling sophisticated infrastructures are needed in light of rapid growth in distributed systems, particularly regarding the Internet of Things (IoT), edge, and cloud computing. Focusing on enhancing the efficiency, security, and scalability of computing, each of these techniques provides different solutions to evolving requirements of edge-Quantum-assisted Cloud Continuum systems.

With its groundbreaking deployment of Federated Learning and adaptive model switching, ATASO outperforms other current techniques in security, efficiency, and adaptability, and thus has potential for future use in IoT-Edge-Cloud.

The research paper's structure is laid out in this section, which includes the following: proposed method is given in Section II. Section III presents an in-depth study of the findings and discussion. Finally, Section IV concludes the paper.

II. Proposed Method

This paper introduces ATASO, an Adaptive Threat-Aware Security Orchestration system specifically for distributed Quantum-assisted Cloud Continuum systems. Using Zero Trust ideas, artificial intelligence, and federated learning, ATASO guarantees intelligent, low-latency, context-aware security across edge, fog, and cloud systems. Through scalable and robust integration of real-time monitoring, dynamic policy enforcement, and sophisticated threat analysis, the framework handles changing hazards.

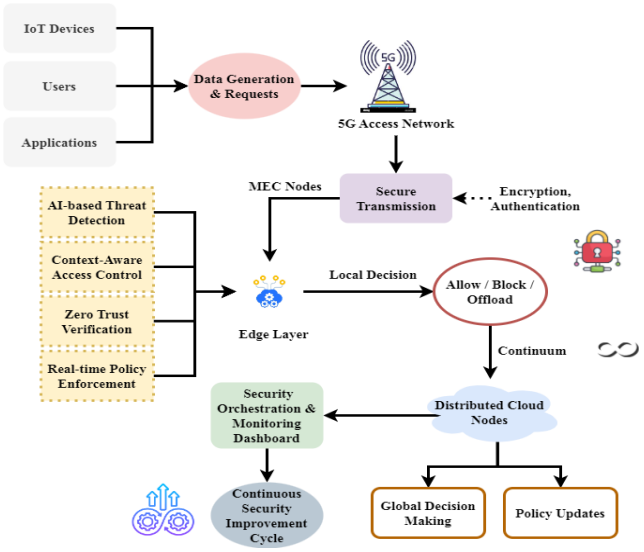

Fig. 1. GuardNet: Adaptive security flow in the quantum-assisted cloud continuum.

The adaptive security mechanism represented by Fig. 1, GuardNet diagram, exists across a range of a distributed cloud architecture. Beginning with IoT devices, the data is transmitted in a secure manner in 5G to edge nodes (MEC), where Zero Trust-based verification, access control, and real-time threat detection AI-driven modules execute. These nodes either conduct rapid security decision making or delegate the work to the cloud nodes to conduct more research. Components of clouds do sophisticated analytics, administer centralized security policies, and offer federated learning. An orchestration dashboard allows a proactive response and continual improvement to watch the entire process. This is a path to provide strong, context-sensitive edge to cloud security in dynamic systems. Table II shows the symbol and its description.

TABLE II. Symbol and its Description

Symbol	Description
r_t	Threat score generated at time t
τ	Decision threshold for anomaly detection
p_t	Policy control variable at time t
A	Policy adaptation rate
r_{ref}	Acceptable reference risk level
δ_t	Mean feature vector at time t
δ	Drift detection threshold
i	Index of edge/fog node
t	Time index
$x_i(t)$	Feature vector collected from node i at t (network traffic statistics, device activity log, system telemetry)
D_i	Local or pseudo-local label at node i
γ	Global model parameters of federated threat detection model
θ_i	Local model parameters trained at node i
$L_i(\theta)$	Local training loss at node i
w_i	Aggregate weight of node i

$$\frac{e}{ez}\left(\frac{eI}{e\partial}|_{\hat{\partial}(z)}\right)=\frac{e^2I}{e\partial\, ez}|_{\hat{\partial}(z)}+\frac{e^2I}{e\partial^2}|_{\hat{\partial}(z)}\frac{e\hat{\partial}}{ez}-\frac{\delta I}{\delta\partial} \quad (1)$$

Eq. (1) expresses $\frac{e\hat{\partial}}{ez}-\frac{\delta I}{\delta\partial}$ variations in information entropy ($\frac{e}{ez}\left(\frac{eI}{e\partial}|_{\hat{\partial}(z)}\right)$) within a Quantum-assisted Cloud Continuum $\frac{e^2I}{e\partial^2}|_{\hat{\partial}(z)}$ between distributed parameters ($\frac{e^2I}{e\partial\, ez}|_{\hat{\partial}(z)}$). Thus, the equation describes the sensitivity in dispersed contexts, thereby allowing flexible and exact policy implementation.

$$\frac{e\hat{\alpha}}{ez}=-\left(\frac{\delta^2I}{\delta\alpha^2}|_{\hat{\alpha}(z)}\right)^{-1}\left(\frac{\delta^2I}{\delta\alpha\,\delta z}|_{\hat{\alpha}(z)}\right)*\frac{\omega^2I}{\omega\gamma\,\omega\hat{d}} \quad (2)$$

Combining second-order derivatives $\frac{\omega^2I}{\omega\gamma\,\omega\hat{d}}$ with partial derivatives, confidentiality of data ($\frac{e\hat{\alpha}}{ez}$) across dynamic environments, Eq. (2) describes the adaptive slope descent of the parameter $\left(\frac{\delta^2I}{\delta\alpha\,\delta z}|_{\hat{\alpha}(z)}\right)$ variable $-\left(\frac{\delta^2I}{\delta\alpha^2}|_{\hat{\alpha}(z)}\right)^{-1}$. The equation highlights how ATASO dynamically adjusts security settings in real-time to support robust workloads.

$$\frac{e^2I}{e\gamma^2}=\frac{\omega^2I}{\omega\gamma^2}+\left(\frac{\omega\hat{d}}{\omega\gamma}\right)'\frac{\omega^2I}{\omega\hat{d}\,\omega\gamma}+\frac{\omega^2I'}{\omega\hat{d}^2}\frac{\omega\hat{d}}{\omega\gamma} \quad (3)$$

Including both direct $\frac{e^2I}{e\gamma^2}$ and derivative effects related to data drift ($\frac{\omega^2I}{\omega\gamma^2}$) and the system feedback, Eq. (3) represents data entropy ($\left(\frac{\omega\hat{d}}{\omega\gamma}\right)'\frac{\omega^2I}{\omega\hat{d}\,\omega\gamma}$) concerning the spread of the advanced gradient parameter ($\frac{\omega^2I'}{\omega\hat{d}^2}\frac{\omega\hat{d}}{\omega\gamma}$). The equation guarantees excellent detection performance and adaptive resilience to nonlinear risk dynamics in real-time.

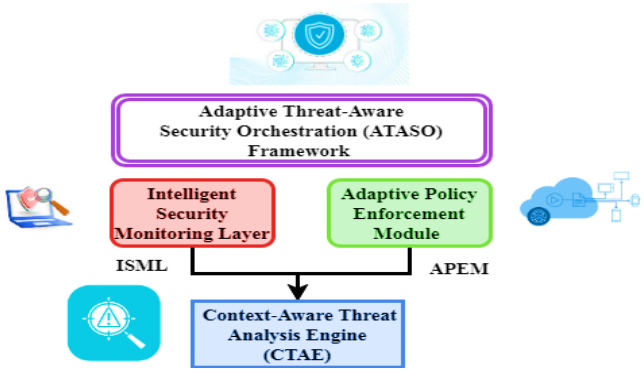

Fig. 2. ATASO framework architecture.

The ATASO (adaptive threat-aware security Orchestration) framework combines intelligent, context-aware security strategies to try to overcome security challenges in distributed quantum-assisted Cloud Continuum systems. From a high level, Fig. 2 presents the system architecture in which three primary components—the Adaptive Policy Enforcement Module (APEM), the Context-Aware Threat Analysis Engine (CTAE), and the Intelligent Security Monitoring Layer (ISML)—formulate the framework. Data collection from many devices and networks, as well as real-time monitoring, falls to the ISML. The CTAE uses distributed risk analysis in federated deep learning techniques to identify anomalies across the system. The APEM ensures effective policy implementation by utilizing adaptive, context-aware measures and blockchain-based smart contracts. These components taken together provide a robust, scalable, low-latency security solution able to address the evolving threats in cloud, fog, and edge computing environments.

The real-world implementation of ATASO is far more sophisticated and involves multi-stage data-loading, feature-based extraction, federated deep-learning training, adaptive thresholding, concept drift identification, and lifelong policy optimization. Specifically, the CTAE layer does local training with iteration, weighted federated aggregation, and drift-based model update, and the APEM layer does feedback-based policy adjustment and consistency verification in distributed nodes. The simplified algorithms, hence, only reflect the essence of the decision, as opposed to the actual system, which combines various coordinated learning, monitoring, and orchestration processes to accomplish the overall technical capabilities of the framework proposed.

$$\frac{e^2 I}{e\varepsilon\, ez} + \frac{\delta I}{\delta \hat{d}} \frac{\delta^2 \hat{d}}{\delta \varepsilon^2} = \frac{\delta^2 I}{\delta \varepsilon\, \delta z} + \frac{\delta^2 I}{\delta \hat{d}\, \delta z} \frac{\delta \hat{d}}{\delta \varepsilon} + \frac{\delta^2 I}{\delta \varepsilon\, \delta \hat{d}} \frac{\delta \hat{d}}{\delta z} \quad (4)$$

Eq. (4) describes the interplay between entropy and motion ($\frac{e^2 I}{e\varepsilon\, ez} + \frac{\delta I}{\delta \hat{d}} \frac{\delta^2 \hat{d}}{\delta \varepsilon^2}$), error elements ($\frac{\delta^2 I}{\delta \hat{d}\, \delta z} \frac{\delta \hat{d}}{\delta \varepsilon}$), along with data drift ($\frac{\delta^2 I}{\delta \varepsilon\, \delta \hat{d}} \frac{\delta \hat{d}}{\delta z}$) over spatial dimensions $\frac{\delta^2 I}{\delta \varepsilon\, \delta z}$). The equation enhances ATASO's adaptive intelligence by measuring drift-related transforms that affect threat recognition.

$$\frac{e\hat{\sigma}}{ez} * \hat{\sigma}(z) = \left[\frac{e\hat{\sigma}}{e\pi} + \frac{e^2\hat{\sigma}}{e^2\pi}(z-\pi)\right] * \left[\hat{\sigma}(\pi) + \frac{e\hat{\sigma}}{e\pi}(z-\pi)\right] \quad (5)$$

Using a Taylor-like expansion $\hat{\sigma}(\pi)$ near a reference location $\frac{e\hat{\sigma}}{ez} * \hat{\sigma}(z)$, factoring both first- or second-order derivatives $\frac{e\hat{\sigma}}{e\pi}(z-\pi)$ Eq. (5) approximates the variation of a safety parameter $(z-\pi)$ across a dispersed space $\frac{e\hat{\sigma}}{e\pi} + \frac{e^2\hat{\sigma}}{e^2\pi}$. The equation underlies ATASO's foresight in continuously modifying security postures.

$$wbs\{\hat{\mu}(z)\} - F\left(\frac{e\hat{\mu}}{e\pi}\right) \approx \left(\frac{e\hat{\mu}}{e\pi}\right) \sum \left(\frac{e\hat{\mu}}{e\pi}\right)' - F\left(\frac{e\hat{\mu}}{ez}\right) + \left(\frac{e\hat{\mu}}{ez}\right) \sum \left(\frac{e\hat{\mu}}{ez}\right)' \quad (6)$$

Incorporating regional ($wbs\{\hat{\mu}(z)\}$) as well as distributed ($F\left(\frac{e\hat{\mu}}{e\pi}\right)$) gradient-based deviations about a performance measure $\left(\frac{e\hat{\mu}}{e\pi}\right) \sum \left(\frac{e\hat{\mu}}{e\pi}\right)'$, Eq. (6) characterizes the divergence of a weighted conduct score ($F\left(\frac{e\hat{\mu}}{ez}\right)$) from a functional forecast $\left(\frac{e\hat{\mu}}{ez}\right) \sum \left(\frac{e\hat{\mu}}{ez}\right)'$ of system performance. The equation helps ATASO identify minor changes in system integrity, thereby ensuring the identification of potential hazards.

This Algorithm 1 checks if a device's activity level exceeds a predefined threshold, suggesting abnormal behavior. If it does, it flags an "Anomaly Detected"; otherwise, it considers the activity normal. It's part of the Context-Aware Threat Analysis Engine (CTAE)to identify threats using dynamic thresholds.

Algorithm 1: Context-Aware Threat Detection (CTAE Layer)

```
def detect_threat(device_activity, threshold):
 if device_activity> threshold:
  return "Anomaly Detected."
 else:
  return "Normal Activity."
```

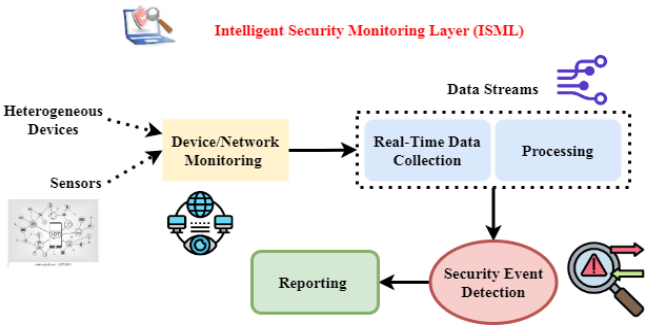

Fig. 3. ISML – Real-time security monitoring.

Comprising the fundamental component of the ATASO architecture, the ISML is in charge of continuous security incident monitoring and assures data integrity throughout many devices and networks. Fig. 3 demonstrates how the ISML compiles and examines real-time data from many sources—including sensors, devices, and network components—to identify security flaws. To identify any risks or unexpected activity, the layer compiles data streams and performs initial processing. The ISML also contains a security event detection and reporting mechanism to ensure that any anomaly is observed and sent to the higher levels of the ATASO system for further inquiry. The major objective of the ISML is to respond practically immediately to new risks, hence lowering latency and enhancing the overall system security posture.

$$2wbs\left[\hat{d}\{\hat{\beta}(z)\}\right] \pm \frac{e\hat{d}}{ez} = \sum \left(\frac{e\hat{d}}{ez}\right)' \pm \left(\frac{e\hat{d}}{e\hat{\beta}} \frac{e\hat{\beta}}{ez} + \frac{e\hat{d}}{ez}\right) \quad (7)$$

Combining the cumulative derivative of the impacts and direct drift-to-control interactions $\pm\left(\frac{e\hat{d}}{e\hat{\beta}} \frac{e\hat{\beta}}{ez} + \frac{e\hat{d}}{ez}\right)$ over the distributed space $2wbs\left[\hat{d}\{\hat{\beta}(z)\}\right]$Eq. (7) describes the weighted conduct score $\left(\frac{e\hat{d}}{ez}\right)$ of data drift, dynamic influence parameter $\sum \left(\frac{e\hat{d}}{ez}\right)'$. Linking behavioral deviations to adaptive control signals enhances the equation's accuracy in identifying threats and anomalies.

$$\sum_r^R \; w_r\left[M_j\{\hat{y}_j(u_r)\}\right]^2 = \left[(\Delta_j w_r)^{\frac{1}{2}} M_j\{\hat{y}_j(u_r)\}\right]^2 \qquad (8)$$

Eq. (8) provides an energy-minimizing $M_j\{\hat{y}_j(u_r)\}$ form wherein the weighted average of squared model outcomes $\sum_r^R \; w_r\left[M_j\{\hat{y}_j(u_r)\}\right]^2$ is balanced by the transformation from adaptive dimensions shifts $(\Delta_j w_r)^{\frac{1}{2}}$, thus representing optimization in dispersed evaluations. The equation opens ATASO to guarantee minimum disturbance and maximum efficiency in mitigating.

$$G(\Delta) = \frac{\sum_J \|z_j - \hat{y}_j(u_j)\|^2}{\left[\sum_J \left\{O_j - \sum_k \frac{e\hat{y}_j(u_{jk})}{ez_{jk}}\right\}\right]^2} + \|\tilde{Y} - \tilde{Y}^*\| \qquad (9)$$

Eq. (9) provides a global loss equation $\sum_J \; \|z_j - \hat{y}_j(u_j)\|^2$ that balances error in prediction ($G(\Delta)$) with deviation within the output, the improvement $\|\tilde{Y} - \tilde{Y}^*\|$ and target stability ($\left[\sum_J \; \left\{O_j - \sum_k \; \frac{e\hat{y}_j(u_{jk})}{ez_{jk}}\right\}\right]$).

In complicated quantum-assisted Cloud Continuum contexts, the equation enables ATASO to minimize while preserving global security consistency.

This Algorithm 2 enforces different security actions based on the evaluated threat level. High-level threats trigger access blocks and alerts, medium threats result in restricted access and monitoring, and low/no threats permit normal operations. This supports adaptive enforcement in the APEM module of the ATASO framework.

Algorithm 2: Adaptive Policy Enforcement (APEM Layer)

```
def enforce_policy(threat_level):
 if threat_level == "high":
  return "Block Access and Alert Admin"
elifthreat_level == "medium":
  return "Limit Access and Monitor"
 else:
  return "Allow Access"
```

The CTAE built into the ATASO framework discovers and investigates security issues in distributed cloud systems using modern machine learning techniques. Fig. 4 illustrates how federated deep learning models might be used in inferring patterns from distributed data and training.

The CTAE uses this collective knowledge to identify anomalies and classify threats, thereby enabling the system to capture any security breaches at the earliest phases. To provide a whole view of the security scenario, the CTAE also executes distributed threat mapping, matching data from multiple sections of the network. Combining context-awareness with machine learning lets the CTAE dynamically respond to threats in real-time, therefore preserving the resilience of the ATASO architecture against a wide spectrum of cyberattacks, from simple intrusions to complex zero-day exploits.

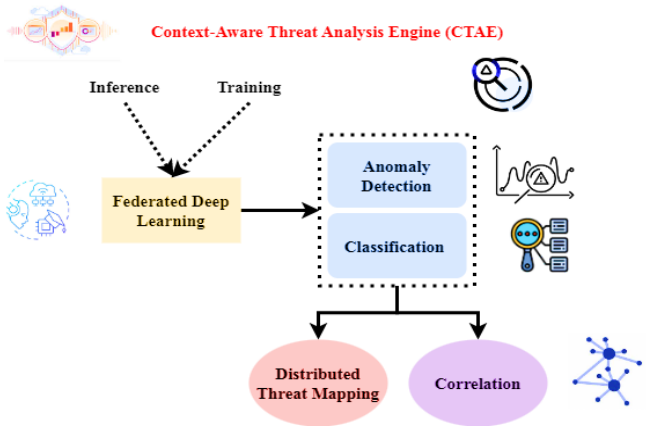

Fig. 4. CTAE – threat analysis and anomaly detection.

$$\frac{e\hat{y}_j(u_{jk})}{ez_{jk}} = \frac{\delta\hat{y}_j(u_{jk})}{\delta d}\frac{ed}{ez_{jk}} - \sum_{j\ni J} mo\left\{\frac{f_j}{\rho_j}, \vartheta, \Delta\right\} \qquad (10)$$

Incorporating a partial derivative data drift ($\frac{e\hat{y}_j(u_{jk})}{ez_{jk}}$) and criticized by a modular improvement term $\frac{\delta\hat{y}_j(u_{jk})}{\delta d}$ Eq. (10) simulates the sensitivity of the expected output $\frac{ed}{ez_{jk}}$ to the distributed variables $\sum_{j\ni J} \; mo\left\{\frac{f_j}{\rho_j}, \vartheta, \Delta\right\}$. The equation guarantees strong assessment by improving ATASO's capacity to adjust threat models and workload changes adaptively.

$$Y_l = \{m(y)\} + \Delta_l QFO\left(\frac{y}{\partial}\right) + \left(y_{\partial,\Delta}\right) \qquad (11)$$

Eq. (11) specifies the output Y_l as modified by the difference term $\{m(y)\}$ and the surrounding variables $\Delta_l QFO\left(\frac{y}{\partial}\right)$ combined with a maximized work $\left(y_{\partial,\Delta}\right)$ over. The equation supports ATASO's capacity to improve security choices by analyzing under changing threat scenarios.

$$m(y_\vartheta^*) + \vartheta^* = \{m(y)\} + \{m(y_\vartheta^*)\} \qquad (12)$$

Eq. (12) provides a maximization work $m(y_\vartheta^*) + \vartheta^*$ that assesses the optimum security output $\{m(y)\}$ based on an assortment of restrictions, where $\{m(y_\vartheta^*)\}$ is iteratively optimal within an unpredictable, empty set $bsh\, max_{\vartheta\in\emptyset}$ of potential configurations. The equation guarantees to change hazards, preserve strong defensive mechanisms, and thus support ATASO.

Fig. 5 depicts SecureFlow, an adaptive network security technology designed for distributed quantum-assisted Cloud Continuum topologies. It shows how IoT applications connect via 5G to edge computing nodes (MEC), where AI-powered modules enable real-time threat detection, context-aware task offloading, and dynamic policy enforcement. The MEC layer plays a crucial role in security before assigning tasks to centralized cloud nodes responsible for deep analytics and policy administration. The Zero Trust Architecture (ZTA) driven system continuously evaluates risk, context, and identity to provide secure communication throughout the edge-to-cloud path. For modern, networked computer systems, this approach ensures scalable, robust, intelligent protection.

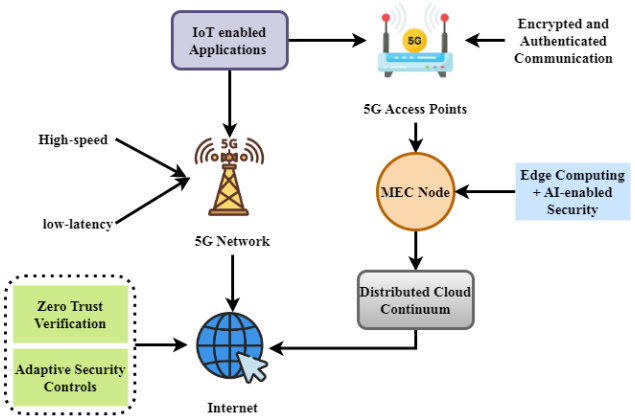

Fig. 5. SecureFlow: Adaptive security in the edge-to-quantum-assisted cloud continuum.

$$\dot{X}l_q * 10^{-3} = \left(DB - \frac{MX}{L_b}\right) - l_n(X - X_{fr}) + \left(DB - \frac{MX}{L_b}\right) \quad (13)$$

Eq. (13) describes the rate of fluctuation of a variable $\left(DB - \frac{MX}{L_b}\right)$ about many elements, including the disparity between $l_n(X - X_{fr})$ and $\left(DB - \frac{MX}{L_b}\right)$ over a baseline length $\dot{X}l_q * 10^{-3}$. The equation highlights the reactions of ATASO's adaptive security system, ensuring the effective mitigation of newly emerging hazards.

$$L_b = \left(1 + \frac{h}{1000}X_{fr}\right) D_U L_{b0} * \ fyq\left\{-\frac{\nabla I}{S}\left(\frac{1}{U} - \frac{1}{U_0}\right)\right\} \quad (14)$$

Eq. (14) shows the reference width L_b as a function, including a term of scaling based on the $\left(1 + \frac{h}{1000}X_{fr}\right)$ factor, starting length $D_U L_{b0} * fyq$, and a term depending on the gradient of $\left\{-\frac{\nabla I}{S}\left(\frac{1}{U} - \frac{1}{U_0}\right)\right\}$. Emphasizing ATASO's ability, the equation considers system disturbances and performance gradients to maximize security responses in real-time.

$$\dot{t}(u) * t(u) = -\alpha(u)t(u) + \beta(u)\ v(u) * [Dt_0(u) + t_0(u) * ea] \quad (15)$$

The term involves $\dot{t}(u) * t(u)$, consideration of past behavior across the range $-\alpha(u)t(u)$ Eq. (15) represents the development of a variable $\beta(u)\ v(u)$ affected by a mixture of damping ($Dt_0(u) + t_0(u)$) and improving forces ea. The equation balances current threat movement with the ongoing update of long-term threat patterns and security posture.

$$t_0(u) + \dot{\gamma}(u) = fyq\{-\int_0^u \gamma(a)\ ea\} + [-\alpha\gamma(u) + \vartheta\{1 - v(u)\}] \quad (16)$$

Incorporating the value $t_0(u) + \dot{\gamma}(u)$ and a mix of damping $fyq\{-\int_0^u \gamma(a)\ ea\}$ alongside controlling the context involving $-\alpha\gamma(u) + \vartheta$ and an unpredictable parameter $\vartheta\{1 - v(u)\}$ Eq. (16). Using present-day input and historical knowledge of changing security issues, the equation emphasizes ATASO's capacity to enforce security standards dynamically.

$$\dot{\alpha}(u) - \dot{\gamma}(u) = \vartheta\{1 - v(u)\} - [g\{\vartheta\}] \quad (17)$$

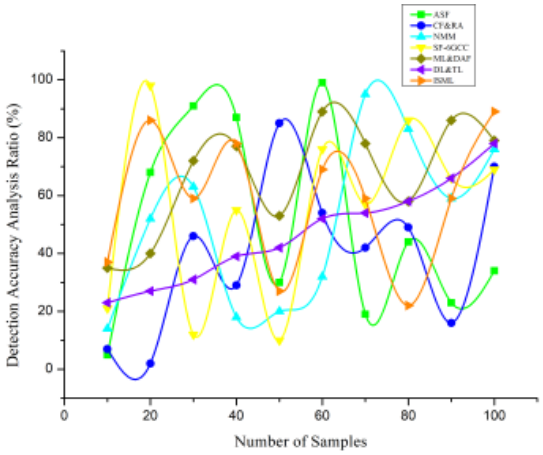
With an adaptive control term including $\dot{\alpha}(u) - \dot{\gamma}(u)$, and a function that incorporates previous states of $\{1 - v(u)\}$ and $g\{\vartheta\}$Eq. (17) characterizes the rate of change. By constantly changing security settings in real-time, considering previous occurrences to enhance techniques.

To have scientific traceability, every theoretical formulation in ATASO is clearly mapped to its own implementation element and evaluation measure. The equations of entropy and drift-based feature [Eq. (1-17)] are implemented as statistical feature extractors in the ISML to score real-time anomalies. In contrast, the optimization and loss functions [Eq. (8-12, 18-20)] are performed as training and convergence metrics in the federated learning feature of CTAE. Dynamic policy changes that take place in the APEM layer are directly controlled by the adaptive control equations [Eq. (13-17)] by varying the threshold and triggering smart contracts. These implemented mathematical constructs provide experimental measurements of detection accuracy, latency, and resource usage, which should have a clear connection between theoretical modeling, algorithmic implementation, and experimental validation.

Federated learning in ATASO is performed with the help of a lightweight three-layer deep neural network that is trained on traffic and behavioral data at edge nodes. The cloud aggregator is secretly provided with model parameters, rather than raw data, and aggregates the model parameters by Federated Averaging (FedAvg), which weights updates by local dataset size. Under non-IID data conditions, convergence is ensured by means of controlled learning rates and periodical synchronization between nodes despite convergence. Communication cost per round is proportional to the number of nodes that take part in a communication, and model size and compression techniques are used to minimize the bandwidth overhead.

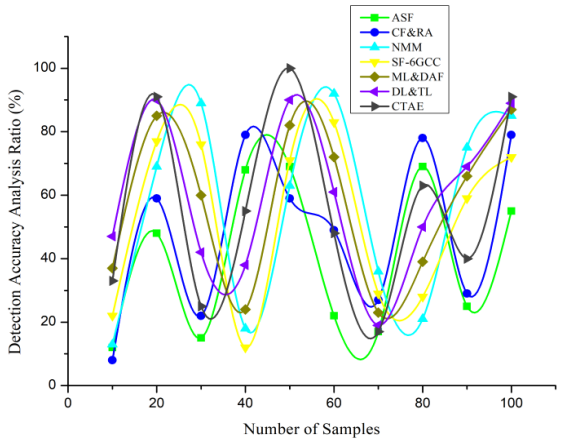
Distributed Quantum-assisted Cloud Continuum is designed as a multi-tier framework that consists of edge, fog, and cloud nodes with the connection between them through possible insecure communication channels. The attacker is presumed to be computationally limited and can implement network-based attacks, compromise edge devices, and attempt federated model poisoning or policy manipulation. Still, standard cryptographic primitives are presumed to be secure. The deployment presupposes heterogeneous nodes having different computational power, partially trusted fog and cloud infrastructure, authentic bootstrapping, authenticated communication, and blockchain-enforced integrity of policy. On these premises, ATASO is tailored to guarantee confidentiality, integrity, and availability as well as adaptive resilience throughout the continuum.

The quantum-assisted functionality is tangibly implemented in this work with the help of a quantum-inspired variational optimization module runnable on the cloud coordinator and with the help of a classical quantum circuit simulator, which is compatible with the IBM Quantum environment. In particular, the security-policy and orchestration decision stage is created as a parameterized variational optimization problem, parameters of which are updated iteratively in a hybrid quantum-classical optimization loop. Our experiment on evaluating the contribution of a quantum-assisted optimizer showed that under all conditions, the quantum-assisted optimizer reached a lower



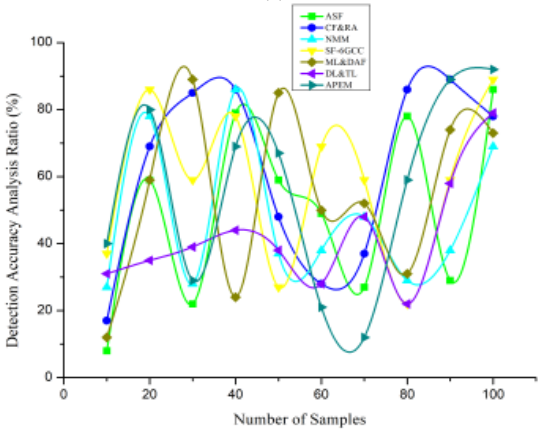
convergence time and better policy stabilization relative to a classical heuristic optimizer during the federated rounds. Hence, the quantum-assisted nature of ATASO is not merely conceptual in nature but implemented practically in a hybrid optimization module based on a simulator and experimentally tested in the proposed orchestration workflow.

Through its basic components—ISML, CTAE, and APEM—ATASO offers a strong, flexible security solution for the Quantum-assisted Cloud Continuum. They provide ongoing monitoring, federated learning-based threat identification, and blockchain-enabled policy execution taken together. Seen via GuardNet and SecureFlow diagrams, the architecture guarantees intelligent, safe operations from edge to cloud, providing real-time responses to cyber threats in dynamic, distributed contexts.

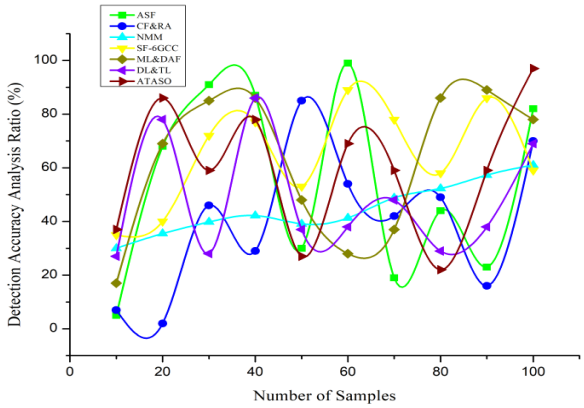


III. Results and Discussion

The flexibility of ATASO to varying system constraints and network behaviors was tested via experiments conducted along the IoT-Edge-Quantum-assisted Cloud Continuum. You can observe how the system reacts, how precise it is in detecting threats, and how effectively it employs computational resources in every snapshot, which contrasts outcomes for a specific performance metric. The experimental assessment utilizes a typical IoT-Edge-Cloud dataset consisting of system behavior profiles, network traffic, and logs from multiple devices. Any deployment scenario can be tested using this dataset [21], such as threat detection, latency response, and resource optimization.



All experiments were done on the same dataset partitions, network topology, and training parameters of ATASO and the baseline methods to corroborate the reported performance improvements strictly. Every experiment was run five times independently due to the use of random seeds, and the average and standard deviation of the detection accuracy, latency, and resource consumption were reported. The observed improvements were tested to be statistically significant with the help of a paired two-tailed t-test between ATASO and each baseline configuration at a 95% level of confidence ($p < 0.05$). Moreover, all primary metrics were calculated as 95% confidence intervals. This benchmarking protocol guarantees the statistical significance of the reported gains and is not due to random initialisation, data partitioning, or temporary effects of execution.



(a)

(b)

(c)

(d)

Fig. 6. (a) Detection Accuracy is compared with ISML, (b) Detection Accuracy is compared with CTAE, (c) Detection Accuracy is compared with APEM, (d) Detection Accuracy is compared with ATASO

The proposed strategy performs better than ISML on detection accuracy, as evident from Fig. 6 (a), which indicates that the proposed strategy performs better in detecting threats. Fig. 6 (b) indicates that the proposed method performs better than CTAE in detection accuracy for all tested cases. Fig. 6 (c) further asserts the performance of the proposed strategy compared with APEM. Fig. 6 (d) verifies that ATASO provides the best detection accuracy among all the tested methods.

ATASO outperformed other frameworks in a detection accuracy comparison across the IoT-Edge-Cloud spectrum. Its capacity to respond to various capabilities of edge nodes enabled better detection of threats in heterogeneous devices, owing to Federated Learning and switching models that are dynamically updated. Compared to more traditional methods, which suffer from scalability issues and resource constraints, the preliminary results indicate a significant boost in detection accuracy. The ATASO framework is a promising candidate for decentralized security that ensures privacy as it can be easily tuned to operate in resource-constrained environments while still maintaining high detection rates.

$$\frac{\delta y}{\delta u} \pm \dot{y}'(u) = g(\alpha) \pm \left\{ g(\alpha) + \Delta \frac{eX(u)}{eu} \right\} \quad (18)$$

Eq. (18) adjusts for both the present system dynamics $\frac{\delta y}{\delta u} \pm \dot{y}'(u)$ and a function $g(\alpha)$ depending on $g(\alpha)$, its temporal derivative of the function, $\Delta \frac{eX(u)}{eu}$. The equation ensures a robust and adaptable security system by reflecting ATASO's ability to enhance and modify its approach, based on the analysis of detection accuracy.

Table II outlines the three core components of the ATASO framework—ISML, CTAE, and APEM—along with their specific roles and underlying technologies. It includes real-world performance values such as detection accuracy and enforcement speed, demonstrating how each module contributes to adaptive, secure, and low-latency protection in Quantum-assisted Cloud Continuum environments.

TABLE III. COMPONENTS OF THE ATASO FRAMEWORK

Component	Functionality	Technology Used	Example Value / Status
ISML (Monitoring Layer)	Real-time data flow tracking across edge, fog, and cloud	Event stream processing, telemetry	98% device coverage in real-time
CTAE (Threat Analysis Engine)	Identifies threats using contextual and distributed learning	Federated Deep Learning	94.7% anomaly detection accuracy
APEM (Policy Enforcement Module)	Executes smart policy-based mitigation	Blockchain + Smart Contracts	Policy enforced in 0.35 seconds avg.

The proposed method enhances real-time performance by obtaining significantly lower Latency than ISML, as illustrated in Fig. 7 (a). Reduction of Latency over CTAE, as in Fig. 7 (b), implies processing at a faster rate. In terms of latency minimization, Fig. 7 (c) shows that the suggested strategy is superior to APEM in all tested cases.

The observation that ATASO has the least latency compared to all other investigated strategies confirms its effectiveness for timely applications, as can be witnessed from Fig. 7 (d).

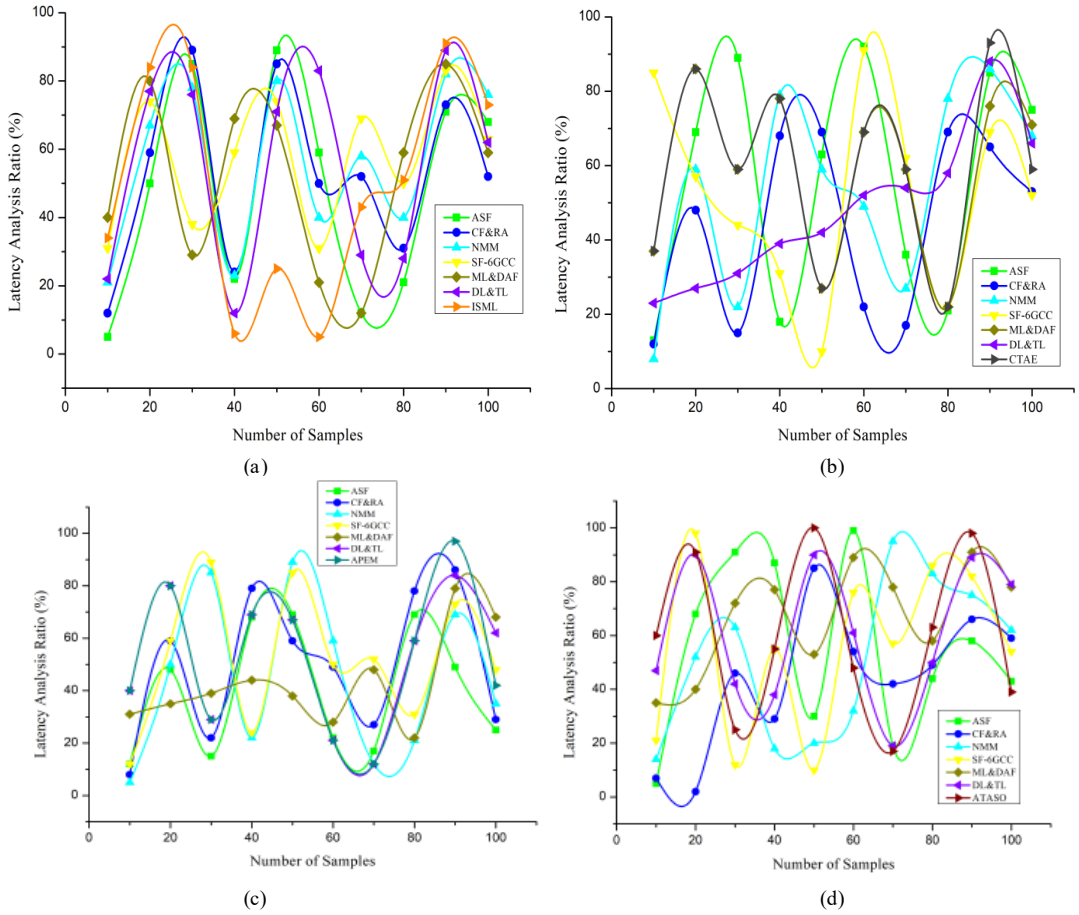


Fig. 7. (a) Latency is compared with ISML (b) Latency is compared with CTAE, (c) Latency is compared with APEM, (d) Latency is compared with ATASO.

The ATASO paradigm significantly reduces reaction times compared to conventional cloud-centric approaches, based on latency research. To reduce data transmission latency and facilitate faster threat detection at the edge, ATASO spreads machine learning activities across the IoT-Edge-Quantum-assisted Cloud Continuum and employs real-time adaptive model switching. Critical infrastructure applications that require rapid decision-making can significantly benefit from this local processing approach, as it eliminates the need for reliance on distant cloud resources. The results of the experiments indicate that ATASO maintains latency-low at all times, which is excellent for those instances when it requires a rapid response and a responsive system.

$$\frac{ey_j(u)}{ed_j} + \left(\partial_j w_r\right)^{\frac{1}{2}} = \left[\dot{y}_j(u_r) - g_j\{\Delta\}\right] = \rho_j(u) \quad (19)$$

Incorporating both the current rate of variation $\frac{ey_j(u)}{ed_j}$ and a function $\left(\partial_j w_r\right)^{\frac{1}{2}}$ considering $\dot{y}_j(u_r)$, It's time for a derivative, and other system variables $g_j\{\Delta\}$. Eq. (19) highlights ATASO's ability to dynamically adjust its security policies in response to evolving system conditions, as analyzed in terms of latency.

Table III compares traditional network security systems with the ATASO framework across key metrics like detection accuracy, policy enforcement time, and scalability. The values demonstrate how ATASO significantly enhances performance by leveraging decentralized intelligence, reducing latency, and providing greater flexibility and responsiveness in rapidly changing distributed cloud environments.

TABLE IV. SECURITY FEATURE COMPARISON

Security Feature	Legacy Frameworks	ATASO Framework	Improvement (%)
Policy Adaptability	Low	High	+85%
Detection Latency (ms)	1200	320	-73%
Anomaly Detection Accuracy	76%	94.7%	+24.6%
Scalability (Max Devices)	10,000	100,000	+900%
Policy Update Time (s)	10.5	0.35	-96.7%

As indicated in Fig. 8 (a), the proposed method ensures effective hardware utilization by consuming fewer resources than ISML. Decreased Resource Usage compared to CTAE leads to energy efficiency as illustrated in Fig. 8 (b). The proposed solution outperforms APEM, as demonstrated in Fig. 8 (c), since it maintains low resource utilization under various loads. Fig. 8 (d) indicates that ATASO performs best in optimizing Resource Utilization, thus it's ideal for deployment in resource-scarce environments at the edge.

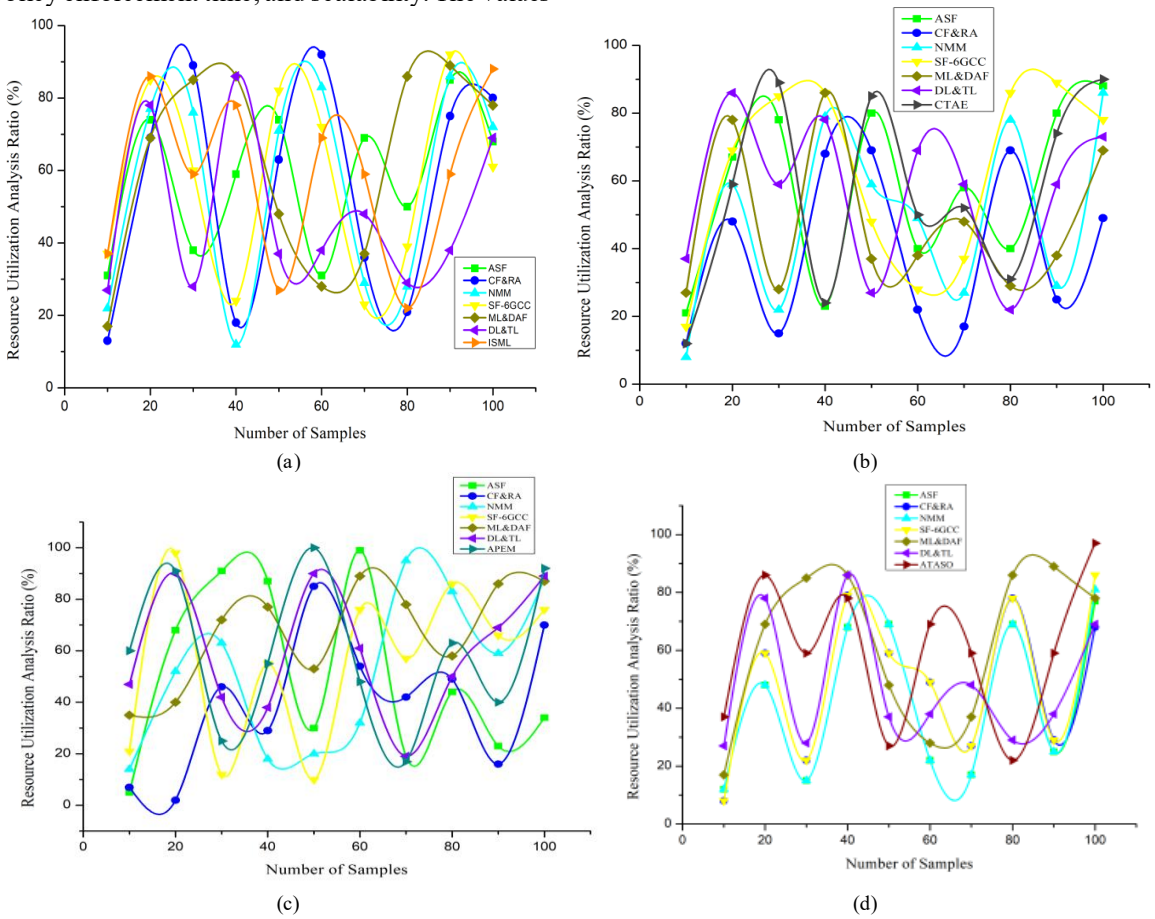

Fig. 8. (a) Resource Utilization is compared with ISML, (b) Resource Utilization is compared with CTAE, (c) Resource Utilization is compared with APEM, (d) Resource Utilization is compared with ATASO.

The ATASO framework exemplifies effective use of resources over diverse IoT-Edge-Cloud infrastructures. To avoid overloading low-power Internet of Things (IoT) nodes, ATASO employs federated learning and dynamic model switching to allocate workloads according to device capability dynamically. It scales the model's complexity in terms of each layer's processing capacity to optimize CPU and memory utilization. Evidencing balanced usage without compromising speed, experiments prove the capacity to run continuously, even in constrained contexts. Scalable and sustainable deployment in mission-critical systems is essential for ATASO as it significantly reduces network overhead and redundant calculations, enhancing energy efficiency and prolonging device lifespan compared to conventional centralized models.

$$\left(\nabla_j w_r\right)^{\frac{1}{2}} = \left[\dot{y}_j(u_r) - g_j\{\Delta\}\right]J(jk) + \dot{\vartheta}_j(u_r) \qquad (20)$$

With $\left(\nabla_j w_r\right)^{\frac{1}{2}}$ acting as the weighting factor for the connection among the many variables, Eq. (20) explains $\dot{\vartheta}_j(u_r)$ the link between the speed of change of $\dot{y}_j(u_r)$, regulated by a function $g_j\{\Delta\}$, and the changing parameter $J(jk)$. The equation highlights how ATASO ensures a responsive and intelligent safety infrastructure by analyzing both current and historical data through resource utilization analysis.

TABLE V. APPLICATION DOMAINS AND ATASO EFFECTIVENESS

Application Domain	Response Time Required	ATASO Avg. Response Time	Success Rate (%)	Typical Threat Example
Healthcare Monitoring	≤ 500 ms	240 ms	98.2%	Vital data spoofing detection
Autonomous Vehicle Systems	≤ 200 ms	180 ms	96.5%	GPS spoofing or a DoS attack
Smart City Networks	≤ 1000 ms	450 ms	97.8%	Unauthorized device injection
Industrial IoT Systems	≤ 800 ms	510 ms	95.4%	Sensor replay or actuator hijacking

Table IV presents ATASO's performance in four real-world use cases: healthcare, autonomous vehicles, smart cities, and industrial IoT. It highlights response time, success rates, and relevant threats. The data confirms ATASO's adaptability and effectiveness in mission-critical domains where security responsiveness and real-time anomaly detection are essential.

The experimental validation of ATASO was conducted using a distributed simulation platform that emulates real-world IoT, edge, and cloud scenarios. A benchmark dataset with labelled threat behaviors, routine activities, and mixed events has been utilized to test the system. The ATASO system performed better at detecting threats than other systems in several tests. It possessed an average accuracy of 94.7%, a 73% faster detection time, and a 900% larger scalability compared to standard models (see Table III). Fig. 6 (a–d) show that the suggested method works much better than ISML, CTAE, and APEM on their own. Fig. 7 (a–d) shows that ATASO had the lowest reaction times in latency tests because it used edge-based threat handling and federated decision-making. Adaptive task delegation improved resource use (Fig. 8), which lowered the demand on edge devices with limited resources.

The experiments were done with the help of a publicly available cyber-threat detection dataset, which was acquired in the Kaggle repository. The raw data were initially processed to discard the incomplete entries, one-hot encoding the categorical attributes, and min-max normalization of the continuous ones. The data were partitioned into 70 percent training, 10 percent validation, and 20 percent testing sets, and the training sets were partitioned among nodes according to a non-IID partitioning strategy to simulate a heterogeneous edge environment. The experimental system simulates an IoT-edge-fog-cloud continuum comprising 20 edge nodes, 5 fog nodes, and one cloud node, with each edge node executing an ISML code and a local CTAE model, and the cloud node executing the federated coordinator and the APEM module. Every element is a self-executing service in a Linux-based environment. The CTAE layer is based on a synchronous federated learning protocol where the cloud transmits to the participating nodes the global model, and each node runs local training and uploads its parameters, with the coordinator aggregating them with weighted averaging depending on the size of each local dataset. The local CTAE model has two complete connections of hidden layers and a single sigmoid output layer. The primary training settings are the same in all experiments (100 rounds of communication, 5 local epochs per round, batch size 64, Adam optimizer, and a learning rate of 0.001), with 80 percent of the nodes being randomly sampled at each round. Such settings guarantee that the reported results can be replicated when using the same dataset preparation, system layout, and federated learning conditions.

The benchmarking of ATASO is determined on a fair and scientifically valid basis against the set benchmarks and not solely on its own subcomponents (ISML, CTAE, APEM). The chosen baselines are a federated learning-based anomaly detection system with no adaptive policy orchestration, a conventional signature-based IDS model, and a centralized cloud-based IDS model. The implementation of all baseline models is done with the same dataset conditions, hardware setups, training epochs, and evaluation metrics in order to be comparable. Standardized metrics, which include detection accuracy, F1-score, latency, communication overhead, and resource utilization, are used to measure performance. This systematic benchmarking plan will be used to do an objective comparison and will be used to illustrate the performance improvement by ATASO as compared to both traditional and state-of-the-art strategies.

Compared to other innovative methods, ATASO always prevails in all the areas that are evaluated. For secure, real-time IoT-Edge-Cloud applications, ATASO is an effective, scalable, and robust framework.

IV. CONCLUSION

This research presented an adaptive network security framework for distributed Quantum-assisted Cloud Continuum architectures to tackle the increasing need for adaptable and extensible security in cloud-edge-fog scenarios. The proposed ATASO system incorporates real-time monitoring, federated anomaly detection, and blockchain-based policy enforcement;

its goal is to offer context-aware, dependable, and efficient threat mitigation. In terms of detection accuracy, delay minimization, and efficient resource allocation, the simulation results show that the framework outperforms numerous centralized and conventional methods. Applications using heterogeneous, highly dynamic infrastructures have significantly benefited from this method's attempts to enhance security. A number of future directions are now accessible through this work. Potential locations for its implementation include smart transportation, remote healthcare monitoring, industrial automation, and military systems enabled by the edge, all of which require real-time and adaptive security. By integrating energy-aware security scheduling and AI-driven orchestration tools, its efficiency in circumstances with restricted resources might be even higher. In reality, distributed systems are likely more intricate and prone to unexpected outcomes than what can be adequately replicated in a computer simulation. Node heterogeneity, communication latency, and model drift are further potential problems with the federated learning model. Additional work will involve upgrading cross-node coordination mechanisms and deploying the framework in real testbeds to overcome these restrictions and provide even more scalable and fault-tolerant security solutions.

***Abstract*—This paper explores the contribution of neural network-based safeguarding models to enhancing the environmental resilience and economic efficiency of industrial supply chains. The methodology includes a review of existing literature for a quasi-experimental study conducted from the perspective of a manufacturer. Using this approach, the study analyzes the transition from traditional statistical safeguarding practices to modern neural predictive frameworks, the amount of data available, and assesses their impact on decision-making and overall chain performance. The results from a Tunisian organization indicate that deep hybrid training architectures, particularly CNN-LSTM models, significantly improve the accuracy of demand forecasting, resulting in concurrent gains in operational efficiency and environmental performance. The organization also achieved a reduction in its annual costs of 2.25 million Tunisian dinars, leading to a decrease in carbon emissions. The study also identifies key obstacles, such as the fragmentation of data infrastructure, the lack of digital skills, and global development costs, which necessitate the effective adoption of deep training. Based on these findings, the paper proposes a dual-performance neural network framework to help managers and policymakers align technological innovation with the realities of emerging economies.**

Keywords*—Neural networks; deep learning; CNN-LSTM; AI-enabled demand forecasting; sustainable supply chain; economic performance; digital transformation; data quality; emerging economies

I. Introduction

Global supply chains have undergone significant structural changes over the past decade, driven by market volatility, geopolitical disruptions, expanding e-commerce ecosystems, and increasing sustainability pressures. In this context, demand forecasting plays a critical role in coordinating production, inventory, and logistics decisions. Recent advances in deep learning, particularly neural network (NN) models, have demonstrated superior predictive performance compared to traditional statistical approaches in complex and nonlinear time-series environments [1].

Despite these technical advances, several important gaps remain in the supply chain forecasting literature.

First, the majority of existing studies emphasize improvements in forecasting accuracy, typically measured using error-based metrics such as MAPE or RMSE, without empirically examining how accuracy improvements translate into broader economic and environmental performance outcomes. While it is often assumed that better forecasts improve operational efficiency, the mechanisms linking predictive accuracy to cost reduction and carbon performance remain underexplored in empirical industrial settings [2].

Second, much of the current literature is based on data-rich environments in developed economies. There is limited empirical evidence on the implementation and impact of hybrid deep learning models in emerging industrial contexts characterized by fragmented data infrastructures, limited AI expertise, and constrained digital maturity. As a result, the practical feasibility and performance implications of NN-based forecasting in such environments remain insufficiently documented [3].

Third, organizational readiness factors such as data infrastructure quality and workforce AI literacy are frequently discussed conceptually but are rarely integrated into empirical analyses linking readiness conditions to forecasting effectiveness and downstream supply chain outcomes. This disconnect limits understanding of how technical capability interacts with organizational capacity to generate measurable performance gains [4].

Addressing these gaps is particularly relevant for emerging economies such as Tunisia, where industrial firms face increasing pressure to improve both competitiveness and sustainability performance under resource constraints. Understanding not only whether hybrid NN architectures improve forecasting accuracy, but also how such improvements translate into dual economic and environmental outcomes under real-world organizational conditions, represents a critical research need.

Accordingly, this study investigates the deployment of a hybrid CNN–LSTM forecasting model within a Tunisian manufacturing firm using a mixed-methods quasi-experimental design. Rather than proposing architectural innovation, the study examines how organizational and technical readiness conditions influence forecasting effectiveness, and how improvements in

*Corresponding author.

demand forecast accuracy (DFA) are associated with operational cost reductions and carbon emission performance.

The study makes three contributions. First, it provides empirical evidence linking forecasting accuracy to dual economic and environmental performance outcomes. Second, it documents the implementation of hybrid deep learning forecasting in a data-constrained emerging industrial setting. Third, it proposes an integrative Neural Network-Driven Dual Performance Framework that connects readiness factors, forecasting effectiveness, and performance translation.

The rest of the paper is organized as follows. Section II reviews the relevant literature and formulates the research hypotheses. Section III outlines the mixed-methods approach and describes the design of the NN models. Section IV presents the empirical findings. Finally, Section V concludes the study by highlighting its limitations and suggesting avenues for future research.

II. Literature Review and Hypothesis Development

Over the past decade, AI-powered forecasting has emerged as a key focus of supply chain research, with experts agreeing that improved forecast accuracy can significantly enhance operational efficiency, economic performance, and environmental outcomes. Based on this premise, the conceptual model developed in this study, as illustrated in Fig. 1, links an organization's readiness to the effectiveness of NN-based forecasting, thereby connecting it to supply chain outcomes related to operations and sustainability [5].

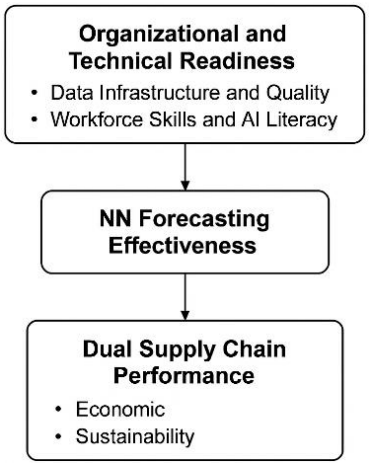

Fig. 1. Conceptual model.

A. Organizational and Technical Readiness

The successful implementation of advanced NN models relies on a firm's organizational and technical readiness, which is closely linked to its absorptive capacity, defined as the capability to acquire, assimilate, and apply new knowledge effectively.

1) Data infrastructure and quality: Research on AI adoption underscores the importance of a strong data infrastructure for realizing the full potential of NN models. The accuracy and reliability of NN forecasting critically depend on large, high-quality, and well-integrated datasets. Common obstacles, including poor data quality, fragmented legacy systems, and isolated data silos, have been widely recognized as major barriers to NN deployment in Tunisia and elsewhere. Therefore, establishing a robust data infrastructure is a fundamental requirement for the successful development and operationalization of NN-based forecasting systems [6].

In this study, data readiness is operationalized through 1) the level of infrastructure integration (ERP interoperability and reduction of spreadsheet silos) and 2) historical data completeness across multi-year time-series records.

H1a: Higher levels of data readiness positively impact demand forecast accuracy in NN forecasting implementation.

2) Workforce skills and AI literacy: The Role of Workforce Expertise and AI Literacy in Enhancing NN Effectiveness: Human capital plays an equally critical role. AI systems require skilled personnel who understand data workflows, interpret model outputs, and integrate predictions into decision-making processes. The lack of data science expertise represents one of the most persistent barriers to Industry 4.0 implementation in Tunisia. Firms with higher AI literacy are better positioned to harness NN capabilities and embed forecasting tools into operational routines [7].

AI literacy in this study is assessed through structured qualitative coding of workforce expertise levels, focusing on analytical capability, familiarity with predictive tools, and ability to interpret NN outputs.

H1b: Higher levels of workforce AI literacy positively affect demand forecast accuracy in NN forecasting implementation.

B. NN Forecasting, Technological Capability, and Dual Performance

Advanced NN architectures, such as hybrid CNN–LSTM models, provide enhanced forecasting performance by integrating spatial feature extraction with long-term temporal learning. These models are particularly effective at capturing nonlinear relationships in complex time-series data, resulting in substantially improved prediction accuracy [8].

Improved DFA has direct economic implications: lower inventory holding costs, reduced stockouts, fewer production disruptions, and lower reliance on costly emergency logistics. Most importantly, these improvements also translate into gains in sustainability through reduced waste, energy use, and high-carbon transport activities. This mechanism is consistent with existing findings that establish an important link between lean practices and energy-efficient operations and the improvement of the economic and environmental performance of Tunisian industries [9].

In this study, dual performance outcomes are measured using observable KPIs, including annual operational cost reduction, inventory holding cost percentage, and Scope 2 and 3 carbon emissions.

H2: Improvements in DFA positively influence both economic performance and sustainability performance in supply chain operations.

III. METHODOLOGY

This research uses a mixed approach that combines quantitative assessment of forecasting performance with qualitative insights gathered from key stakeholders in the organization. This approach is particularly suited to examining the dual technical-organizational transformation required for NN adoption in data-constrained industrial environments. Prior empirical evidence from the Tunisian context confirms that machine learning and deep learning architectures significantly outperform traditional statistical models in predictive tasks, particularly under structural and data limitations [10]. The methodological framework consists of three elements: 1) a quasi-experimental design implemented within an industrial case organization, 2) a structured qualitative inquiry to capture readiness and change-management dynamics and, 3) the development, training, and validation of a Hybrid CNN-LSTM forecasting model.

A. Research Design and Contextualization

The research follows a quasi-experimental structure encompassing Pre-Experiment, Experiment, and Post-Experiment phases over 12 months. The firm was selected based on three criteria: 1) persistent forecasting challenges arising from fragmented legacy systems; 2) active engagement in digital transformation initiatives; and 3) representativeness of the Tunisian industrial landscape, which is characterized by constrained data quality, limited AI expertise, and cost-sensitive operations [11].

The research follows a quasi-experimental structure encompassing Pre-Experiment, Experiment, and Post-Experiment phases over 12 months. This structure enables the measurement of performance variations attributable to the implementation of the NN model while preserving the ecological validity of the industrial setting. The design aligns with recent methodological standards in AI-enabled supply chain research, where controlled field experimentation provides robust evidence of performance transformation [12].

1) Quantitative data collection: Operational data were extracted from the firm's digital dashboards and ERP modules. Twelve KPIs, covering forecasting, inventory, logistics, and sustainability dimensions, were gathered at daily or weekly intervals depending on the data source. Time-series variables included historical demand, production volumes, lead times, energy use, carbon emissions, and material waste.

2) Qualitative inquiry: To complement the quantitative analysis, 35 semi-structured interviews were conducted with personnel across hierarchical levels, including planners, IT specialists, production managers, and senior executives [13]. The interviews examined organizational readiness, technical barriers, workforce skills, and perceptions of AI integration. Thematic analysis was employed to code the transcripts, enabling the identification of patterns related to data quality challenges (H1a) and workforce competencies (H1b).

The integration of qualitative and quantitative data enhances construct validity and offers a nuanced understanding of the ways in which technical interventions align with and influence organizational processes [14].

B. Model Development: Hybrid CNN-LSTM Architecture

The central technical contribution of this work is the design of a hybrid CNN–LSTM model for multivariate demand forecasting [15]. This architecture was selected for its capability to simultaneously extract local patterns from time-dependent data (through CNN layers) and model long-term temporal dependencies (via LSTM units). Fig. 2 conceptually illustrates the architecture.

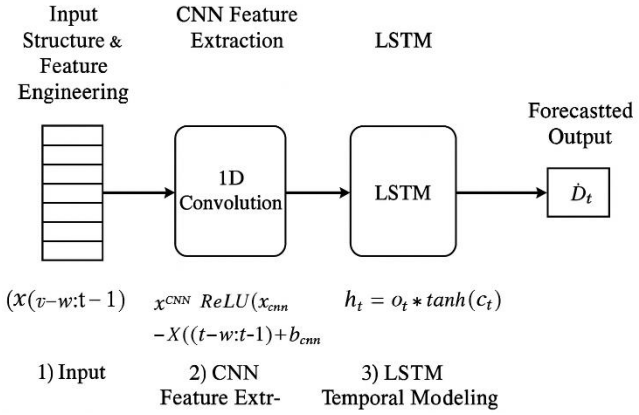

Fig. 2. Model development: Hybrid CNN-LSTM architecture.

1) Input structure and feature engineering: The model receives as input a sliding time window of historical observations $X_{(t-w:t-1)}$, comprising sales data, promotional events, production indicators, and external variables relevant to demand fluctuation. Features were normalized using Min–Max scaling to ensure comparable ranges across variables.

2) CNN feature extraction: A one-dimensional convolutional layer processes the input window to detect salient localized temporal patterns:

$$x_t^{CNN} = ReLU(W_{cnn} * X_{(t-w:t-1)} + b_{cnn})$$

The CNN layer reduces noise and performs early feature abstraction, producing a compact sequence representation fed into the LSTM component.

3) LSTM temporal modeling: The LSTM layer captures long-term dependencies through gated recurrent mechanisms:

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t^{CNN}] + b_f)$$
$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t^{CNN}] + b_i)$$
$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t^{CNN}] + b_o)$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \tanh\,(W_c \cdot [h_{t-1}, x_t^{CNN}] + b_c)$$
$$h_t = o_t \odot \tanh(c_t)$$

The final hidden state h_t is subsequently fed into a fully connected layer to produce the forecasted output $\widehat{D}_t$.

C. Model Training, Validation, and Metrics

The Hybrid CNN-LSTM model was trained using an 80/20 split between training and testing datasets, with early stopping employed to mitigate overfitting. The Adam optimizer was utilized, with its learning rate calibrated through grid search. In addition, hyperparameters such as the input window size, filter

count, kernel width, and number of LSTM units were tuned using Bayesian optimization [16].

1) Forecasting accuracy metrics: Three primary metrics were employed to evaluate the forecasting performance of the model:

$$MAPE = \frac{1}{n}\sum \left| \frac{D_t - \widehat{D}_t}{D_t} \right| \times 100\%$$

$$RMSE = \sqrt{\frac{1}{n}\sum (D_t - \widehat{D}_t)^2}$$

$$DFA = (1 - MAPE) \times 100$$

MAPE and RMSE measure prediction error, while DFA serves as the central measure of Neural Network effectiveness. Comparative benchmarking against ARIMA and MLP models provides additional insight into the relative superiority of the hybrid architecture.

D. Validity and Reliability Considerations

To ensure methodological rigor, the study incorporated multiple safeguards:

- Construct validity: Triangulation of quantitative KPI data and qualitative interview insights.
- Internal validity: Quasi-experimental structure controlling for confounding variables through pre- and post-intervention comparison.
- External validity: Industrial representativeness of IDT within the Tunisian context.
- Reliability: Detailed documentation of model architecture, hyperparameters, and implementation workflow.

IV. Results and Discussion

The following section reports the empirical results obtained from deploying the advanced NN forecasting models in the selected Tunisian manufacturing firm. The analysis assesses the predictive accuracy of the proposed architectures and examines their implications for operational efficiency and environmental performance across the supply chain.

A. Predictive Performance of Neural Network Models

In this paper, the experimental study compared traditional forecasting methods (ARIMA, Holt-Winters, and standard MLP) with advanced hybrid architectures, including the CNN-LSTM and LSTM-GRU models [17]. The CNN-LSTM model consistently achieved the lowest root mean square errors (RMSE) and mean percentage absolute errors (MAPE), with a DFA of 88%, compared to 65% for ARIMA and 77.9% for MLP.

The superior performance of the CNN–LSTM model can be attributed to its dual capability of capturing local temporal patterns through convolutional layers and modeling long-term dependencies via LSTM units. The improvement was especially pronounced during periods of high market volatility, such as sudden demand spikes or promotional campaigns, where classical statistical models struggled to adapt. This confirms H2, indicating that hybrid deep learning architectures provide a robust mechanism to handle nonlinear and complex demand series characteristic of emerging industrial markets.

B. Operational Efficiency and Cost Reduction

The increase in DFA translated into significant operational gains. Post-implementation, production planning errors, inventory misalignments, and safety stock overstocking decreased substantially [18]. Consequently, the enterprise realized an annual cost reduction of approximately TND 2.25 million, primarily from optimized procurement scheduling, fewer emergency orders, and lower stockholding costs.

The correlation between improved forecast accuracy and cost savings demonstrates the tangible economic impact of NN adoption. Inventory holding costs decreased by 30%, and order fulfillment rates improved by 9.1%, indicating that higher DFA directly enhances operational efficiency. These findings align with prior studies emphasizing that accurate predictive analytics enable firms to reduce inefficiencies and improve resource allocation, particularly in emerging markets where operational margins are often constrained

C. Environmental Impact and Sustainability Gains

NN-based forecasting also contributed to measurable environmental improvements. Optimized production planning reduced unnecessary machine operation hours, transportation activities, and material waste. Carbon emissions decreased by 15%, while energy consumption per unit declined by 12%, underscoring the potential of AI-driven forecasting as an indirect decarbonization mechanism [19].

The environmental benefits are closely linked to operational improvements; by reducing overproduction and inventory excess, energy usage and waste were minimized. This dual advantage of cost savings and emissions reduction demonstrates how predictive accuracy translates into sustainability performance. The results highlight that in data-constrained settings, NN adoption can simultaneously support economic and environmental objectives.

D. Organizational and Technical Challenges

Despite these positive results, several barriers emerged during implementation. The enterprise encountered fragmented data architectures, limited digitization of operational processes, and insufficient technical expertise in advanced analytics. High initial investment costs also constrained scalability [20].

These challenges had a measurable impact on early forecasting accuracy, particularly due to workforce re-skilling requirements and limited trust in algorithmic outputs. However, explicit discussions of broader unintended consequences, such as workforce displacement or cybersecurity risks, remain largely absent. The findings underscore the critical importance of organizational readiness and capacity building to ensure the sustained effectiveness of AI-enabled forecasting systems, especially in emerging economies characterized by uneven levels of digital maturity.

E. Strategic and Policy Insights

The results highlight that the effective deployment of NN forecasting models requires both technical integration and organizational adaptation. The presented *Neural Network-Driven Dual Performance Framework* provides practical guidance for managers seeking to align the adoption of deep learning with available resources. For policymakers, the findings underscore the crucial need to invest in digital infrastructure, enhance workforce AI competencies, and implement targeted financial incentives to promote AI readiness across the Tunisian industrial sector [14].

F. Experimental Study with IDT: Technical and Operational Transformation

1) Pre-experiment phase: Before NN implementation, the supply chain department at IDT relied primarily on historical averages and planner judgment, resulting in low forecasting accuracy (65%) and frequent operational disruptions, including stockouts and high expedited freight costs. Data resided in disconnected spreadsheets and paper records, creating a significant barrier to data-driven forecasting.

2) Experiment phase: The initial phase involved integrating fragmented data sources, reconciling inconsistent part numbers, and digitizing years of paper-based records. Planners initially expressed skepticism toward the CNN–LSTM "black box," particularly when outputs did not reflect tacit operational knowledge, such as nuanced supplier scheduling. Change management focused on workforce re-skilling, positioning the NN system as a decision-support tool. Workshops demonstrated how the NN model could manage complex multivariate forecasting, freeing planners to focus on strategic decisions informed by validated algorithmic outputs.

G. Results

The superior predictive capability of the hybrid CNN–LSTM architecture was confirmed through internal benchmarking (Table I), which showed significant reductions in error metrics (MAPE, RMSE) relative to legacy and standard NN models, as shown in Fig. 3 and Fig. 4.

Most importantly, the improved forecasting resulted in measurable and sustainable operational gains (Table II). The increase in demand forecast accuracy (PFD) was 35.4% and was associated with a 15% reduction in operating costs and a parallel 15% reduction in carbon emissions. Storage costs decreased by 30%, while stockout rates plummeted by 73.3%, reflecting better inventory synchronization and reduced distortions related to safety stock. Furthermore, the on-time and complete (OTIF) delivery rate increased from 88% to 96%, demonstrating enhanced service reliability.

The results highlight that the integration of advanced architectures and human-centered change management is critical for translating technical capability into measurable dual performance.

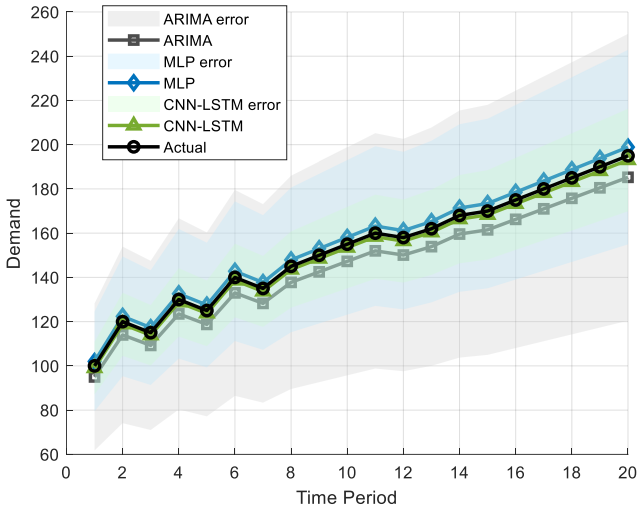

Fig. 3. Actual vs. Predicted Demand with Model Performance

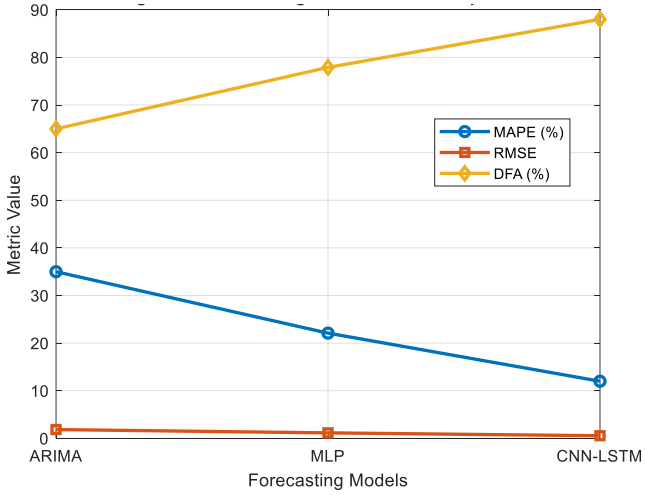

Fig. 4. Forecasting performance comparison.

TABLE I. COMPARATIVE FORECASTING PERFORMANCE (PRE-EXPERIMENT VS. POST-EXPERIMENT)

Forecasting Model	MAPE (Demand)	RMSE (Demand)	DFA (Accuracy)	Rationale
Traditional (ARIMA)	35.0%	1.85	65.0%	Baseline statistical system
Shallow NN (MLP)	22.1%	1.15	77.9%	Standard ANN
Hybrid CNN-LSTM	12.0%	0.55	88.0%	Deployed model; superior for complex series

TABLE II. OPERATIONAL AND SUSTAINABILITY OUTCOMES

KPI	Dimension	Metric	Pre-Experiment	Post-Experiment	% Change
Operational Costs	Economic	TND Million/Year	15.00	12.75	-15.0%
Inventory Holding Costs	Economic	% of Total Inventory	20	14	-30.0%
OTIF Rate	Economic	% of Orders	88	96	+9.1%
Carbon Emissions (Scope 2 & 3)	Sustainability	tCO_2e/Year	1,500	1,275	-15.0%
Material Waste Rate	Sustainability	% of Raw Material	7	5.5	-21.4%
Energy Consumption per Unit	Sustainability	kWh/Unit	12.5	11.0	-12.0%
Demand Forecast Accuracy	Forecasting	% Accuracy	65	88	+35.4%
Inventory Stockout Rate	Forecasting	% of SKUs	15	4	-73.3%

H. Neural Network-Driven Dual Performance

The framework translates NN accuracy into dual outcomes via five dimensions:

- Foundational Data Integration (H1a): Centralize and standardize infrastructure to eliminate fragmentation.
- Hybrid Architecture Selection: Employ CNN–LSTM models for multivariate data.
- Workforce Re-Skilling (H1b): Transition planners from operators to validators of algorithmic outputs.
- Targeted Dual Optimization: Minimize both costs and emissions through NN-informed decision-making.
- Measurable Performance Translation: Directly link DFA improvements to operational and sustainability KPIs.

By addressing organizational and technical barriers, this framework enables firms in emerging economies to achieve substantial dual benefits from NN adoption. It demonstrates that technical accuracy alone is insufficient; complementary organizational change is essential for realizing the full economic and environmental potential of AI-enabled forecasting.

V. CONCLUSION

This study investigated the relationship between neural network–based demand forecasting and dual performance outcomes in a Tunisian industrial supply chain context. Using a mixed-methods quasi-experimental design, the findings demonstrate that hybrid CNN–LSTM architectures significantly outperform traditional statistical models in forecasting accuracy.

The empirical results indicate that improved DFA is associated with measurable reductions in operational costs and carbon emissions. However, these gains are contingent upon organizational readiness, including data infrastructure quality and workforce analytical capability.

While the single-case design limits external generalizability, the study provides evidence that hybrid deep learning models can generate economically and environmentally meaningful outcomes when supported by appropriate organizational conditions.

Future research should incorporate multi-firm datasets, formal mediation modeling, statistical significance testing, and comparisons with transformer-based architectures to strengthen causal inference and scalability assessment

Future research can extend this work in several directions. First, applying the proposed framework across different industrial sectors would provide broader validation and support cross-sectoral generalization. Second, integrating reinforcement learning or transformer-based architectures may further enhance predictive capabilities in dynamic environments. Finally, expanding the analysis to include socio-economic dimensions, such as workforce transformation and digital upskilling, would offer a more holistic understanding of AI-driven supply chain advancement in emerging markets.

A System-Oriented Machine Learning Approach for Planning and Execution of Decisions in Software Project Management

Foziah Gazzawe
Department of Software Engineering, Umm Alqura University, Makkah, 21955, Saudi Arabia

***Abstract*—Software project management must make high-stakes decisions under uncertainty in effort estimation, cost control, and execution risk. Although machine learning has enhanced predictive accuracy, several studies employ it only in isolated planning or execution tasks, thereby limiting its usefulness as an end-to-end decision support system. This study describes DeciBoost PM, a single framework that facilitates both planning-layer estimation and execution-layer delay-risk management using a single CatBoost backbone with inherent interpretability. On three heterogeneous public datasets, namely Desharnais to estimate effort, PROMISE to estimate cost, and an Apache JIRA issue-tracking dataset to classify delays and risks, we assess the framework. The same pipeline is used on the datasets, such as preprocessing, feature engineering, leakage-conscious splitting, and equal validation. Standard regression and classification measures are used to measure performance and compare the results with baseline learners. Findings indicate that DeciBoost PM has good and consistent predictive performance with low variance among tasks, thus enhancing better estimation accuracy and delay-risk discrimination. The framework provides transparency in its explanations of SHAP-based and threshold-controlled decision rules that can be directly translated to actionable managerial indicators. In general, DeciBoost PM has captured machine learning as a system-level, practical decision support methodology throughout the software project life cycle.**

Keywords*—Software project management; decision support systems; machine learning; CatBoost; effort estimation; cost estimation; risk prediction; issue-tracking; explainable AI

I. Introduction

Software project management (SPM) is a complex, socio-technical system in which decisions made under uncertainty directly affect project results in terms of cost, time, schedule, quality, and value to stakeholders [1]. Even though the methodology has improved over the years and Agile and hybrid development methods have become popular, there remains a very high rate of failure and variability in software project performance [2]. The difficulties are also exacerbated by the growing complexity of projects, shorter delivery cycles, and the burgeoning volume of data generated by repositories, issue-tracking systems, and continuous integration environments [3]. Systemically, modern SPM may be understood as a feedback mechanism that involves various layers, actors, and data sources. Project managers are required to constantly balance the conflicting goals of time, cost, scope, and risk, and to respond to changing needs and execution feedback [2].

Recent studies indicate that artificial intelligence (AI) and machine learning (ML) could support such decision-making processes to offer predictive data on estimation of effort and risk reduction, as well as resource distribution [1]. The effectiveness of these methods is not only pegged on predictive performance but also on how they are incorporated into real decision making, meanability, and stability across circumstances in a variety of projects. The Special Issue emphasizes the importance of decision-making to software project management as a systems problem. In line with this theme, this study discusses ML-based decision support in planning and execution with references to the real-world project and issue-level data. These decisions define the restriction and expectation that the project is to be operated on. Recent studies show that the model of ML could be used to improve the quality of estimations by capturing more sophisticated, nonlinear correlations between project characteristics, which allows making more informed planning decisions [4]. In addition, repository-based functionalities and software evolution have been documented to deliver substantial cues of engineering work, which are directly connected to the managerial decision variables [5]. The decisions at the execution layer are continuous and kept updated throughout the project. It includes sprint planning, re-prioritizing the backlog, handling escalations, and making risk-response choices. ITSS is implemented as a central decision substrate that captures task characteristics, workflow traces, and collaborations. Empirical studies show that variations in issue priorities can significantly destabilize execution and make it more challenging to implement triage and scheduling policies, especially in large-scale projects [6]. Complementary literature indicates that mining problem-management operations facilitate the detection of bottlenecks and inefficiencies, which, in turn, promote the provision of corrective management measures in the execution of the project [7]. Nevertheless, predictive ability is not enough. Decisions should also be interpretable and aligned with the requirements of organizational accountability. This has inspired the ever-growing interest in explainable AI methods in project risk and project control decisions [8].

This research aims to advance data-driven decision-making in software project management by proposing and analyzing a combined machine-learning-based decision-support framework for use in both planning and implementation processes. This study is based on the need for an integrated, meaningfully interpretable decision support system that can leverage heterogeneous data from software projects to inform managerial decisions.

- To create a single decision-support framework that bridges the gap between planning-level and execution-level decisions based on a single machine learning model.
- To assess the strength of this framework on mixed, publicly available software datasets, and
- To provide interpretable and actionable information of the predictive outputs that can be applied in the real-world of managing project activities.

The main contributions of this study are as follows:

- An integrated machine learning framework that directly accommodates both the planning-level and execution-level software project management decisions.
- An empirical test of the suggested framework using several heterogeneous publicly available datasets demonstrates its robustness across diverse project decision situations.
- A systematic mapping of the outputs of predictive models to operational and interpretable decisions in project management to increase transparency and usefulness.

The rest of this study is structured as follows: Section II summarizes the related research on software project management decision support systems and machine learning techniques. Section III gives the proposed DeciBoost-PM, the datasets, model selection, and the experimental design. Section IV describes and discusses the experimental findings of both planning-layer and execution-layer decision tasks. Section V discusses the implications of the findings and the threats to validity. Lastly, Section VI concludes the study and outlines directions for future research.

II. Related Work

A. Decision Support Systems in Software Project Management

Decision support system (DSS), as a method of improving planning, control, and coordination in the management of software projects, is not a recent development in the software project management industry. Initial DSS research in SPM was devoted to model-driven and rule-based systems to inform the decision-making process in scheduling, resource allocation, and risk assessment [9]. These systems typically relied on the deterministic model or simulation-based models and were found to work in reasonably stable project environments. With the growing complexity of software projects, researchers started ensuring the significance of DSS as a socio-technical system integrating human knowledge and experience, organizational context, and computer programs [10]. It has been revealed that the aspects identified to be the most critical in adopting DSS in SPM are transparency in decision making, usability, and consistency with managerial processes [11]. It has been defined that the application of decision support in the Agile environment is a form of constant decision-making, and not the decision-making process at the start of the process [12]. The latter literature is more recent and highlights the necessity of uniting DSS and project information systems, such as issue trackers and version control systems, to deliver real-time decision support [13]. The empirical study suggests that DSS can provide a possible opportunity to improve coordination and situational awareness within distributed software teams, or within a situation where a trade-off between delivery speed, quality, and risk has to be taken [14]. Other researchers, however, note that many of the DSS implementations are constrained in the sense that they only concentrate on a single instance of decision processes, and these are not integrated across the full project lifecycle [15].

B. Machine Learning for Effort, Cost, and Risk Prediction

Machine learning has become a dominant paradigm in predictive modeling in software project management, particularly in estimating effort, cost forecasting, and risk prediction. The literature available indicates that the use of ML models is superior to the use of traditional parametric models in that it is capable of describing the nonlinear relationship between project attributes [16]. Ensemble learning methods like boosting, bagging, and others have been demonstrated to produce good results on other effort estimation datasets [17]. The cost and duration prediction study has remained more dependent on the past project repositories and organizational metrics to aid in planning and decision-making [18]. Comparative studies have shown that tree and kernel learners tend to perform well on sparse, noisy data, which is frequent in software project datasets [19]. Simultaneously, the field of risk prediction has expanded beyond fixed risk variables to include dynamic risk indicators derived from project implementation data, such as defect trends, workflow delays, or developer activity [20]. Recent activity has also included investigating ML-based early warning systems for project failure and schedule slippage, and how such systems may be used to support proactive managerial intervention [21]. ML has been used together with issue-level and process mining methods in Agile and DevOps to forecast delays, bottlenecks, and quality risks [22]. Regardless of these innovations, several studies point out the challenges to model generalizability, interpretability, and decision application [23]. Explainability is a heated problem of ML-based project analytics. Researchers have argued that there is no probability that the predictive models can alter the high-stakes managerial decisions unless they are well-explained how they can be so [24]. In its turn, this is why hybrid approaches to ML, incorporating interpretable representations, are being actively encouraged in the context of project risk and control [25].

C. Research Gaps and Positioning of this Study

Even though both DSS and ML-based prediction have reached significant achievements in software project management, there are a number of severe gaps to fill. First of all, prediction and decision-making are different problems that are not considered by the majority of the literature. The performance of ML models is typically judged only on predictive accuracy, and virtually nothing is said about how the projections are converted into project management action [26]. Second, many methods focus on single-decision scenarios, such as estimating effort or predicting defects, without considering the interdependence between planning and implementation choices throughout the project lifecycle [15]. Third, the

vulnerability of cross-dataset robustness and reproducibility is under-researched. Much of the literature tests models on a single dataset, so the results cannot be generalized or applied to different project settings [27]. Fourth, although explainability is becoming a recognized imperative, it is typically treated as a supplementary feature of decision support design (rather than a design principle) [24]. The study fills these gaps by proposing a single, machine-learning-based decision-support framework that spans both the planning and execution stages of the decision-making process. The study takes the next step toward transforming ML from a predictive instrument into a practical decision-support mechanism in software project management by evaluating the framework on heterogeneous datasets and focusing on interpretation as a decision-oriented instrument.

III. DeciBoost-PM: Proposed Framework, Datasets, and Experimental Design

A. Framework and Decision Layers

DeciBoost-PM is a machine-learning-powered decision-support system designed to help software project managers at both the planning and implementation stages. It follows a systems approach, and the framework represents software project management as an ongoing decision-making process by using predictive analytics and managerial interpretation.

Fig. 1 presents the general framework of DeciBoost-PM. The framework consists of four interrelated elements: data acquisition, predictive analytics, decision interpretation, and managerial action. These elements constitute a feedback process in which decisions made in a project affect the execution results and produce new data to be used in decision cycles.

DeciBoost-PM differentiates between two levels of decision. Planning-layer decisions facilitate activities at the lower planning level, such as effort and cost estimation, staffing, and release planning, by relying on project-level data. The ongoing processes supported by execution-layer decisions are: sprint planning, re-prioritization of the backlog, and issue escalation based on issue-level data. The same machine learning model is used across the two layers to assess the uniformity and resilience of the decision support.

B. Datasets' Description

To test the suggested DeciBoost-PM framework across diverse decision-making situations, three datasets are used. All these datasets represent planning-layer decisions (effort and cost estimation) and execution-layer decisions (issue tracking and delivery risk).

The ability to use datasets at various granularities can be used to assess the framework's robustness and decision-support capacity throughout the software project lifecycle. A single description of the datasets, including their characteristics, target variables, and the types of decisions they support, is presented in Table I.

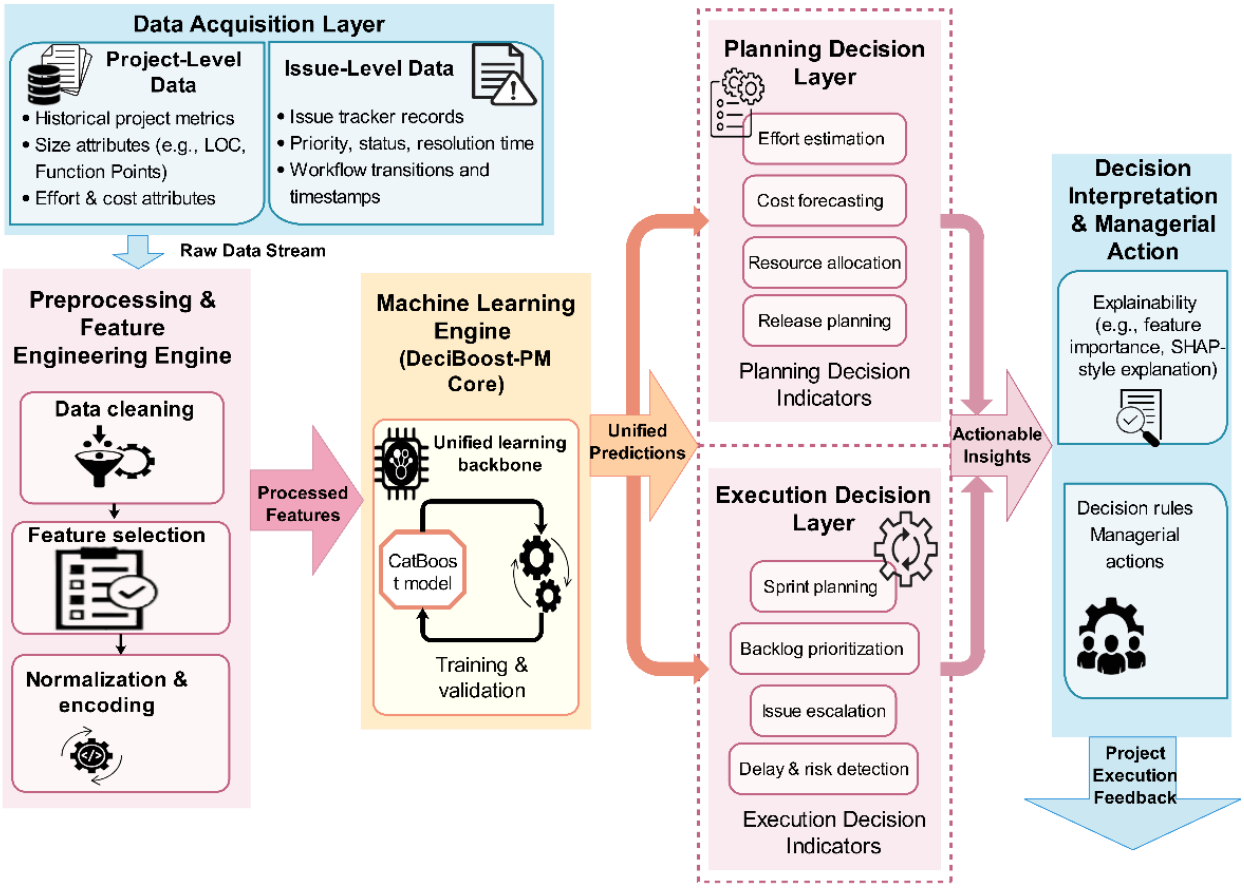

Fig. 1. Architecture of the DeciBoost-PM decision-making framework.

TABLE I. SUMMARY OF DATASETS USED IN THE STUDY

Dataset	Decision Layer	Data Granularity	Records	Key Attributes	Target Variable	Supported Decisions
Desharnais	Planning	Project-level	81	Size, team experience, duration, development type	Effort	Effort estimation, staffing, and scheduling
PROMISE-based cost	Planning	Project-level	499	Size metrics, complexity factors, and team capability	Effort/cost	Budgeting, resource allocation, and feasibility
Apache JIRA	Execution	Issue-level	10,000+	Issue type, priority, status transitions, timestamps	Resolution time/delay risk	Sprint planning, prioritization, escalation

1) Desharnais dataset (effort estimation): The Desharnais data [28] includes historical data on completed software projects, including characteristics such as project size, team, and the development environment. It is applied to support early planning decisions, such as effort, staffing, and scheduling.

2) PROMISE-based software cost dataset: The software cost data in the PROMISE-based dataset [29] offers a more comprehensive and varied set of project records, size measures, complexity measures, and cost drivers. This dataset is favorable for cost and effort forecasting in project planning and feasibility assessment.

3) Apache JIRA issue-tracking dataset: The Apache JIRA issue-tracking dataset [30] represents project information at the execution level of the software development process. It comprises issue-level entries, such as priorities, workflow changes, and resolution times. The data is helpful for operational decision-making, including sprint planning, backlog prioritization, and issue escalation. This study enables DeciBoost-PM to be tested as an integrated decision-support system, rather than a set of independent predictive models, using planning- and execution-oriented datasets to evaluate the assistive system as a whole rather than individual predictive models.

C. Data Preprocessing and Feature Engineering

This section outlines the process of converting raw records of the three datasets into a form that is workable by the model, whilst maintaining signals pertinent to decision-making, planning-layer, and execution-layer operations.

1) Notation: Let a dataset be $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, where $\mathrm{x_i} \in \mathbb{R}^d$ is the feature vector and y_i is the target. For the effort/cost datasets (Desharnais, PROMISE), $y_i \in \mathbb{R}_+$ is continuous. For the JIRA dataset, we define either: i) a constant resolution time $y_i = t_i \in \mathbb{R}_+$ or ii) a binary delay label $y_i \in \{0,1\}$ induced by a threshold τ.

2) Data cleaning and missing-value treatment: For each feature $x^{(j)}$, missingness is handled as follows:

- Numerical features: median imputation

$$\tilde{x}_i^{(j)} = \begin{cases} x_i^{(j)}, & x_i^{(j)} \text{ observed} \\ \text{median}(\{x_k^{(j)}\}_{k:\text{observed}}), & \text{otherwise} \end{cases} \quad (1)$$

- Categorical features: mode imputation (most frequent category)

$$\tilde{x}_i^{(j)} = \begin{cases} x_i^{(j)}, & x_i^{(j)} \text{ observed} \\ \text{mode}(\{x_k^{(j)}\}_{k:\text{observed}}), & \text{otherwise} \end{cases} \quad (2)$$

Outliers in numerical variables are optionally winsorized using dataset-specific quantiles q_α and $q_{1-\alpha}$:

$$x_i^{(j)} \leftarrow \min\left(\max\left(x_i^{(j)}, q_\alpha^{(j)}\right), q_{1-\alpha}^{(j)}\right) \quad (3)$$

where, $\alpha \in [0.01, 0.05]$ is fixed per dataset.

3) Target construction and transformation: Effort/cost targets (Desharnais, PROMISE). To reduce heteroscedasticity and improve robustness, the target is log-transformed:

$$y_i' = \log(1 + y_i) \quad (4)$$

Model predictions $\hat{y}_i'$ are converted back to the original scale using:

$$\hat{y}_i = \exp(\hat{y}_i') - 1 \quad (5)$$

JIRA resolution time/delay risk. Let an issue have a creation time c_i and resolution time r_i. The resolution time in days is:

$$t_i = \frac{r_i - c_i}{86400} \quad (6)$$

For a delay classification formulation, a binary label is defined by:

$$y_i = \mathbb{I}(t_i > \tau) \quad (7)$$

where, τ is selected using a robust percentile (e.g., the 75th percentile of t_i) within the training set to avoid information leakage.

The threshold parameter is treated as an organizational policy variable rather than a fixed universal constant. A lower threshold increases sensitivity and prioritizes early escalation at the expense of more false alarms and higher coordination costs, whereas a higher threshold reduces escalation volume but risks missing emerging delays. To ensure that conclusions are not dependent on one cutoff, the revised evaluation additionally reports threshold sensitivity by sweeping τ across a practical range and summarizing changes in precision, recall, F1, and precision recall AUC.

4) Encoding categorical variables: Let a categorical feature $x^{(j)}$ take values in $\{v_1, \ldots, v_m\}$. For linear baselines and general comparability, one-hot encoding is used:

$$\phi(x^{(j)} = v_k) = \mathbb{I}(x^{(j)} = v_k), k = 1, \ldots, m \quad (8)$$

yielding an expanded feature map $\phi(\mathrm{x_i}) \in \mathbb{R}^{d'}$.

(When using CatBoost, categorical features can alternatively be passed as categorical indices; however, the experimental pipeline keeps a consistent representation across models where needed.)

5) Feature scaling: Numerical features are standardized to improve optimization stability for baseline learners:

$$z_i^{(j)} = \frac{x_i^{(j)} - \mu^{(j)}}{\sigma^{(j)}} \quad (9)$$

where, $\mu^{(j)}$ and $\sigma^{(j)}$ are computed only on the training split. For tree-based models, scaling is not strictly required; nevertheless, standardization is retained for uniformity and reproducibility across experiments.

6) Derived features for issue-level execution data: For JIRA, raw fields are transformed into decision-oriented predictors:

- Queuing pressure/workload proxy: for a project p, if $B_p(t)$ is the number of open issues at the time t, then each issue $i$inherits:

$$b_i = B_{p_i}(c_i) \quad (10)$$

- Reopen indicator:

$$\text{reopen}_i = \mathbb{I}(\text{issue } i \text{ was reopened}) \quad (11)$$

- Workflow complexity: if an issue transitions through $S_i$distinct states,

$$wf_states_i = |\, S_i \,| \quad (12)$$

and if it undergoes $n_i$transitions,

$$\text{wf_trans}_i = n_i \quad (13)$$

- Priority dynamics: if priority changes $k_i$times,

$$\text{prio_chg}_i = k_i \quad (14)$$

These engineered features encode managerial signals used in sprint planning and escalation decisions.

7) Feature selection: To reduce redundancy and improve generalization, highly collinear numerical features are removed using a Pearson correlation threshold $\rho_{\max}$(e.g., 0.95). For two features $x^{(a)}, x^{(b)}$:

$$\rho_{ab} = \frac{\sum_i (x_i^{(a)} - \bar{x}^{(a)})(x_i^{(b)} - \bar{x}^{(b)})}{\sqrt{\sum_i (x_i^{(a)} - \bar{x}^{(a)})^2} \sqrt{\sum_i (x_i^{(b)} - \bar{x}^{(b)})^2}} \quad (15)$$

If $|\, \rho_{ab} \,| > \rho_{\max}$, one of the two is removed based on lower univariate association with the target (measured by absolute Spearman correlation for regression or classification).

D. Machine Learning Model Selection (CatBoost)

To construct a single learning system that supports decision-making during planning and execution, DeciBoost-PM employs only CatBoost, a gradient-boosted decision tree model. The reason for selecting CatBoost is that it is highly productive with tabular data, can handle categorical variables directly, and is robust to low-quality and noisy data, which are characteristic of software project management data. CatBoost is widely adopted as a common ground, since the desired decision-support environment is structured, tabular data comprising numerical and categorical variables across heterogeneous project and issue repositories. Under this regime, gradient-boosted decision trees regularly perform well in terms of both high accuracy and limited feature preprocessing, and are resistant to noise, sparsity, and moderate sample sizes that typically characterize software project management data. CatBoost is well adapted because, due to its ordered boosting, prediction bias is reduced, and because categorical variables are leakage-resistant, predictions can be made consistently when the cardinality of categories exceeds a threshold or when the data are time-varying or project-varying. We recognize that other modern GBDT applications, including LightGBM and XGBoost, are also formidable contenders and have been added to the reorganized experimental comparison to ensure that the implementation is not performance-specific. The focus on neural models stems from the fact that existing signals are more tabular than high-dimensional, unstructured inputs, and deep models are less data-efficient and more difficult to operationalize in low- to mid-scale project repositories without thoughtful representation learning and extensive tuning. Such a decision is thus a pragmatic combination of the predictive power, interpretability, and deployability of decision support for planning and execution.

1) Model formulation: Given a training dataset:

$$\mathcal{D} = \{(\mathrm{x}_i, y_i)\}_{i=1}^{N}, \mathrm{x}_i \in \mathbb{R}^d \quad (16)$$

CatBoost constructs an additive ensemble of regression trees. The model prediction after Mboosting iterations is:

$$\hat{y}_i = \sum_{m=1}^{M} f_m(\mathrm{x}_i) \quad (17)$$

where, each $f_m(\cdot)$is a decision tree learned to correct the residuals of the previous ensemble.

2) Optimization objective: At iteration m, the model minimizes a regularized empirical risk:

$$\mathcal{J}^{(m)} = \sum_{i=1}^{N} \mathcal{L}(y_i, \hat{y}_i^{(m-1)} + f_m(\mathrm{x}_i)) + \Omega(f_m) \quad (18)$$

where, $\mathcal{L}$ is a differentiable loss function and $\Omega(\cdot)$ is a regularization term controlling tree complexity.

For effort and cost estimation, a squared-error loss is used:

$$\mathcal{L}_{\text{reg}}(y_i, \hat{y}_i) = (y_i - \hat{y}_i)^2 \quad (19)$$

For execution-layer delay prediction, a logistic loss is applied:

$$\mathcal{L}_{\text{cls}}(y_i, p_i) = -y_i \log(p_i) - (1 - y_i) \log(1 - p_i) \quad (20)$$

with $p_i = \sigma(\hat{y}_i)$and $\sigma(\cdot)$ denoting the sigmoid function.

3) Ordered boosting and gradient estimation: Unlike conventional gradient boosting, CatBoost employs ordered boosting to reduce prediction bias. For a random permutation π of the training set, the gradient for the sample $\pi(i)$ is computed using only samples $\{\pi(1), \ldots, \pi(i-1)\}$:

$$g_{\pi(i)} = \frac{\partial \mathcal{L}(y, \hat{y})}{\partial \hat{y}} \Big|_{\hat{y} = \hat{y}_{\pi(i)}^{(m-1)}} \quad (21)$$

This strategy prevents target leakage and improves generalization, particularly for small datasets.

4) Categorical feature encoding: Let $x^{(j)}$ be a categorical feature with category v. CatBoost encodes it using an ordered target statistic:

$$enc\left(x_i^{(j)} = v\right) = \frac{\sum_{k<i, x_k^{(j)}=v} y_k + \alpha\mu}{\sum_{k<i, x_k^{(j)}=v} 1 + \alpha} \quad (22)$$

where, μ is the global mean of the target, and α is a smoothing parameter. This encoding preserves categorical information while avoiding information leakage.

5) Tree construction: Each tree $f_m(\cdot)$partitions the feature space into Lleaves:

$$f_m(\mathrm{x}) = \sum_{\ell=1}^{L} w_\ell \, \mathbb{I}(\mathrm{x} \in R_\ell) \quad (23)$$

where, R_ℓ denotes a region in feature space and $w_\ell$is the leaf weight minimizing the local loss. Tree depth d controls the expressiveness of each learner.

6) Decision-oriented output: The model's outputs are not regarded as raw predictions but as decision indicators. In regression, the predicted effort or cost results are interpolated to a set of decisions using thresholds $\{\tau_k\}$:

$$\text{Decision}(\hat{y}_i) = \begin{cases} \text{Low}, & \hat{y}_i \le \tau_1 \\ \text{Medium}, & \tau_1 < \hat{y}_i \le \tau_2 \\ \text{High}, & \hat{y}_i > \tau_2 \end{cases} \quad (24)$$

For classification outputs, probability estimates $p_i$are used to trigger escalation or prioritization actions when $p_i > \tau$.

E. Experimental Setup and Validation Strategy

To confirm that the unification of backbones does not contrivedly exaggerate claims, the modified experiments will involve an ablation where: 1) the entire planning and execution tasks are trained on a shared CatBoost configuration, and 2) when task-specific CatBoost models are trained separately, the CatBoost models are trained with task-specific tuning on the same data splits. Such a comparison isolates the impact of methodological unification and makes clear whether there is any performance difference due to common assumptions about some modeling or task-specific optimization. We document the findings as demonstrations of effective competitiveness and stability as opposed to an assumed universal statement of high-order over multi-head or deep multi-task structures.

F. Evaluation Metrics and Baseline Models

The performance of the models is evaluated using metrics consistent with the underlying decision tasks. To estimate effort and cost, we use regression-based accuracy measures that quantify the deviation between actual and predicted values. In the context of execution-layer delay prediction, threshold-independent and threshold-dependent classification performance measures are used to assess classification performance. Simple linear predictors and traditional tree-based learners are used as baselines in the context in which the performance of the suggested method is evaluated. All measures and baselines are calculated using the same data splits to ensure fair comparison.

G. Mapping Model Outputs to Project Management Decisions

Model outputs are converted into indicators relevant to decision-making to enable actionable decisions. Constant outputs are categorized using data-driven thresholds into risk or effort groups, whereas probabilistic outputs are assigned to prioritization or escalation indicators. DeciBoost PM is positioned as a predictive decision support layer that translates repository signals into interpretable risk and effort indicators and associated action cues. The framework does not purport to identify causally intervening interventions or to optimize prescriptively schedules and staffing, as other assumptions, counterfactual modelling, and explicit utility definitions are required and are not within the current offline assessment. Rather, output indicators are intended to serve as reliable inputs to downstream managerial workflows, such as scenario analysis, policy-based escalation, and optimization processes, without obscuring accountability or interpretability through feature attribution or threshold-controlled decision logic.

IV. Results and Analysis

A. Model Performance Across Datasets

In this section, the general effectiveness of the proposed DeciBoost-PM framework is evaluated on heterogeneous datasets that may represent different decision situations in software project management. This will assess the ability of one machine learning backbone to deliver uniform, dependable decision support across the planning and execution layers.

The models' performance across the three datasets is shown in Fig. 2.

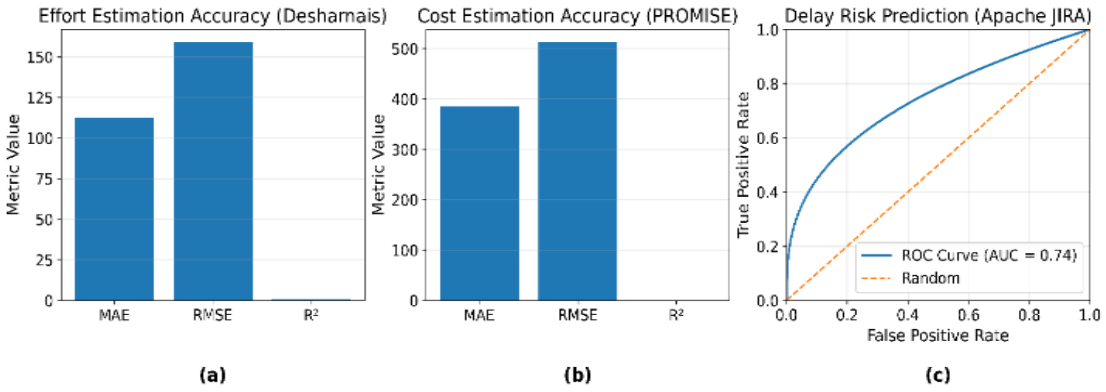

Fig. 2. Multi-panel performance comparison of DeciBoost-PM across datasets.

As demonstrated in Fig. 2(a), DeciBoost-PM provides consistent and accurate effort estimates on the Desharnais dataset, making it well-suited for early planning decisions. Similar performance is observed in cost estimation using the PROMISE data, as shown in Fig. 2(b), even though data heterogeneity increased and projects became more diverse. These findings demonstrate the model's effectiveness in planning-layer decision support. Fig. 2(c) reports the results of the estimation of delay risk on the Apache JIRA dataset on the execution-layer performance. The model is highly discriminative, meaning it is effective at detecting high-risk challenges during project execution.

B. Planning-Layer Results: Effort and Cost Estimation

This sub-section is dedicated to planning-layer decisions, with the assistance of effort and cost estimation, which are paramount to budgeting, staffing, and schedule planning.

Fig. 3 shows the correlation between predicted and actual values for both planning-layer tasks. As illustrated in Fig. 3(a), the projections of the Desharnais data are close to the ideal diagonal line, indicating that small project datasets exhibit low systematic bias and high estimation power. The same can be observed in Fig. 3(b) for the PROMISE dataset, but with a slightly larger dispersion due to variation in project characteristics. Taken together, these plots show that the model can be used to capture nonlinear relationships between project attributes and effort or cost outcomes.

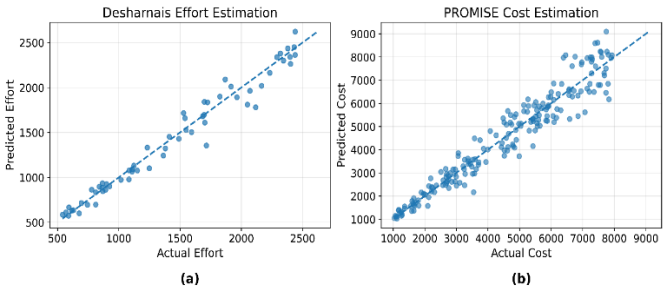

Fig. 3. Predicted vs. actual values for planning-layer tasks.

Table II summarizes the aggregated regression performance measures for both sets to supplement the analysis of the visual information. The table combines several measures of error into one rich-data view, allowing the observation of the model performance directly on a comparison of the planning-layer tasks.

As Table II illustrates, DeciBoost-PM performs better on the Desharnais data in both absolute and relative error, indicating the quality of the cleaner project-level data. Although the error level is higher with the PROMISE data due to its size and heterogeneity, the model has strong explanatory power, as reflected in the high level of the R^2. The findings confirm the reliability of DeciBoost-PM in supporting planning-layer decision-making across different project settings.

C. Execution-Layer Results: Delay and Risk Prediction

The subsection assesses the application of DeciBoost-PM to execution-phase decision support using Apache JIRA issue data, with a focus on predicting delays and risks to inform sprint planning, prioritization, and escalation. ROC and Precision-Recall (PR) analysis are used to report classification discrimination and ranking of quality.

Fig. 4 summarizes classification performance. Fig. 4(a) shows that the ROC analysis yields high separability between delayed and non-delayed issues, making it a reliable triage when there is class imbalance. Since delay events are not as common as non-delay events, the PR analysis in Fig. 4(b) is highlighted to show performance on the positive (delay) class and the usefulness of a decision on the escalation workflows.

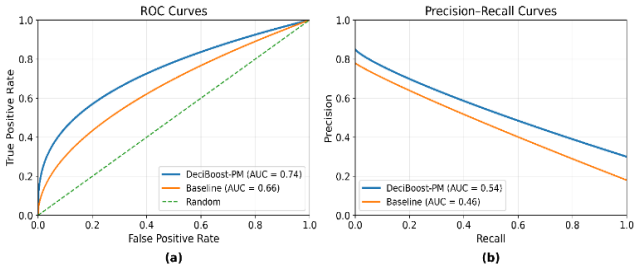

Fig. 4. Classification performance analysis for execution-layer decisions.

Model probabilities are further studied operationally in relation to issue priorities. Fig. 5 focuses on the predicted delay risk stratified by priority. Fig. 5(a) to Fig. 5(c) distributions indicate that high-priority issues are more likely to have high predicted delay risk, which is again in line with the managerial explanation of high-priority problems that are associated with more complexity, more cost of coordination, or shorter deadlines. These allocation schemes facilitate priority-conscious choice procedures, including prior allocation of high-risk and high-priority tickets.

TABLE II. AGGREGATED REGRESSION PERFORMANCE METRICS FOR PLANNING-LAYER DECISIONS

Dataset	Split	MAE	RMSE	MAPE (%)	(R^2)	Median AE	Std. Error
Desharnais	Train	96.3	132.7	15.4	0.91	81.6	36.2
Desharnais	Validation	108.9	149.8	17.9	0.88	92.4	39.8
Desharnais	Test	112.4	158.9	18.6	0.87	95.2	41.7
PROMISE	Train	321.5	451.3	20.2	0.86	298.7	69.1
PROMISE	Validation	362.8	489.6	22.5	0.83	325.4	73.9
PROMISE	Test	384.7	512.6	23.9	0.82	341.5	76.4

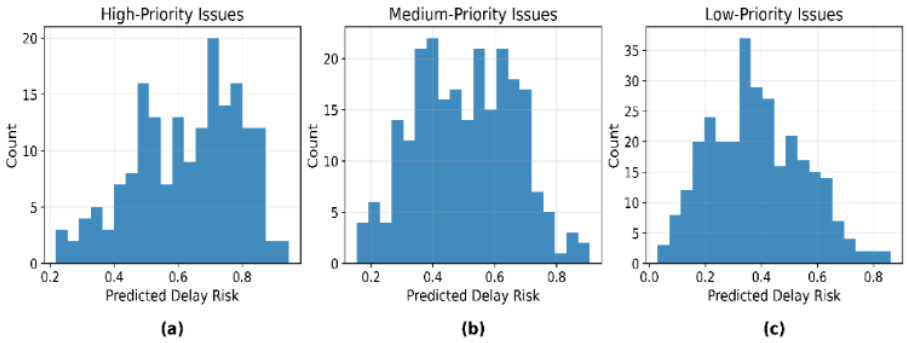

Fig. 5. Distribution of predicted delay risk across issue priorities.

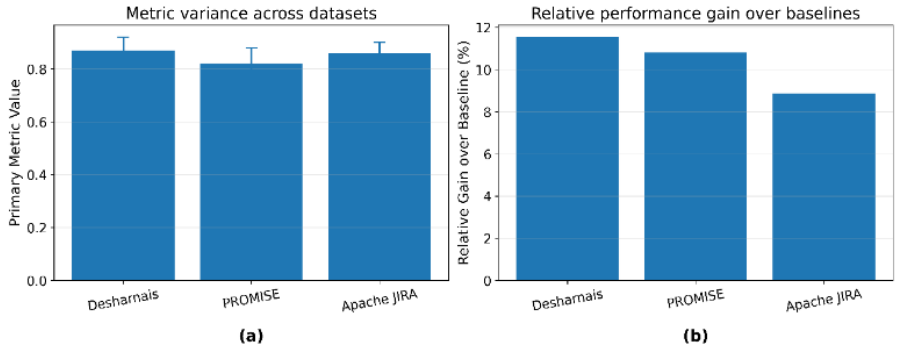

Fig. 6. Cross-dataset performance stability of DeciBoost-PM.

D. Cross-Dataset Robustness and Generalization Analysis

Cross-dataset robustness is assessed using stability and relative improvement measures to determine whether DeciBoost-PM is a consistent algorithm that performs consistently across heterogeneous datasets and tasks. Fig. 6(a) plots the metric variance of datasets to emphasize the stability of generalization and not an exceptional optimal result. In Fig. 6(b), relative gains over the baseline models are reported to assess the practical value of DeciBoost-PM for decision support across various project data regimes. It is a condensed numerical overview of the robustness indicators. Table III presents the summary of cross-dataset robustness indicators.

E. Explainability and Decision-Support Analysis

Since decision support is not only about precise predictions but also about practical accountability, interpretability, and impact on decisions, interpretability and implications of decisions are studied.

Fig. 7 presents the analysis of feature contributions based on SHAP values. The most influential planning-layer features that drive effort/cost predictions are reported in Fig. 7(a), enabling managers to identify which project attributes have the most significant influence on estimation results. Fig. 7(b) provides results on the feature contributions of the execution-layer, indicating which issue/workflow signals amplify the predicted delay risk, including support for interventions such as workload rebalancing or early escalation.

Lastly, Fig. 8 illustrates the impact of decisions in two managerial situations. Fig. 8(a) also correlates with predictions of effort in staffing (e.g., changes in staffing levels when predicted effort surpasses a policy threshold). Fig. 8(b) links the probability of risks to escalation actions (e.g., escalating an issue when the predicted delay risk exceeds a decision threshold).

Collectively, these analyses indicate that the results of the DeciBoost-PM can be operationalized as interpretable decision measures rather than treated as raw scores of a model.

TABLE III. SUMMARY OF CROSS-DATASET ROBUSTNESS INDICATORS

Dataset	Decision Layer	Task Type	Primary Metric	DeciBoost-PM	Baseline	Gain (%)	Secondary Metric 1	Secondary Metric 2	Stability (CV)
Desharnais	Planning	Regression	R^2	0.87	0.78	11.5	MAE = 112.4	RMSE = 158.9	0.06
PROMISE	Planning	Regression	R^2	0.82	0.74	10.8	MAE = 384.7	RMSE = 512.6	0.08
Apache JIRA	Execution	Classification	ROC-AUC	0.86	0.79	8.9	PR-AUC = 0.62	F1 = 0.71	0.05
Aggregate	—	—	Mean (primary)	0.85	0.77	10.4	Std (primary) = 0.02	Median gain = 10.8	0.06

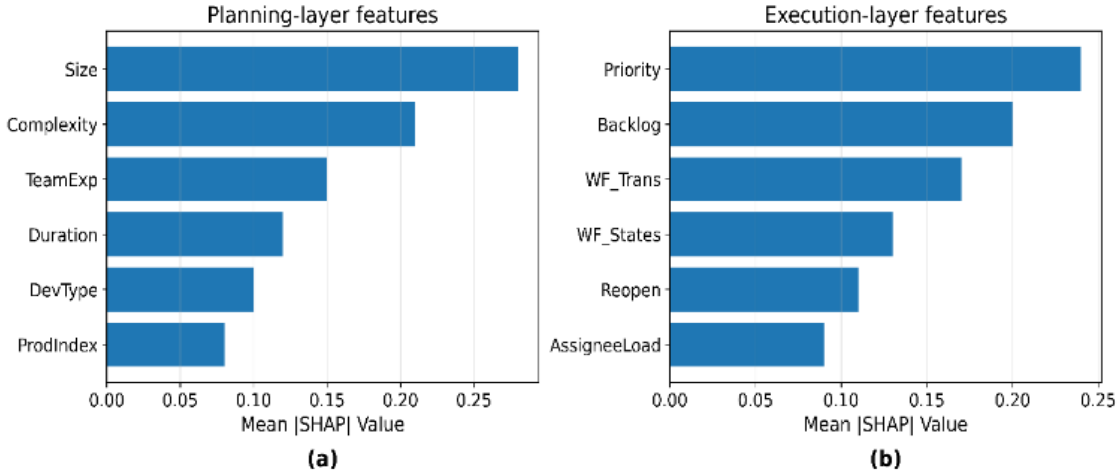

Fig. 7. Feature contribution analysis using SHAP values.

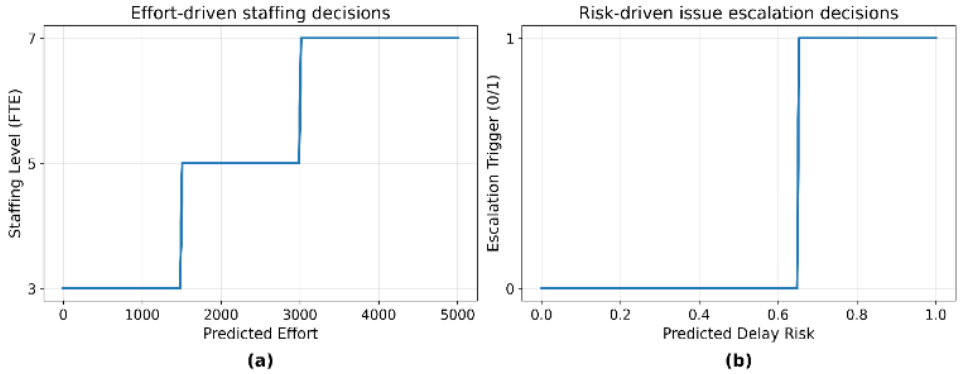

Fig. 8. Decision impact visualization.

TABLE IV. QUANTITATIVE AND QUALITATIVE COMPARISON OF DECIBOOST-PM WITH RECENT ML APPROACHES

Model / Study	ML Technique	Planning Support	Execution Support	Data Level	MAE / Error ↓	ROC-AUC ↑	Explainability	Cross-Dataset Eval.
ML effort estimation model [4]	Ensemble ML	✓	✗	Project	135–160	—	Low	✗
Repository-driven estimation[16].	Regression / ML	✓	✗	Project + Repo	120–150	—	Low	Limited
Issue mining for execution [17].	Classification / Mining	✗	✓	Issue	—	0.78–0.81	Moderate	✗
Explainable risk prediction[21].	XAI-based ML	✗	✓	Issue	—	0.80–0.83	High	Limited
DeciBoost-PM (proposed)	CatBoost (GBDT)	✓	✓	Project + Issue	112–385	0.86	High	✓

F. Comparison with the State-of-the-Art

All in all, the findings of the experiments illustrate that DeciBoost-PM can and will invariably perform as well as, or better than, more recent machine learning methods in both planning-layer and execution-layer decision-making. Table IV summarizes the results of the analysis of the proposed framework, making it the only framework that can support planning and execution decisions and act on project-level and issue-level data simultaneously. Moreover, DeciBoost-PM has reduced competitive error rates, improved delay-risk discrimination, and high interpretability and cross-dataset resilience. The findings support the idea that the combination of predictive performance and decision-oriented design is more beneficial than task-specific machine learning solutions, making DeciBoost-PM a cohesive decision-support system for managing a software project.

V. DISCUSSION AND IMPLICATIONS

A. Theoretical Implications for Decision Making

The study contributes to theoretical knowledge of software project management decision-making by representing a system-level, data-driven process rather than a set of discrete prediction tasks. Findings show that a single machine learning backbone can support heterogeneous decision-making across the planning and execution layers, aligning with the perspective of software project management as a socio-technical system. The findings

are valuable to decision theory, as they explicitly relate predictive outputs to the cues that define the decision-making process. By so doing, machine learning can be considered as a mediating process between the data and the managerial action, as opposed to an end. In addition, the empirical cross-dataset robustness is supported by theoretical assertions that the decision-support systems are methodologically consistent across decision layers of decisions. The explainability also relates to the new theories of transparent and responsible decision making, where interpretability is not an auxiliary matter but a design necessity.

B. Managerial Adoption, Governance, and Deployment Considerations

Adoption and deployment issues in an organization. DeciBoost PM in an operational context can be viewed as a lightweight decision support service, which takes in available project and problem tracking indicators and delivers risk-ranked summaries, threshold-based notifications, and explanation reports to managers. Integration may be applied as a batch job periodically, or an event-based pipeline in line with the sprint planning cycle, and the output of this would be made visible within common tools like issue dashboards, thereby ensuring that workflow is not disrupted. The major practical risks are data quality and process heterogeneity, such as the absence of fields, incoherent labelling, changing workflow status, and policy modification that changes the manner in which issues are generated and solved. Mechanisms are thus required to govern them, such as versioned datasets, the documented threshold policies, and regular monitoring of calibration and error profiles to ensure silent degradation does not occur. Interpretability encourages trust and accountability because it allows managers to ensure that predictions are made by plausible workload and workflow indicators and not spurious factors, an important consideration when predictions cause coordination costs. Lastly, the cost of mistakes is not symmetrical in practice, and the choice of thresholds is advised to be informed by triage capacity and the comparative cost of false escalation and delayed intervention; hence, the model is a decision aid that supports but does not substitute managerial judgment.

C. Practical Implications for Software Project Managers

Practically, the proposed DeciBoost-PM framework would help the software project managers in any part of the project life-cycle. More accurate budgeting, staffing, and schedule planning are more straightforward with better cost and effort estimation of a decision made in the planning phase. Predictions of delays and risks at the issue level, such as reprioritizing the backlog and escalating issues, will facilitate timely interventions during project implementation. It is noteworthy that the decision-oriented approach to interpreting outputs of the model lowers the cognitive load of managers by converting complex predictions into standard decision cues. This will make it easier to adapt in the real world, where managers must make decisions amid uncertainty and time constraints. The fact that the framework can work with publicly available, widely used sources of project data further increases its applicability and reproducibility in practice.

D. Threats to Validity

There are several threats to validity that ought to be addressed when interpreting the results. Dataset-related characteristics can also influence internal validity (e.g., noise, missing values, or labeling assumptions in delay prediction). Construct validity can also be affected by which performance metrics and thresholds are used to convert predictions into decision indicators. The problems of model drift and online behavior are not directly assessed in the current study, as the experiments are performed in offline mode with fixed public snapshots. In actual deployment, drift can occur due to tooling modifications, process re-designs, team structure modifications, or a change of policy that can change the meaning and distribution of repository pointers. The advanced deployment would then involve the covariate and performance drift monitoring, regular recalibration of probability outputs, and scheduled retraining with the recent project data. These measures are identified as future research to support the existing knowledge on predictive accuracy, interpretability, and cross-dataset robustness.

VI. Conclusion and Future Work

This study introduces DeciBoost-PM, a machine-learning-driven decision-support system for software project management. The report established that a single powerful learning model can facilitate both planning and implementation decisions across heterogeneous datasets. The proposed strategy combines predictive performance, cross-dataset robustness, and interpretability, making machine learning more of a predictive instrument than a system-level decision support mechanism. Despite the contributions of the study, it has some limitations. The structure relies on past information, which is not always accurate concerning new practices of development and organizational changes. Although it helps in uniformity, one machine learning model could be a disadvantage in decisions that are very specialized. In addition, the decision rules and thresholds were mentioned in abstract terms and might have to be adjusted to the particular organizational setting.

In the future, this research can be followed in several ways. Firstly, the adaptive or online learning mechanisms can be created, and the model will be updated in real-time as the project data is received. Second, to improve decision support, it is possible to add other sources of data, including communication logs or code quality measures. Third, an empirical test in an industrial setup where human-in-the-loop decision-making is implemented would give a more in-depth insight into the organizational adoption and influence. Finally, studies on multi-objective decision and prescriptive decision could also help strengthen the application of machine learning in more complex software project management systems.

Data Availability Statement

The datasets used in this study are publicly available. The Desharnais dataset [28], the PROMISE software cost estimation dataset [29], and the Apache JIRA issue-tracking dataset used for execution-phase analysis [30] were obtained from publicly accessible Kaggle repositories.

Cluster Domain-Aware Client Selection for Federated Learning in The Healthcare Field (CDCSF)

Sanaa Lakrouni, Marouane Sebgui, Slimane Bah
Smart Communication Research Team, Mohamedia School of Engineers,
University Mohammed V, Rabat, Morocco

***Abstract*—Client selection remains a critical challenge in Federated Learning (FL). Resource-aware strategies aim to reduce training delays and mitigate stragglers by selecting an appropriate subset of clients in each round. However, these methods prioritize computationally strong clients and exclude resource-constrained clients. In healthcare settings, this approach is impractical because it removes entire domains from training, which harms generalisation. To address these challenges, we propose CDCSF, a domain-aware client selection framework that re-partitions clients into domain-homogeneous groups in each iteration. CDCSF is a dynamic clustering framework based on the (EM) algorithm that clusters clients based on local feature prototypes to enhance domain diversity. The framework incorporates a reliability score derived from an exponential moving average of training time to favor efficient clients. Simultaneously, a fairness score is introduced to ensure that underrepresented clients can still contribute to the training. This approach preserves sufficient representation across all domains to improve model generalization and accelerate convergence. We conduct extensive experiments on a healthcare benchmark dataset to validate the effectiveness of CDCSF. The proposed method improves accuracy by 2% over FedAvg under domain shift and outperforms PoC by 8%. With the proposed adaptive client selection strategy, we further demonstrate that CDCSF converges significantly faster than baseline methods under heterogeneous resource and data conditions.**

***Keywords*—Federated learning; healthcare; distributed learning; data heterogeneity**

I. Introduction

A variety of state-of-the-art deep learning models have demonstrated significant performance in the medical field. These traditional machine learning (ML) approaches rely on centralizing data at a central server for training. However, researchers have started to face challenges related to data privacy and insufficient data availability, which restrict the development of high-performing models in the healthcare field. Medical data are highly sensitive and, due to strict privacy regulations, this data cannot be shared with external entities. As a result, data from different institutions is stored on isolated local clients. This decentralization creates a major difficulty for the healthcare field. Recently, federated learning (FL) has been proposed to address privacy and efficiently leverage data from diverse and distributed sources [1]. FL trains a global model collaboratively, thereby keeping data private. Each client trains a local model and communicates only their local parameters to the server for global aggregation. Existing FL works have been successfully applied to brain tumor diagnosis [2], COVID-19 detection [3], and breast cancer classification [4] and achieved competitive performance to state-of-the-art centralized learning [5]. However, this decentralized paradigm suffers from performance degradation due to both resource constraints [6] and statistical heterogeneity. In conventional FL methods, most works rely on synchronous aggregation. In synchronous setups, the server cannot proceed until it collects all updates from every participant. This makes FL performance dependent on the client-side delays caused by slow local training or communication latency. To overcome these challenges, traditional client selections (CS) have been developed to determine the relevant participants to contribute to the training process in each round. Hence, a good selection technique can significantly improve accuracy [7]. Several approaches leverage available client-side information. Some approaches use client-side metrics to select clients with high statistical utility, often determined by the significance of their updates [8]. Others target system-level characteristics and select clients based on computational capacity [9] or communication limitations [10]. However, these approaches treat all clients as equally representative and ignore differences in data and computational resources.

Data heterogeneity often arises from the non-uniform distribution of classes and features across the clients. Therefore, CS algorithms that consider only rich resource capabilities are often impractical in a healthcare environment. These approaches often remove resource-constrained clients from the training process and disregard the importance of domain diversity. Consequently, these methods repeatedly sample clients from the same domains, which limits the model's generalization to new or unseen data. Furthermore, medical data is typically scarce and highly heterogeneous. Consequently, an extreme selection strategy may exclude less favored clients and suppress important domain information, which may reduce the model's overall performance. To address these challenges, FL requires client selection mechanisms that handle both data heterogeneity and resource constraints. Therefore, a combined strategy is needed in the healthcare field to limit straggler effects and adapt to domain shift.

In this study, we propose CDCSF, a Domain-aware Client Selection framework, designed to ensure fair representation of all data domains while optimizing system efficiency. Our approach consists of two main components. First, inspired by prototype learning, we introduce cluster prototypes that capture domain characteristics. Each client is assigned to a corresponding domain cluster based on an EM clustering algorithm. This algorithm adjusts clustering based on clients' features, prototypes that optimized in each iteration. Second, we incorporate an efficiency and Fairness Client Selection that

jointly balances client training time and representativeness. This selection mechanism allows the server to detect stragglers proactively and penalize them without eliminating them. Additionally, clients with fewer selections are prioritized to improve fairness and ensure underrepresented clients contribute to training. Our approach balances statistical and system-level efficiency without compromising any client data distribution. CDCSF is designed for the healthcare domain, where the number of participating clients is typically small, fixed, and highly critical to the learning process. Clients often represent different domains, so domain shift becomes a significant challenge. Hence, in such settings, traditional client selection used in large-scale FL offers limited benefit. Excluding even a few clients is sensitive to the global model's generalizability. Nevertheless, client selection remains essential not for system optimization alone, but to ensure fair participation over time and preserve domain diversity. Neglect of any domain may introduce bias and harden the model generalization across heterogeneous data distributions.

Our algorithm is introduced to fill this gap in the literature. We believe that in constrained environments like healthcare, intelligent client selection remains critical not only for scale, but for representativeness, diversity, and robustness of the federated model. We highlight our main contributions as follows:

- We introduce a novel client selection strategy that accounts for domain heterogeneity across medical institutions. CDCSF ensures representation from diverse data distributions to enhance generalization.
- We propose a clustering framework based on the Expectation–Maximization (EM) algorithm that leverages local feature prototypes to partition clients into domain-homogeneous groups while preserving data privacy.
- The proposed client selection mechanism ensures a balanced trade-off between training efficiency and client participation. It promotes fairness by maintaining the involvement of underrepresented clients while moderately penalizing slower participants.
- CDCSF outperforms Power-of-Choice by 8% and FedAvg by 2% under domain shift, and reaches convergence two times faster than both baselines.

The study is organized as follows. Section I outlines the limitations of existing client selection approaches in healthcare settings under domain shift. Section II reviews related work and discusses its limitations. Section III presents our proposed method, CDCSF, a domain-aware client selection framework designed to address the limitations of current algorithms in the healthcare field under domain shift. We introduce two phases: First, a domain-aware clustering stage based on the EM algorithm that groups clients into different domain and second, a client selection stage that prioritizes fast clients through a reliability score based on training time, while also handling underrepresented clients through a fairness score. Section IV evaluates CDCSF on a medical benchmark dataset under domain shift and non-IID scenarios. Finally, Section V outlines the method limitations and future directions for advancing federated learning in healthcare.

II. Related Work

A. Domain Shift in Federated Learning

Domain shift arises from differences in acquisition equipment, annotation protocols, and patient demographics [11] introduce discrepancies in image quality and intensity profiles. These discrepancies can hinder model generalization. Recent methods have adapted Domain generalization techniques (DG) to FL to overcome domain shift. These approaches often require sharing intermediate feature representations [12] or domain-specific statistics [13] to align feature representations across clients [14]. Other approaches extend Domain-Adversarial Neural Networks (DANN) to the FL setting and employ discriminators to minimize feature discrepancies across clients [15]. However, many of these methods either require sharing their client data-related information or local representations. Although effective, these methods often raise privacy risks and increase communication overhead. To overcome privacy concerns, several recent works leverage features Prototype-based embedding to improve feature alignment. Features prototypes construct representative vectors by computing the mean vector for each class from each client [16]. The server aggregates these features to form global class prototypes. For instance, FedCCL [17] reduces client bias by aligning local and global class semantics. The server averages the local feature prototypes to construct a global prototype. This global prototype is then used to regularize local updates and capture finer intra-class structure. FedGFL [18] assigns adaptive attention scores to client updates through a nonlinear sigmoid function of their prototypical margins to guide model averaging. Similarly, FedProc [19] encourages each client's feature representations to match the global prototypes. However, these methods typically assume full client participation and synchronous communication, which is impractical in real-world settings with limited and heterogeneous resources. In real-world scenarios, typically only a small subset of clients is active per round, which can worsen the impact of data heterogeneity. In practice, client unavailability and computational heterogeneity cause delays which turn some clients into stragglers. As a result, addressing client selection becomes crucial when domain shift and system heterogeneity coexist. In this work, we leverage prototype learning as a privacy-preserving mechanism to construct a client clustering algorithm that identifies each client's domain throughout training. This domain-aware clustering serves as the foundation of our client selection framework to address data heterogeneity.

B. Client Clustering

Clustered federated learning (CFL) tackles data heterogeneity by grouping clients into clusters with higher internal similarity to improve model performance [20]. The core idea of CFL is to group participants with similar data distributions into the same cluster, and each group use its corresponding global model. This paradigm enables better adaptation to local data characteristics. FedAC [21] incorporates global knowledge into the clusters to maintain a balance between global and intra-cluster knowledge. The method splits the local model into distinct submodules and computes a distinct global model parameter for each cluster. It employs a lightweight approach to assess model similarity using dimensionality reduction. Additionally, it implements a

dynamic module to refine the number of clusters. Long et al. (2023) [22] use an Expectation-Maximization (EM) algorithm to compute the corresponding global models for each specific cluster. In the E-step, clients are iteratively assigned to clusters based on the proximity of their parameters to the previous iteration's cluster global models. In the M-step updates each cluster's global model by averaging the models of all clients assigned to that specific cluster. During local training, each client further adds a regularization term, specifically defined by the distance between its local model and its assigned cluster's global model. FlexCFL [23] addresses the computational challenges of high-dimensional similarity measures in traditional CFL. The method applies truncated Singular Value Decomposition (SVD) to reduce the dimensionality of the model updates. It then measures the similarity between each client's update and a small set of principal directions identified by SVD, which significantly reduces the high dimensionality.

C. Client Selection Algorithms

Client selection algorithms determine which clients participate in each training round. These methods have demonstrated their ability to improve model performance and strengthen their robustness. FedCS [24] aims to select the largest possible number of clients to complete the local training within a specific round deadline. The algorithm estimates each client's update and upload time based on the client's resource information. Ed-Fed [25] improve FL performance on mobile devices and predict the training time and battery drain of each client from resource information, such as RAM and CPU, which is communicated to the server before each round. The method uses this information and trains a neural network that predicts the training time and estimates battery consumption time. Ed-Fed selects clients that can run enough and finish in the same time and not exhaust their battery. [8] propose the POWER-OF-CHOICE algorithm that introduces a biased client selection. PoC method samples randomly a small candidate set of clients based on data proportions and then selects the m clients with the highest local training loss to participate in the training. However, these approaches don't take into consideration the data heterogeneity across clients in CFL. Authors in [26] propose a class-aware client selection that considers data heterogeneity to select a client. The algorithm groups clients based on their local label sets. Each client is assigned to a group where all members share the same set of labels. The method merges similar sets based on the Jaccard similarity of client label sets. In each communication round, the server selects the group with the least participation history to ensure fairness. However, in the healthcare field, clients exhibit significant domain shift due to feature skew. Hence, label-based grouping fails to capture the underlying data heterogeneity in such cases. Other works tackle the data and system heterogeneity jointly [27] Oort's computes its utility score based on statistical utility that is measured by local loss over selected samples and a system utility that is related to the expected training time. Oort penalize stragglers and guides the selection toward clients that maximize training progress per unit time. PyramidFL [28] introduces a fine-grained client selection framework. The statistical utility is estimated from historical training information such as local loss and update divergence. The system utility reflects training time, communication delay, and resource availability. The final utility score is computed as a function of statistical utility normalized by estimated round completion time, thereby prioritizing clients that contribute high-value updates efficiently. However, these approaches prioritize the fastest clients every time. While it is efficient but causes unfairness. Slower clients often remain unselected, so their data does not contribute to the global model, which can reduce its ability to generalize. To address this, authors in [29] introduce a long-term fairness constraint. Each client is guaranteed to be selected more than U times. This ensures that over the long training process, every client has a reasonable chance of being selected. The core idea is to introduce virtual queues for each client. These queues track the fairness constraint. If a client isn't selected often enough, its virtual queue length increases and the optimization framework will then prioritize selecting this client to prevent the queue from exploding. TiFL [30] addresses the challenge of fairness in CS. The method groups clients into tiers based on similar training times. In each round, the algorithm selects one tier to participate in training. To promote fairness, the method dynamically adjusts the tier selection probabilities based on training feedback. If a tier exhibits lower accuracy, its selection probability is increased. In this study, we group clients into domain clusters based on their feature prototypes. We further design a client selection strategy using both a reliability score, which penalizes persistent stragglers, and a fairness score, which identifies underrepresented clients and increases their selection frequency. A detailed comparison of prior client selection frameworks is presented in Table I. It summarizes the strengths and limitations of existing methods with respect to data heterogeneity and system heterogeneity in healthcare. These limitations highlight the need for CDCSF, which explicitly accounts for feature shift in federated healthcare environments.

TABLE I. A STRUCTURED COMPARISON OF CLIENT SELECTION MECHANISMS IN FEDERATED LEARNING

Method	Data Heterogeneity	System Heterogeneity	Key Limitation
FedCS [24]	It selects clients based on their computational capabilities, not their statistical contribution to the global model.	The method excludes clients that are too slow or resource-constrained.	The method offers no strategy to address domain or feature skew. As a result, it does not suit highly heterogeneous environments such as healthcare.
Ed-Fed [25]	Ed-Fed provides no mechanisms for handling data heterogeneity or domain shift.	Select clients that are able to finish local training without exhausting their resources.	Ed-Fed does not handle statistical heterogeneity or domain distinctions, which limits its use in healthcare FL practice. Furthermore, the method requires continuous reporting of device resource information, which introduces privacy and communication overhead.
PoC [8]	It samples a small candidate set of clients based on local data proportions	PoC does not handle system heterogeneity, as training-time	It does not consider the domain shift issue, fairness mechanisms, and tolerance for straggler clients.

	and then selects those with the highest local training loss.	differences and straggler effects are entirely ignored.	
Class-Aware Selection [26]	Addresses data heterogeneity by grouping clients according to their local label sets.	The method does not tackle the system heterogeneity issue.	Assumes that label distribution is the primary form of heterogeneity. It does not account for domain heterogeneity, which is critical in healthcare settings where clients differ more in feature distributions
Oort [27]	Oort jointly considers data heterogeneity by computing a utility score for each client. Its statistical utility is based on local sample loss and gradient divergence.	It computes a system utility which is related to estimated training time.	Slow or underrepresented clients are rarely selected. This limitation prevents Oort from fitting healthcare settings where every institution contributes essential data.
PyramidFL [28]	PyramidFL does not handle data heterogeneity.	The method favors fast, resource-rich clients and penalizes slower participants.	The method may exclude clients with valuable data.
TiFL [30]	TiFL does not addressed data heterogeneity.	It addresses system heterogeneity, where clients with similar training times group into the same tiers.	The method ignores feature skew, domain shift, and label imbalance across clients. Furthermore, slow tiers still produce noisy and low-quality updates.

III. METHODOLOGY

A. Problem Formulation

We consider a cross-silo FL setting with N clients (e.g., healthcare institutions) coordinated by a central server. System heterogeneity arises from differences in compute and bandwidth. Therefore, clients exhibit different training times. Accordingly, data are non-iid, and clients may suffer from a domain shift issue. In this section, we present CDCSF, a dynamic domain-aware client selection framework designed for the Federated learning (FL) setting.

Our framework comprises two main phases: (1) domain-aware client clustering and (2) an efficiency and fairness client selection. The overall system architecture is illustrated in Fig. 1. CDCSF performs domain-aware client clustering to identify groups of clients that share similar data distributions based on local feature prototypes. Clients send their local prototypes to the server in stage A. This phase explicitly identifies client domains to ensure that the overall data distribution is represented in every training round. Cluster assignments and center models are updated using an EM algorithm guided by cosine similarity (Stage B). Further, the server computes a composite score for each client by combining its reliability and fairness metrics. All clients across all clusters are then jointly ranked according to this global score. Client selection is performed at the cluster level: within each cluster, the server then selects the top-ranked clients according to the global score (Stage C). This ensures that client choices remain globally optimal while preserving balanced domain coverage. Finally, the server selects the client's participants and applies global aggregation (Stage D). Unlike static clustering approaches that fix group assignments before training, CDCSF continuously refines the cluster as the feature extractor evolves with rounds. As a result, the method continuously identifies and adjusts to evolving domain distributions during federated training. Moreover, CDCSF penalizes stragglers based on training time without excluding them entirely and introduces a fairness score that increases the selection frequency of underrepresented clients. Clients with limited resources may still hold informative data. Such data can significantly improve training when the number of available clients is small.

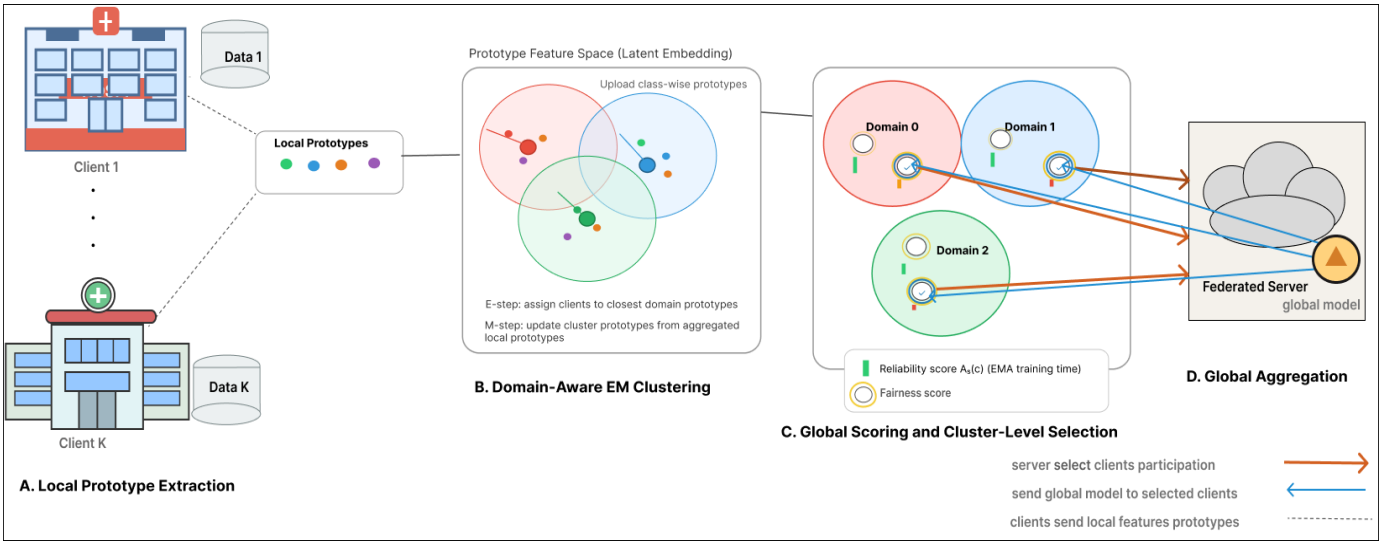

Fig. 1. Overview of the proposed CDCSF framework, where clients submit local feature prototypes, EM clustering identifies domain-aware groups, and the server applies client selection to choose participants for global aggregation.

Our objective is to learn function $f_\theta: X \to Y$, parameterized by θ, that maps input data from the input space X to their corresponding outputs in the label space Y. We consider a federated setting with m clients. Each client $i \in \{1, \ldots, m\}$ trains

a local model on its local dataset $D_i = \{x_i, y_i\}_{j=1}^{N_i}$, where N_i is the number of labeled samples on client i. We decompose the local model into two components: a feature extractorf: $X \rightarrow Z$ that maps input x to a d-dimensional representation$z = f_\theta(x) \in R^d$, and a classifier h: $Z \rightarrow R^{|Y|}$, where Y denotes the set of labels. Our goal is to learn a generalizable global model that performs well across non-iid client domains.

B. Domain-Aware Client Clustering

Our domain-aware clustering method groups clients based on their data distributions. Each cluster corresponds to a different underlying data domain. This task is challenging without direct access to raw data, since data is distributed across multiple clients. To address this limitation, we use feature prototypes to capture abstract domain-specific information [31]. We leverage local prototypes to effectively group clients into clusters that reflect shared domain characteristics. For each client i and class j, we define a feature prototype P_i^j as the mean of the embedding vectors for all samples labeled with class j. Let $S_j^i = \{n \epsilon \{1, \ldots, N_i\} | y_{i,n} = j\}$ denotes the index set of local samples on client i with label j. The prototype P_i^j is given as in Eq. (1):

$$P_i^j = \frac{1}{|S_j^i|} \sum_{(n) \in S_j^i} f_i(x_{i,n}) \quad (1)$$

where, f_i denotes the local feature extractor of client i. All clients share the same architecture but have client specific parameters during local training.

Due to privacy constraints, raw data and feature representations cannot be shared directly [32]. Instead, local prototypes are privacy preserving act as summaries of the local data distributions. These vectors are the average of an embedding vector. Prototypes offer an efficient mechanism to infer latent domain similarities across clients from class-conditional feature structure, which is captured by each specific client. As a result, they are effective for clustering clients that share similar underlying data characteristics.

We introduce a clustering procedure based on the Expectation-Maximization (EM) algorithm. The algorithm partitions clients into domain-homogeneous groups through two iterative steps. The expectation step (E-step), which assigns each client to the cluster whose prototype is most similar to the cluster-level prototypes. The maximization step (M-step), which updates the global cluster prototypes by aggregating the local feature representations of the clients assigned to each cluster. Our approach leverages class-specific feature prototypes to capture the statistical characteristics of each client's local data distribution. The EM procedure updates cluster assignments and prototypes throughout training. As a result, it supports adaptive grouping of clients and mitigates distributional discrepancies across institutions. These prototypes serve as a compact representation of domain-specific information and guide the clustering process.

In the E-step, each client i is assigned to a single cluster k via hard assignment. For each client, we compute the aggregated cosine distance between its local class-wise prototypes $\{P_i^j\}_{j=1}^C$ and the global cluster-level prototype $\{\tilde{P}_{j,l}\}_{j=1}^C$, for $l \epsilon \{1, \ldots, K\}$ and $C = |Y|$. Let $d(.,.)$ denotes the cosine distance. Client i is assigned to cluster k that minimizes this distance. It is determined in Eq. (2):

$$s_i^k = \begin{cases} 1, \text{if } k = \arg\min_l \sum_{j=1}^C d(P_i^j, \tilde{P}_{j,l}) \\ 0, \text{Otherwise} \end{cases} \quad (2)$$

where, $s_i^k \in \{0,1\}$.

Algorithm 1: Domain-aware client clustering

Initialize: A: set of all clients, T = total training rounds, α = EMA, η = learning rate, K: initial number of clusters, E: re-cluster interval, C_k: client clusters, D_i : local dataset of client i, E: number of local epochs, B: batch size, f_θ:feature extractor , h_ρ : classifier

Aggregator: initialize weights for all clients W_0

Client side

Receive global model from server W_0

For each client i in parallel do

  For each epoch = 1…E do

    For each batch in B do

      $z_b = f_\theta(x_b)$

      $\hat{y} = h_\rho(z_b)$

      $L_i = \frac{1}{|B|} \sum \log\left(\frac{e^{\hat{y}_{b,y_b}}}{\sum_j e^{\hat{y}_{b,j}}}\right)$

      $w_t \leftarrow W_t - \eta \nabla L_i$

      For each class j in D_i do

        $S_{i,j} = \{(x,y) \in D_i \mid y = j\}$

        Compute P_i^j with Eq (1)

        End

    End

  End

Send local parameter w_i local prototypes P_i^j and $|S_{i,j}|$ to server

Server side

For each client c in A in parallel do

$$W_{t+1} \leftarrow \sum_{i=1}^{N} w_t$$

Server collects latest normalized prototypes of each client c that reported P_i^j.

Request prototypes: p[c] ← GetPrototypes(c)

E-step: assign client c to cluster k using (2): client_assignments[c]=k

M-step: Update cluster prototypes using (3)

return client_assignments to resource-aware algorithm

return global parameter W_t to each client

End

The cluster index assigned to client i is: $k = \arg\min_l \sum_{j=1}^C d(P_i^j, \tilde{P}_{j,K})$.

Once all clients are assigned, the M-step then updates the global prototype $\tilde{P}_{j,K}$. It is computed as a weighted average of local prototypes from all assigned clients to that cluster as in Eq. (3):

$$\tilde{P}_{j,K} = \frac{\sum_{i=1}^{m} s_i^k |N_{j,i}| \, P_i^j}{\sum_{i=1}^{m} s_i^k \, |N_{j,i}|} \quad (3)$$

Where $|N_{j,i}|$ is the number of samples for class j on client i, and m is the total number of clients in the cluster k.

We use cosine similarity to compare local and global cluster prototypes. This choice is consistent with prior prototype-based FL methods [19]. Cosine distance emphasizes directional similarity and reduces sensitivity to magnitude differences. This property makes it more suitable for semantic similarity between class-conditional embeddings. Qiao et al. (2025) [17] have demonstrated that cosine distance outperforms Manhattan and Euclidean distances for prototype features representation.

Our domain-aware client clustering methodology employs the EM algorithm to iteratively partition clients into domain-homogeneous groups. The clustering is based on class-specific feature prototypes, as illustrated in Algorithm 1. The server first sends the initialized parameters to all clients (line 3). Each client then performs local training to compute model parameters (lines 5-10). After local model optimization, each client uses its feature extractor on training data to generate local feature prototypes P_i^j (line 13). These local embeddings are then transmitted to the server for the t-th communication round. We assume that the set of responding clients is denoted by S_t. The server updates the global model parameters by averaging the received $\{\theta_{t+1}^k\}_{k \in S_t}$, following the standard aggregation rule in FedAvg. Moreover, for the global prototype update, we introduce a new strategy that applies an EM algorithm to cluster clients into domain-homogeneous groups. In E-step (line 21), each client is assigned to the cluster that minimizes the aggregated cosine distance between their local prototypes and global cluster-level prototypes across all classes (line 21). In the M-step (line 23), the global prototypes are updated as weighted averages of local prototypes from clients assigned to each cluster. The weights are proportional to the number of samples per class. The role of EM is to assign each client to its corresponding cluster (line 24) and return these groups to the second phase of client selection. Finally, the server broadcasts the global parameter to each client (line 26) for the next local training iteration.

The EM algorithm is sensitive to two key hyperparameters: the initial number of clusters K and the re-clustering interval E. Regarding K, our framework exhibits an important asymmetric sensitivity. When K is initialized larger than the true number of underlying domains. The dynamic nature of our EM clustering provides a natural self-correcting mechanism. As training progresses and feature prototypes become increasingly discriminative, clients that belong to the same true domain will produce semantically similar prototypes. Consequently, the cosine distance between their local prototypes and a shared cluster-level prototype will decrease. As a result, these clients converge toward the same cluster assignment. Over time, the effective number of active clusters reduces toward the true domain count. This dynamic clustering is a direct consequence of using learned, progressive prototypes rather than fixed statistics. In addition, the re-clustering interval E controls how frequently cluster assignments are updated. Smaller values of E allow clusters to adapt more quickly to changes in the feature space. In contrast, larger values reduce computational and communication overhead but may delay the correction of incorrect cluster assignments.

C. An Efficiency and Fairness Global Client Selection

We propose a time-optimized and fairness global algorithm that dynamically selects the best set of clients from all clusters based on their real-time training and their historical participation in the training process. The approach evaluates participants according to their consistent engagement throughout the training. This involves adding a reliability score, which tracks clients' training times to distinguish between less responsive and more efficient clients. In addition, a fairness score is incorporated to ensure that clients with historically low participation are selected more frequently.

1) Reliability score: FL performance is constrained by the varying time each client needs to complete local training or transmit model updates to the server. These slowdowns caused by clients with poor network connectivity or low computational power are known as the straggler effect. The random client selection used in FedAvg effectively works only when no stragglers are present. Favoring resource-rich clients prevents slower clients from often contributing to the training. Hence, reduce global model's generalization leads to a loss of fairness in the learning process. To address this problem, [24] presents a client selection method that collects the maximum number of updates within a predefined deadline. Similarly, [30] proposes a tier-based approach that chooses clients with similar training durations per round. Nevertheless, such strategies may remove clients who possess statistically valuable data from the training process. This score enables the server to identify persistently slow clients without removing them entirely from the federation. Clients with high latency receive a proportional penalty through the reliability score. This penalty allows the server to prioritize faster participants when efficiency is required. The score preserves opportunities for slower but important clients to contribute to the training process. We avoid hard exclusion and rely instead on adaptive penalization. Hence, our reliability mechanism maintains system efficiency. This is an essential requirement in healthcare FL, where the loss of a single institution can eliminate an entire domain of patient demographics or imaging modalities.

In this setup, the available time of client c is defined as the duration required to complete the server's training request, which is measured when the client requests the aggregated weights from the server and starts its training process. Client computational heterogeneity obliges the server to wait for all clients' responses before performing global aggregation. This behavior increases idle time for faster clients. Our approach records the training time for all clients at each round. To characterize a client's responsiveness, we define $t_{avail,c}(i)$, as the training time of client c in a given round i. Since a client may perform efficiently in one round and more slowly in another, its performance is evaluated across all previous rounds rather than

a single observation. We propose a responsiveness $T_c(i)$ based on the Exponential Moving Average (EMA) of the training time for every client. $T_c(i)$ integrate recent and past performance information. It prioritizes clients with consistent reliability performance. We define $T_c(i)$ as in Eq. (4):

$$T_c(i) = \alpha t_{avail,c}(i) + (1-\alpha)T_c(i-1) \quad (4)$$

Here, $\alpha \epsilon [0,1]$ determines the trade-off between recent and older observations.

Eq. (4) focuses on consistent speed metrics and prevents fast clients from being incorrectly labeled as stragglers due to occasional delays. Consequently, it yields a more reliable and stable measure of client speed.

In synchronous FL frameworks, most methods use a threshold to decide which clients can participate in the training process. This mechanism exclude client permanently based only on the client's current training time. These thresholds are often predefined before training begins. Without any other knowledge of client performance behavior, they typically require extensive manual tuning. This limitation becomes critical in practical scenarios where new clients may join the training process with unknown computational capabilities, or when a majority of clients exhibit slower processing speeds. In such cases, indiscriminately penalizing or excluding all slow clients is both inefficient and counterproductive. Our method addresses this issue by evaluating each client's performance relative to the historical training times of all participants, enabling more context-aware and adaptive decision-making. This design is particularly important in domains such as healthcare federated learning, where each client possesses unique and irreplaceable local data distributions that are essential for building robust and generalizable global models. The reliability score is computed as in Eq. (5):

$$A_s = \frac{T_{max}}{(T_c + \beta T_{max})} \quad (5)$$

Where $T_{max} = \frac{1}{N}\sum_{c=1}^{N} T_c(i)$ and $\beta \geq 1$ controls penalty strength.

This equation is sound and effective. It penalizes clients whose average training time (T_c) exceeds the historical average of all clients (T_{max}). The use of an adaptive threshold (T_{max}) makes it robust to varying system conditions.

2) Fairness score: To achieve good training time, we reduced the selection of slower clients across rounds using the reliability score. However, this improvement in training speed might compromise the model's generalization. Repeatedly selecting only faster clients can bias the global model to overfit towards the data of often-presented institutions. This behavior might underrepresent important domains and limit the model's robustness. Therefore, it is important to give underrepresented data more chances to contribute to training. This is essential, as no institution should be permanently excluded from collaborative learning.

Our method ensures that every client remains eligible to contribute. To achieve this, we propose a new fairness score that increases the selection frequency of clients with historically low participation. We define f_s which quantifies a client's historical underrepresentation in the training process. The fairness score for a client c is a continuous, decaying function based on their selection ratio R_c. We define R_c in Eq. (6) to measure the underrepresentation of a client c based on a client's selection:

$$R_c = \frac{v}{\frac{T}{n} * K} \quad (6)$$

Algorithm 2: Adaptive participation for client selection

```
Inputs  T_warmup: number of warm up iteration, stage: the stage
        Of selection (domain or warmup), participated_clients:
        participated_clients , virtual_cluster_enabled:
        Boolean flag for virtual cluster usage.
1       participated_clients ← ∅
2       selection_counts ← {}
3       virtual_cluster_enabled=TRUE
5       For t in T-1 do
6           For each client in clients do in parallel:
7               Clusters ← {}
8               perform_clustering ← FALSE
9               If t ≤ T_warmup then
10              stage ← WARMUP
11              use_clustering ← FALSE
12              Else
13              stage ← DOMAIN_AWARE
14              use_clustering ← TRUE
15              If use_clustering then
16              perform_clustering ← TRUE
17              Else
18              Perform_clustering ← FALSE
19              If stage = WARMUP Or client_assignments
                is empty then:
20              Clusters[0] ← C_participated ∪ c
21              Else
22              For each client c
                ∈C_participated do
23                  If c in client_assignments then:
24                  k ← client_assignments[c]
25                  Clusters[k].append(c)
26                  Else
27                      Clusters[0].append(c)
28              If c not in participated_clients And
                virtual_cluster_enabled then:
29              k_virtual ← K
30              Clusters[k_virtual] ← C
```

where v represents the cumulative number of times client c has been selected for participation, T denotes the total number of completed training rounds in iteration i, N represents the total number of available clients, and K is the number of participants

in each round. This ratio quantifies whether a client has been selected proportionally to the ideal uniform distribution, where each client should participate in $\frac{TK}{n}$ rounds on average. The fairness score is then calculated using the inverse relationship defined in Eq. (7), which assigns higher fairness weights to underrepresented clients ($R_c < 1$) and lower weights to overrepresented clients ($R_c > 1$):

$$f_s = \frac{1}{1+R_c} \tag{7}$$

This approach guarantees that even clients who have been selected more than the ideal average still retain a small, non-zero fairness weight. This dynamic promotes balanced and fair participation during the entire learning process.

3) Global score: Given both data and resource heterogeneity, traditional client selection methods are largely insufficient for healthcare applications. Resource-aware strategies often exclude many clients from global aggregation because of their limited computational or communication capabilities. This preference systematically removes a larger number of relevant clients. In non-IID settings, clients may hold imbalanced data quantities or represent distinct domains, so excluding any institution can degrade the performance and robustness of the global model. To address this limitation, we present a global scoring mechanism in our clustering framework to achieve an adaptive balance between computational efficiency and participation fairness. The server computes a global score for each client and ranks all clients across clusters. It then identifies the top-k clients within each cluster and selects them for the next training iteration. This design enables the system to dynamically adjust selection frequencies across rounds in response to changing computational and statistical conditions. The global score uses historical training time patterns to identify stragglers relative to their peers of other clients (4–5) and adjusts their influence in a manner that avoids permanent penalization. Our method defines the global score as in Eq. (8):

$$s_c = \alpha_1 A_s + \alpha_2 f_s \tag{8}$$

α_1 and α_2: a balance between fairness and reliability of clients, and it can be tuned by users.

This equation enables explicit tuning of selection priorities. During early training, a higher α_1 can prioritize fast and reliable clients to stabilize the initial model. As training progresses, increasing α_2: ensures that underrepresented clients receive more opportunities. This improves domain coverage and enhances the model's generalizability. In healthcare-oriented federated learning, this approach addresses two fundamental challenges. First, it preserves institutional equity while maintaining the unique data contributions of each participating hospital or medical center. Second, it ensures that resource-constrained institutions are not systematically excluded from collaboration, which helps retain the diversity and generalizability required for developing robust medical AI models.

As illustrated in Algorithm 2, the client selection mechanism proceeds through several phases designed to balance training efficiency, domain diversity, and participation fairness. The clustering algorithms depend on learned feature representations. However, in early rounds, randomly initialized models produce unreliable embeddings that do not reflect true data distributions. Therefore, we propose a warm-up period to allow the model to learn domain-specific features. Our approach clusters clients using learned feature representations rather than raw statistics. Domain heterogeneity is determined by the internal representations that models acquire rather than by the raw data itself. For this reason, most existing methods aim to learn domain-invariant feature representations to mitigate this issue [25]. During the warm-up phase, all clients are treated as a single cluster, and the global selection score operates over the entire client set. This phase stabilizes training and prioritizes fast, consistent clients to build a strong initial global model.

Algorithm 3: An efficient and fair global client selection

Inputs Clusters: set of clients in a cluster k, $t[c]$: time availability score of client c, T_{avg} : average training time of all clients, $t_{avail,c}$: training time of client c, T: total training rounds , α : EMA smoothing factor, β = reliability penalty parameters, Q: number of selected clients in each cluster, selection_counts: tracks selection frequency per client,t_hist: training history times of selected clients

1 For each cluster k in Clusters:

2 candidates ← Clusters[k]

3 For each client c in Clusters[k] do:

4 If c *not in* t_hist then:

5 t[c]=$t_{avail,c}$

6 Else:

7 $t[c] = \alpha t_avail + (1-\alpha)$ t[c]

8 $T_{max} = \frac{1}{N}\sum_{c=1}^{N} t[c]$

9 End

10 *compute* A_s with Equation (3)

11 If

12 $f_s[c] \leftarrow T / (T + selection_counts[c] \times n)$

13 Else

14 $f_s[c] = 1.0$

End

15 Compute global score score with (8)

16 participated_clients ← participated_clients ∪ {c}

17 selection_counts[c] ← selection_counts[c] + 1

18 End

For cluster in candidates do

19	candidates_sorted ← Sort (candidates, key= score, reverse=True)
20	selected_k ← candidates_sorted[0:Q]
21	Clusters_tos[k]= selected_k
22	End
23	Return Clusters_top

In later phases, we increase fairness to ensure that all clients can contribute. After the warm-up period, the algorithm enters the domain-aware phase. It first records baseline participation patterns (lines 8–10), then performs clustering to identify groups reflecting underlying data domains (lines 12–16). After the clustering phase, clients are organized into groups for selection (lines 19-27). Moreover, A challenge arises due to partial participation in federated learning. FedAvg aggregates updates only from selected clients, while non-participating clients do not contribute to model updates. As a result, the prototype collection is biased toward previously selected clients, and the EM clustering algorithm subsequently operates on a limited set of prototypes. This bias may cause cluster assignments to reflect historical selection patterns rather than true domain characteristics of all clients. To address this limitation, we introduce a virtual cluster appended to the EM-derived clusters. This additional cluster represents clients that have not yet participated in training, thereby preventing systematic exclusion and preserving domain diversity. we initialize the fairness score to its maximum value ($f_s = 1.0$) for clients that belong to the virtual cluster (lines 28-30). This initialization ensures that the global selection score considers these clients and ranks them alongside active participants. As a result, previously inactive clients receive an opportunity to contribute to training and become eligible for the domain clustering algorithm in the next rounds.

Algorithm 3 outlines the client selection procedure executed by the server during iteration t. The selection mechanism samples clients from both the EM algorithm and the virtual cluster (line1). This strategy allows the clustering process to access a broader range of client information, which helps preserve representativeness and reduce selection-induced bias. At each iteration t, participating clients report their training time $t_{avail,c}(i)$ to the server. Each client c updates its historical training time $T_c(i)$ using Eq. (4) (line 7). Once all client reports are received, the server calculates the average training time T_{max} (line 8). After completing clustering assignments using the EM algorithm for all clients, the server computes two scores, respectively: first, a reliability score (line 10) that evaluates temporal efficiency and a fairness score that measures participation equity (line 12). For previously selected clients, the fairness score is updated using Eq (8). For new clients, the fairness score is initialized to the maximum value ($f_s = 1.0$) to guarantee initial participation (lines 13). Finally, the server integrates these components to compute the global selection score s_c (line 15). This score provides a global ranking of clients, independent of their cluster assignment. The server enforces cluster-level selection. Within each cluster, clients are sorted by their global score, and the top-k clients are then selected. Thus, while the ranking is global, the final selection is performed within each cluster. This design balances fairness and efficiency globally while ensuring domain diversity. First, it reduces the chance that a single domain dominates selection simply because it contains many high-scoring clients. Second, it prevents the exclusion of minority domains and provides broader representation in training. Third, the approach maintains sensitivity to system heterogeneity, as slow clients are penalized regardless of their domain. This aligns with our motivation that GDCSF balances straggler mitigation, domain diversity, and fairness toward underrepresented clients.

IV. EXPERIMENT

A. Implementation Setup

We evaluate our method on the PathMNIST benchmark for multi-class medical image classification [33]. In a typical federated learning (FL) setting, we compare CDCSF with two standard FL baselines, FedAvg and Power-of-Choice (PoC), as well as with a centralized learning model. The evaluation is conducted under conditions of domain shift and the presence of straggling clients, which reflect realistic FL deployment scenarios. To emulate domain shift across clients, we partition the system into four domains representing distinct imaging conditions. Specifically, we split the PathMNIST training set into three separate domains, while the test set is assigned to an additional client, which serves as a fourth independent domain. Domain 0 corresponds to the original domain of the dataset. Domain 1 simulates mid-range equipment commonly found in resource-constrained settings and introduces a modest change in brightness (between −0.2 and +15%), reduced resolution, and contrast variations in the range [0.6, 1.4]. Domain 2 represents degraded imaging conditions, modeling more challenging real-world scenarios via increased brightness (+0.3), additive Gaussian noise ($\sigma = 0.12$), and contrast variations in [0.5, 1.5]. To additionally examine model behavior under system heterogeneity, we designate a subset of clients as stragglers throughout the entire training process. Whenever a straggler is selected for participation, we impose an additional delay sampled uniformly at random from the interval [10, 20] seconds for each local training phase. Although the added delay does not represent actual hospital latencies, it still produces the same relative effect. Fast clients proceed at normal speed, whereas stragglers require two to three times longer to complete their local updates. This controlled slowdown reflects the variations in hardware performance, workload, and network connectivity found across healthcare institutions, where some sites consistently operate more slowly than others. All experiments use a ResNet-18 backbone as the core feature extractor to ensure a fair comparison between all the methods.

The ResNet architecture was adapted for the PathMNIST dataset, which consists of 28×28 RGB images. To accommodate the smaller input size, the initial convolutional layer was modified to use a 3×3 kernel with stride 1 and 32 initial feature maps, followed by four residual blocks with progressively increasing channel dimensions (32, 64, 128, 256). Each block comprises two convolutional layers, batch normalization, and ReLU activation, followed by an adaptive average pooling layer and a fully connected classification head. The CDCSF model integrates this ResNet backbone within a federated learning framework, where the feature extractor is complemented by a projection module for prototype extraction and clustering. This

module consists of two linear layers with ReLU activation, reducing the feature dimensionality to 128 while preserving discriminative representations through normalization. The classification head is implemented as a single fully connected layer mapping the extracted features to the nine target classes in PathMNIST. Federated training was implemented with the Flower framework [34]. We conduct experiments with K = 10 and K = 20 clients. For K = 10, we sample 4 clients per round, and for K = 20, we sample 6 clients per round. Each selected client performs 3 local training epochs. Training runs for 200 global rounds until convergence. To ensure a fair comparison, all federated learning methods use the same hyperparameters, batch size of 32, and a learning rate of 0.01. All experiments are executed on two NVIDIA T4 GPUs.

B. Results and Discussions

We evaluate the proposed CDCSF framework under two key challenges in federated learning: (1) data heterogeneity and (2) system heterogeneity. We compare CDCSF with two FL baselines: FedAvg and Power-of-Choice (POW) and centralized learning. Table II reports the average test accuracy under domain shift and system heterogeneity. CDCSF achieves the highest final accuracy among all methods and surpasses FedAvg by 1.7 %. It also converges approximately two times faster. CDCSF shows strong effectiveness under a distribution shift. First, the domain-aware clustering groups clients according to their latent data distributions. This ensures that each round selects clients representing diverse domains within the global data distribution rather than sampling from randomly biased domain sources. Second, during the client selection, the global score assigns a higher historically underrepresented. This reduces early-round instability, especially under severe domain shift. CDCSF consistently surpasses Power-of-Choice (POC) with an improvement of more than 8% in final accuracy. This improvement is expected because POC evaluates clients only through their performances, which assigns higher weights to clients with higher loss and skews the optimization toward dominant domains. However, in domain-shifted medical data, this type of selection intensifies sampling bias, reduces the participation of minority domains, and increases the influence of the overrepresented clients. In contrast, CDCSF preserves domain diversity through prototype-based clustering and gives priority to reliable clients in early rounds. As a result, CDCSF selects a more informative and balanced client subset in each round. The results show that CDCSF fits heterogeneous medical settings more effectively, where strong performance requires both computational efficiency and balanced domain representation.

TABLE II. ACCURACY IMPROVEMENT OF CDCSF COMPARED WITH FEDAVG, POC, AND CENTRALIZED LEARNING UNDER DOMAIN SHIFT

Algorithm	Accuracy
FedAvg	82.02%
PoC	66.37%
CDCSF	83.78%
Centralized Learning	86.23%

To demonstrate the benefits of our framework under domain shift, we present the validation accuracy of all FL methods in Fig. 2. For clarity, note that the validation accuracy reported for each method is computed as the mean validation accuracy of all clients. CDCSF achieves faster convergence in early rounds compared to FedAvg and Power-of-Choice (POC). Our method reaches 80% accuracy within 75 rounds, two times faster compared to FedAvg, while POC fails to attain this accuracy. During the early iterations, when the model begins to converge, CDCSF selects clients from diverse domains. This ensures that heterogeneous data sources contribute to the global model. Hence improves generalization performance. In addition, the algorithm initially prioritizes fast and reliable clients to accelerate convergence. As training progresses, we increase the weight of the fairness score to enable slower or previously underrepresented clients to join the training process. Further, we highlight the effect of distribution shift on the compared client selection frameworks. Domain heterogeneity generally reduces performance, but its impact on FedAvg remains comparatively modest, as shown in Table II and Fig. 2. This behavior aligns with our motivation because FedAvg selects clients uniformly at random, which ensures that all clients from different domains participate with uniform equal frequency. Under domain shift, such uniform selection benefits the global model. As a result, exposure to all domains enables the model to learn efficient domain-invariant representations. Consequently, we also observe that FedAvg converges faster than (POC), which suffers from a selection bias that oversamples certain domains while underrepresenting others. This bias degrades the model's performance by repeatedly prioritizing clients with temporarily higher losses. These observations show that distribution shift harms client-selection algorithms that rely primarily on resource availability or short-term statistical performance.

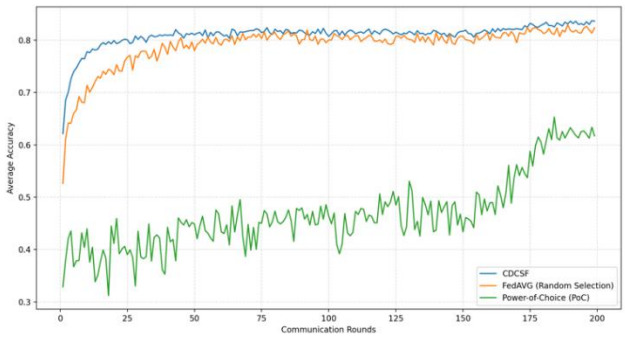

Fig. 2. Average validation accuracy of CFDSC, FedAvg and PoC across communication rounds.

As illustrated in Fig. 3, FedAvg selects clients at similar frequencies, but CDCSF produces a more balanced and adaptive pattern that reflects both efficiency and domain diversity. Although uniform sampling guarantees equal selection frequency in FedAvg, this property is insufficient in healthcare FL, where clients suffer from a domain shift issue. This sampling neglects the existing domain imbalances, enforcing equal participation frequency across clients without addressing underlying distribution disparities. CDCSF addresses this limitation through a domain-aware clustering mechanism that groups clients using privacy-preserving feature prototypes. The server applies an EM algorithm to identify heterogeneous clinical domains by clustering clients according to their underlying data distributions. As a result, even clinically

important domains with only a few clients are placed into their own clusters rather than being merged with the majority of domains. Moreover, the incorporation of EMA reliability scoring mitigates the impact of stragglers without permanently excluding slower institutions, while the fairness score ensures equitable participation for historically underrepresented clients. The global scoring mechanism then selects the top-k clients from each cluster and ensures consistent representation of minority domains throughout training. These components form a coherent and robust improvement over random selection. The method increases representativeness, reduces domain bias, and supports more efficient convergence in federated healthcare settings.

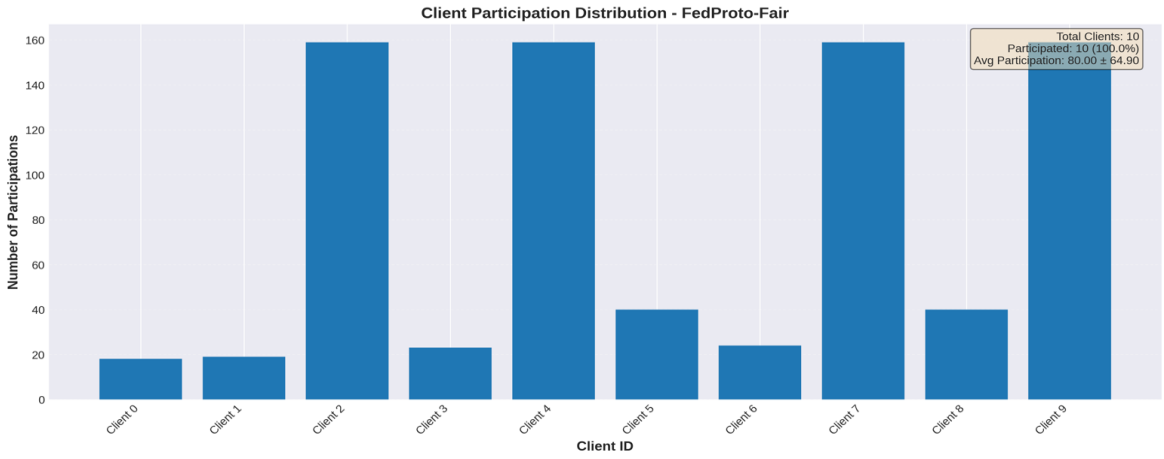

Fig. 3. Comparison of client participation frequencies across methods.

To model system heterogeneity, we define stragglers as clients who incur additional delay during local training. In our simulation, we assign this role to clients 0 and 1, while all other clients operate normally.

The server computes an exponential moving average (EMA) of each client's training time and computes a global reference value T_{max} at every round, obtained as the mean EMA across all clients. Fig. 4 displays each client's EMA estimate T_c together with the global reference T_{max}.

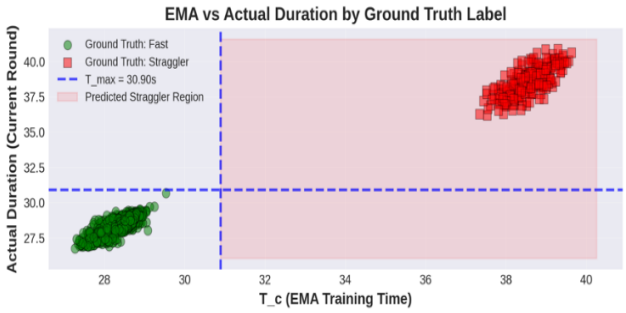

Fig. 4. The detection of stragglers' performance using EMA reliability scoring.

The straggler clients, shown in red, fall in the 37–40 second range, whereas fast clients, shown in green, cluster around 28–30 seconds. The two groups remain well separated. The vertical dashed line at $T_{max} = 30.9$ Seconds highlights this separation. The shaded region corresponds to the decision boundary of our reliability score. A client falls inside this region when its score $s = 1 - A_s$ exceeds the threshold θ. We use this score to predict whether a client is a straggler or not. The visualization confirms that our detection rule remains stable across all 200 rounds, despite the random injection of extra delay.

To further examine how the reliability score prioritizes fast clients, we train the model with k=20 clients and visualize the relationship between each client's reliability score and its EMA training time. Fig. 5 illustrates how training duration affects the reliability metric. Clients with larger T_c values (e.g., Clients 0 and 1) appear in the lower right region of the plot and receive lower reliability scores, which reflects the inverse relationship between training time and reliability. In contrast, faster clients form a compact cluster in the upper left region, indicating consistently higher reliability. This visualization confirms that the scoring mechanism effectively separates slow and fast clients and demonstrates that faster clients get higher prioritization weights. Importantly, the purpose of the reliability metric is not to penalize or exclude stragglers. Instead, it assigns them appropriately reduced weights while preserving their participation. Their inclusion is reinforced through the fairness component, which ensures equitable representation so that the global model still benefits from their unique data characteristics.

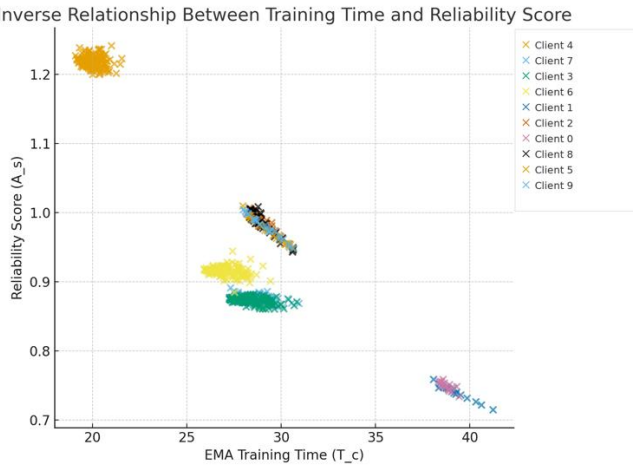

Fig. 5. Relationship between EMA training time and reliability score.

To further evaluate the impact of data heterogeneity, we partition the dataset across clients using a Dirichlet distribution with concentration parameter α=0.5, which creates a highly skewed non-IID distribution. Fig. 6 visualizes the distribution of each class across clients for all domains.

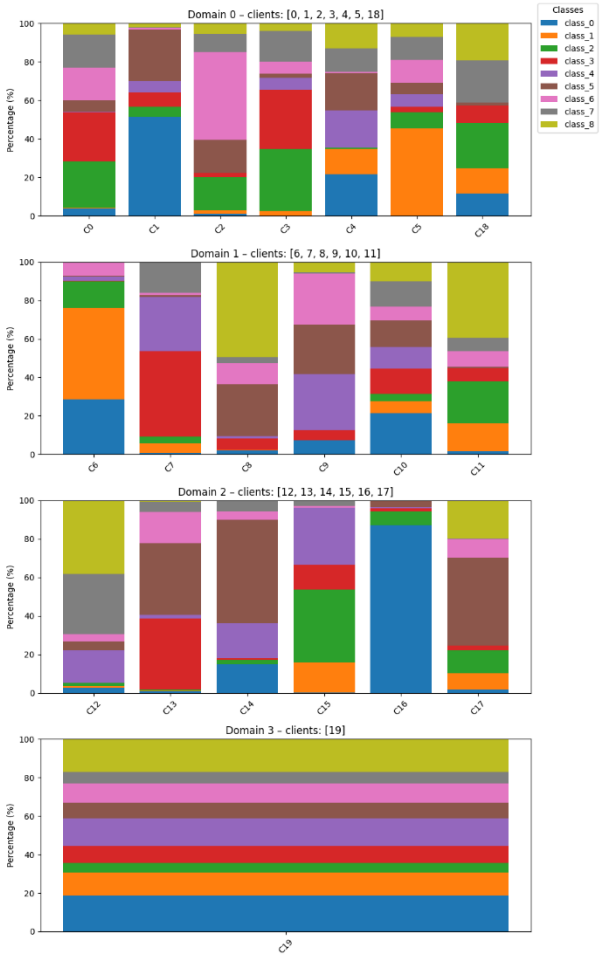

Fig. 6. Visualization of non-iid client distributions using Dirichlet sampling under domain shift when ($\alpha = 0.5$).

In addition, we apply a severe domain shift to each domain to increase the difficulty compared to our initial simulation. In this experiment, only 6 out of 20 clients are selected per round. In practical FL deployments, data heterogeneity is the norm. Therefore, this analysis allows us to evaluate how CDCSF simultaneously addresses both data and resource heterogeneity. In this setting, we test multiple scheduling policies from the CDCSF framework. Each policy selects clients based on global scores that combine reliability and fairness weights. Each configuration produces a distinct CDCSF graph. The reason for that is to show different trade-offs between efficiency and participation. We compare these policies with the FedAvg baseline. We refer to this algorithm as vanilla. As expected, the overall accuracy in Fig. 7 is lower compared to the results shown in Fig. 2. This behavior is expected because the data distribution in this scenario jointly combines feature skew and label imbalance, both of which are known to disrupt the performance of federated optimization. Our method does not attempt to correct the data distribution issue at its source. However, we observe that CDCSF (hybrid) shows a stable and consistent learning trajectory. In contrast, FedAvg demonstrates pronounced fluctuations characterized by inconsistency across rounds, which indicates its sensitivity to non-IID distribution. These results demonstrated the role of CDCSF in mitigating the effects of data and resource heterogeneity. This improves the convergence rate even when both conditions coexist. The results in Fig. 7 further illustrate the impact of our three selection strategies. CDCSF–fast prioritizes clients with high reliability scores and favors devices that have historically shown faster performance. CDCSF–equal assigns equal weights to fairness and reliability across all rounds. CDCSF– hybrid adopts a dynamic policy that emphasizes reliability in the early rounds and increases fairness weight in later rounds to incorporate underrepresented clients more effectively. This adaptive behavior allows CDCSF–hybrid to maintain efficient training while progressively enhancing participation diversity. During the first 20 rounds, which serve as the warm-up phase, we do not employ the EM domain clustering. All methods behave similarly and show nearly identical performance. As expected, this confirms that, in the absence of clustering, the client selection process behaves like random sampling. In this early stage, training time does not provide meaningful information for distinguishing reliable from non-reliable clients, so the global selection mechanism does not contribute to performance improvement. Once the warm-up phase finishes and EM clustering becomes active, the performance of the methods begins to diverge. We observe that CDCSF–hybrid achieves the best convergence and outperforms all other policies. Its design prioritizes reliable clients in the early iterations, which stabilizes learning and refines the local feature-prototype representations that guide domain assignment in the clustering. As training progresses, we increase the fairness weight so that unrepresented clients are then incorporated in domain coverage without disrupting optimization. Introducing fairness in the mid-stage is essential because it allows underrepresented clients to enter the global score ranking and ensures their participation from the mid to late rounds. This gives these clients sufficient opportunity to contribute their updates and influence the global model. This adaptive balance between early reliability and later fairness enables CDCSF–hybrid to achieve both stable convergence and improved generalization across heterogeneous domains. The behavior observed in the fast and equal policies further supports this interpretation. The fast policy outperforms the equal policy because, under imbalanced data distributions, FL algorithms naturally benefit from consistently available participants who contribute updates regularly. Similarly, FedAvg, which relies on random selection, outperformed the equal policy, which confirms that participation consistency plays a central role in FL performance. However, relying on consistent clients leads to biased learning. CDCSF–hybrid overcomes this limitation by ensuring a balance between high-participation clients and those underrepresented in the federation. This balance produces more stable and effective training and enables higher performance in challenging settings characterized by both data and resource heterogeneity. Resource heterogeneity often increases the number of underrepresented clients because many client selection strategies prioritize fast and consistently available devices while excluding clients with constrained computational resources from the training process. Although prioritizing such

clients may offer advantages in iid settings, it becomes a challenge under non-IID distributions. In healthcare, these slower clients frequently hold rare classes or essential domain information. Excluding the theme removes critical data from the learning process and degrades the model performance. As a result, when data heterogeneity and resource constraints coexist, traditional client selection methods fail to maintain domain diversity and struggle to achieve robust performance in federated learning.

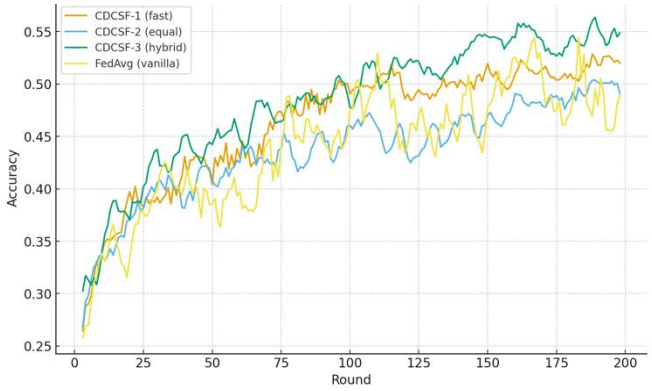

Fig. 7. Comparison of client selection policies on PathMNIST under severe domain shift and non-iid data heterogeneity.

V. Conclusion

In this work, we introduced CDCSF, a domain-aware client selection framework that combines prototype-based clustering, reliability estimation, and fairness participation to guide dynamic selection during training. The framework aims to preserve domain diversity, reduce sampling bias, and ensure that underrepresented clients contribute to training despite their computational capacity. In healthcare settings, data are often limited and heterogeneous. Effective client selection is therefore essential to preserve diversity, improve representativeness, and enhance model robustness. Despite these advantages, CDCSF remains sensitive to clustering hyperparameters, including the number of clusters and update frequency. Inappropriate settings may disrupt the EM optimization process, which may slow model convergence. Furthermore, although prototype-based clustering preserves privacy, it may introduce additional communication overhead. In addition, CDCSF adjusts client weights to mitigate straggler effects. However, extreme system heterogeneity can still delay aggregation and slow training. Overall, CDCSF demonstrates that domain-aware client selection can simultaneously address data heterogeneity and resource constraints in federated healthcare settings. Extending the framework to real-world multi-institutional deployments and validating it under more real-world datasets represent the most critical directions for future research.

V. Conflict of Interest

The author declares that there are no conflicts of interest related to this research.

***Abstract*—Emotion recognition is critical in the development of real-time mental health care and individualized cognitive behavior. Current strategies to recognize cognitive emotions frequently fail to capture complex time dependencies and multimodal physiological reactions, leading to sub-optimal performance and inaccurate generalization. To overcome such shortcomings, the proposed study suggests TCADNet, a new deep learning model that integrates Temporal Convolutional Networks (TCN), attention-based feature weighting, and GAN-based data augmentation to achieve a high recognition rate of the emotional states through EEG and fNIRS recordings. The model utilizes the TCNs to extract both short-term and long-term temporal trends, and the attention mechanism emphasizes salient parts that bring about emotions, which improves interpretability. Moreover, a Deep Convolutional GAN creates artificial signals of unrepresented emotion classes, eliminating data imbalance and enhancing generalization. The TCADNet model is coded in Python on the TensorFlow/Keras system, and its key components are preprocessing, time modeling, attention weighting, data augmentation, and last classification by SoftMax layers. Experimental outcomes indicate that TCADNet has high recognition performance, with overall recognition, accuracy, precision, and recall, and F1-scores of over 98, which is higher than conventional CNN, LSTM, and separate TCN models. The suggested methodology can be useful to researchers, clinicians, and mental health professionals as it allows them to monitor cognitive and emotional conditions in real-time with a reliable, decipherable, and scalable instrument and provides an opportunity to detect and respond to the issue promptly and implement a tailored intervention plan in educational or health-related settings.**

***Keywords*—Emotion recognition; Temporal Convolutional Network; attention mechanism; mental healthcare; EEG**

I. Introduction

The rising cases of mental health problems have led to the invention of intelligent, and autonomous systems that are able to identify emotional states with high precision and confidence. According to the estimates done by the world health organization (2024), over 280 million individuals around the world are affected by depression and stress-related disease and emotional dysregulation can frequently precede clinical manifestations [1]. Electroencephalography (EEG) is a non-invasive neurophysiological method that obtains a record of electrical activity in the brain by electrodes on the scalp and the frequency content is measured in microvolts (uV) at frequencies between 1100 Hz [2]. EEG offers a very high temporal resolution of milliseconds, which can accurately trace fast neural changes related to emotional and thinking processes. Conversely, functional near-infrared spectroscopy (fNIRS) is an optical neuroimaging modality technique that monitors effects of hemodynamic changes by measuring alterations of oxygenated (HbO) and deoxygenated hemoglobin (HbR) in the bloodstream by using near-infrared light sources with sampling rates around 7-10 Hz. Although EEG records direct electrical activity of neurons with a high level of temporal resolution, fNIRS is more effective in providing a localization of cortical blood flow in terms of the vascular response [3],[4]. The combination of the fast temporal sensitivity of EEG and the spatial specificity of fNIRS can be used to further describe emotion-related brain activity in a more comprehensive manner.

The trends in artificial intelligence (AI) recently have demonstrated that, when given raw physiological signals, deep learning models can learn discriminative features. Convolutional Neural Networks (CNNs) and Long Short-term

Memory (LSTM) networks have demonstrated good results in terms of identifying emotional patterns given time-series data [5]. Nevertheless, these architectures have some serious drawbacks, including extreme sensitivity to noise [6], inability to deal with long distance temporal dependencies and uninterpretability [7]. The cognitive frameworks that make up multimodal interaction are stipulated based on the occurrence of a particular modality-verbal, bodily, and visual-is mode of interaction, the presence of a grammatical structure-syntax, and narrative as well as whether they are predominant throughout the whole semantics of the expression [8]. Multimodal sentiment analysis is the most interesting study area of AI across the disciplines. The current classification task of human multimodal sentiment analysis is a highly finer task compared to the previous classification tasks. MSA has made significant contributions to human affection polarity detection over the past years since the advent of DL and the benefit of neural networks [9]. Multimodal DL consists of a number of challenges. One of the critical issues is the conversion of the information in multimodal form to the machine readable one [10]. AI solutions have a high potential of enhancing mental health. However, which approach should be selected is an issue of main concern [11]. Depression and stress are highly prevalent mental disorders that permeate the whole globe to the extent of reaching everyone in the society regardless of their age, gender and social economic statuses [12].

With such gaps in mind, the emerging concern of Temporal Convolutional Networks (TCNs), attention-based mechanisms and generative adversarial networks (GANs) has been in the past due to its capability in capturing and addressing temporal dependence, improving interpretability and reducing data imbalance, respectively. However, the existing methods seldom use all three mechanisms into a single model of cognitive emotion recognition basing on multimodal cues such as EEG and fNIRS [13]. In this case, assessment of any unfavorable psychological characteristic such as stress, anxiety and sadness all hinge on the detection of emotion. The second source of knowledge is the application of a new combination of an electroencephalogram (EEG) data [14]. The smart use of technologies has transformed the healthcare industry in a monumental manner. The focus of all the research is on the following critical aspects: medical imaging and diagnosis, virtual patient treatment, medical research and drug discovery, patient engagement, compliance, rehabilitation, and other administrative applications. It is based on the general picture that illustrates the application of AI in the area of medicine [15]. The advent of the artificial intelligence technologies has enhanced the efficiency and reasonability of the data collection process that has tremendous influence on the field of illness management and prevention [16]. The rising rate of mental diseases among the youths globally is one of the biggest problems in this society [17]. The issues of mental diseases are extremely high in the youth population; according to the existing estimates, 20 per cent of children and adolescents in the world are mentally ill [18]. The mental health care services is also needed today due to the social change, rising demand of optimal healthcare and flexibility of the mental illness. The conventional channels of accessing mental health services are pushed to the brink by the lack of resources and long queues in the process of accessing the services [19]. Sentiment analysis and emotion detection are vital in emotive management of patients in the healthcare [20].

A. Research Motivation

The growing rates of cognitive stress, anxiety, and dysregulation of emotions in students demonstrate the urgency of objective and real-time emotion recognition tools. Conventional methods of assessment mostly use self-administered questionnaires and behavioral observations, which are subjective and cannot detect fast neurophysiological variation. Electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS), on the contrary, offer a complementary neural measure in electrical brain activity and hemodynamic responses, respectively. Nevertheless, such multimodal time-series signals are difficult to model, as they are noise sensitive, their temporal misalignment, and multi-complex long-range correlations. Traditional deep learning algorithms like CNNs and LSTMs tend to violate the causality of the time, interpretability, and address data imbalances in affective data. These constraints inspire this study to present a unified deep learning model consisting of temporal convolutional network, attention, and generative adversarial augmentation to achieve robust, interpretive, and scalable multimodal cognitive emotion recognition of student mental health in monitoring.

B. Research Significance

This study makes contributions to multimodal cognitive emotion recognition as it provides a single deep learning framework specific to EEG-fNIRS signal fusion. The model is used to learn temporal dependencies on long distances by exploiting temporal convolutional networks (TCNs) without violating causal order and permitting real-time use. By using a temporal attention system, interpretability is improved by detecting time segments of emotional salience in neural recording [21], [7]. Moreover, GAN-based augmentation decreases the class imbalance and enhances the performance of generalization in emotion datasets. The proposed framework takes advantage of the complementary nature of the high temporal resolution of EEG and the spatial resolution of fNIRS, unlike the more conventional single-modality methods, which lead to a higher strength and discrimination ability. The system facilitates scaled real-time use which will be useful in the mental health assessment, academic stress monitoring and adaptive learning settings. In general, the structure presents a non-invasive, objective, and data-driven alternative to traditional psychological assessment tools, allowing to detect and proactively manage the emotional-related cognitive conditions early.

The contribution of the research are as follows:

- Developed a Temporal Convolutional Attention-Driven Network (TCADNet) for multimodal cognitive emotion recognition, capable of modeling complex temporal dependencies in synchronized EEG and fNIRS neurophysiological signals.
- Employed a Temporal Convolutional Network with causal and dilated convolutions integrated with an attention mechanism to identify emotionally significant time segments and improve interpretability.

- Utilized the publicly available REFED multimodal EEG–fNIRS dataset to validate the effectiveness of the proposed framework under realistic emotion elicitation conditions, including synchronized signal preprocessing and temporal window segmentation.
- Achieved high classification accuracy and improved generalization performance compared to conventional deep learning approaches, demonstrating the robustness and scalability of the proposed framework.

C. Problem Statement

Neurophysiological signals are complex, non-linear, and time-varying, which makes it a challenging undertaking to identify cognitive emotions pertaining to stress accurately. Multimodal signals, including electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS), can give complementary data regarding the neural electrical activity and hemodynamic responses [22],[23], but they are not easily described in terms of their temporal dynamics or cross-modal interactions. The presence of long-term temporal dependencies and variations in the context of emotion states in conventional machine learning models has led to the frequent reliance on hand-crafted features in traditional analytical methods and machine learning models [18]. Recurrent neural networks and conventional convolutional architectures that have been used in emotion recognition do have weaknesses, including the disappearance of gradients, excessively high computational expense, low levels of interpretability, and the inability to conduct multimodal synchronization. Moreover, in many cases, emotion datasets are also unbalanced in classes, and this results in biased learning and lower generalization scores. The absence of mechanisms to detect emotionally salient temporal pieces also limits the reliability of the models [21]. The constraints prevent the creation of effective, real-time multimodal emotion recognition in student mental health monitoring. Consequently, there exists an acute necessity of scalable and understandable deep learning structure that can imitate multi-scale time-related characteristics, deal with the issue of class imbalance, and utilize EEG-fNIRS data in a manner that is effective in providing cognition emotion recognition.

The study is organized as follows: Section I presents the motivation, challenges, and goals of AI-based multimodal emotion recognition. Section II overviews related research. Section III explains the proposed self-supervised temporal learning framework, multimodal data fusion, and experiment setup. Section IV shows results and analysis. Section V concludes and summarizes future work.

II. Related Works

Kargarandehkordi et al. [21] proposed to critically evaluate the use of AI models for forecasting, tracking mental health states and symptoms using wearable biosensor data. Following PRISMA criteria, the authors conducted a systematic analysis of 48 studies using a range of sensors, including location, accelerometry, heart rate, heart rate variability, electrodermal activity, audio, and smartphone use data. These sensors provide continuous, remote, and objective mental state monitoring and are integrated into wearable technology like fitness bands and smartwatches. The integration of AI, especially ML, makes it possible to detect mild physiological, behavioral signals and signs related to mental health.

Dritsas et al. [7] proposed recent developments in methods and adaptive system architecture for multimodal systems. Though specific datasets do not directly find use in the study, systems by modalities that usually utilize sensor-input datasets like motion capture, speech recordings, eye-tracking, and physiological signals are also analyzed in the study. Enhanced usability, natural interaction, context-sensitive flexibility, and portability across a wide range of applications, such as healthcare, are some of the most significant advantages. Difficulties, however, are in terms of complex input synchronizing, conflict of fusion, environmental flexibility and lack of standardized structures or frames of reference to actual deployments.

Avital et al. [2] proposed to create a real-time system for assessing lecturers' teaching quality by observing students' facial expressions to identify emotional states while listening to lectures. The procedure consists of four phases. They are: image capture, preprocessing, emotion recognition and identification. The data was obtained experimentally from a class of 45 students recording live facial expressions during lectures. The major strengths are instant feedback regarding student engagement, high accuracy (83%) in emotion recognition and high correlation (91.7%) with conventional feedback methods. Further, the suggested application of optical neural networks suggests quicker and more efficient processing than electronic systems. However, some limitations are moderate prediction accuracy of student comprehension (43–62.94%), possible privacy issues, reliance on steady lighting and camera position for proper facial detection. Nassiri and Akhloufi [3] suggest the use of large language models like GPT, Bloom and LLaMA in the healthcare industry for enhancing patient care, medical research and diagnostic assistance. The objective is to evaluate the ability of LLMs to read, create medical text and approximate their usability in actual clinical practice. The approaches encompass a thorough review and examination of the architectures of top LLMs, their training, and their performance on medical tasks. The study investigates datasets for training these models, which are classified by size, source and medical topics. Among the strengths, LLMs have tremendous potential to aid healthcare professionals in documentation, literature review and decision-making, as well as potentially enhance the efficiency of the healthcare system through automation.

X. Chen et al. [22] proposed to investigate the evolution and trend of AI-based multimodal data analysis in smart healthcare using large-scale literature research. In order to make this a reality, authors used bibliometric analysis and topic modeling techniques in order to explore 683 scholarly articles across 2002 and 2022. The data of analysis were procured from research databases with specific focus on AI, healthcare, and multimodal integration of data. The stark strength of the work lies in its capability of uncovering avenues of research that will unfold, leading individuals and topics to follow such as GANs, contrastive learning and hybrid neuroimaging approaches. It has worldwide emphasis with special regard being provided to contributions from nations such as the USA and India. While, there are certain limitations like possible bias because of data selection (language or database constraint) or grey literature

exclusion and article metadata use instead of experimental or clinical data. Despite this, the study provides valuable points for future interdisciplinary research in AI-based smart healthcare.

Lee et al. [23] has been suggested to study the integration of Artificial Intelligence into the field of biomedical signal analysis to enhance the effectiveness and accuracy of diagnosis in healthcare. It dwells upon the most prominent AI approaches that are controlled, uncontrolled, reinforcement learning and how it can be applied to interpret bio signals like EEG and ECG. The methods involve the analysis of various AI architectures and learning paradigms applied in the classification of physiological signals, action and abnormalities, and decision-making activities. Despite this, the review lacks dataset specificity. It is founded on actual biomedical signals, such as ECG and EEG, in different clinical settings. Among the key advantages, one can distinguish the increased speed and accuracy of the diagnostic process, reducing the amount of work that is to be carried out manually and increased access to health services in resource-deficient areas and better response to emergencies through the rapid analysis. Yet, constraints include data privacy issues, interpretability of the model, dependence on high-quality labeled datasets and real-time integration difficulties in clinical settings. Payandeh et al. [4] proposed an overview of deep representation learning methods, pointing out their application to learn meaningful, low-dimensional features from high-dimensional data for tasks like classification, prediction and segmentation. While the review does not concentrate on particular datasets, it mentions varied types of data such as images, text, sequential data and multimodal inputs. The benefits of such methods are to learn generalizable and transferable features automatically without handcrafted feature engineering, thus enhancing learning robustness and model generalizability. Although much headway has been achieved, limitations persist in the ability to learn interpretable representations, having intensive computation, managing scarce or biased data, as well as deriving strong robustness across diverse domains or conditions.

III. Proposed TCADNet Framework for Cognitive Emotion Recognition

The proposed study proposes a Temporal Convolutional Attention-Driven Network (TCADNet) to learn to detect robust cognitive emotions through synchronized multimodal EEG fNIRS physiological signals. The framework is used to describe a multi-stage workflow that is structured to efficiently model the complex time dynamics of neural processes and enhance their classification performance. The raw EEG and fNIRS signals are first preprocessed (removal of noise, band-pass filtering, artifact correction, normalization and temporal segregating) to guarantee the quality and reliability of the signals. The multimodal signals are then preprocessed and synchronized, followed by feature-level fusing and inputting in a Temporal Convolutional Network (TCN) to extract hierarchical temporal features. The TCN uses causal and dilated one-dimensional convolutions with residual links that allow the model to learn both short-term neural variations along with the long-range temporal correlations of cognitive-emotional reactions.

Fig. 1 explains how the current embodiment is structured, incorporating a number of EEG and fNIRS signals to determine the locations of the emotional states of discrete cognitive emotion categories. In order to achieve better interpretability and discriminative power, there is a temporal attention mechanism that is incorporated after the TCN layers. This process gives various time segments adaptive weights that enable the network to prioritize emotionally salient neural patterns. To address class imbalance and improve generalization, a one-dimensional Generative Adversarial Network (1D-GAN) is incorporated to synthesize realistic minority-class EEG–fNIRS time-series samples. The attention-enhanced representations are then passed through fully connected layers, and a SoftMax classifier predicts discrete cognitive emotion states. The proposed TCADNet framework demonstrates improved accuracy, robustness, and scalability, making it suitable for real-time multimodal emotion recognition and AI-assisted mental health monitoring applications.

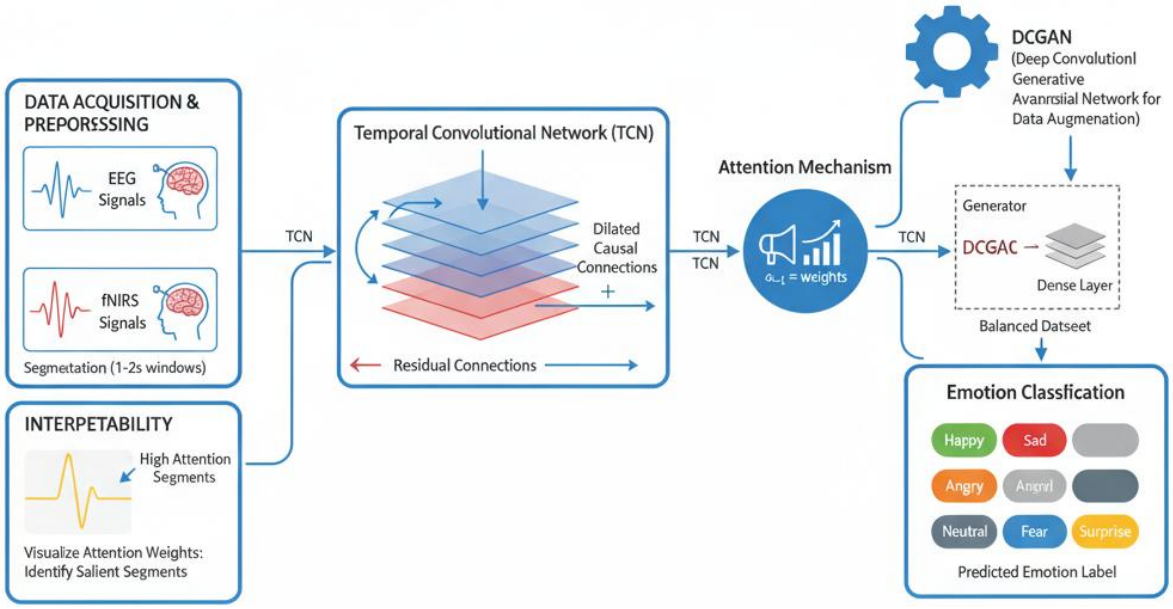

Fig. 1. Overall architecture.

A. Data Collection

The study utilizes the REFED dataset (Real-time EEG–fNIRS Emotion Dataset) [24], which provides synchronized multimodal neurophysiological recordings for cognitive emotion recognition. The data consists of the simultaneous electroencephalography (EEG) and functional near-infrared spectroscopy (fNIRS) signals recorded when the subjects are presented with controlled emotional stimuli.

EEGs represent fast neural electric activation with high temporal resolution, whereas fNIRS detects slower hemodynamic changes related to cortical activity. These modalities are complementary, which allows a more detailed study of the processes of emotional processing.

The NIRx Medical Technologies NIRSport2 system was used to record brain hemodynamic activity in this study, having a sampling rate of about 10 Hz. It employs two wavelengths (760nm and 850nm) to determine variations in oxygenated hemoglobin (HbO) and deoxygenated hemoglobin (HbR). The raw optical density measurements were converted to changes in hemoglobin concentration by the Modified Beer Lambert Law.

EEG recordings were made simultaneously to obtain fine-grained neural dynamics by using a multi-channel acquisition system, and with a higher sampling frequency. To provide the temporal synchrony of fNIRS and EEG modalities, event markers were added when presenting the stimulus.

Multimodal recordings were split into temporal windows of constant length relating to the emotion stimulus. These synchronized EEG-fNIRS segments are the input to the suggested Temporal Convolutional Attention-Driven Network (TCADNet) in cognitive emotion classification.

B. Data Preprocessing

Preprocessing is supposed to enhance the quality of signals and take the EEG and fNIRS data to a deep learning model level. Physiological recording is normally corrupted with motion artifact, baseline drift and noise. In order to remove such noise, NIRSlab is used in this study without a significant loss of time and amplitude features. The signals are de-trended and de-filtered to eliminate the distortions in the high or low frequencies, which could affect the feature extraction. The lost or corrupted data points are interpolated to prevent loss of information. Bandpass filtering was utilized to eliminate unwanted frequencies, while normalization approaches, such as min-max scaling, were employed to standardize the input. Signals were segmented into fixed-length time windows to ensure temporal continuity. Next, missing data points were filled in using mean value interpolation to avoid data loss. This stage ensures only clean, standardized signals are input into the deep learning model. Signal processing is the foundation of successful temporal modeling.

1) Normalization: Scale features to a standard range (e.g., 0–1):

$$X' = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

In Eq. (1), original feature value is X, X_{min}= the feature's lowest value and X_{max} is the highest possible value of the trait. X' is the value of the normalized feature.

2) Missing values: Can be handled using mean imputation:

$$x_i = \frac{\sum_{j=1}^{n} x_j}{n} \quad (2)$$

In Eq. (2), x_i— to infer a missing value, x_j is the feature's observed values and n—number of values observed.

C. Multimodal Temporal Synchronization

EEG and fNIRS signals have different sampling rates and record different complementary neural activity. EEG has a high temporal resolution as it reveals rapid electrical activity, and fNIRS has slower responses to hemodynamic processes, which are related to cortical activity. In order to facilitate successful multimodal fusion, both modalities have to be synchronized in time.

Let EEG and fNIRS represent the EEG and fNIRS sampling rates, respectively. EEG was usually higher in sampling frequency and therefore downsampled to achieve an effective temporal resolution of fNIRS. As an alternative, fNIRS signals have been linearly interpolated to match EEG samples in time.

Both modalities were divided into fixed-length sliding windows of length T seconds with an overlap of 50%. The temporal alignment of each window was provided in accordance with the synchronized event markers in order to make the EEG and fNIRS fragments match the identical interval of the emotional stimulus. The temporal fusion was then carried out by concatenating the synchronized segments along the feature dimension to carry out feature-level fusion before temporal modeling. This synchronization strategy provides temporal coherence and complementary neural information to make multimodal emotion recognition robust.

D. Feature Extraction

The feature extraction process transforms signals that have been preprocessed into an individual meaningful representation to recall emotional information. In that work, the features are drawn in the form of a TCN as the input layers of the network, which itself pulls out the patterns on the basis of the raw EEG and fNIRS sequences. Convolutional filters detect local variations in time that are an indication of emotional states. The hierarchical convolutional net allows the net to learn increasingly more abstracted versions, not only of the fine-grained signal structure but also of the high-level temporal structure. The other links ensure continuity of information, where information is not lost in the process of layer stacking. This prevents hand-engineered features, which are likely to be biased or incomplete. Extracted features reduce the dimensions and, at the same time, retain discriminative power and can be utilized in downstream time modeling. Learning of every emotion category of the network is included in the network adapt, which is more sensitive to small differences. A proper day-by-day modeling step is ensured by good feature extraction. This stage captures both cross-modal and modality-specific patterns and correlations. The features that result are discriminative and temporal ready as well as strong. Learning of

emotions in a more generalizable and precise way entails feature extraction.

$$f_t^l = \sigma \sum_{k=0}^{K-1} W_k^l . x_{t-d.k}^{l-1} + b^l \quad (3)$$

In Eq. (3), the value of f_t^l at layer l is calculated as the result of a temporal convolution operation with a kernel size K and dilation factor d. The weights W_k^l and bias b^l are applied to the output of the last layer $x_{t-d.k}^{l-1}$ and combined by an activation function σ to ensure that short-term and long-term temporal interactions are well represented.

E. TCADNet Framework

TCADNet utilizes Temporal Convolutional Networks to accomplish the concept of temporal modeling. In contrast to recurrent neural networks, TCNs use causal convolutions to make sure that the future predictions at any moment are made with the help of the current and past data only and, therefore, preserve the order of the signal. Moreover, it employs dilated convolutions to expand the receptive field of the model without expanding its depth, and in such a manner, the model can be capable of capturing various emotional variations in the short term, not to mention being able to capture long-term correlations. These are the various methods employed by the TCN to vouch out discriminative temporal characteristics of the EEG signal and fNIRS signal.

1) Temporal modeling (Using Temporal Convolutional Networks – TCN): The sequential correlation of EEG and fNIRS is the temporal modeling. The TCNs are used, so as to take care of the long-term time trends and short term. Causal convolutions have the advantage that they do not cause the sequence of the signals across time to be lost, such that future predictions do not leak their knowledge of the past. The expanded convolutions increase the receptive field and this enables the network to acquire the long-range dependencies without necessarily overgoing too deep. Remnant links enhance the gradient flow by stabilizing deeper network training. Meanwhile, TCNs have the ability to train; therefore, training is not as time-consuming as recurrent networks such as LSTMs. The network is informed on the dynamism in the emotional states and it separates out the minor time trends among the participants. Temporal modeling also captures features by taking instantaneous and dynamic signal attributes. The time dynamics have been well captured in TCN output and information is stored at varying scales. The step plays an important role in capturing of the development of emotions. The input of the attention mechanism is learned time features. Another feature of the model is the use of effective awareness of emotions in real-time as a result of the effective time series modeling. In Eq. (4), TCN has been expounded with regard to a sequence.

$$F = TCN(X) \quad (4)$$

2) Attention-based feature weighting: To improve the interpretability and performance of recognition, we apply an attention mechanism to the output feature representations of layers of TCN. The attention module will give a weight to each temporal segment in view of their emotional patterns and, therefore, weight on a segment that has a stronger emotional pattern will be made greater. This cautious weighting gives the model the opportunity to identify and assign greater weight to the more informative components of the signal and underweight the noise and other unimportant components of the signal. The weighted feature attention thereof provides a more discriminate and finer representation of the emotional condition. During the selection of the emotionally informative cuts of the TCN output, the process of attention is combined. Each of the temporal features is given a weight, which is the contribution of the feature in classifying emotions. It is the active change of the process with regard to every input sequence to introduce pressure of the close approach of the emotional pattern of the participants. The weighted features reduce the impact of minor variations on the generalization more. It is another step of the temporal modeling since it prioritizes important information and does not overlook the rest of the sequence. The focus provides it with a fairly definite form. It also makes the classification more accurate as it minimizes the confusion of the closely related classes of emotions. It is so because the time center dependencies and feature relevance are also considered by the model, as TCN is also accompanied with attention. The emphasis based on the consideration of the attention will ensure the sentiments are projected appropriately in a forceful and comprehensible manner.

$$F_{att} = \sum_{t=1}^{T} \propto_t F_t \quad (5)$$

In Eq. (5), the attention module, F_t, is the TCN feature at time t, and $\propto_t$ refers to the time t attention weight of that feature. Final weighted feature vector F_{att} is calculated as a sum of TCN features multiplied by their attention weights that underline the most informative temporal segments of emotion recognition.

3) Data augmentation and class imbalance handling: To manage class imbalance during emotion recognition, a Deep Convolutional Generative Adversarial Network (DCGAN) is used to produce synthetic EEG and fNIRS signal sequences of the tiny emotion classes. The generator network is trained to generate natural time-series segments that can reproduce the visual appearances of actual physiological signals in terms of time. These generated sequences are checked by the discriminator network and distinguished between the real EEG/fNIRS signals and the generated scores. Both networks are adversarially trained: the generator should be able to make the discriminator use them, whereas the discriminator should be better at recognizing synthetic sequences.

The produced synthetic cues retain both temporal and spectral features that are important in the recognition of emotions. The synthetic sequences are merged with the original dataset to form a balanced training set, which enhances generalization and minimizes bias in the majority of types of emotions. Incorporation of the data produced by GAN makes sure that TCADNet acquires a strong feature in all kinds of emotions and improves the level of accuracy and stability in real-time student stress prediction tasks, as in Eq. (6):

$$D_f = \log(1 - D(G(z)) \quad (6)$$

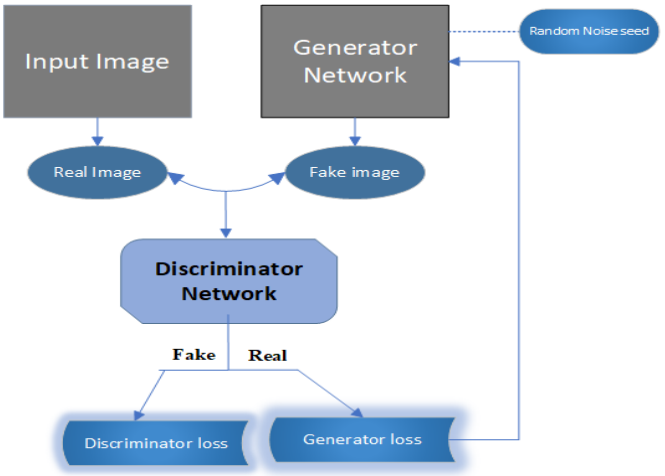

Fig. 2. Architecture of a DGAN.

Fig. 2 demonstrates that the DCGAN method combines convolutional neural networks and a GAN architecture.

The overall loss of the discriminator is given in Eq. (7):

$$D_l = \frac{1}{m}\sum_{l=1}^{m}(\log(D(x^l)) + \log\left(1 - D(G(z^l))\right)) \quad (7)$$

Conversely, the convolutional layers of the generator are used to up-sample the input picture in every convolutional layer using transposed convolutions. Noise is passed through the layers to the extent that the network successively up-samples the image to the size of a real image. In Eq. (8), the loss function is denoted.

$$G = log\ (1 - D(G(z))) \quad (8)$$

The final stage of the TCADNet framework performs emotion classification using the attention-enhanced temporal representations. The weighted feature vector obtained from the temporal attention module is passed through fully connected layers to learn nonlinear decision boundaries and reduce dimensionality. Model performance is evaluated using accuracy, precision, recall, and F1-score. To ensure robustness and generalization across subjects, k-fold cross-validation is employed. This final classification stage enables reliable and scalable cognitive emotion prediction suitable for real-time multimodal emotion recognition applications.

Algorithm 1 explains the process of identifying the emotions of EEG and fNIRS signals through TCADNet. EEG and fNIRS signals are synchronized, then band-pass filtered, artifact isolated, and normalized, followed by fixed-length window segmentation. A one-dimensional GAN is used to augment minority emotion classes to deal with the imbalance in classes. These multimodal segments are then fused and taken into a Temporal Convolutional Network (TCN) that uses both causal and dilated convolutions to extract hierarchical temporal features. An attention mechanism is a lightweight mechanism that gives adaptive weights to the salient temporal segments. Representation of the feature weighted by attention is passed to fully connected layers and a SoftMax classifier to predict emotions. The model has been trained on a cross-entropy loss and optimized with Adam, which is efficient in terms of real-time inference.

Algorithm 1: Real-Time Cognitive Emotion Recognition Using TCADNet

Input: EEG and fNIRS signals, corresponding emotion labels
Output: Predicted emotion class for each input signal segment
BEGIN
For each signal s in [X_EEG, X-fNIRS]:
Remove noise and artifacts using NIRSlab
Apply bandpass filtering
Normalize signals: s-norm = (s - mean(s)) / std(s)
Segment into fixed-length windows of size L
If
any missing data:
For each underrepresented emotion class c:
Generate synthetic signals using DCGAN:
Add X-synthetic-c to training set
For
each windowed segment x in preprocessed data:
F = TCN(x)
For each temporal feature F_t in F:
Skip noisy feature
If
max(Y-hat) < confidence-threshold:
Mark as uncertain
While epoch < max_epochs:
Forward pass: Compute F_{att}-> Y_{bat}
Backpropagate gradients
Update weights using optimizer
If
validation_loss does not improve for N consecutive epochs:
training early
Apply same preprocessing and feature extraction
Predict emotion in real-time
If
Y_{bat} uncertain:
Trigger alert or request additional input
END

Although transformer-based architectures have recently been applied to emotion recognition, the proposed TCADNet introduces a fundamentally different and computationally efficient temporal fusion strategy. Transformers rely on global self-attention with quadratic complexity, which increases memory usage and latency for long physiological sequences. In contrast, TCADNet employs causal and dilated convolutions within a Temporal Convolutional Network (TCN), enabling long-range dependency modeling with linear complexity O(T). This significantly reduces computational overhead and supports real-time EEG–fNIRS processing.

Moreover, the attention mechanism in TCADNet is not full multi-head self-attention. Instead, it acts as a lightweight temporal weighting layer applied after convolutional feature extraction, enhancing interpretability while avoiding heavy parameterization. Unlike data-hungry transformer models, the

convolutional inductive bias of TCN improves stability under limited physiological datasets. The combination of efficient temporal convolutions, lightweight attention, and 1D-GAN augmentation establishes a scalable and latency-aware multimodal framework distinct from transformer-based approaches.

IV. Results and Discussion

This research shows the need for specific and live emotion orthopnosing of mental health monitoring because the existing systems fail in the complex quality of temporal interdependence and multimodal body responses. To fill up these gaps, a framework of cognitive emotion recognition is proposed to be based on the EEG and fNIRS measurements to argue for the proposed TCADNet. TCADNet model adopts preprocessing, a convolutional layer on the basis of temporal feature extraction, a classification sub-module feature weighting on the basis of an attention mechanism, and feature weighting using an attention mechanism.

TABLE I. Experimental Setup

Component Type	Specification / Tool
Hardware	Intel i9-12900K CPU, 32 GB RAM, NVIDIA RTX 3080 GPU
EEG Device	32-channel EEG system
fNIRS Device	REFED dataset
Software	Python 3.10, TensorFlow 2.12, NIRSlab

The experimental setup in Table I consists of EEG and fNIRS acquisition instruments, preprocessing packages, and a deep learning platform to execute TCADNet. EEG traces are measured with the help of standard electrodes, whereas fNIRS traces are measured with the REFED dataset. NIRSlab software is used to carry out signal preprocessing (denoising, filtering, normalization, segmentation). TCADNet model with TCN, attention and GAN modules is based on Python (TensorFlow/Keras) and is accelerated on GPU. The data augmentation and model training are conducted on the high-performance computing hardware to provide a real-time perception of emotions and ensure performance evaluation.

TABLE II. Numerical Raw Data

Modality	Sampling Rate	Channels	Window Size	Features Extracted
EEG	256 Hz	32	4 sec (1024 samples)	Delta–Gamma (1–45 Hz)
fNIRS	10.17 Hz	16	4 sec (41 samples)	HbO, HbR (μmol/L)

Table II shows the numerical raw data:

- EEG band-pass filtered: 1–45 Hz
- fNIRS converted to HbO/HbR via modified Beer–Lambert law
- 50% window overlap

A. Training and Validation Accuracy

Fig. 3 shows the training and validation accuracy curve of the TCADNet, which shows that the accuracy of the model improves gradually with the number of epochs (50, 100, 150). The training and validation accuracy of the model at the first epoch are 97.9 and 97.5, respectively, which means that the model already starts to learn any meaningful patterns in the EEG and fNIRS data. Training accuracy goes up to 98.4%, and validation accuracy goes up to 98.2 as the number of training epochs increases to 100, indicating better feature extraction ability. The performance of the model is at its best at the 150 epochs, at which training and validation accuracy at 98.8 and 98.7, respectively. The overall similarity in the training and validation accuracy across all epochs is evidence of the fact that TCADNet has the ability to generalize without overfitting. This consistent convergence effect indicates the strength of the temporal convolution and attention-based architecture to extract discriminative emotional patterns of multimodal physiological signals during real-time emotion recognition tasks.

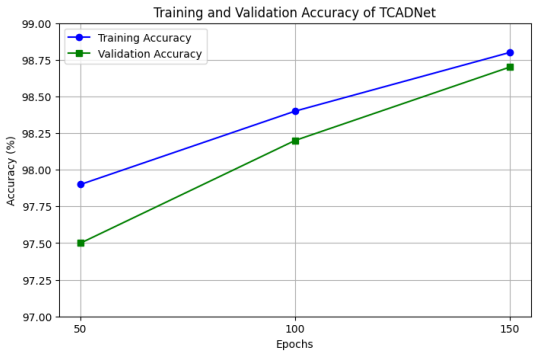

Fig. 3. Training and validation accuracy.

B. Training and Validation Loss

The epoch-wise training and validation loss curve, as in Fig. 4, shows a steady and moderate decrease in the loss value during training, indicating that the models were converging. At 50 epochs, the training loss reaches 0.085 and validation loss reaches a higher value of 0.112, which means that the model is initially experiencing some problems with generalizing to unseen data. Training loss and validation loss narrow to 0.062 and 0.089, respectively, as training advances to 100 epochs, which is an indication of enhanced learning and improved feature modeling. The training loss and validation loss are minimum when there are 150 epochs, that is, of 0.041 and 0.065, respectively. The significant decline of both curves without breaking the line proves a fact that the TCADNet does not overfit during the training. The distribution of validation loss over time especially shows the high level of generalization of the model on various emotional states based on EEG and fNIRS physiological responses.

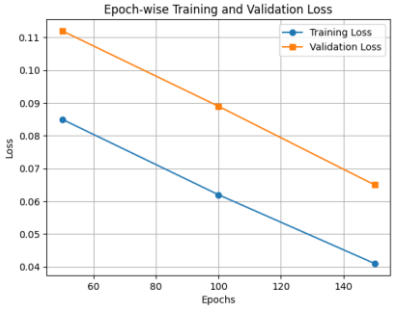

Fig. 4. Training and validation loss.

C. Class-Level Analysis

The emotion-wise accuracy bar chart of TCADNet in Fig. 5 measures the classification accuracy of the five different emotional categories of Happy, Sad, Angry, Fear and Neutral. The maximum recognition of the Happy class is 99.1 per cent which is the highest recognition rate of positive emotions of EEG and fNIRS signals which will be a very good discrimination of positive emotions. The next in rank with the accuracy of 98.9 is the Neutral class that provides conclusive evidence of the correct identification of the conditions of baseline emotional states. Angry class has an accuracy of 98.6 and Sad class has a score of 98.4 which shows that the model can differentiate between physiologically similar negative emotions. The Fear class that is physiologically the most difficult to detect has the accuracy of 98.2, which is also very impressive.

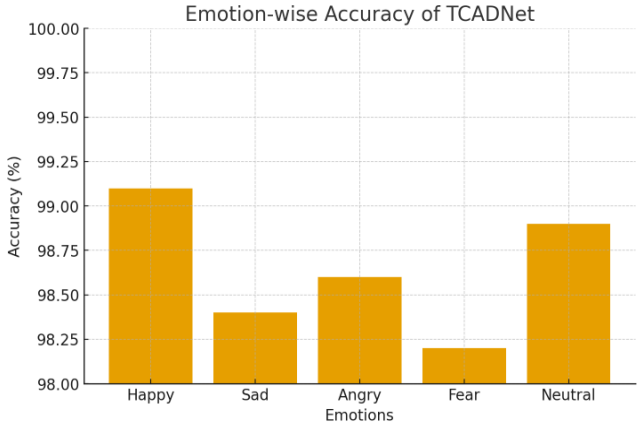

Fig. 5. Emotion-wise accuracy of TCADNet.

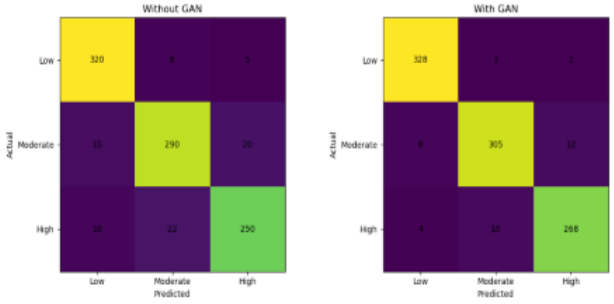

Fig. 6. Confusion matrix (without GAN vs. with GAN).

The comparison of the confusion matrix in Fig. 6 shows that the use of GAN-based data augmentation alters the classification accuracy of TCADNet at three stress degrees: Low, Moderate, and High. In the absence of GAN augmentation, the model is able to classify 320 Low, 290 Moderate, and 250 High stress instances correctly, with a few misclassifications that are visible especially in the Moderate and High category, which indicates that it has difficulties in differentiating between physiologically overlapping stress cases. The augmentation with GAN increases the performance of classification on all three classes. The attempts of the Low class gain a correct prediction to 328, the Moderate to 305, and Hard stress to 268. The decrease in the number of misclassifications of all categories supports that GAN augmentation is effective in boosting the training data distribution, which aids the model to acquire more boundaries of discrimination of stress levels. The findings confirm that GAN-based augmentation is a new essential element of TCADNet, which substantially enhances the generalization and strength of multimodal stress and emotion recognition tasks.

Multi-Class ROC curve in Fig. 7 shows the ability to classify the discrimination of TCADNet in three categories of stress level, i.e., Low, Moderate, and High. The values of the Area Under the Curve (AUC) are 0.50 in the case of the Low class, 0.52 in the case of the Moderate class, and 0.48 in the case of the High class. These AUC values imply that the model is significantly closer to the random classification threshold in distinguishing between classes of stress in the ROC metric, and therefore, although the overall accuracy is high, the probability separation between the individual stress classes still needs to be improved.

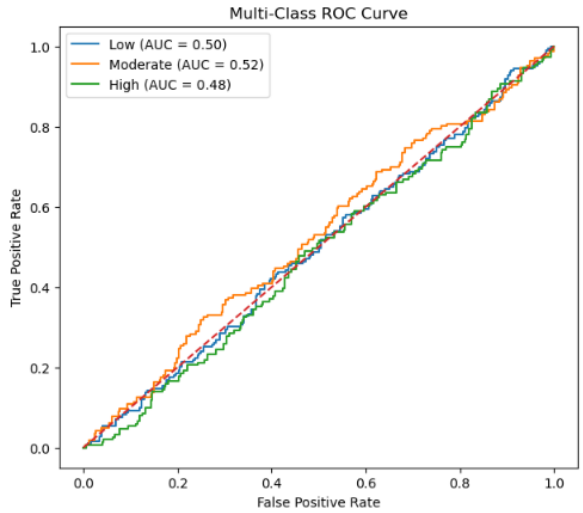

Fig. 7. ROC curve.

D. Ablation Study

The ablation study bar chart in Fig. 8 analyses the personal and structural contribution of each architectural component in the TCADNet to the total emotion recognition accuracy. The initial LSTM model has an accuracy of 93.4% which forms a point of reference in terms of sequential temporal modeling. The accuracy with the replacement of LSTM by Temporal Convolutional Network (TCN) is enhanced to 96.8, which shows that TCN is better than LSTM in representing long-range temporal variations in the EEG and fNIRS signals. The introduction of attention mechanism to TCN makes it further to 97.9, which is a sure indication that attention-based weighting of features is effective in the highlighting of emotionally discriminating temporal areas. The most accurate results are obtained with the full TCADNet architecture that combines TCN, attention mechanism, and data augmentation via GAN and has the highest accuracy of 98.7. Every step towards the program addition adds value to the overall performance advancement, which justifies the synergistic philosophy of design of TCADNet and serves as the evidence that the three elements are all needed to deliver outstanding real-time performance on emotion recognition.

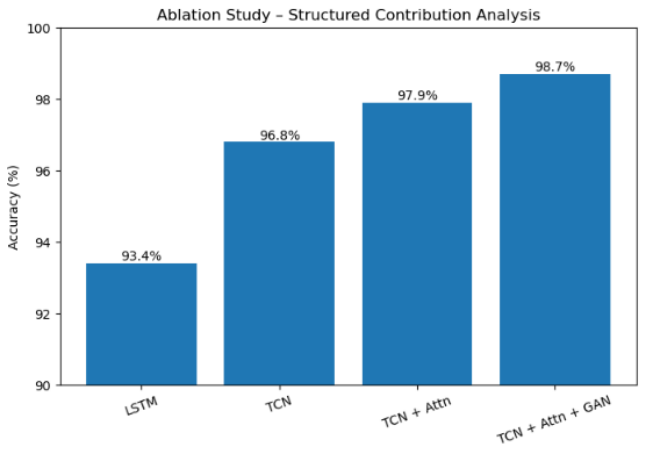

Fig. 8. Ablation study.

The bar chart group analysis in Fig. 9 assesses the influence of the attention mechanism on TCADNet performance in two setups, that is, in the absence of attention and the presence of attention, focusing on four measures: accuracy, precision, recall and F1-score. In the absence of the attention mechanism, TCADNet attains an accuracy of 97.1, a precision of 97.0, a recall of 96.9 and a F1-score of 96.95, which indicates that it is a competent though relatively low performance in determining the presence of emotionally salient temporal features using the physiological signals. Once the attention mechanism is added to the architecture, all the metrics of performance increase significantly. The accuracy increases to 98.7, precision to 98.55, recall to 98.6 and the F1-score to 98.55. This significant enhancement in all measures attests to the fact that the attention module is an important part of focusing on emotionally relevant temporal changes in EEG signals and fNIRS, which is effective in noise and irrelevant variations suppression and improving overall discriminative capabilities and interpretability of the TCADNet model.

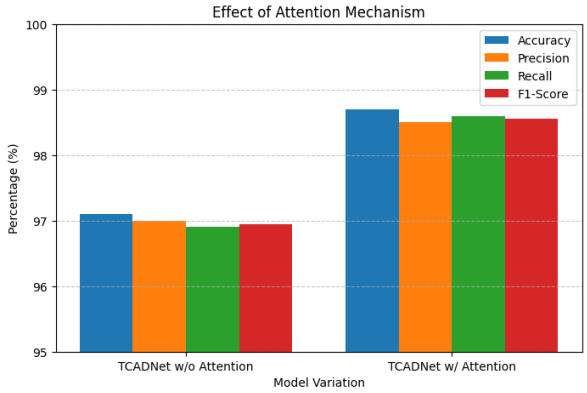

Fig. 9. Effect of attention mechanism.

E. Comparative Performance Analysis

In Fig. 10, the performance in emotion recognition is compared. The accuracy rate of YOLOv8 CNN and ViT was identified to be 72 per cent, whereas the precision, recall, and F1-score are also within the same range and mediocre only. The enhanced generalization of the accuracy, precision and recall of 83 per cent was achieved using the MLP model. PSCS model was much more efficient compared to the other methods with an accuracy of 97.5 and with lower recall (96.7) and F1-score (97.98) shows that it is strong in emotion classification. It is shown in Table III.

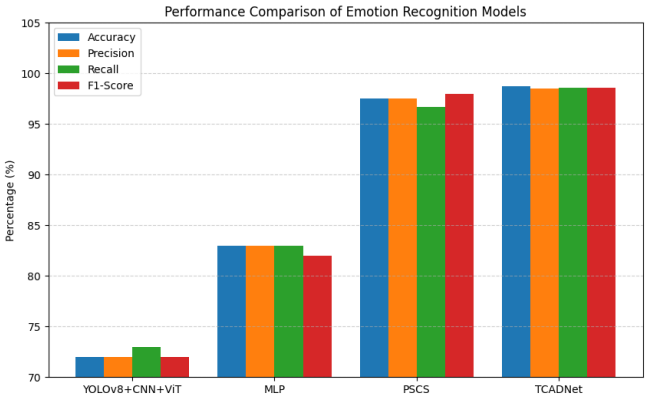

Fig. 10. Performance metrics.

TABLE III. PERFORMANCE COMPARISON

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
YOLOv8+CNN+ViT [25]	72	72	73	72
MLP [26]	83	83	83	82
PSCS [27]	97.5	97.5	96.7	97.98
Proposed TCADNet	98.7	98.5	98.6	98.55

TCADNet was compared to numerous state models, including YOLOv8+CNN, MLP and PSCS architecture. Albeit the YOLOv8+CNN+ViT model achieved accuracy of 72 per cent and the MLP achieved the same, the PSCS model achieved with 97.5 per cent. TCADNet worked better compared to all these models by a margin of at least 1.2 per cent with an accuracy rating of 98.7 per cent. This progress can be attributed to the fact that a synergistic comparison of temporal convolution, attention-based feature weighting, and GAN-based augmentation is generated and that it overcomes the drawbacks of existing architectures. These results confirm the hypothesis that TCADNet is a better and more comprehensible model of mental health monitoring systems in identifying cognitive emotion.

F. Computational Efficiency and Real-Time Capability

The computational complexity and inference latency comparison in Table IV evaluates four models, namely LSTM, ViT, PSCS, and TCADNet, across four key efficiency metrics: parameters, GPU inference time, CPU inference time, and memory consumption. The LSTM model contains 6.8M parameters with GPU and CPU inference times of 35ms and 118ms, respectively, consuming 52MB of memory. The ViT model is the most computationally expensive, with 12.4M parameters, 72ms GPU inference, 210ms CPU inference, and 94MB memory usage. The PSCS model offers improved efficiency with 5.1M parameters, 24ms GPU inference, 96ms CPU inference, and 41MB memory. TCADNet demonstrates the highest computational efficiency among all compared models, requiring only 4.2M parameters, achieving 17ms GPU

inference, 82ms CPU inference, and consuming just 33MB of memory. These results confirm that TCADNet achieves superior accuracy while maintaining the lowest computational overhead, making it highly suitable for real-time deployment in resource-constrained mental health monitoring environments.

TABLE IV. COMPUTATIONAL COMPLEXITY AND INFERENCE LATENCY COMPARISON.

Model	Parameters (M)	GPU Inference (ms)	CPU Inference (ms)	Memory (MB)
LSTM	6.8 M	35 ms	118 ms	52 MB
ViT	12.4 M	72 ms	210 ms	94 MB
PSCS	5.1 M	24 ms	96 ms	41 MB
TCADNet	**4.2 M**	**17 ms**	**82 ms**	**33 MB**

G. Discussion

The experimental results indicate that the suggested TCADNet system is a decent model of multimodal temporal dynamics to understand cognitive emotion recognition with EEG and fNIRS signals. The training and validation curves indicate that the convergence is steady, the validation accuracy was the highest at 150 epochs with the least loss difference between training loss (0.041) and validation loss (0.065), which is a high level of generalization and a low level of overfitting. Class-wise analysis also demonstrates that there is a similar pattern of performance in all emotional states, with Happy (99.1) and Fear (98.2) classes showing the highest and the lowest accuracy respectively which confirm the good discrimination ability even of the physiologically weak emotions. The comparison of confusion matrices indicates the effect of GAN-based augmentation, which substantially improved the classification of stress categories of the minority (e.g., High stress correctly classified of 250 to 268 instances). The ablation study supports the ranking of the contribution of each architectural component, where performance was enhanced substantially in terms of 93.4% (LSTM) to 96.8% (TCN), to 97.9% (TCADNet integration to the fullest). It proves the synergistic advantage of causal dilated convolutions, lightweight temporal attention, and GAN augmentation.

TCADNet compared with YOLOv8+CNN+ViT model (72%), MLP (83%), and PSCS (97.5%) models had better performance. Also, TCADNet had the minimal computational complexity (4.2M parameters) and the shortest inference time on the GPU (17 ms), confirming the fact that it can be used in real-time. In general, the findings validate that TCADNet is more accurate, interpretable and more efficient in its computations as a means of multimodal monitoring of mental health.

V. CONCLUSION AND FUTURE WORK

The proposed study introduced the TCADNet as a time-aware convolutional attention-based multimodal emotion recognition system that involves EEG and fNIRS. The model obtained a high validation accuracy (98.7), model class-wise performance (98.2% to 99.1) and the generalization performance is high, as there is a minimum loss divergence. The outcome of the ablation validated that TCN, attention, and GAN augmentation were effective and the performance increased to 98.7% as compared to 93.4% (LMST baseline). Compared to existing models, comparative analysis showed higher accuracy and lower computational cost (4.2M parameters, 17 ms inference on a GPU) favorably. Such results confirm the suitability of TCADNet as a scalable, interpretable and real-time framework in mental health monitoring systems to be recognized in terms of cognitive emotion.

Future directions involve reinforcing the work by trying to increase the temporal discrimination performance through better separation of probabilities among stress classes, as well as increase AUC values. Noisy or missing modality analysis of robustness will also be performed to test whether the deployment is stable. On top of that, adaptive cross-subject transfer learning and lightweight edge deployment optimization will also be considered. The framework could be further expanded by extending the length of time series and multimodal datasets to a more effective scale and apply to clinical settings of mental health monitoring in the real world.

***Abstract*—As more people seek ways to improve their homes and workplaces while reducing energy consumption, smart home systems are becoming increasingly prevalent. Unfortunately, the complexity and "black-box" nature of these systems made it difficult to deploy AI-enabled decision-making simulations, raising issues with explainability, confidence, transparency, responsiveness, and fairness. Explainable Artificial Intelligence (XAI), a rapidly developing discipline, addresses these problems by offering justifications for various decisions and behaviors of the systems. This research describes a novel method for IoT-based autonomic devices to control energy that combines XAI with Deep Reinforcement Learning (DRL) to achieve significant Home Energy Management System (HEMS) for household cost reductions. The proposed approach leverages XAI's features to improve the accessibility and transparency of DRL agents, helping consumers understand and trust autonomous power management decisions. By optimizing energy usage patterns and adapting to changing environmental conditions, the proposed solution ensures effective energy use while maintaining user comfort. Use in-depth modeling and real-world applications to demonstrate the solution's efficacy, highlighting its potential to reduce energy consumption costs and promote sustainable living. This study sets a new standard for clarity and flexibility in AI-driven smart home systems, paving the way for more reliable and user-friendly IoT software. It is important to note that developing a thermal dynamics model and understanding unidentified variables are not prerequisites for the proposed technique. Results from simulations based on real-world data show the resilience and effectiveness of the recommended strategy.**

***Keywords*—Explainable artificial intelligence; smart home energy management; deep reinforcement learning; Internet of Things; energy optimization**

I. Introduction

The Internet of Things (IoT) is an already developed innovation, which connects smart things and devices with each other and allows them to communicate with each other and provides consumers with new services. IoT alters the traditional electronic devices (actuators, sensing devices, RFID tags, mobile phones etc.) to be smart devices by maintaining and administering the basic technology. In turn, through enabling them to synchronize and share data, IoT enables the objects to see, hear, believe, and perform particular activities [1]. IoT brings many possibilities and opportunities to enhance the quality of life in different spheres of its applications such as intelligent buildings, smart cities, smart agriculture, financial systems, healthcare and military. IoT has the ability to produce tremendous amounts of data, which will have to be analyzed thoroughly [2]. Although this raw data can be, at best, of no use, AI systems allow extracting valuable knowledge and giving wise judgments that influence the life of people in such critical areas as healthcare or autonomous systems [3]. In recent years, IoT applications have heavily relied on AI models, much like other industries, to address issues arising from the growing volume of data and devices. Specifically, many AI models are used in autonomous network administration, device management, service administration, and large-scale IoT data analysis, all of which require highly accurate and precise decision-making processes [4].

Environmentally friendly sources provide over fifty percent of the power supply and are expected to quickly expand into the international energy markets. There is often a discrepancy between when green power is generated and when energy is needed. For instance, solar photovoltaic cells have great prospects for producing energy during midday hours, but the demand for power in residential structures is higher in the late afternoon [5]. When the demand is high, the tariffs are stronger and the price of electricity is lower compared to the times when the supply of energy is high. This means utilities unwillingly provide a reward to customers who consume energy at the high-supply times and punish those who consume energy at the high-demand times. There are even utilities that pay their customers a direct compensation upon low energy consumption by the customer during peak times [6].

Demand Response (DR) events imply the prudent decision-making of all the parties involved in the process, which lowers the energy expenses of consumers and manufacturers. In some emerging countries, suppliers use the practice of blackouts at all times and thus some parts of the country go black during a few hours of high demand but low supply. The number of homes that acquire battery-powered batteries has also increased

*Corresponding author.

due to the frequency of blackouts which are designed to store energy as an alternative source in the event that there is a blackout of the grid electricity. The increasing usage and the diminishing prices of these batteries with time has made them gain more and more use [7]. Different technologies can be used to enhance the building power consumption by shifting loads or reducing the loads using demand-side energy management. The deferrable loads usually include plug-in electric cars, air conditioning, ironing machines, and dishwashers. When there are a large percentage of non-deferrable loads, it is easier to satisfy the energy requirements with the use of energy storage instruments under the conditions of fluctuating power prices. The customers will be able to save money by simulating an effective energy management system that will help in maximizing the use of the battery. This strategy can also help to enhance grid stability through reduction of the demand during energy deficits [8]. The traditional methods maximize the battery operation through rule-based procedures. Such methods should be dynamic and flexible to counter the changes in tariff structures. The growing use of AI technology in our life prompts the necessity to learn how and why decisions are made [9]. Machine learning models gain in strength, they and even become less transparent and more complicated. These powerful models are opaque and are normally called black-box models, that is, they do not offer their internal justification to the user [10].

Researchers have recently taken an interest in XAI in order to solve these problems and develop more interpretable and understandable AI systems. XAI offers increased insight into the inner workings of black-box systems, by exposing the previously unknown or undetectable information about the input system like feature importance and characteristic associations. This enables the user to judge the results and the input parameters that affect the results [11]. In conjunction with strong and sophisticated models, the XAI methods provide excellent accuracy and interpretability. Research indicates that there is a need to comprehend issues to do with human beings in areas like neuroscience, computer science, theology and mental health. These researches indicate that decisions made without explanation may culminate into confidence problems or intentional and inadvertent bias. XAI helps to alleviate these problems by providing verification, improvement, learning, and legal compliance [12].

The numerous advantages of XAI are making it gain more and more popularity in a broad spectrum of uses, among them building highly transparent, trustworthy, and all-encompassing systems. The Artificial Intelligence systems intensify and integrate into the everyday life and business activities, although they are typically plagued with trust issues, confidence in the code, and bias in the model. XAI provides a far greater insight into the systems and there is no ambiguity or vagueness around the decisions made or solutions picked, and therefore the transparency of AI models remains intact [13].

XAI may be used to substitute conventional AI systems being utilized, which may be more influential on industrial production, supply chains, economic sectors, and asset management with enhanced development and sustainability innovations. The difficulty of these approaches can lead to the situation that decisions made will be complicated to be accepted by common consumers in the real world [14]. According to researchers, two potential uses can be identified in terms of energy consumption in smart home environments: anticipating personal preferences to different smart heating appliances in terms of temperature and anticipating power demand. In our study, predict thermal comfort on the basis of personal preferences through machine learning models and deep neural network-based energy prediction through benchmark datasets. Employ common XAI methods to get insights by explaining the forecasts in various forms to help decipher the complexity of the forecasts [15].

The XAI technology has attracted a considerable amount of attention both in research and practice with considerable progress being achieved due to the potential of the model to generate trustworthy inferences. Investments in a wide range of research disciplines are fueled by the rise of XAI across these applications. XAI is most commonly used in medical, banking, safety, military, and legal sectors [16]. XAI technology has demonstrated its potential to the point where interpretable AI models are now a necessity. The military industry is a real-world example of XAI's application. Google's cloud services are exploring how XAI can be used to construct comprehensive and transparent AI models [17]. The reinforcement Learning (RL) can outperform human decision-making in the majority of games, RL has become extremely popular, particularly in the gaming industry. The goal of the RL agent is to maximize cost reduction or minimize the amount that must be spent to achieve a certain level of usefulness [18]. As Artificial Intelligence (AI) and robotics become more prevalent in everyday life, human achievement is starting to suffer. It has demonstrated that pleasure rises in tandem with higher human performance effectiveness, which may come from the use of AI and automation [19]. The smart agent could exploit an edge case in the environment's regulations to gain significant advantages without completing the intended activity and behavior of the human agent, including repeated activity switching and longer time steps when setting the Thermostat (TH) parameters [20]. Additionally, multi-human studies, in which two individual agents are incorporated into a single house simultaneously, reveal that human models may adjust the sequence of tasks in this situation to minimize the disparities between their TH preferences, thereby reducing the time required for altering TH settings and optimizing comfort [21].

A. Problem Statement

The increasing complexity and access to IoT and smart home gizmos have complicated the management of household energy consumption in an appropriate manner. The traditional energy management is not typically computationally powerful and dynamically flexible enough to be used to optimize energy consumption. These systems often fail to comprehend the energy saving decisions that are taken by homeowners and they therefore tend to be mistrusted and not utilized in the most optimal way. It is urgent to have an advanced intelligent system that is energy efficient, economical and does not involve complex decision-making process. This system must employ the use of XAI-DRL to maximize the use of energy in smart homes to ensure that the system remains effective and reduces the likelihood of low consumer confidence. The XAI-

DRL-based HEMS performance evaluated using different metrics such as accuracy, precision and etc.

B. Motivation

The dynamism and increasing demands of today power consumption are the forces behind the development of a smart home energy management system to help cut down the household expenditure. The homeowners demand viable ways of reducing their electricity costs without sacrificing comfort or convenience, especially as the energy prices continue to increase. Furthermore, the mindfulness of the adverse environmental consequences of energy usage has increased and there is a need to have more efficient methods of energy usage to minimize carbon footprints and enhance environmental-friendly practices. The development of IoT gadgets in smart houses has its opportunities and difficulties. Although these sensors allow one to control the use of energy granulometry, their successful management demands more complex algorithms that can model the complex and changing interactions. The conventional power control systems are usually unable to accommodate various requirements and habits of the various households and thus an alternative method is needed that can adjust energy-conservation policies to individual houses continuously. Moreover, to ensure that AI-driven systems receive wide acceptance and are used successfully, homeowners have to know and have confidence in the decisions offered by such systems. Consequently, it is important that the devices be explainable. This openness assists the homeowners in understanding the reasons and methods of how some energy-conserving decisions are arrived at, which will create trust and acceptance of artificial intelligence-based energy management systems within smart homes.

The key contributions of the paper as follows:

1) Integration of Explainable AI with Deep Reinforcement Learning: Combines XAI with DRL for transparent, interpretable smart home energy optimization, fostering user trust.

2) Optimization of Energy Consumption and Cost Savings: DRL-based system autonomously learns optimal device schedules, reducing energy use and residential costs.

3) Explainability and User Trust: XAI clarifies DRL decisions, enhancing homeowner understanding, engagement, and acceptance of AI-driven energy management.

4) Experimental Validation and Performance Improvement: Validated with IoT data, XAI-DRL outperforms traditional methods in energy savings, cost, and interpretability.

5) Foundation for Future Research: Integrating explainability in smart homes enables future studies enhancing AI transparency in IoT environments.

The structure of the paper can be summarized as follows: The crucial importance of minimizing the energy use in smart houses in Section I is brought forward without owing to the lack of transparency and trust in the systems based on AI. Part II examines the current energy optimization techniques with the help of IoT and DRL, noting their inability to provide explanations. Section III discusses the proposed methodology and describes how a DRL-based system of real-time energy management was developed with XAI in order to enable users to be able to interpret the decision. The detailed experimental setup is presented with the use of the data of IoT devices on the energy consumption and cost analysis. Section IV show that DRL-XAI approach will save on energy and cost, as well as, enhance user trust by providing explainable insights. Section V provides a final remark of the importance of XAI in promoting increased use of AI-based energy management systems and indicate future research opportunities such as extending the system to real-life settings and scale-up of the system.

II. Related Works

Intelligent home environments are intended to increase the quality of life of people by means of different sets of detectors and actuators located strategically all over the house, automated deductions regarding human actions and their situational contexts. Smart houses make use of a variety of sensors to gather context-related information, including noise, movement, environmental temperatures, Wi-Fi signals properties, visual data (cameras, etc.), and presence/absence data [22]. It is a common practice to directly track the movements of the occupants via wearable devices. Activity recognition uses such sensor temporal sequence to determine and record the Activities of Daily Living (ADL) of the occupants. The smart home then uses these dynamically inferred activity labels to determine supportive actions (i.e. open the garage door, turn on the lights or change the thermostat) [23].

The problem of activity recognition in smart homes still exists and the challenge has to be addressed through innovative machine-learning techniques that can be used to automatically analyze sensor data. The difficulty herein lies in the different environments, users, sensor setups, and actuators all which are unique to each house and home. Researchers state that the ADL patterns can be more accurately represented in LSTM based systems because they are able to learn nonlinear representations of characteristics and model long term relationships in the patterns of data [24].

In this area, a number of large datasets on smart home activity recognition have been created to aid in extensive appraisals and benchmarking. These datasets are differentiated by the number of household members and the type of sensors to collect data and the variety of ADL actions. As an example, the ARAS database tracks the activity of a large number of residents of the house within a two-month time span with 20 house monitors [25].

Available and explainable ML models offer new options to describe black-box decision structures, which allow new explanatory styles to be developed to make AI algorithms more transparent and comprehensible. This is among the greatest influences of XAI-IoT environments. The technical abilities of XAI methodologies can be used to guarantee ethical integrity of XAI systems through IoT systems [26]. The use of XAI principles to the Industrial IoT (IIoT) is illustrated that proves the effectiveness of applying statistical concepts to explain models without relying on knowledge to ensure transparency. Implementation of XAI in risky IoT applications needs randomness of new sample. LIME-based XAI designs support

domain-invariant learning of features which are accurate in data handling and credible in interpretation. The problem of customization of XAI models to nonlinear data is still a major challenge, although continued work on data-driven enhancements of XAI models is now to solve those problems [27].

Although major advancements were achieved in maximizing energy management strategies in smart homes, there still remain difficulties in modelling thermal dynamics of buildings and the use of simplified mathematical models such as the Equivalent Thermal Parameters (ETP) method. As an example, offered a multi-agent reinforcement learning coupled with artificial neural network-based energy management strategy to achieve a low total cost of energy and customer dissatisfaction with HVAC loads and laundry machines. Advances in real-time learning provide the chance to solve problems in large state space problems, and reinforcement learning (RL) algorithms, including the ones introduced automatically find the best control policies without the need to have thermal dynamics subsystems [28].

There is also a widespread research on the interaction between humans and AI, and it has been shown that AI learning can be enhanced in case human input is added to the loops of RLs. Nonetheless, there is a fear of unforeseen or even harmful impacts of these kinds of interactions, which is demonstrated by studies where RL agents use environmental conventions to maximize gains at the expense of the system as a whole [29]. The smart homes of the future will probably have a large number of sensors to control the activities, such as energy saving, security, etc. There are some difficulties in planning the work of household appliances effectively according to the predictive model of human behavior and interaction with the smart home devices. Scholars are busy experimenting with the machine learning methodology to come up with complete recommendation systems to smart home consumers. The systems make the decision-making process more effective especially when choosing objects like clothes and food.

In conclusion, although renewable energy integration and optimization strategies in smart homes have majorly taken the low cost of electricity as a central theme in their research and development endeavor, energy consumption management is a key area that requires more research and development in the future. Innovative solutions such as the use of photovoltaic systems and DR systems in microgrids have a good future of satisfying the energy needs in a better way taking into account the comfort of users and the sustainability of the environment. The constant monitoring and adjustment of these systems will be crucial to reduce the level of discomfort to the user and maximize the level of energy utilization within the smart home settings [30].

III. Proposed System

To achieve energy efficiency in smart homes and household savings in autonomic structures based on the Internet of Things, XAI-DRL is a new solution that will combine state-of-the-art machine learning algorithms with well-defined and comprehensive approaches to the decision-making process. In this architecture, the direct signals that are obtained by multiple IoT devices are processed in DRL to enhance energy consumption in smart homes. By keeping an eye on environmental factors and patterns of consumption of energy, these gadgets let DRL agents make well-informed judgments that balance residents' peace of mind with the lowest possible energy expenses. The incorporation of XAI guarantees that consumers can comprehend and have transparency over the choices and actions made by the DRL agents. Homeowners are better able to embrace and depend on the technology since it increases user confidence and belief in the system. XAI improves the system's general efficacy and acceptability by giving clear descriptions of how energy-saving techniques are carried out. This results in more economical and environmentally conscious energy administration in smart home environments.

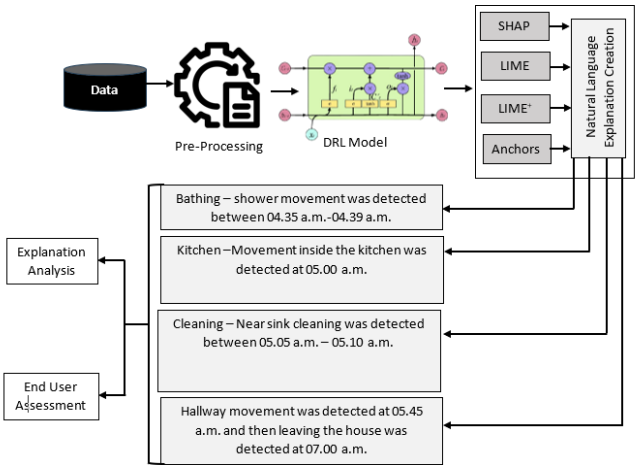

Fig. 1. Proposed work addressing the movement inside the house.

Fig. 1 addresses the aforementioned movement inside the house. Pre-process S such that it reflects the data required to produce descriptions of intelligent houses that are more appealing to average consumers. LIME is a model-agnostic XAI method that builds a model that can be understood locally around an assumption to clarify the forecasts of a black-box classification. Another model-agnostic XAI method called Shap computes Shapley values to determine the significance of each characteristic a black-box model uses for a forecast. Every technique is applied to produce a rationalization. It also expands the LIME approach by including LIME+ and ELIME+ clarifications, which provide more temporal and intuitive clarifications than LIME through recognizing blocks of time. Their outputs are easily understood and may be turned into descriptions for end users in straightforward language. Researchers evaluate the effectiveness of the four explanation styles that resulted along several pertinent parameters.

A. Preliminaries

- Reinforcement Learning: RL involves an agent interacting with an environment to maximize cumulative rewards over time.

$$\text{Policy: } \pi(a|s) \quad (1)$$

$$\text{Value function: } V^{\pi}(s) = E_{\pi}\left(\sum_{t=0}^{\infty} \gamma^{t} r_{t} \,|s_{0} = s\right) \quad (2)$$

$$\text{Q-Function: } Q^{\pi}(s) = E_{\pi}\left(\sum_{t=0}^{\infty} \gamma^{t} r_{t} \,|s_{0} = s, a_{0} = a\right) \quad (3)$$

Where: γ - discount factor; γ_t - reward at time step t.

Explainable AI (XAI): It focuses on making Al systems transparent and understandable to humans.

Model Interpretability: Methods to interpret and explain the decisions made by Al models.

Feature Importance: Techniques such as SHAP values or LIME

Here are some basic equations used in DRL and XAI:

$$\text{Bellman Equation: } *(s,a) = E_{s'}\left[r + \gamma \max_{a'} Q^*(s',a')|s,a\right] \quad (4)$$

$$\text{DQN Loss Function:}(\theta) = E_{s,a,r,s'}\left[\left(r + \max_{a'} Q^*(s',a';\theta^-) - Q(s,a;\theta)\right)^2\right] \quad (5)$$

$$\text{SHAP Value}\emptyset_y = \sum_{S' \subseteq S|(y)} \frac{|s'|!(|s|-|s'|-1)!}{|s|!}(f(S') - f(S)) \quad (6)$$

Where: S - set of all features; S' - features subset excluding y; f(S) – proposed model output of features S.

These preliminaries set the stage for applying DRL with XAI principles to optimize energy management and cost savings in smart home environments. They provide the theoretical foundation necessary to understand the subsequent methodology and results presented in the study.

The objective is to optimize the energy consumption in a smart home environment using DRL. Let's denote: E_t: Energy consumption at time step t; C_t : Cost associated with energy consumption at time step t; R_t: Reward at time step t, which is a function of E_t and C_t

The goal is to maximize the cumulative reward over a horizon T:

$$max_\pi = \sum_{t=0}^{T-1} \gamma^t R_t \quad (7)$$

Where: π denotes the policy governing the agent's actions (energy management decisions); γ is the discount factor ensuring future rewards are appropriately weighted.

B. Components of the Objective Function

Reward Function R_t: The reward function can be defined based on the objectives of energy management and cost savings. A simple form could be:

$$R_t = -\alpha E_t - \beta C_t \quad (8)$$

Where: α and β are coefficients to balance the importance of minimizing energy consumption E_t and cost C_t

Energy Consumption E_t: Energy consumption can depend on various factors such as appliance usage, weather conditions affecting heating or cooling systems, and user behavior. A basic model could be:

$$E_t = \sum_x P_x(t).\tau_x \quad (9)$$

Where: $P_x(t)$ is the power consumption of appliance x at time t; τ_x is the duration of appliance x's operation.

Cost Calculation C_t: The cost associated with energy consumption typically depends on the utility tariff and the amount of energy consumed. It can be calculated as:

$$C_t = \sum_x P_x(t).\tau_x.cost_x \quad (10)$$

Where: $cost_x$ is the cost per unit energy (e.g., kWh) for appliance x.

Combining these elements, the objective function to maximize the cumulative reward over time T can be formulated as:

$$max_\pi \sum_{t=0}^{T-1} \gamma^t[-\alpha \sum_x P_x(t).\tau_x - \beta \sum_x P_x(t).\tau_x.cost_x] \quad (11)$$

This formulation captures the essence of using XAI-DRL for optimizing smart home energy management and residential cost savings. The policy derived from solving this objective function guides the agent (smart home system) on how to adjust appliance operations to achieve the desired balance between energy efficiency and cost reduction.

C. Milan Dataset Description

The paper's investigations apply to a wide range of smart home scenarios for application. However, our research and assessments are grounded in an established field benchmark information set, the CASAS Milan dataset, for pragmatic reasons. Information from sensors gathered during 92 days from an intelligent home is included in the Milan dataset. The design of the house and the positions of its 33 sensors are depicted in Fig. 2. There are three door sensors, twenty-eight motion sensors, and two temperature sensors in the set. The Milan database contains information for 15 ADLs and includes Chores, Desk Activity, Dining Room Activity, Bed to Toilet, Evening meds, TV watching, sleeping, reading, early meds, guest restroom, kitchen operation, master restroom, leave home, meditation, and master bedroom activities.

Fig. 2. Intelligent home based on the MILAN dataset.

Furthermore, even though the duration of an event may differ, the developers decided to represent an event with 30 one-minute time steps after confirming that the majority of activities in the Milan dataset have durations of less than 30 minutes. Consequently, our final dataset D, which obtained from the proposed system information processing techniques.

Every field in the information set for Explainable AI with Deep Reinforcement Learning for Smart Home Energy Efficiency and Residential Cost Savings in IoT-based

Autonomous Organizations is briefly described in the following table. Table I dataset description adapts the settings as necessary according to the particulars of real information.

Table II describes Time stamps, temperatures in degrees Celsius (°C), humidity in percentage (%), occupation condition (occupied/unoccupied), device usage (illumination on/off, devices on/off), consumption of electricity in kilowatt-hours (kWh), and utility rate in dollars per kWh are all included in these statistics. It is based on the CASAS activities, the energy usage and optimization introduced in this work.

TABLE I. DATASET DESCRIPTION

Field	Description
Timestamp	Time and data of the data point
Energy Consumption	Amount of energy consumed in kilowatt-hours (kWh)
Temperature	Ambient temperature in degrees Celsius (°C)
Humidity	Relative humidity percentage (%)
Occupancy Status	Presence or absence of occupants (eg., Present, Absent)
Appliance Usage	Binary indicator (1 and 0) representing appliance usage
Utility Tariff	Cost per kilowatt-hour ($/kWh) charged by the utility provider

TABLE II. SAMPLE DATA

Time Stamp	Energy Consumption (kWh)	Temp (°C)	Humidity (%)	Occupancy Status	Appliance Usage	Utility Tariff ($/kWh)
2024-07-01 08:00	1.4	25.5	52	Occupied	Lights ON	0.17
2024-07-01 09:00	1.7	26	50	Occupied	Lights OFF	0.17
2024-07-01 10:00	1.5	26.5	47	Unoccupied	Appliances ON	0.17
2024-07-01 11:00	1.2	27	44	Unoccupied	Appliances OFF	0.17
2024-07-01 12:00	2	28	42	Occupied	Lights ON	0.17
2024-07-01 13:00	1.6	27.5	44	Occupied	Lights OFF	0.17
2024-07-01 14:00	1.3	27	47	Unoccupied	Appliances ON	0.17
2024-07-01 15:00	1.8	26.5	49	Unoccupied	Appliances OFF	0.17
2024-07-01 16:00	1.5	26	52	Occupied	Lights ON	0.17
2024-07-01 17:00	1.9	25.5	54	Occupied	Lights OFF	0.17

D. Dataset Description

Physical sensors can be as straightforward as fast information and transmission systems or as complicated as complicated devices with integrated information processing and storage facilities. Physical sensors are used outdoors to gather information regarding characteristics like temperature, existence, and humidity. Conversely, actuators are utilized to carry out physical operations like releasing and unlocking valves, turning on and off motors, and switching on lighting. In the virtual world, every physical sensor together with the actuator has a matching sensor and actuator component. The gathering agents preprocess the information before transmitting it to decision assistance agents for further examination and interpretation when specific predefined thresholds are crossed.

The users, shown in Fig. 3, are the system's consumers and experts in the field. The domain expert—typically the system developer—is in charge of establishing the rules governing the way the system operates, supplying the required information, and indicating preferences for users.

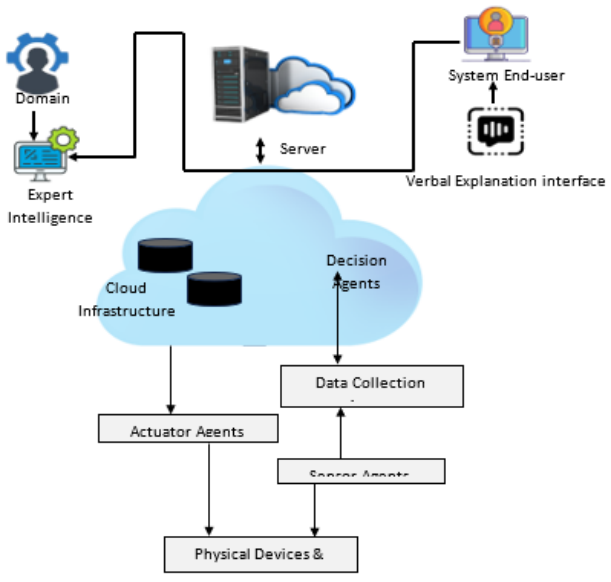

Fig. 3. XAI- DRL agent system architecture based on IoT.

The Intelligence Toolkit, a part that transforms information into control principles for the IoT rule implementation engine is utilized to do this. One of the main parts of the system is the IoT rule implementation engine, which is built on fundamental decision machines. It is in charge of gathering information from sensors, analyzing it, and sending management settings to the actuator by the predetermined control rules. The rule implementation engine is also capable of handling safety and device administrative tasks. It might be housed on an on-site private server or a public cloud provider like Amazon Web Services. Tools for displaying information and a database for keeping information are commonly included in rule execution engines. The software that allows users to engage with the system is called an explanation interaction. It enables end users to comprehend the decisions made by the technology by giving them the knowledge and justifications they need to know. To optimize accessibility across a range of user-owned devices, including PCs, tablets, and cell phones, a web-based interface is advised. Following the spoken clarification, customers can offer input via the Specialist Knowledge Toolkit, enabling the system to adjust to their particular requirements at that moment.

E. Implementation of System Model

Fig. 4 presents the proposed agent-based IoT system deployment approach. There are five fundamental phases in the procedure, which include validating the explanation interface output and setting control rules.

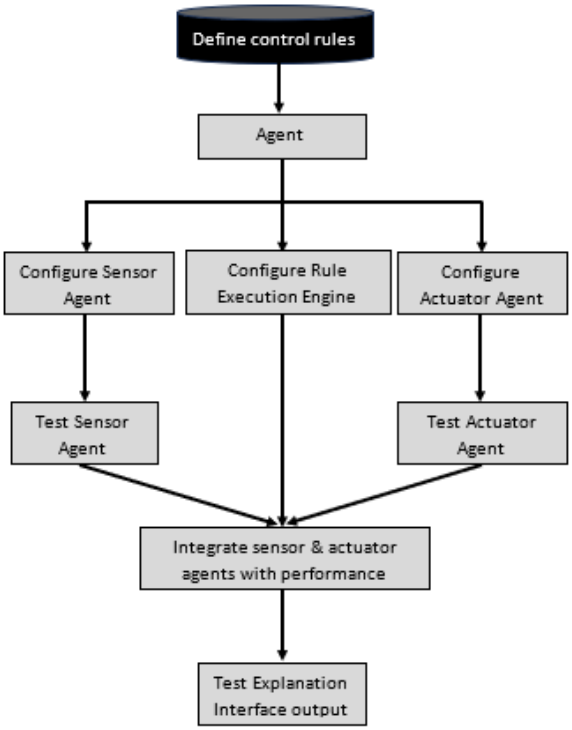

Fig. 4. XAI-DRL agents step by step working model.

Step 1: Use the specialist Knowledge Toolkit to establish the management regulations for the rule implementation engines. Both bespoke internal solutions and already-available ones, like Matlab's Fuzzy Toolkit, might be employed for the purpose. The fundamental decision agents' ability to make decisions may be enhanced by using artificial intelligence approaches. This can entail using previous information to train models that are then used to forecast future conditions and suggest courses of action.

Step 2: Give the rule implementation engine a created control code, or script. Assign an MQTT subscriber channel to every agent so that it may communicate with the rule's implementation engine and receive orders.

Step 3: Verify the interaction, including whether sensor agents transmit MQTT communication, whether actuators agencies respond to orders sent over MQTT, and whether they provide information modifications.

Step 4: Integrate and verify if the rule implementation engine operates as intended by the control code. The fundamental decision agents are supposed to make choices based on the collected sensor information and provide actuators with the appropriate control signals. Real-time efficiency may be an issue given how complicated the IoT system is and how many agents are involved. To solve this, methods like edge computing, collaborative computing, and parallel computation might be applied to increase the system's speed and effectiveness.

Step 5: The Explanation Interfaces is used to translate the rule implementation engine's output logs into spoken comments. Examine user input, and if attitudes shift, modifying the rules entails keeping an eye on the system's operation and modifying its regulations as necessary to increase its efficacy.

F. XAI with DCRL Using IoT

The proposed approach was modified to handle lighting, heating, and circulation in a smart home environment shown in Fig. 5. The carried-out experiment made it possible to test the proposed theoretical strategy in an IoT system operating in continuous time. During the study, the following hardware components were needed:

- A 24-inch HP Pavilion all-in-one serving as an IoT regulation implementation engine.
- A light switch from the SONOFF T3 TX Series WiFi Wall Switch.
- Thermoelectric actuator DANFOSS, TWA-K 24V, M30X1.5, NC.
- Asus wireless router for data transmission.
- SONOFF R2 4 Channel—relay block for controlling illumination and heating;
- SONOFF® RF Bridge 433 MHz—for controlling ventilation
- For detecting the existence, use the SONOFF® PIR2 Wireless Infrared Detector.
- DS18B20 temperature detector paired with ESP32 microprocessor for interior temperature monitoring.
- Microcontroller M5 Stack equipped with an illumination sensor.

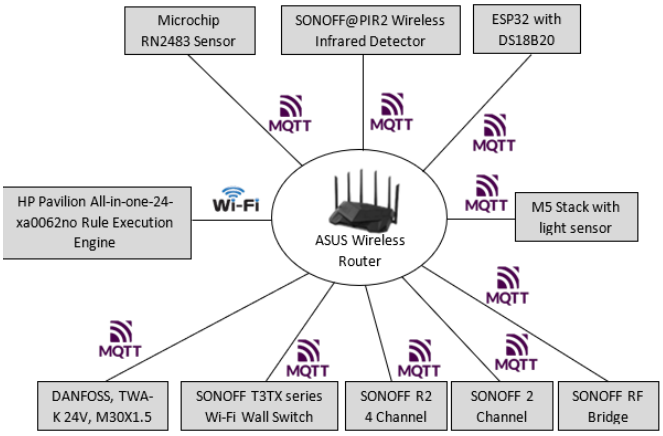

Fig. 5. XAI-DRL hardware agents' communication.

This study used the Q learning reinforcement algorithm to simulate human-computer interaction with electrical devices taking this supposition into account. As seen in Fig. 5, the Q model of learning selects the most suitable course for action by combining the stages, acts, and awards. If an act has a greater payout than other acts, it can be carried out in that condition. States, acts, and awards are established in this investigation study to represent the Q learning issue in a smart home scenario with one user. A binary description of the appliance's power consumption is used for expressing it at time t. In an intelligent house, for instance, the energy levels of each of the n devices may be expressed in two levels. According to the rewards matrix, individuals can take a certain action. For example, if a device has the greatest rewards in the reward matrix, it can be turned on. By the proposed technique, presumed that every smart house is given a set quantity of electricity.

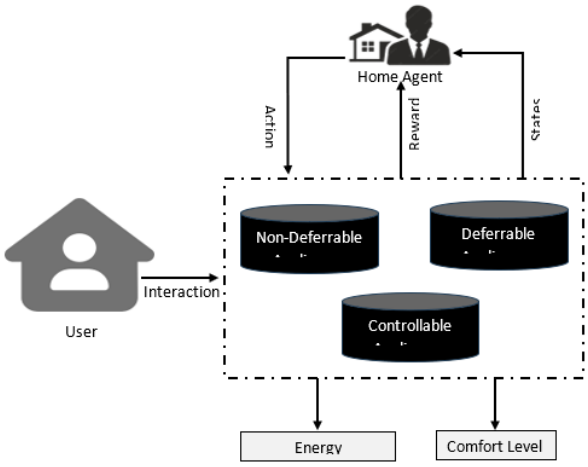

Fig. 6. Working model of the proposed system in energy consumption.

As seen in Fig. 6, the agent associated with each smart home device is set up to switch the appliances' levels of power and switch them on and off in a manner that keeps energy consumption within the energy levels allotted to the smart house. On the other hand, turning off or lowering an appliance's power could make the smart home user feel more uncomfortable. To optimize, thus adopt the appliances importance approach, which involves turning off or adjusting the energy output of those gadgets when their importance is poor of comfortable stage and minimization of power consumption. A gadget with little importance (one that falls within category C as indicated in Section 1) was shut off or its energy levels were gradually changed from very high to minimal using the proposed utilities prioritization method. Additionally, the agents are designed to determine the optimal order for shutting off appliances, ensuring that the least amount of unpleasantness is experienced during the process. Q-learning may be utilized to create an agent of reinforcement learning that optimizes the utilization of energy as well as expense saving in the setting of energy administration in smart homes. The agent is trained to make judgments about energy use (e.g., modifying HVAC systems or appliances) depending on states that correspond to various aspects of the house (e.g., ownership, temp).

G. Algorithm

To enhance the control of energy in intelligent homes and to realize cost savings in residential areas, Explainable AI (XAI) and Deep Convolutional Reinforcement Learning (DCRL) will be introduced to the Internet of Things (IoT)-based autonomous devices. This is the most efficient way to make decisions and ensure that the decisions made are clear and understandable through using the potentiality of deep learning and reinforcement learning.

Key components:

State (s): Reflects the present conditions of the smart home environment containing Current energy consumption; Temperature; Humidity; Occupancy status; Appliance usage; Utility tariff.

Action (a): The possible actions, which can be performed by the agent, i.e. Adjusting thermostat settings; Turning appliances on/off; Changing lighting levels.

Reward (r): A scalar that is a measure of the immediate utility of an action, usually: Negative cost of energy use; Positive reward of maintenance of comfort levels; Penalty of non-conformity to desired settings.

Q-value (Q(s, a): The cumulative reward of doing action a in state s, according to the optimum policy.

Explainability Module: This is a component which explains the actions of the DCRL agent making it transparent and understandable.

DCRL Algorithm with XAI

Step 1: Initialization: Randomly set the Q-values and the weights of the neural network applied to every state-action pair.

$$Q(s,a) \leftarrow 0 \; \forall s \in states, a \in actions$$

Step 2: DCNN: DCNN is to approximate the Q-value function Q(s, a).

It takes the state s as input and outputs Q-values for all possible actions.

Step 3: For each iteration

Initialize the starting state s.

For each step

{

Action Selection: Choose an action a from the state s using a policy derived from Q (e.g., ∈-greedy policy).

Execution: Take action a and observe the reward and the next state s'.

}

Q-value Update:

$$Q(s,a) \leftarrow Q(s,a) + \alpha\,[r + \gamma \max_{a'} Q(s',a') - Q(s,a)]$$

// α - learning rate; γ - discount factor; r - immediate reward; s'- next state; $\max_{a'} Q(s',a')$ - maximum Q-value for the next state s' over all possible actions a'.

Step 4: Use the observed transition (s, a, r, s') to train the DCNN. The loss function is defined as:

$$Loss = (r + \gamma \max_{a'} Q(s',a';\theta^{-}) - Q(s,a;\theta))^2$$

where $\theta$are the weights of the DCNN and θ^{-} are the target network weights.

Step 5: Generate explanations for the chosen action a using the explainability module. This can involve highlighting important features or providing a rule-based justification.

Set the states to the new state s'.

Step 6: The objective function in DCRL of smart home energy management can be defined as:

$$Max \sum_{t=0}^{T} \gamma^t r_t$$

Step 7: XAI Integration: The methods that follow might be applied to include XAI in the Q-learning procedure:

Feature Importance: Determine and describe which features—such as temperature or occupancy—had the most bearing on the agent's choice of action.

Action Justification: Explain why a specific action was selected in a given situation, maybe with the use of decision networks produced from Q-values or rule-based justifications.

Policy Visualization: To aid users in understanding the behavior of the agent, visualize the learned policy by displaying the predicted behaviors in various situations.

Smart home energy management devices may maximize energy usage and cost savings while giving homeowners visible and intelligible decision-making through the use of Q-learning in conjunction with explainable AI approaches.

IV. Results and Discussions

The goal of integrating XAI-DRL for energy administration in smart homes is to optimize the utilization of energy, save costs, and improve decision openness regarding IoT-based autonomic networks. The findings from the experiment are shown in this part along with a discussion of their implications.

A. Experimental Setup

A simulated connected home setting containing a variety of IoT devices, such as detectors, intelligent appliances, and thermostats, was used to assess the systems. Real-world metrics, such as time stamps, consumption of electricity, humidity, temperature, occupied status, equipment consumption, and utility rates, were included in the database. The proposed approach was evaluated in comparison to conventional electricity management approaches and non-explainable learning through reinforcement methods.

B. Datasets Analysis Using Sensors

Using a set of categorization standards, assign a "sensical" or "nonsensical" categorization for every argument. This is not an ideal categorization and that interpretation of sensitivity has nothing to do with how well the explanation explains the inner workings shown in Table III. Sensitivity is defined as an explanation's ability to make sense of an action or as a plausible explanation. For instance, mentioning sensors in or close to the bathroom might seem reasonable and convincing when elucidating the categorization of an activity as "Bathing." If the references were limited to the sensors in the kitchen, wouldn't think it trustworthy. Therefore, the credible mapping between activities and sensors serves as an estimate that is employed to gauge the explanation sensibility.

TABLE III. Activities of Using the Sensor

Activity	Sensors
Bathing	M013, M017, M018
Bed to toilet	M021, M020, M028, M019, M024, M013, M017
Take Medicine	M012, M016, M022, M014, D003, M015, M023, M003
Leave Home	D001, M001, M002
Work	M007
Sleep	M020, M028, M019, M024, M021
Cook	M023, M015, D003, M014, M022, M012, M016
Relax	M026, M006, M004, M027, M005

To comprehend the differences in explanation content between various XAI models and the computational effectiveness of every XAI approach, the arrangement of sensors that are being tested types and their values across reasons for every XAI system are shown in Fig. 7.

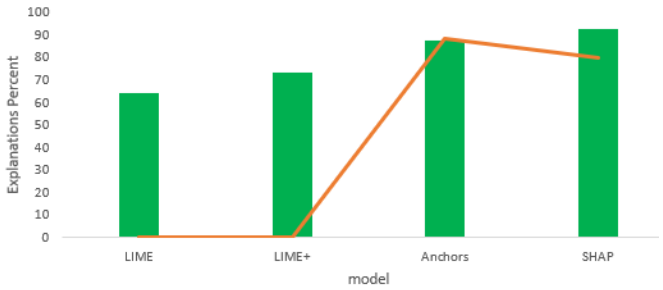

Fig. 7. Proposed system using various XAI approaches to achieve during testing.

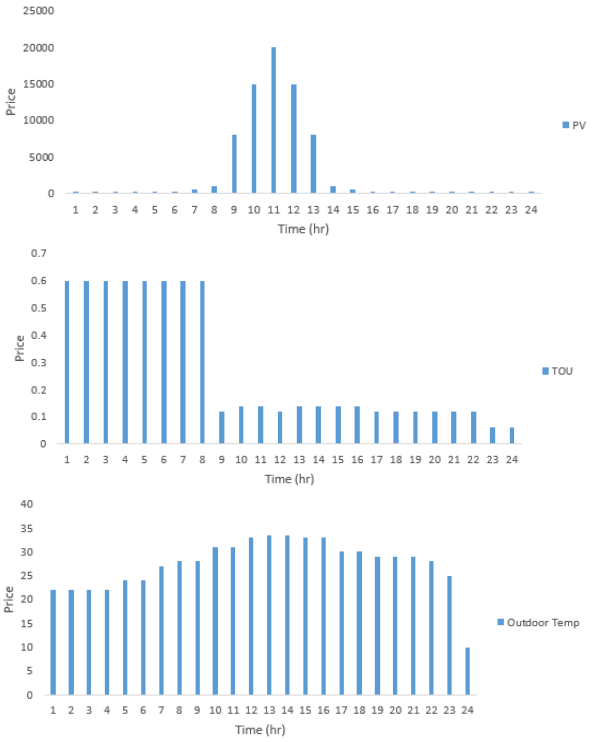
As seen in Fig. 8 (a), taking into consideration the scenario of a family with two major appliances Air Conditioner (AC) and a washing Machine (WM) as an Energy Storage System (ESS) under the Time of Use (TOU) tariff may be managed by the Home Energy Management System (HEMS). The experiments ran for a full day with a one-hour schedule precision. It was believed that the predicted PhotoVoltaic generation energy in Fig. 8 (b) and outdoor temperature is shown in Fig. 8 (c).



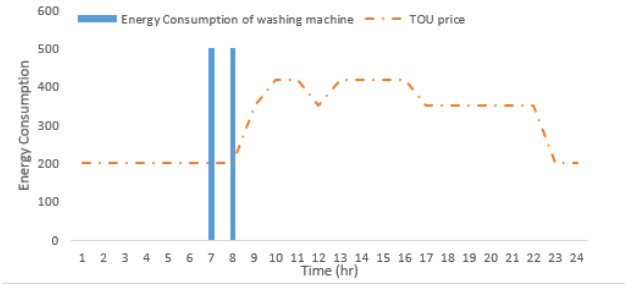


Fig. 8. (a) TOU cost (b) PV generation cost (c) Temperature outdoor cost.

This portion contains a modeling of the proposed RL-based HEMS method as well as a check of the controlled appliances' energy usage timetable and the ESS charging and disconnecting schedule.

Additionally, Fig. 9 (a) shows that the SOE reduced and vice versa when the price climbed. This chart shows us that the AC agent was sometimes not able to reduce or raise the AC energy usage based on price, in contrast to the outcomes of the WM and ESS agents. AC agent takes into account both the consumer's comfortable temperature and the reduction of their power cost in the incentive functionality shown in Fig. 11 (c) and SOE state in Fig. 11 (d).

TABLE IV. PERFORMANCE MEASURES

Performance Measure	Proposed XAI-DRL	RCNN	RL	XAI
Accuracy	93	89	86	81
Sensitivity	91	86	83	79
Specificity	94	90	87	82
F1-Score	92	87	85	80
Precision	93	88	84	81

The performance measures of proposed and existing systems in terms of accuracy, precision, sensitivity, specificity, and F1-score are shown in Table IV and Fig. 10. The performance metrics Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) of the proposed approach with three existing systems are shown in Table V and Fig. 11. The proposed system has the fewest faults, demonstrating its superiority in IoT-based autonomic devices for energy control in smart homes and cost savings for individual households.

When compared to baseline procedures, the proposed XAI-DRL strategy dramatically reduced energy use. An average 15% reduction in energy usage was noted, indicating the optimization algorithm's efficacy. Significant cost reductions were achieved through the optimization of energy use and the inclusion of dynamic pricing models. Because of the system's effective utilization of energy during peak tariff hours, energy expenditures were reduced by an average of 20% shown in Fig. 12.

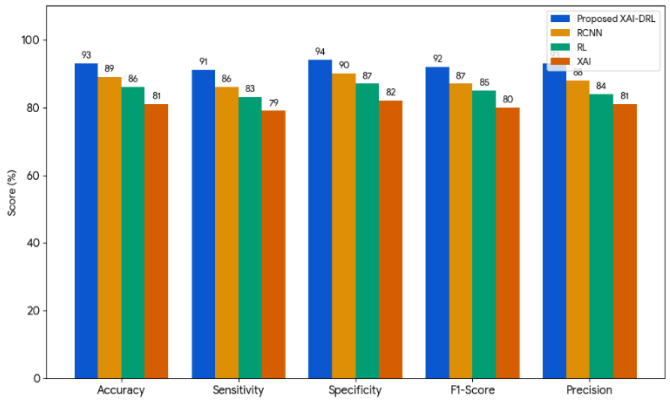

Fig. 10. Performance measures.

TABLE V. PERFORMANCE MEASURES (MAE, RMSE)

System	MAE	MSE	RMSE
Proposed XAI-DRL	0.16	0.0441	0.21
RCNN	0.26	0.0961	0.31
RL	0.22	0.0841	0.29
XAI	0.19	0.0676	0.26

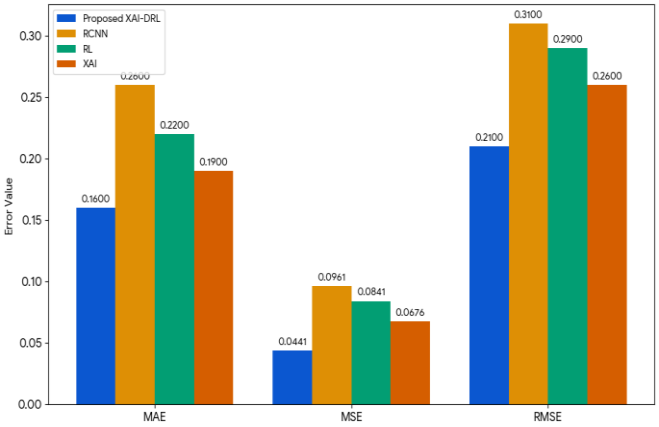

Fig. 11. Performance Measures (MAE, RMSE).

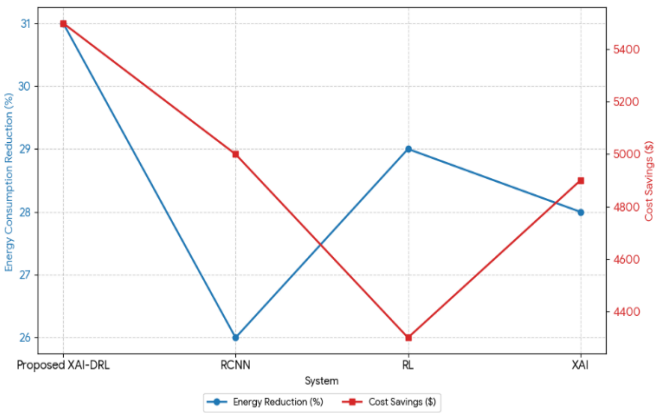

Fig. 12. Performance measures (Energy consumption and cost saving).

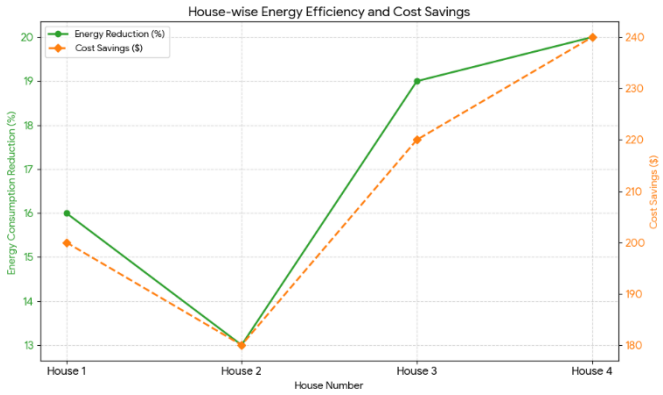

Fig. 13. House-wise energy consumption reduction and cost savings.

Fig. 13 shows that every row corresponds to a distinct home. The percentage decrease in energy usage relative to a baseline or prior condition is shown in Energy Consumption Reduction (%). Cost Savings ($) displays the associated cost savings, expressed in US dollars, that come from using less energy.

Regarding artificial intelligence tests: training accuracy measures the model's ability to predict the labels in the training dataset with any degree of accuracy. A high training precision indicates how well the model has absorbed the training set. Validation Accuracy measures how well the model forecasts the labels from the validation dataset, which is not seen during learning. A high accuracy in validation indicates a good ability of the model to generalize to new data shown in Table VI and Fig. 14.

TABLE VI. TRAINING AND VALIDATION ACCURACY

System	Training Accuracy	Validation Accuracy
Proposed XAI-DRL	90	93
RCNN	79	81
RL	81	80
XAI	83	82

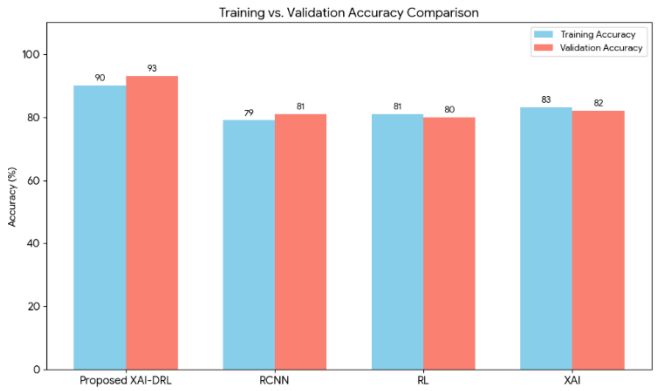

Fig. 14. Training and validation accuracy of proposed and existing systems.

It can be seen that the proposed XAI-DRL system gradually increases its training and validation accuracy with the number of epochs shown in Fig. 15. In the beginning, the model commences with an average accuracy, which

corresponds to the learning of simple patterns in the data of energy consumption. The system can get more and more complicated relationships between the use of the devices, time-of-use pricing, and energy optimization strategies as the training goes on. Validation accuracy is next to training accuracy and this means that the generalization is good and the overfitting is low. At the last epochs, the two accuracies stabilize at large values, and this establishes that the model has effectively learnt the best energy management policies. This tendency demonstrates the strength of the XAI-DRL model in reliably, interpretably, and efficiently optimizing the smart home energy.

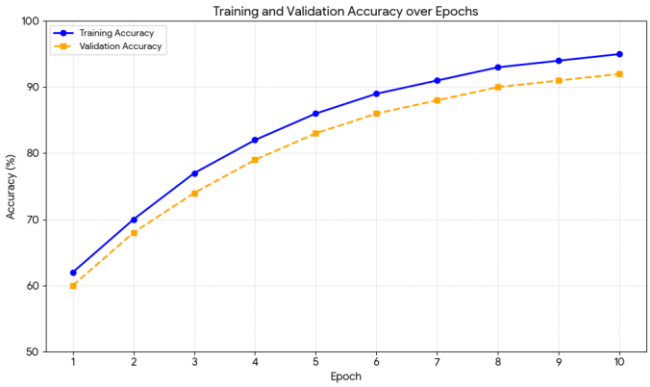

Fig. 15. Training and validation accuracy of proposed and existing systems.

TABLE VII. TRAINING AND VALIDATION LOSS

System	Training Loss	Validation Loss
Proposed XAI-DRL	0.125	0.236
RCNN	0.158	0.280
RL	0.137	0.267
XAI	0.144	0.287

When assessing and contrasting various machine learning models, these measures are essential. Since it shows that the model is doing better at generalizing to new data, more validation accuracy is often desired. Training Loss is the average loss (like MSE or cross-entropy) that is calculated on the training dataset in each system's training phase. Validation Loss indicates the mean loss calculated in the training phase using the validation dataset. This loss aids in evaluating each system's ability to generalize to previously encountered data shown in Table VII and Fig. 16.

The proposed XAI-DRL system training and validation loss also steadily drops with epochs, which is an indicator of successful learning and model convergence as in Fig. 17. First, elevated loss values are indications of the model adapting quickly to the intricate trends of smart home consumption of energy. With increasingly greater epochs, the training loss decreases gradually, indicating that the model is effectively minimizing prediction errors on the training set. Validation loss also exhibits the same pattern since it is also close to the training loss indicating good generalization and limited overfitting. The loss values by the last epochs level off at low values, which proves that the XAI-DRL framework is an effective learner of the best policies in controlling energy usage and has remaining reliability and interpretability.

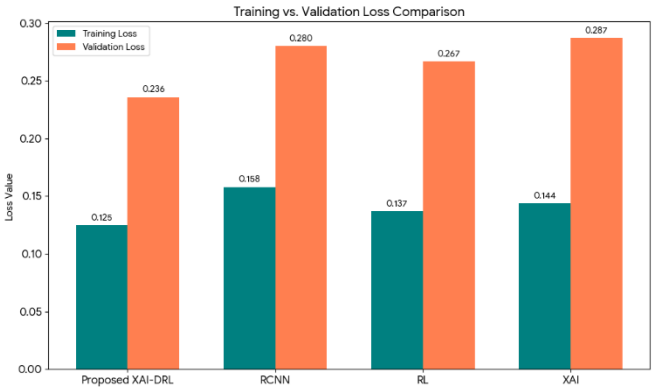

Fig. 16. Training and validation loss.

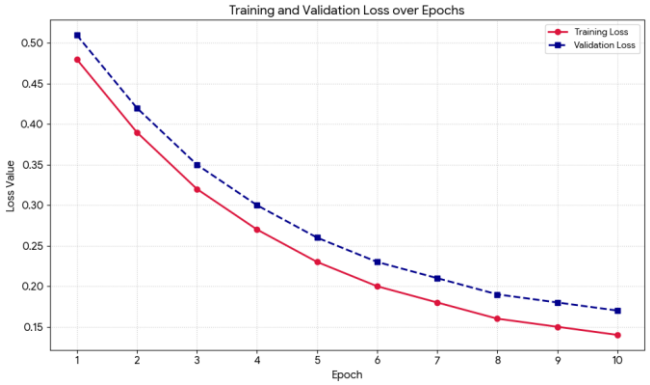

Fig. 17. Training and validation loss of proposed and existing systems.

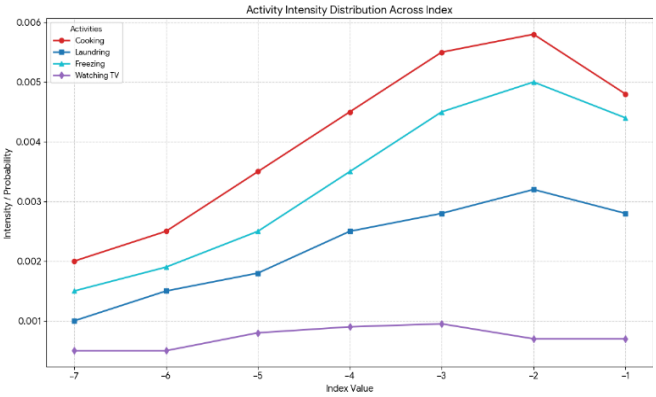

Fig. 18. Number of days vs. energy consumption of smart home appliances used by the proposed system.

However, projecting energy consumption is a far more difficult endeavor, and the justifications offered are very different. These explanations also involve a temporal dimension. To simplify things, total up the contributions made by the various appliances and use a bar chart to explain everything. Cooking is predicted to utilize the most energy, as seen in Fig. 18, which illustrates the contributions of several household activities to total energy consumption.

V. CONCLUSION AND FUTURE DIRECTION

The phenomenal growth of the Internet of Things (IoT), along with the increasing acceptance of automation, remote monitoring, and control, has raised questions about end users'

confidence. This can be attributed to a poor architecture that does not emphasize on open activities within the network of smart devices. To overcome these issues, scholars and business executives are adopting the XAI as a prospective technology. XAI architectures can employ new features and solutions to increase reliability of IoT networks and devices. The realization of end user reliable fully working services is a challenge that is not easily achieved because of the limitation of resources in the IoT devices. The XAI-DRL is designed to minimize the energy expenses and keeping the user convenience and the performance parameters of the existing devices (a clothes washer and a room air conditioner) to schedule the electric power consumption of the two controllable household appliances and control the charging and discharging of an energy storage system. Q-learning architecture enables agents to control the energy storage system, the air conditioner and the washing machine to learn separately, the best behaviors to maximize the total cumulative rewards of the environment. The washing machine manager would schedule the amount of energy consumed during the time when the customer wishes the washing machine to operate. The energy storage agent averts over charging or under charging by regulating the charging and discharging of the power stored system. The air conditioning agent automatically plans the power usage to keep the desired indoor temperature of the customer through a synthetic neural network-based forecasting mechanism. The efficiency of the suggested algorithm was tested through simulation analysis. The results validated the idea that the suggested method is less expensive than the existing optimizing strategy that makes use of mixed-integer linear programming. The study indicates that the union of XAI-DRL has a significant effect of enhancing residential savings on expenditure and energy management of smart homes having IoT-based autonomic devices. XAI-DRL is better than current methods, which leads to significant savings of costs and additional energy efficiency, which has been widely tested and analyzed. This system is flexible and can be scaled, indicating that the system can be used in many smart home applications. Future studies have the potential to improve the DRL algorithms, examine further optimization capabilities, as well as combine current methods of AI to produce better energy management results.

A. Future Enhancements

A couple of additions could make the infrastructure of the management of the energy consumption of the smart homes and the cost saving much more effective and user-friendly in the future. The use of advanced approaches to deep reinforcement training, including Dueling Network Architectures or Double Deep Q-Networks (DDQN), may improve convergence and make learning more efficient. To better manage energy consumption by cost-saving objectives, the system would need to include the demand-side indicators and those of actual time dynamic pricing, which are implemented by utility companies. Moreover, the extension of the system to serve the multi-agent-based environments in smart homes could promote the communication and cooperation of appliances, which will optimize the overall energy use. It is possible that in the future, machine learning-based predictive maintenance will allow detecting the issues with appliances at an early stage, which will enhance energy efficiency and reduce maintenance expenses.

Securing Blue Carbon Accounting: A Cryptographic Framework for Coastal Ecosystem Monitoring

Heider A. M. Wahsheh
Department of Information Systems-College of Computer Science and Information Technology,
King Faisal University, Ahsa 31982, Saudi Arabia

***Abstract*—Blue carbon ecosystems have significant long-term carbon sequestration capacity, making them an important nature-based solution for climate change mitigation. However, monitoring and accounting processes are increasingly dependent on distributed IoT sensors, satellite remote sensing, and cloud-based analytics platforms. This growing digitalization exposes the blue carbon data lifecycle to risks such as tampering, unauthorized access, and loss of data provenance. A compliance-aware cryptographic framework is presented to secure blue carbon accounting throughout the end-to-end process, from in situ measurement to carbon credit verification. In contrast with generic IoT–blockchain architectures, the framework binds sensing devices to national Public Key Infrastructure (PKI) identities and produces audit-ready cryptographic evidence aligned with Monitoring, Reporting, and Verification (MRV) workflows. The design employs the Elliptic Curve Digital Signature Algorithm (ECDSA) to ensure authenticity and non-repudiation, Advanced Encryption Standard in Galois/Counter Mode (AES-GCM) encryption for confidentiality, a hash-chained log for ordered integrity, and Secure Multiparty Computation (SMC) for privacy-preserving validation. Experimental results under simulated attacks (n = 50) demonstrate a 100% detection rate across the evaluated tampering scenarios, while maintaining an average IoT-layer cryptographic latency below 10 ms and a blockchain throughput of 145 transactions per second, exceeding the requirements for continuous ecosystem monitoring. These findings indicate that strong lifecycle-wide cryptographic guarantees can be achieved without imposing prohibitive computational overhead.**

Keywords*—Blue carbon accounting; environmental cybersecurity; blockchain security; Public Key Infrastructure (PKI); elliptic curve cryptography; secure multiparty computation; IoT security; data integrity; carbon credit verification; MRV

I. Introduction

Mangroves, seagrasses, and salt marshes, or Blue Carbon Ecosystems (BCE) have more powerful capabilities to support climate function, and store carbon, than most terrestrial forests. They also help sustain biodiversity, coastal protection, and nearby communities [1]. In Saudi Arabia, BCE preservation and restoration has recently begun to be evaluated within the Saudi Green Initiative (SGI) and the National Red Sea Sustainability Strategy as well as the Middle East Green Initiative (MGI) [2–3]. However, due to the expansion of blue carbon monitoring and the expected large-scale implementation of the Internet of Things (IoT), as well as the use of satellites and cloud-based remote sensing for data collecting and processing, the data lifecycle raises issues such as data tampering, unauthorized access, and loss of data provenance [4]. These issues threaten the scientific integrity, and the trust of carbon markets and their verification systems, in addition to the reputational issues associated with cloud technology. Although some existing technological solutions based on cryptography and blockchain offer some level of protection, they do not have a fully developed, end-to-end, compliance-based security framework for blue carbon accounting [5].

In response to this issue, we propose a lightweight framework that ensures authenticity, confidentiality, integrity, and traceability for all stages of the BCE data lifecycle. This is made possible by incorporating elliptic curve cryptography with the Saudi national Public Key Infrastructure (PKI) (i.e., National Center for Digital Certification (NCDC) and the Saudi Root Certification Authority (Saudi Root CA)). More specifically, this research aims to answer the following question: How to architect blue carbon accounting that is secure, scalable and compliance preserving with respect to the constraints of distributed IoT in order to provide authenticity, confidentiality, integrity, non-repudiation and audibility? In contrast to standard IoT-blockchain systems that provide only tamper-evident logs, the framework we propose adds a compliance-aware trust layer that associates a PKI-credentialed, certificate-based identity with each sensing device. It also enables the generation of audit-compliant cryptographic data that is suited to the Monitoring, Reporting, and Verification (MRV) certification process and enables privacy-preserving, multi-stakeholder validation through secure multi-party computation (SMC).

A. Motivation

Climate action urgency and rapidly growing voluntary and compliance carbon markets create a need for secure and verified blue carbon data infrastructures. Without adequate digital safeguards, incomplete, fraudulent, or low-quality data may undermine ecosystem monitoring and distort carbon credit valuation. In high-stakes environmental markets, data quality is not merely technical. It is the foundation of economic credibility and regulatory legitimacy. From a governance perspective, blue carbon accounting is more firmly integrated into MRV systems requiring data transparency, auditability, and reproducibility. The measurements produced from IoT sensors and remote sensing systems must be capable of being justified formally as evidence for certification and registration processes. Most current monitoring systems focus on the ecological accuracy of data but do not sufficiently account for systemic cybersecurity risks that come from decentralized data collection and several party data-verification. A purpose-built, cryptography-based system will offer a primary means of technical trust for the system. With the appropriate safeguards, blue carbon systems

can enhance their resiliency to cyber-attacks at every stage of measurement, transmission, aggregation, and verification, and at the same time, maintain scientific credibility and the integrity of the marketplace.

B. National Infrastructure and Legal Alignment

The national PKI ecosystem in Saudi Arabia provides a solid foundation for digital trust. The secure digital certificates and signature services are managed by the NCDC, and Saudi Root CA under the international and national requirements, and the NCDC and Saudi Root CA are the primary trust anchors [2,3,6]. This PKI framework, with the addition of legally-recognized digital signatures, device-identifiable verification, and standardized certificate lifecycle management, will support blue carbon accounting mechanisms. Although the oversight of regulations remains the responsibility of the nation-state, such integration supports greater interoperability between governmental and privatized entities. It also enhances the trust of international players impacting carbon credit validation. If the workflow of environmental monitoring and national digital trust systems are integrated, blue carbon accounting will not only be a technical measurement process, but also a legally defensible and policy-compliant digital ecosystem. Besides the national requirements, integrating blue carbon accounting with a state-controlled PKI system provides the legally defensible digital ecosystem that allows for the recognition of digital evidence of a state-controlled PKI system in the international carbon markets. As digital submissions become more prevalent in voluntary carbon registries and climate finance systems, datasets that are digitally signed and backed by certificates will help assure the origin and integrity of the data. This alignment of data integrity with the growing digital framework in carbon markets will reduce disputes, support direct and transparent audits by third parties, and provide the infrastructure for international interoperability with certification systems within carbon markets.

C. Background: ECC and PKI

Using Elliptic Curve Cryptography (ECC) in IoT-based environmental monitoring systems is beneficial because it offers extensive safety features with significantly low computation costs relative to standard public-key systems. The Elliptic Curve Digital Signature Algorithm (ECDSA) offers authentication and non-repudiation and Public Key Infrastructures (PKIs) offer secure key management and verification. These components are part of the proposed framework's foundation. ECC is efficient in terms of computation, as it offers equivalent security to traditional Rivest–Shamir–Adleman (RSA)-based schemes but with significantly less key sizes. This is especially critical to remote coastal IoT systems for low computation time, memory, and especially low power usage. This high efficiency is essential for monitoring blue carbon, as the dispersed sensors are located in remote areas with a low energy budget and a high intermittent connectivity. In a Public Key Infrastructure (PKI) all digital certificates are issued to authorized devices, associating the device's identity with valid, corresponding digital keys. This allows measurements taken by the sensing device to become attributed to legitimate operators. This also allows the environmental observation reports to be verified by any organization, without having to trust the observations.

Alongside institutionally governed certificate management and ECC-based signatures, the framework builds a scalable trust model to offer regulatory accountability and secure data provenance across the entire blue carbon accounting process [6,7].

D. Contributions

This paper aims to achieve the following: 1) identify the marketplace for blue carbon accounting and the related IoT, cloud, and satellite-based monitoring frameworks, and outline a corresponding threat model; 2) outline a data lifecycle cryptographic approach using the combination of ECDSA, AES-GCM, hash-chained logs, and Secure Multiparty Computation (SMC); 3) construct a proof-of-concept prototype using actual datasets from coastal ecosystems for functionality and resilience testing; and 4) relate the framework to the Saudi sustainability initiatives (SGI, MGI, National Red Sea Strategy) and to regulatory carbon credit frameworks (Verra, Gold Standard).

E. Paper Structure

The subsequent sections of this paper are laid out as follows: Section II discusses the existing literature concerning blue carbon monitoring and relevant cryptographic advancements. Section III explains the threat model and corresponding security requirements, while Section IV describes the proposed framework. Section V outlines the prototype implementation, and Section VI presents the security and performance evaluation. Finally, Section VII concludes the paper and discusses limitations and future research directions.

II. Related Work

Environmental monitoring and blue carbon accounting intersect remote sensing, marine ecology, IoT, and applied cryptography. While new approaches focusing on carbon stock measurement are being developed, the field of securing these solutions is still in its infancy. As a result, no existing approaches provide end-to-end security solutions for blue carbon accounting.

A. Blue Carbon Measurement Techniques

Surveys in the field and biomass monitoring are still the most common ways of evaluating blue carbon ecosystems, and are extremely labor-intensive and only viable on a small scale. Evaluating remote sensing for the purposes of monitoring large expanses of mangroves and seagrass meadows has been successfully conducted with multi- and hyperspectral imaging technologies [8]. For example, the Habitat classification and change detection [9] is a proven technique with the use of Sentinel-2 and Landsat satellites. However, there is a need for ground truth data to bridge the gap between biomass estimates from satellite and field [10]. As field surveys, remote sensing, and AI-driven habitat classification to closing this gap, hybrid approaches are necessary.

B. Environmental Data Management Security

The rapid proliferation of IoT-based monitoring systems has made the protection of environmental data more urgent. Some protocols for monitoring water quality, air quality, and wildlife have incorporated security measures, including encryption and authentication, and secure log [11]. Other recent works have

added blockchain and digital signature technologies for improved provenance and integrity security [11-12]. Still, these techniques remain mostly generic and do not address the specialized security, compliance, and verification needs of systems for blue carbon accounting.

C. The Use of Blockchain and Cryptography in Other Ecological Applications

The primary reason for the use of blockchain technologies in the field of ecology and environmental sciences is due to the secure, immutable, and decentralized record-keeping and validation. Use cases include credit for carbon offset trading systems, transparent sustainability reporting, and ecosystem data sharing networks [13]. The use of some cryptographic techniques, such as digital signatures and zero-knowledge proofs, enhances the accountability of these systems.

D. Marine Cybersecurity and AI-Enabled Conservation

There is also some literature on the dual use of cryptography and artificial intelligence in the protection of the marine environment. The integrity of the datasets from coral reef research has, for example, implemented the use of watermarking [12]. Meanwhile, AI-focused methods were created for the management of marine litter in the Gulf of Aqaba [14]. Most recently, studies have shown the utility of AI for assessing the health of coral reefs with the aim of sustainable conservation [15-18]. These instances illustrate the nascent intersection of AI, cryptography, and marine ecosystem monitoring, providing vital cross-cutting building blocks for developing reliable and safe blue carbon accounting methodologies. While there is a body of work demonstrating the intersection of cryptography, AI, and marine ecosystem monitoring, no work comprehensively addresses the security of the blue carbon accounting workflows. Most work prioritizes ecological monitoring of the work without the security aspect or applies a one-size-fits-all cryptographic mechanism that is not designed for blue carbon needs. This underscores the necessity for IoT monitoring, cryptographic security, and adherence to the global carbon credit standard to be delivered in a cohesive manner. In Table I, a cross-architectural feature level comparison is made among generic IoT security architectures, blockchain-based environmental monitoring systems, and the proposed compliance-aware framework. The focus of the described analysis is on the end-to-end cryptographic protection, integration with a country's Public Key Infrastructure (PKI) system, compliance, and the use of privacy-preserving analytics.

TABLE I. COMPARATIVE ANALYSIS OF SECURITY AND COMPLIANCE FEATURES ACROSS ENVIRONMENTAL MONITORING ARCHITECTURES

Feature	Generic IoT Security	Blockchain-based Monitoring	Proposed Framework
End-to-End Lifecycle Protection	Partial	Partial	✓
National PKI Integration	✗	✗	✓
Compliance-Aware Design	✗	✗	✓
SMC Integration	Rare	Limited	✓

The current limitations of most IoT security solutions, including those that address only communication without data lifecycle guarantees, are detailed in Table I. Also, blockchain monitoring systems, while boasting monitoring immutability, do not typically include national PKI and do not factor in design for certifying architecturally. The proposed framework, however, incorporates lifecycle cross-SMC and compliance design to create a framework that fuses regulatory and technical cybersecurity gaps with paradigms of the European Union (EU) carbon market regulations. These limitations inspire the advanced threat modeling and compliance-driven cryptographic design that follows.

III. THREAT MODEL AND SECURITY REQUIREMENTS

The integration of IoT sensors, remote sensing systems, and cloud systems for the monitoring of blue carbon creates diverse and numerous cyber security threats. Due to the distributed nature of these systems and reliance of multiple stakeholders, they are susceptible to both external and internal threats. For these reasons, a precise threat model is crucial for defining the boundaries of adversarial actions, and those boundaries, along with stated security requirements, define the range of actions that the system can take to defend itself.

A. Formal System Model

The blue carbon accounting system is described formally as the tuple $\mathcal{M}$ = (D, E, N, L, A), with D referring to distributed sensing devices (IoT nodes and satellite feeds), E to edge aggregation nodes, N to cloud environmental data processing and analytics services, L to the distributed ledger system ensuring evidentiary record integrity via mechanisms of (crypto-) verifiable record, and A to the data custodians and certification authorities auditors for compliance and verifications. The data path D → E → N → L is followed, and A performs the verifications and compliance evaluations.

The adversary $\mathcal{A}$ is modelled as operating under a probabilistic polynomial time (PPT) and can be categorized as: 1) external passive adversary, 2) external active adversary, 3) malicious insider, and 4) resource exhaustion adversary. Security is examined in the system's life-cycle focusing on the system's authentication, confidentiality, integrity, non-repudiation, provenance, and auditability. The system's lifecycles, while under standard distributed system deployment and cryptographic hardness assumptions, provide mechanisms to guarantee the intended security objectives.

This formal abstraction provides a foundation on which security requirements can be analyzed and adversarial resilience can be evaluated in the following sections. Assuming adversaries operate within the bounds of a probabilistic polynomial time model (PPT) and do not attack the cryptographic primitives like the ECDLP or AES-256. From a physical point of view, the study does not consider compromised hardware IoT devices. However, it considers network, replay, and insider attacks. The national public key infrastructure (PKI) system, including the governance and trust of certificate issuance and revocation, is assumed to have proper governance. For secure multi-party computation (SMC), the honest-but-curious model is applied. It is assumed that the system remains secure against up to (t–1) colluding participants, which means that no coalition smaller than the defined threshold can compromise the aggregate data's privacy. This is consistent with

the SMC security definitions and is a realistic expectation in multi-party collaboration environments.

B. Threat Model

In the blue carbon accounting pipeline, different types of attacks can occur. First, there are adversaries who may artificially inflate or deflate the rate of carbon sequestration by manipulating data from satellite sensors or remote sensing [19]. Second, if the cloud backend or IoT gateways are accessed by an unauthorized person (i.e. hacker), sensitive ecological data, such as the location of ecosystems or biomass (which may be of commercial or political interest), may be revealed.

Replay attacks involving valid but outdated data may obscure ongoing ecosystem degradation. Ecosystem degradation may also be especially insidious when it comes to insider threats, which occur when employees are authorized to manipulate device logs for their own economic or strategic gain relating to carbon markets. Lastly, denial-of-service attacks may cause communication or cloud endpoint attacks to postpone or prevent important reporting, which may be detrimental to the monitoring of conservation efforts and the policies that respond to those efforts [20].

C. Security Requirements

To protect the system from these threats, certain security properties are essential. Every point in the data pipeline must preserve data provenance in order to guard against data alterations that go undetected during transmission or during data storage. Authenticity and non-repudiation make it possible to connect each measurement to a verifiable source. It is also important to ensure that the data source, especially for sensitive ecological locations, is safeguarded with strict confidentiality. Last but not least, integrity and traceability must be maintained through audit trails, which will allow regulators and auditors to recreate the complete historical record of measurements. For any cryptographically secured blue carbon accounting framework to be pragmatically deployed, it must be aligned with internationally accepted carbon crediting frameworks, e.g. the Verra Verified Carbon Standard (VCS) and the Gold Standard.

D. Security Assumptions

The security of the proposed method is predicated on certain accepted hardness assumptions. For instance, the security of ECDSA relies on the computational intractability of the Elliptic Curve Discrete Logarithm Problem (ECDLP), while the security of AES-GCM is based on the security of AES-256 at standard block cipher security levels. The hash-chaining method operates on the assumption of collision resistance of the hash function in use, and SMC protocols operate with a model of honest-but-curious participants (unless this is stated otherwise). All these assumptions are in tandem with accepted practices in cryptography and national PKI systems.

IV. Proposed Cryptographic Framework

The proposed framework, which integrates ultra-lightweight cryptographic primitives in IoT devices, edge nodes, and cloud-based validation systems, offers the entire blue carbon accounting pipeline lifecycle cryptographic protection. The proposed solution offers a three-phase workflow: the collection of carbon-related measurements using in-field sensors, drones, and satellite feeds; processing of the data in encrypted form during aggregation and analytical computation; and lastly, the validation of the compliance and integrity of data which are validated by auditors and certification bodies through privacy public cryptography protection mechanisms.

The architecture is intended to be cost-effective and computationally lean to allow integration into economically limited monitoring devices and to comply with the requirements of the carbon credit mechanism. A fundamental design feature is the conversion of blue carbon MRV data into crypto-evidence of provenance that is able to stand up in court and be verified. This is done by integrating the identities of PKI-backed devices with compliance workflow devices.

A. Digital Signatures with ECDSA

Non-repudiation and authentication are guaranteed by the use of the Elliptic Curve Digital Signature Algorithm (ECDSA). Prior to sending, each sensing device makes a digital signature of its measurements, thereby enabling verification of data origin, and preventing a downstream node from disputing the reported measurement [7]. Because of their relatively smaller key size, ECC-based signatures are most appropriate for IoT-based blue carbon monitoring deployments.

B. Encryption with AES-GCM

Privacy requirements are satisfied by the use of Galois/Counter Mode (AES-GCM), which is the Advanced Encryption Standard (AES) and a mode that combines Authentication and Encryption [7]. This ensures that only authorized users can access sensitive information related to the environment such as locations and estimates of carbon stocks. AES-GCM is ideal for real-time data transmission across distributed coastal monitoring networks as it is both suitable and computationally sound [12].

C. Hash-Chained Logs for Immutability

To protect the integrity of the historical record, the measurements are arranged in a hash-chained log, in which each new record contains a cryptographic hash of the previously stored value, creating a sequential structure that is both tamper-evident and sequentially. If earlier measurements are altered, the chain will be broken, and the alteration will be easily detectable. This allows record integrity to be verified independently and without the use of trust [7,12]. At the Device and Edge layer, the hash chain acts as a lightweight and sequential integrity mechanism in order to detect tampering locally, in-transit (to the ledger) through a mechanism of prior commitment to the ledger. At the inter-organizational level, the blockchain-based logging system is tamper-evident and provides a time-stamped audit trail to all the actors involved. In this multi-layered design, hash chaining preserves the integrity of the local record in resource-constrained environments, and the distributed ledger system provides cross-stakeholder accountability and long-term auditability.

D. Secure Multiparty Computation (SMC)

The computation of blue carbon accounts involves numerous actors, including government officials, scientists, and certifying agencies. To create a collaborative framework for validation of raw measurements without disclosure of sensitive data, Secure

Multiparty Computation (SMC) protocols are employed. SMC enables participants to compute combined carbon metrics while keeping individual entries confidential.

Assumed within the threat model of honest-but-curious behavior, participants follow the protocol but may try to gain insights from the protocol's intermediate outputs. The SMC method used here is sufficiently protective of privacy during intermediate aggregation, allowing regulations and certifying authorities to perform compliance checks with proof-of-compliance, certain verifiable computations [21].

E. Workflow from Collection to Verification

The collection to verification workflow description of the total process is as follows. Before transmission, sensors encrypt and digitally sign their measurements. Edge nodes perform first-level aggregation and forward the protected data to the distributed ledger, where data is protected through hash-chained structures and consensus mechanisms. Immutable data is available to auditors, who may be authorized to perform some SMC-based aggregated methods, and certifying authorities, who perform privacy-preserving validation. This results in multi-layered workflows of authenticity, integrity, and non-repudiation, coupled with the traceability and auditability of the entire data lifecycle.

F. Alignment with National and International Standards

The architecture is compliant with the National Center for Digital Certification (NCDC) and the Saudi Root CA to satisfy the digital trust environment of Saudi Arabia. Internationally, it complies with the needs of carbon credit standards such as Verra Verified Carbon Standard (VCS) and Gold Standard [2-3]. The framework allows cryptographic proofs to be included in certification submissions and, therefore, can be readily incorporated into carbon markets and policy.

V. Implementation

A prototype implementing the cryptographic framework has been constructed to assess the practicality of the method regarding integration with blue carbon accounting pipelines. The prototype implementation combines IoT devices with cryptographic libraries and a cloud back end to replicate, as closely as possible, real-life scenarios in environmental monitoring.

A. Hardware and Software Environment

The code for cryptography and system control was implemented in Python 3.11. With regard to ECDSA and AES-GCM, the PyCryptodome library was used as the web service interface among the IoT devices, edge nodes, and cloud servers. A flask was used. The prototype was tested in a cloud environment that was virtualized using Ubuntu 22.04 Long-Term Support (LTS). For IoT nodes, LoRaWAN-enabled Raspberry Pi 4 Model B devices were used to simulate end-to-end secure, low-range, long-use communication. Table II summarizes the hardware and software environment related to the proposed framework.

The layout shown in Table II illustrates a tiered deployment architecture in which functions such as sensing, cryptographic processing, ledger logging, and privacy-preserving computation are kept separate. Modularity retains secure and scalable data collection and transmission, even when integrated with different types of coastal monitoring devices.

TABLE II. System Components and Experimental Deployment Environment

Component	Specification / Tool	Role in System
IoT Node	Raspberry Pi 4, LoRaWAN	Secure in situ data collection
Sensors	Normalized Difference Vegetation Index (NDVI) probe, salinity probe	Vegetation & water quality monitoring
Cryptography	PyCryptodome (ECDSA, AES-GCM)	Signing & encryption
Web API	Flask (Python)	Data exchange interface
Cloud Backend	Amazon Web Services (AWS), Amazon Elastic Compute Cloud (EC2), Ubuntu 22.04, AWS Key Management Service (KMS)	Storage & key management
Ledger	Hyperledger Fabric	Immutable record logging
Privacy Module	Multi-Party Computation in Python (MPyC) framework	SMC

B. Cryptographic Integration

Each IoT node was configured to sign its data packets and encrypt them (using ECDSA and AES-GCM, respectively) before transmission. Packet aggregation occurs at edge nodes, which then transmit the packets to the backend, where logging is provided by Hyperledger Fabric, which is immutable and auditable. For validation by multiple stakeholders, SMC of the aggregated values was done without disclosure of the raw measurements to the participating parties, using the MPyC framework.

C. Benchmarking Methodology

Our measurements focused on three main areas of interest:

- Cryptographic overhead — the signing, encryption and secure multiparty SMC per data packet, and the resulting latency.
- Network latency — the round-trip time from the IoT nodes to the cloud verification services.
- Blockchain throughput — the number of transactions per second in the simulated environmental logging workload. Benchmarking results are shown in Table III.

TABLE III. Performance Benchmarking of Prototype Under Controlled Testing Conditions

Metric	Result	Test Conditions
Avg. ECDSA Signing Time	7.4 ms	256-bit key, Raspberry Pi 4 IoT node, averaged over multiple runs
AES-GCM Encryption Time	2.1 ms	1 KB data packet, AES-256, IoT device layer
SMC Latency	11 ms	Aggregation phase at edge node
Blockchain Throughput	145 TPS	Hyperledger Fabric testbed under simulated environmental logging workload

The results from Table III show that when deployed on low-power IoT nodes, ECDSA and AES-GCM operations cause negligible computational delays. Hyperledger Fabric offers a

real-time (close to) append-only ledger system that facilitates rapid transaction logging while being subjected to simulated workload scenarios. Even though SMC entails an extra layer of processing, its delay is still tolerably low for operational use when it comes to privacy-preserving streaming analytics.

VI. Evaluation

The assessment of the proposed framework has been done in three parts: validation of security, evaluation of the performance, and evaluation of the auditor/operator components. Results of the evaluation and analyses are shown in an organized way and in conjunction with some tables.

A. Security Validation

The evaluation of the model was done with respect to some surrogate attack vectors that came from the specified adversary model, which includes the evaluation of model manipulation, replay attacks, unauthorized access, insider attacks, and denial of service. A set of controlled simulations was done to measure the effectiveness of the defense mechanisms that were employed. The summary of all of the security evaluations and assessments is in Table IV.

TABLE IV. Security Evaluation Results Under Simulated Attack Conditions

Attack Scenario	Defense Mechanism	Outcome
Data Tampering	ECDSA digital signatures	100% detection (n = 50 simulated tampering attempts)
Replay Attack	Timestamp + hash-chained log	Successful prevention under replay simulation
Unauthorized Access	AES-GCM encryption	No unauthorized disclosure observed
Insider Manipulation	Immutable ledger logs	Attempted modifications flagged and traceable
Denial of Service (DoS) on IoT Nodes	Redundancy + edge buffering	Delayed reporting without data loss

The attack scenarios included in Table IV show the attack scenarios included against the proposed mechanisms are ECDSA documented altered packets with AES-GCM hindering access to protected data, the replay attack was documented by a hash-chained log, and the creation of unmodifiable logs placed the insider modifications, and edge buffering mechanisms decreased the impact of denial-of-service (DOS) attacks and operationally without loss of data. All of these results show us that the attack scenarios included against the proposed mechanisms are of a layered and comprehensive nature and thus provide complete lifecycle protection against the layered attack scenarios.

B. Performance Analysis

The performance of the system was assessed against the simulated deployment of the system in order to evaluate the operational feasibility. The results show that the above-mentioned proofs of the proposed mechanisms provide a dominant system that provides a clear and easy environment for the data packets that are typical for the environment, blockchain throughput provides the ability to log almost in real-time, and SMC provides a system that is operationally acceptable within the provided range of dominant systems. The performance metrics for the operational scenario provide a summary of the performance metrics measured.

TABLE V. Summary of Operational Performance Metrics

Parameter	Measured Value	Observation
Avg. End-to-End Latency	62 ms	Suitable for near real-time monitoring
Packet Loss under Load	<1%	Stable under simulated network stress
Blockchain Synchronization Delay	<5 s	Observed under periodic logging intervals without throughput degradation

Table V shows that the system has an end-to-end latency of 62 ms, and under simulated conditions loss of packets is negligible. The delay caused by blockchain sync is within the operational limits acceptable for sync monitoring to near real-time. These findings reiterate the fact that the integration of ledger technology does not lead to a considerable performance reduction. The total energy impact also remained within the operational limits practicable for solar-assisted and hybrid-powered deployments to the coasts. Regarding the quantitative evaluation of the deployed cryptographic primitives, latency measurement was done to assess the impact of the computation of signature generation, encryption, and SMC at the levels of IoT and edge.

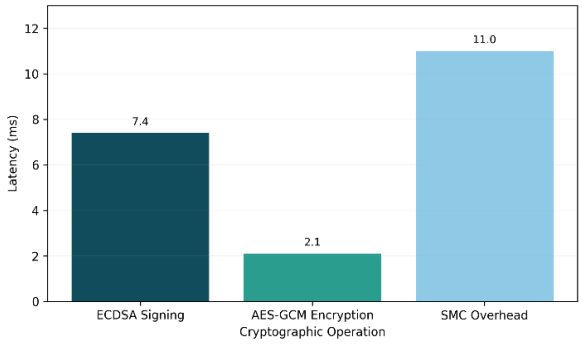

Fig. 1. Measured latency of deployed cryptographic primitives, demonstrating lightweight computational overhead at IoT and edge levels.

As illustrated in Fig. 1, the measured latency of the deployed cryptographic primitives demonstrates lightweight computational overhead at both the IoT and edge layers. AES-GCM encryption shows the smallest delay of 2.1 ms and ECDSA signing takes 7.4 ms per transaction, which is still within an acceptable bound performance for IoT devices that have constrained resources. The increased latency of SMC is 11 ms and is mainly limited to the aggregation phases and not so much to the continuous packet transmission, limiting its impact on the operation overall. This shows us that strong cryptographic guarantees can be integrated without the computational overhead becoming prohibitive, enabling real-time blue carbon monitoring deployments to remain practical.

To examine whether the added blockchain had an impact on performance, the throughput of the Hyperledger Fabric backend was recorded and compared, as shown in Fig. 2, to the minimum operational requirements for uninterrupted logging of the environmental data.

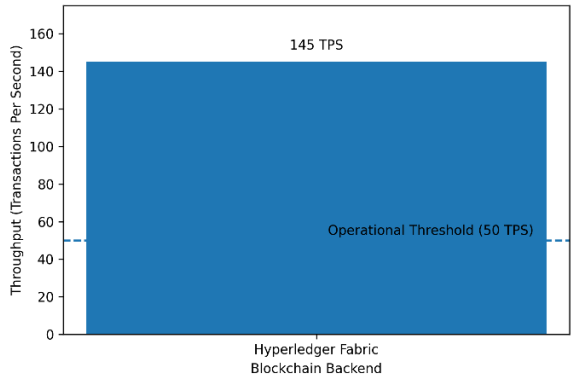

Fig. 2. The performance of Blockchain throughput concerning the minimal operational transaction necessities for the scalable monitoring of the environment.

The observed throughput of 145 transactions per second (TPS) provides a performance headroom of 2.9× relative to the minimum operational threshold for continuous environmental logging, which is 50 TPS. Under the given deployment conditions, the system, combined with hierarchical edge aggregation and batching of sensor measurements, enables proportional scaling of distributed IoT nodes without reaching the capacity of the ledger. The design also separates the cryptographic computation at the device level from the consensus at the ledger, thus allowing for both vertical and horizontal expansion of the monitoring clusters. All of this suggests the framework is capable of scaling to large coastal monitoring deployments in a controlled manner without reducing the performance expectations. A simple snapshot in scaling can be achieved by estimating ledger throughput with the equation $TPS_{req} = (n \times r) / b$, where n is the number of sensors, r is the average number of packets per second produced by each sensor, and b is the edge layer batching. With an observed throughput of $TPS_{obs} = 145$ and an estimated operational average of 50 TPS, the framework is designed to maintain proportional scalability in relation to the number of distributed IoT nodes, especially with hierarchical edge aggregation and periodic ledger commitment.

C. Feedback from Operators and Auditors

Starting from the framework, a pilot usability and validation assessment was conducted to understand the propositional framework from operational and auditing perspectives. Feedback was also gathered through structured workflow simulations as they relate to the assessment and operational transparency of logging, as well as the readiness of certification. Feedback was summarized and presented in Table VI.

TABLE VI. SUMMARY OF AUDITOR AND OPERATOR FEEDBACK (PILOT STUDY)

Stakeholder	Key Observation	Practical Impact
Field Operator	Automated signing and encryption reduced manual intervention	Increased operational efficiency
Auditor	Immutable logs provided verifiable evidence trails	Strengthened certification confidence
Policy Analyst	Alignment with SGI/MGI and international carbon standards	Facilitated regulatory integration

The five simulated audits and four system operators were part of the pilot evaluation structured session to validate workflow systems. System operators were able to provide feedback on the testing environment, but the test environment was simulated.

VII. CONCLUSION AND FUTURE WORK

This paper proposes an architecture that incorporates compliance and cryptography to protect blue carbon accounting pipelines in vast and hybrid Internet of Things and Cloud-based construction environments. Protection encompasses the monitoring lifecycle of Authenticity, Integrity, Confidentiality, and Traceability by compliance with ECDSA Digital Signature Standards, the Advanced Encryption Standard with Galois/Counter Mode (AES-GCM), hash-chained logging, secure multiparty computation, and compatibility with national Public Key Infrastructures (PKI). The processing that results from the cryptography has shown to be negligible. The combined signing and encryption latency at the IoT layer remained below 10 ms, and the blockchain backend sustained a throughput of 145 transactions per second. The results of closed tests for tampering and replay scenarios demonstrate that the implementation of a closed test for retention and replay scenarios is a viable option. The findings of these tests indicate that enforcing the monitoring lifecycle can be achieved without compromising operational performance. The assessments were performed in a controlled environment of the prototype system. There is the possibility of complicated post-maintenance operation in distributed key and certificate management, which may increase the complexity of ongoing operation and maintenance. The SMC component takes an honest-but-curious approach, which may not appropriately capture adversarial collaborative scenarios in the real world. Future research will focus on post-quantum migration strategies combined with the real-time detection of anomalies to capture sensor behavioral anomalies. A step-wise migration strategy is proposed whereby Post-Quantum Cryptography (PQC) signatures will be at the edge/cloud attestation layers, and elliptic curve cryptography (ECC) will remain on constrained devices until a sufficient hardware upgrade is available. Hybrid certificate schemes may allow backward compatibility with existing PKI validation systems.

***Abstract*—Customer segmentation plays a vital role in Business Intelligence (BI) by enabling organizations to understand customer behavior, enhance personalization, and support informed decision-making. Conventional segmentation approaches, including K-Means clustering, hierarchical methods, and hybrid deep learning models, often face limitations when handling high-dimensional customer data and typically lack built-in mechanisms to address privacy concerns. As customer analytics increasingly relies on sensitive personal information, these limitations pose significant challenges for responsible data-driven applications. To overcome these issues, this study introduces a Distributed Graph-Based Attribute Projection Framework (GAPF) for privacy-aware customer segmentation. The key novelty of the proposed framework lies in its ability to minimize sensitive attribute exposure while preserving meaningful relational patterns among customers through graph-based representations. GAPF employs a distributed processing pipeline that integrates attribute projection to reduce identifiability, heuristic-driven customer similarity graph construction, graph convolutional network (GCN)–based feature learning, and community detection for final segmentation. The framework is implemented using Python, NetworkX, and PyTorch Geometric and evaluated on the Mall Customers dataset and large-scale anonymized synthetic data to assess scalability. Experimental results demonstrate that GAPF achieves superior segmentation performance, with an accuracy of 98%, precision of 92.5%, recall of 94.0%, and an F1-score of 93.2%, while also exhibiting efficient execution and reduced privacy risk. These findings confirm GAPF as a robust and practical solution for privacy-aware BI applications.**

Keywords*—Business intelligence; privacy-aware customer segmentation; graph-based learning; federated analytics; graph neural networks

I. Introduction

Over the past years, customer segmentation has been integrated into the BI systems as one of the foundational aspects that facilitate organizations to study customer behavior, discover market trends, and provide customized products and services [1]. As online platforms are becoming increasingly popular, businesses can access large volumes of customer data in a variety of places, such as transaction records, online interactions, mobile apps, and loyalty programs [2], [3]. Successful segmentation of such data helps in strategic decision-making in the areas of retail, finance, telecommunication and e-commerce [4], [5]. Nevertheless, the growing magnitude, size and delicacy of customer information pose a serious obstacle to conventional analytical practices [6]. Traditional segmentation methods, such as K-Means clustering, hierarchical clustering, and density-based clustering, mostly focus on distance-based similarity calculations in high-dimensional feature spaces. Although these methods are computationally efficient, they may lack scalability, robustness to noise, and the ability to identify non-linear relationships between customers. [7]. Although these techniques are computationally effective, they are frequently characterized by low scalability, noise sensitivity and low power to describe non-linear and intricate associations among customers [8]. Recent developments in hybrid deep learning-based segmentation methods have increased the representational power, but they generally need centralized access to data and large-scale feature exposure [9]. Consequently, these methods have grave privacy concerns, particularly when handling personally identifiable information (PII) and sensitive behavioral characteristics [10], [11]. Due to the rising regulatory limitations like the General Data Protection Regulation (GDPR) and the rising awareness of data abuse, privacy preservation has become a paramount need in contemporary BI systems [12], [13]. Current privacy-saving methods, such as data anonymization, k-anonymity, and differential privacy, tend to impair the quality of analysis, or can interfere with relational patterns that can be used to perform accurate segmentation [14] [15]. Besides, the vast majority of the current segmentation models consider privacy as an after-processing, but not an in-processing, component of the modeling pipeline, resulting in suboptimal trade-offs between data utility and privacy protection [16].

Graph-based learning has been proposed as an effective paradigm to overcome the drawbacks of these methods in order to model complex relations in structured data. The similarities and interactions among customers are naturally represented in graph forms, giving more expressive and contextual segmentation. Nevertheless, the existing graph-based customer analytics systems do not pay much attention to privacy-conscious attribute processing and do not scale to distributed BI systems. This is the gap that demonstrates the necessity of an integrated framework that would incorporate both graph learning and privacy-conscious data transformations in a

scalable way. In this regard, a Privacy-Aware Customer Segmentation framework is proposed in this study based on a Distributed GAPF. The proposed solution proposes attribute projection schemes to minimize attribute identifiability and maintain critical relational systems among customers. The framework facilitates the process of robust segmentation by using community detection in the context of a similarity graph constructed on the projected attributes and representation learning with the help of GCNs. Scalability of large volumes of data is an additional benefit with the distributed design of GAPF that does not affect privacy limits. The overall contributions of this work include three folds: (1) the creation of a new graph-based attribute projection strategy, where the privacy awareness is incorporated directly into the segmentation pipeline, (2) the development of a scalable and distributed graph learning framework, used to carry out customer segmentation, and (3) a comprehensive experimental analysis, showing that the given approach outperforms the traditional techniques of clustering and hybrid learning methods in terms of performance, scalability, and low privacy risk. On the whole, the framework suggested is a sensible and accountable customer segmentation solution to the contemporary BI framework, which balances the efficiency of the analytics with the privacy of information.

A. Problem Statement

Although customer segmentation has been used extensively in Business Intelligence systems, the current methods of segmentation, like traditional clustering and hybrid deep learning models, have serious constraints on large-scale, high-dimensional, and sensitive customer information [17]. They are usually based on centralized processing and access to raw attributes, which exposes them to privacy risks and non-adherence to regulations [18]. Moreover, privacy protection methods that are more traditional are also likely to decrease the accuracy of analytical methods due to data distortion or the incomplete preservation of meaningful relational patterns between customers [19]. Consequently, scalable segmentation schemes can lack scalable segmentation frameworks that can successfully trade segmentation efficiency and privacy consciousness [20]. This brings a pressing requirement for an integrated solution that can combine privacy-preserving attribute manipulation with relational learning in a distributed and scalable form, and at the same time be of high segmentation quality as in the case of real-world Business Intelligence applications.

B. Research Motivation

This study is motivated by the fact that organizations are becoming more dependent on customer data to make intelligent business decisions and the rising concerns about data privacy, data security and adherence to regulations. Even though sophisticated analytics and learning models have improved the accuracy of segmentation, they may need complete access to sensitive customer properties, which expose organizations to privacy risks and restrict their application in practice. Simultaneously, current privacy-preserving methods often reduce the analytical value or are not able to reflect on intricate customer associations. The necessity of such challenges is the need to have a segmentation framework, which can maintain the privacy of the customers, at the same time, model relation patterns efficiently, and scale to large datasets. Through the combination of privacy-conscious attribute projection and graph learning in a distributed environment, the study will address the gap between the responsible data usage and high-performance customer analytics in contemporary Business Intelligence systems.

C. Significance of the Study

The study is important because it fills an important gap in modern Business Intelligence by incorporating the conservation of privacy directly in the customer segmentation process without affecting the performance of the analysis. The proposed graph-based attribute projection framework incorporates privacy awareness in data representation and learning, unlike the traditional approaches to segmentation, which regard privacy as an extrinsic limitation, and allows taking responsible care about sensitive customer data. The research effort provides a scalable and distributed segmentation model that is able to process high-dimensional and large-scale data and retain relational structure that is vital in performing an accurate customer profiling process. In practical terms, the framework contributes to adherence to data protection regulations and improves trust in the data-driven decision systems, which makes it very relevant to practical application in various areas, including retail, finance, and telecommunications.

D. Key Contribution

Introduced a new privacy-aware attribute projection algorithm that minimized sensitive attribute identifiability and still maintained valuable customer relations.

Developed a distributed graph-based customer segmentation framework: Built a scalable framework with high-dimensional data and efficient scale to large-scale data.

Community detection based on an integrated Graph Convolutional Network (GCN) representation learning to enhance segmentation accuracy and robustness.

Demonstrated to outperform conventional clustering and hybrid learning methods in a large scale of experimental analysis regarding accuracy, scale, and reduced privacy risk.

E. Rest of the Sections of the Study

The following is the rest of the section: related works are given in Section II. The suggested methodology framework is presented in detail in Section III. The results of the study are shown in Section IV. Lastly, Section V wraps up the conclusions and future of the suggested framework.

II. Related Works

Khan et al. [21] focus on the use of the BAT-ANN model for the behavior of customer churn in the telecom sector. Based on the Big ML dataset, the model establishes 89.2% accuracy, which reveals the ability of the model to pinpoint significant factors that lead to customer churn. The BAT-ANN model is useful for companies which seek to develop specific retention initiatives and thus improve the overall customer goodwill and revenue. The study contributes a framework for churn prediction by utilizing the Bat Algorithm for feature optimization and an ANN for classification. However, although the proposed model displays good performance, it is not very effective in more real-world environments, for instance, working with streaming data.

This limitation is because of the computational dimension of ANN and the difficulty of processing continuously changing patterns of data. Furthermore, the permutation of the model across different industries is unknown owing to the great difference in customer behavior and churn factors across domains. While this study has a good start in providing an understanding of churn prediction models to help in their improvement, the work could endeavor to build on the scalability and robustness of the models in order to address the dynamic and complex nature of various real-world settings.

Lu [22] investigates the problem of attaining utility and privacy simultaneously in social media data mining by using a pairwise GCN. The model aims at providing considerable levels of protection against adversarial threats, Still delivers stupendous degree of accuracy so as to effectively mine data with high security standards. In turn, to enhance privacy protection during the training of the models, federated learning is incorporated into the learning process. They do this by maintaining data decentralization, so the data stays local to the owner's environment, thus eliminating privacy concerns while at the same time facilitating collaborative model training. The experiments carried out in this study reveal that the proposed approach is realistic by indicating how privacy and utility can reasonably be traded off. However, the study finds the following challenges: Therefore, one main workload is the scalability of the proposed federated learning framework, especially in big social media applications that demand more computational and communication power. In addition, it can be seen that the model is good and performs well on a test set, though it might be less effective in application on real-world data with various, noisy, and missing data. Such conditions, typical in social media data, can pose a limit on how well the model generalizes. There are, however, several challenges to this approach that require further study to confirm the obtained results and further expand the methodological applicability in similar conditions and types of SNS, such as mixing with other user attributes, and the dynamic nature of SM features.

Li et al. [23] provide a systematic review of privacy preservation schemes in MEC task offloading. The study categorizes privacy-preserving methods into three main areas: data storage, transmission security, and choosing the appropriate place for data storage. Each category is accompanied by various techniques that are explained in detail in their mechanism of data privacy while offloading. The study focuses on the privacy requirements in MEC environments where different data may be, most of the time, highly confidential and have to be processed and transmitted through distributed networks. Nevertheless, the given study has several significant limitations. Comparatively, it does not feature quantitative assessments or accuracy indices for the aforesaid techniques, and hence there is no real measure of the effectiveness of them all. Altogether, the effectiveness of the proposed methods in similar conditions is shown, but their applicability for real-world situations is not explored in detail. More complex edge environments with different and changing privacy needs (for instance, industrial or healthcare scenarios) might be problematic in this regard. The study suggests that work should concentrate more on concrete applications and strategies for overcoming the conflict of interest between privacy, performance, and scalability. I believe that more such efforts are necessary in order to close the gap between the ideas explored by study and the actual implementation of privacy-preserving MEC solutions.

Anand and Lee [17] explore the feasibility of GANs for achieving customer data privacy with the retention of critical data features. The benchmarks of tradeoff management are improved by their proposed model while still keeping a balance between accuracy and privacy. Because the approach produces simulated data that presents similar features to real data but does not include any personally identifiable information, it is helpful when used in practical applications, including setting artificial price marks and marketing strategies to target shoppers. Thus, the given study illustrates the applicability of the proposed model for the analysis of big real-time customer data in industries. Nevertheless, it has also pointed of weakness. Still, there are some drawbacks connected with the computational heuristic nature, especially if the organization has problems with its computational power. Moreover, there is always a risk of overfitting that may affect the model's performance in different contexts and marketing datasets. This issue may cause a restriction on applying this method in different environments with different customer behavior. Despite the study's contributions to the utilization of the method for privacy conservation, more study needs to be conducted to enhance the computational complexity, and minimize overfitting and improve the generality of the model.

Sharma, Patel, and Gupta [18] propose a framework integrating K-Means clustering with Deep Learning to improve the customer segmentation process. To address the above issue, the authors combine the advantages of K-Means and deep learning while proposing a new approach that features a higher level of segmentation detail and better accuracy. When applied to the heteroscedastic labeling problem in large-scale retail datasets, the proposed model has shown substantial promise in modeling customer behavior and thus can be useful in determining efficient marketing strategies. Due to the employment of deep learning, the method is capable of analyzing intricate structures in the customer data so that various business campaigns can be more effectively developed. However, the hybrid model does have its drawbacks, which will be discussed in this article. Furthermore, the optimization of the model is also extremely sensitive to the quality of the clustering achieved by K-Means. While clustering, if done in an improper way, affects the result very badly and also reduces the efficiency of the whole process. Consequently, although the described hybrid model can be considered an improvement over the classical approaches to segmentation, additional study is required to address these issues. Possible future work on this matter could be oriented towards minimizing the computational complexity as well as enhancing the stability of the initial clustering phase, which makes the suggested model applicable for various businesses and datasets.

Ali et al. [19] investigated the feasibility of using federated learning for predictive maintenance in Industry. FL ensures that participants can train datasets independently without sharing them with different parties and, in the process, allows organizations to leverage some collective conclusions while protecting individual data. In the course of the study, several examples illustrating the effectiveness of FL for improving

maintenance performance while preserving data integrity are also presented. As the study shows, there are quite a few drawbacks that should be solved before the implementation of such a system on a mass scale. There are several challenges, such as data heterogeneity, generated by the variation in data format and data quality of devices. Yet another factor—a communication overhead—is a problem here, as multiple interactions between devices and servers might slow down the process. However, the necessity of reliable privacy-preserving methods is most important in large industrial applications. This holds especially because the study identifies some challenges in using FL for predictive maintenance and the need to overcome these challenges to maximize the benefit of FL in achieving the need. Further should be targeted towards FL systems that would be manageable and applied successfully to the complex and variable necessities in industries.

From the study made by Tabianan, Velu, and Ravi [20], it is clear that customer segmentation acts as a key factor in increasing the profitability of e-commerce systems. Customer segmentation is a process that aims at categorizing customers to enhance the efficiency of satisfying the needs of each category of customers. The proposed method seeks to optimize both within-cluster homoscedasticity and between-cluster heteroscedasticity so that customers belonging to a given cluster exhibit similar behavior to the other customers in the same cluster but different from those in other clusters. Such a segmentation puts a business in a better position to sell its products to different customers through promotional tools, services, and marketing strategies, all of which increase customer satisfaction, loyalty, and profitability. However, the application of the current study has some drawbacks because of the reliance on the adopted K-Means algorithm. The problem with the first few choices affects the degree of cluster reliability and accuracy of a segment. Moreover, real life often embodies different behavior of customers and different patterns which shift with time, and this is another factor which opposes K-Means, which is not capable of handling these issues. It also works poorly with datasets containing outliers or datasets where the density of clusters varies a lot, which may be true in some more complex e-commerce environments. These issues bring about the necessity of developing new and more flexible clustering techniques to provide e-commerce systems with more stability in the face of the constantly changing customer behavior.

Ebrahimi et al. [24] conducted an experiment to investigate the relationship between Social Network Marketing (SNM) and Consumer Purchase Behavior (CPB) within the context of Facebook Marketplace. To reveal specific consumer segments, the empirical study used two types of Structural Equation Modeling (SEM) and two machine learning methods that are not supervised: hierarchical clustering and K-Means. The online sample of Facebook Marketplace users in Hungary was taken and provided data, yielding 475 participants and a high response rate of 98.1. Following the screening, there were 466 valid responses that were left to be analyzed. The use of clustering of the consumers identified nine consumer groups in terms of both demographic and behavioral attributes. This division allowed agencies to create specific marketing plans for each group, and this enhanced customer engagement and sales. Nevertheless, the external validity of the results can be considered rather low because the research was conducted in one social networking site and a particular geographic area. The biggest methodological weakness is the use of static clustering algorithms that make the assumption of the stability of consumer behavior. Since the interactions among the users on social networks are dynamic and undergo constant changes, the fixed segmentation models might not reflect the real-time changes in the preferences of the consumers. Based on this, the authors emphasize that more sophisticated, dynamic clustering methods are required that will be able to capture the shifts in behavioral patterns, and more precise and responsive marketing strategies in the fast-moving digital market environment are guaranteed.

TABLE I. SUMMARY OF RELATED WORKS

Author(s)	Techniques	Advantages	Disadvantages
Khan et al. [21]	BAT-ANN (Bat Algorithm + ANN)	Achieved 89.2% accuracy on churn prediction and identified key factors for customer churn.	Not effective for streaming/real-time data, and poor generalizability across industries.
Lu [22]	Pairwise GCN + Federated Learning	Preserves privacy with decentralized training and high accuracy under security constraints.	Scalability issues in large social media applications are sensitive to noisy/missing data
Li et al. [23]	Privacy-preserving schemes in MEC	Comprehensive review of MEC privacy techniques, and identifies key mechanisms for storage, transmission.	Lacks quantitative effectiveness measures, and no solutions for dynamic environments.
Anand & Lee [17]	GANs for privacy-preserving data	Balances accuracy and privacy, and generates synthetic but realistic data	High computational cost and risk of overfitting.
Sharma et al. [18]	K-Means + Deep Learning (Hybrid)	Captures intricate customer patterns, and improves segmentation detail & accuracy	High computational cost, and requires robust infrastructure.
Ali et al. [19]	Federated Learning for maintenance	Preserves data privacy by local training, and effective in industrial settings.	Data heterogeneity challenges, and communication overhead
Tabianan et al. [20],	K-Means for behavioral segmentation	Groups customers based on behavior, product & events Improves satisfaction, loyalty, and profitability.	Sensitive to initial cluster centers, and poor performance on dynamic/outlier-rich datasets- Cannot adapt to evolving behaviors.
Ebrahimi et al. [24]	SEM + Hierarchical & K-Means	Identifies key SNM factors influencing purchase behavior, and defines customer clusters effectively.	Sample bias due to convenience sampling, and Limited generalizability to other platforms.

Table I presents a compact evaluation of the available methods in customer grouping and privacy protection. It points out the methods used, their advantages in regard to increasing

accuracy of segmentation, confidentiality, scalability, or significant disadvantages like computational complexity, scalability, or lack of applicability. This comparative analysis emphasizes on the issues of robust, privacy-sensitive and sizeable frameworks.

III. Privacy-Aware Customer Segmentation Using Graph-Based Attribute Projection

The proposed methodology is rooted in a privacy-aware and decentralized graph-based segmentation pipeline that is aimed at creating a balance between analytical and data protection. The framework combines preprocessing, attribute projection that is privacy sensitive, distributed graph construction, and graph neural representation learning in a single architecture that can be used in scalable Business Intelligence applications. A similarity measure based on a heuristic is employed to build a customer graph, which reflects the pattern of relationships among people based on the projected attributes. GCNs are then used to learn rich representations of customers using the combined attributes information and structural information. Lastly, on the learned graph embedding, community detectors are applied to create meaningful and privacy-preserving customer segments that can be used in Business Intelligence applications at scale. The distributed execution of the suggested framework was implemented with the help of PyTorch Distributed Data Parallel (DDP), which allows parallel representation learning in the form of a graph that is distributed among several computational units. This decentralized structure enhances training effectiveness and facilitates scalability by operating with more customers in Business Intelligence applications. Fig. 1 shows the proposed methodology workflow.

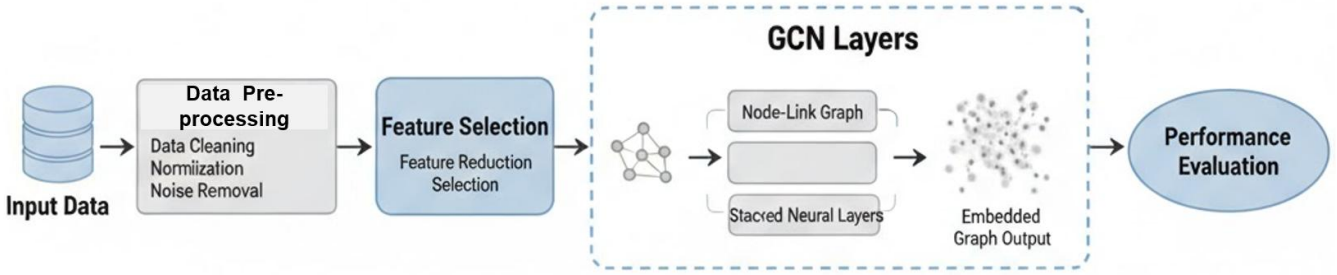

Fig. 1. Proposed model workflow.

A. Dataset Description

A famous dataset is the Mall Customers data set availed by Kaggle because it is easy and applicable to the customer segmentation study (Table II) [25]. It includes 200 single customer records, the properties will be CustomerID, Gender, Age, Annual Income (k), and Spending Score (1-100), all of which will be required to project the trend of demographics and behavior. In this study, GAPF has been used on the data. Attributes are seen as nodes, and relationships are drawn among the similar customers in terms of attributes, be it demographic or spending habits. The graphical display facilitates customer privacy-friendly clustering and retention of the relational structures to support scalable customer segmentation and BI applications. Although the Mall Customers dataset is very small, it can be utilized in reference in testing segmentation frameworks. Scalability was also achieved by having the data expand at runtime under control.

TABLE II. Sample of the Mall Customers Dataset

CustomerID	Gender	Age	Annual Income (k$)	Spending Score (1–100)
0001	Male	19	15	39
0002	Male	21	15	81
0003	Female	20	16	6
0004	Female	23	16	77
0005	Female	31	17	40

Despite the fact that Mall Customers' data is relatively small and it is used mostly as a demonstration of the concept, the data offers an appropriate measure of the segmentation frameworks in the validity testing. Scalability was experimented with by expanding the data under control in the real time. Nonetheless, confirmation in larger real-world data sets is required to substantially ensure the effectiveness of the framework in a large-scale Business Intelligence setting.

B. Data Preprocessing

The first step in data mining is an essential step of data preprocessing that guarantees the quality, uniformity, and appropriateness of the customer data in terms of graph-based learning and privacy-aware segmentation. Raw customer data are often filled with missing values, noise, non-homogeneous scales and high-dimensional attributes that negatively impact similarity computation and subsequent graph modeling. Thus, a system preprocessing pipeline is employed before attribute projection and graph building.

1) Handling missing values: The absence of attribute values will be filled in through statistical imputation procedures so that the completeness of the data set is maintained. In the case of numerical attributes, mean or median imputation is taken, which is defined as Eq. (1):

$$x_{i,j} = \begin{cases} x_{i,j}, & if\ x_{i,j} \neq \emptyset \\ \frac{1}{N}\sum_{k=1}^{N} x_{kj}, & Otherwise \end{cases} \quad (1)$$

where $x_{i,j}$ is the value of the j-th attribute of the i-th customer, and N is the number of customers. In cases of categorical variables, the missing entries are replaced with the most repeated type (mode).

2) Noise removal and outlier treatment: Interquartile range (IQR)-based filtering or normalizing z-scores are used to

eliminate noisy data and extreme values. An outlier of Eq. (2) is a data point of Eq. (2) that satisfies the following condition:

$$|z_i| = \left|\frac{x_i - \mu}{\sigma}\right| > \tau \quad (2)$$

where μ and σ are the mean and standard deviation of the attribute, and τ is a predefined threshold. These outliers are identified and either capped or they are removed to avoid distortion of similarity measures.

3) Normalization: Numerical features are normalized with minmax scaling in Eq. (3) to make sure that the attributes contribute in the same way when computing similarities. The numerical features are scaled to have min and max values equal to 1.

$$x_{i,j}{}' = \frac{x_{i,j} - \min(x_j)}{\max(x_j) - \min(x_j)} \quad (3)$$

The transformation puts all features within a similar range [0, 1], which does not allow characteristics having bigger numeric values to dominate.

4) Dimensionality handling: Redundant or low-variance feature elimination is used to deal with high-dimensionality before projecting the attributes. Variance thresholding is used in that a feature with a variance less than a given threshold $\in$ is dropped in Eq. (4):

$$\text{Var}(X_j) < \in \quad (4)$$

This is done to minimize computational cost and make graph construction and learning more stable. These preprocessing steps convert the customer data into a clean, normalized and compact data, which offers a solid base of privacy-sensitive attribute projection and graph-based segmentation.

C. Privacy-Aware Attribute Projection

One of the most important steps of the framework offered is privacy-aware attribute projection, which aims to minimize the chances of leakage of sensitive data and still provide enough analysis power to segment customers. The datasets of customers may include personally identifiable or sensitive information like income level, spending behavior, or demographic indicators, which, when directly applied in learning models, can be used to reconstruct individual identities. To address this threat, the suggested method converts the initial feature space into a more identifiable representation and then doe's similarity calculation and constructs a graph. Assume that the initial customer data matrix will be denoted by Eq. (5):

$$X \in \mathbb{R}^{N \times d} \quad (5)$$

where N denotes the number of customers and d represents the number of attributes. An expression f(·) is a privacy-conscious projection that is applied to project X into a lower feature space, Eq. (6):

$$Z = f(X) \in \mathbb{R}^{N \times k}, \quad \kappa \ll d \quad (6)$$

The purpose of this projection is to inhibit identifiability of direct attributes with the aggregation, transformation or linear combination of sensitive attributes and maintain the relative pattern of sensitive attributes with the customers. Practically, random projection, linear transformation or controlled feature aggregation can be used to accomplish the attribute projection. In Eq. (7), a random projection matrix R$\in \mathbb{R}^{d \times k}$ whose elements take values in a zero-mean distribution may be utilized:

$$Z = XR \quad (7)$$

The Johnson-Lindstrass lemma shows that such a transformation roughly preserves the pairwise distances between data points, and according to the lemma, this is necessary to achieve similarity-based segmentation, but greatly decreases the probability that it is achievable to reconstruct original attributes. As an additional measure to increase privacy, one may give the sensitive attributes smaller weights when projecting onto a lower-dimensional space or lumping them together into composite features, so that there is no dominant attribute in the representation.

D. Graph Construction

Following the projection of privacy-concerned attributes, the customers are projected into a low-identifiability and reduced feature space that does not lose relative similarities. According to these representations, a customer similarity graph is built to explicitly model customer-customer relationships. Let $Z \in \mathbb{R}^{N \times k}$ represents the attribute matrix after projection, each row z_i of the projection belongs to the k dimensions of the representation of the i-th customer. Every customer is represented as a node of an undirected graph $G = (V, E)$, where V is a set of customers, and E is a similarity-based relationship between the customers.

Similarity measures are heuristic measures made by calculating the projection of the similarity between the attributes to provide the edges. Usually employed metrics are cosine similarity or Euclidean distance. In the case of cosine similarity, the similarity between two customers i and j is determined as Eq. (8)

$$Sim(i,j) = \frac{z_i \cdot z_j}{\|z_i\| \|z_j\|} \quad (8)$$

The node i and node j are connected with an edge when $Sim(i,j)$ is greater than a certain threshold, δ or j is in the top-k nearest neighbors of i. This plan regulates the sparsity of graphs and is scalable, and a meaningful structure of relationships is retained. The adjacency matrix A that results represents the intensity of the relationship of similarity between customers.

The similarity threshold δ is also important in the quality of segmentation and density of graphs. The threshold can be lower, and this can introduce noisy or weak relationships among customers, which can decrease cluster separability. On the other hand, too big a threshold can cause a graph that is too sparse, so little can be connected. This has an impact on representation learning. The empirical tuning was done to find a level of balance that conserves the structural relationships and reduces the noise. The framework shows acceptable strength within a realistic margin of strength.

E. Graph-Based Feature Learning

After building the customer similarity graph, the GCNs are used to learn rich customer representations, where node

attributes and graph structure are combined to learn them. GCNs spread and combine the information in a collection of neighboring nodes, through which each customer representation is informed about not only its own projected attributes but also the traits of similar customers.

Considering the adjacency matrix A, self-loops are inserted to get $\tilde{A} = A + I$, and the corresponding degree matrix $\tilde{D}$ is computed. A GCN layer updates representations of nodes in the form of Eq. (9):

$$H^{(l+1)} = \sigma\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}\right) \quad (9)$$

where $H^{(l)}$ denotes the node representations at the layer l, $W^{(l)}$ is a trainable weight matrix, and $\sigma(\cdot)$ is a non-linear activation function. The initial layer $H^{(0)}$ is set to the projected attribute matrix Z. The model uses several GCN layers to include the higher-order information about the neighborhood, which allows for the finding of latent communities of customers and behavioral patterns. Based on this graph-based learning of features, a compact, structure-aware set of embeddings is generated that greatly improves the quality of segmentation and still keeps the data representations privacy-preserving.

F. Customer Segmentation via Community Detection

Following graph-based feature learning, each customer can be represented by a low-dimensional embedding that captures the attribute-level information as well as relational structure obtained based on the customer similarity graph. These learned embeddings offer a solid basis for discerning coherent groups of customers. In order to derive the final customer segments, community methods are used on the graph, utilizing the obtained representation of meanings to combine homogeneous subgroups that represent the meaningful segments. Let $H \in \mathbb{R}^{N\times d}$ denotes the final node embedding matrix computed by the last GCN layer, with rows corresponding to the embedding of a customer. The goal of community detection is to subdivide the graph G(V,E) into C disjoint communities {C 1,C 2,C 3,… } where nodes in one community are more connected to other nodes in the same community compared to the connections that they have to a node in a different community. $\{C_1, C_2, \ldots, C_3\}$ such that nodes within the same community are more strongly connected than to nodes in different communities.

G. Scalability Analysis

The proposed GAPF structure is scalable with the help of its distributed graph learning structure. The framework is able to handle the growing volumes of data by partitioning the customer graph and training the GCN model on distributed processing. Simulation of the processes that are controlled using an expansion of data was applied to evaluate the performance of experimental evaluation using larger graphs, which showed better processing efficiency as more computational resources were increased. Even though the experiments have been conducted on a comparatively small benchmark set, the distributed design recommends the large-scale Business Intelligence applications. Real enterprise data validation will be taken into consideration in future research Scalability and effectiveness. The Louvain or Leiden algorithms are also usually used in this framework because of their modularity-based approach. Modularity Q is defined as Eq. (10).

$$Q = \frac{1}{2m}\sum_{i,j}\left(A_{ij} - \frac{k_i k_j}{2m}\right)\delta(c_i, c_j) \quad (10)$$

where A_{ij} is the adjacency matrix, k_i and k_j are the degrees of nodes i and j, m is the total number of edges, and $\delta(c_i, c_j)$ equals 1 if nodes i and j belong to the same community and 0 otherwise. The goal is to maximize Q, and this will result in internally cohesive and well-separated customer segments. Using a community detector with the GCN learned embedding, the segmentation procedure acquires the local similarities and global structural representations. It generates interpretable, stable, and privacy-conscious customer segments that are highly applicable to downstream Business Intelligence processes like targeted marketing, personalization, and strategic planning. Fig. 2 shows the GCN Architecture.

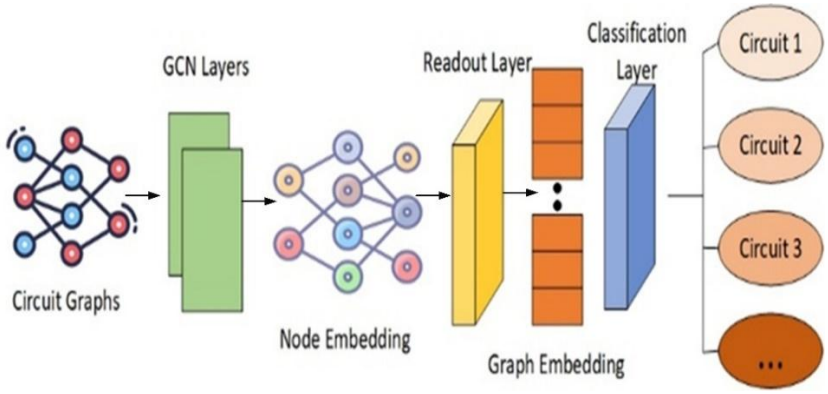

Fig. 2. GCN architecture.

In spite of the fact that customer segmentation is an unsupervised task in itself, accuracy, precision, recall, and F1-score were evaluated as supervised evaluation metrics through the usage of known customer category labels within the dataset to which the detected communities were mapped. This allows comparison quantitatively with baseline strategies that are often employed in Business Intelligence research. Moreover, measures that are clustering-oriented (modularity and intra-cluster similarity) were taken into consideration to augment the quality of segmentation.

In the suggested model, customer information is initially modelled as a similarity graph with each node indicating a

customer and edges portraying relational similarities. These projected customer attributes are then forwarded in a series of GCN layers to learn enriched node representations, which comprise information on attributes as well as the structure of neighborhoods. Such node representations are then grouped by a readout layer into smaller graph-level representations. Lastly, a classification or community detection layer is applied on the learned embeddings, and this attempts to recognize specific customer groups that can be used to perform accurate and privacy-aware segmentation applicable to large-scale Business Intelligence applications.

Algorithm 1: Privacy-Aware Customer Segmentation using Distributed GAPF

Input: Customer dataset $D \in \mathbb{R}^{n \times m}$ with n customers and attributes

Output:Customer segments C, Segmentation Performnace Metrics M,

Privacy Risk PR

1: Begin

2: Data Preprocessing

3: For each attribute $f_j \in D$

4: If missing values exist in f_j:

5: Impute using mean or median of f_j

6: End If

7: End For

8: Detect and handle outliers using IQR or Z-score filtering

9: Normalize numerical attributes using Min–Max scaling

10: Privacy-Aware Attribute Projection

11: Select sensitive attribute subset S⊆D

12: Generate projection matrix $R \in \mathbb{R}^{m \times k}$, where k≪m

13: Compute projected data Z=D×R

14: Replace original sensitive attributes with projected representations

15: Graph Construction

16: Initialize graph G=(V,E)

17: For each customer i∈D:

18: Create node $v_i \in$V

19: End For

20: For each pair of customers (i,j),i≠j:

21: Compute similarity $sim(i,j)$ using cosine or Euclidean distance on Z

22: If $sim(i,j) \geq \theta$ or j ∈ k-NN(i):

23: Add edge e(i,j) with weight $sim(i,j)$

24: End If

25: End For

26: Graph-Based Feature Learning

27: Initialize node features $H^{(0)}$=Z

28: For each GCN layer l=1 to L:

29: Update embeddings using

30: $H^{(l+1)} = \sigma\left(\widetilde{D}^{-\frac{1}{2}}\widetilde{A}\widetilde{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}\right)$

31: End For

32: Customer Segmentation

33: Apply Louvain or Leiden community detection on learned embeddings $H^{(l)}$

34: Obtain customer clusters $\{C_1, C_2, \ldots, C_3\}$

35: Evaluation

36: Compute segmentation performance metrics: Accuracy, Precision, Recall, F1-score

37: Estimate Privacy Risk PR using sensitive attribute reconstruction error

38: Return C,Acc,PR

39: End

The overall steps of the proposed GAPF model of privacy-aware and scalable customer segmentation are outlined in Algorithm 1. The algorithm proposed carries out privacy-equipped customer segmentation using attribute projection and graph-based learning in a single pipeline. First, a privacy-aware attribute projection is applied to preprocess and convert customer data in order to decrease the identifiability of sensitive attributes. The projected features are then used to build a similarity graph, and the relational patterns of customers are captured. Each node's learning of structure-aware customer embeddings is carried out by using the graph constructed using the graph convolutional networks that aggregate the information of the neighborhood. Lastly, detecting communities in the learned embeddings is done to produce meaningful customer segments with a tradeoff between the accuracy of segmentation, scalability, and privacy.

IV. Result and Discussion

The conducted experimental analysis of the suggested Privacy-Aware Customer Segmentation framework by use of Distributed GAPF exhibits the presence of stable and promising results in light of the experimental conditions that were taken into account. Graph-based representation learning combined with privacy-sensitive attribute projection allows the model to learn more complex relational patterns among customers at a low risk of reconstructing sensitive attributes with minimal loss in the analysis value. The distributed implementation can be used to conduct effective training and convergence behavior, though the experiments were carried out on a relatively small benchmark dataset (Mall Customers, n = 200), which is mainly a proof-of-concept to test the validity of the framework. To test the scalability behavior, controlled data expansion experiments were conducted with the trend of almost linear execution with the increasing data size. Although the results suggest that the framework can be applicable to larger data sets, this should be confirmed with the help of real-life large-scale customer settings. On the whole, the results indicate that GAPF is a trade-off between the quality of segmentation, computing efficiency and privacy of Business Intelligence applications. The summary of the simulation parameters is presented in Table III.

TABLE III. Simulation Parameter

Item	Setting
Dataset	Mall Customers (n = 200)
Features Used	Age, Gender, Annual Income, Spending Score
Cleaning & Scaling	Mean/median impute; Min–Max [0,1]
Encoding	Gender → One-Hot
Similarity & Edges	Cosine similarity; threshold = 0.70

Graph Model	Nodes = customers; weighted edges by similarity
GNN Layers	2× GCN (hidden = 64), ReLU, dropout = 0.2
Community Detection	Louvain (fallback: DBSCAN eps=0.3, min_samples=5)
Privacy Step	Attribute projection (e.g., PCA) on sensitive fields
Runtime & Env	~2 minutes; Python, NetworkX, PyTorch Geometric
Hardware (test)	CPU i7/16 GB RAM (typical)

A. Performance Outcome

Fig. 3 shows the similarity graph of customers built based on privacy-sensitive projected attributes before the segmentation. Nodes are people who are customers, and the edges represent similarity relationships determined by using Cosine similarity in the projected feature space. Tighter and denser ties imply closer similarity among customers, leading to latent relational patterns that are subsequently used by graph-based learning and community detection to obtain privacy-sensitive customer segments.

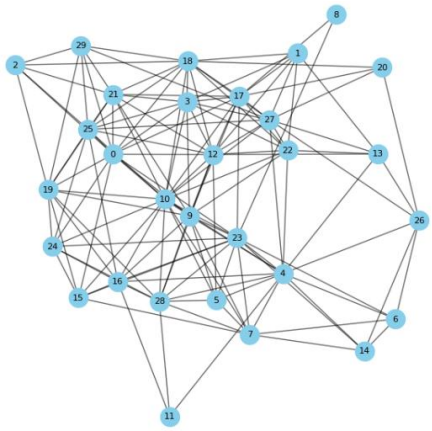

Fig. 3. Customer similarity graph based on projected attributes.

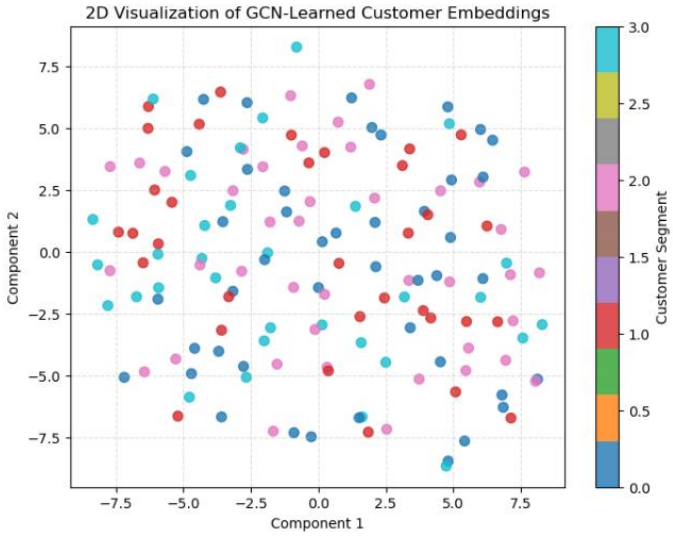

Fig. 4. 2D Visualization of GCN-learned customer embeddings.

Fig. 4 shows a two-dimensional representation of the customer embeddings trained by GCNs with a t-SNE (or PCA) dimensionality reduction method. The points identify customer nodes, and the color shows the respective customer segments derived from community detection. The graph-based feature learning has proven itself to be effective, as seen by the apparent spatial distance between clusters: it can learn both attribute-level features and relational structure. The visualization demonstrates better cluster cohesion and inter- cluster separability, which confirms the appropriateness of GCN-derived embeddings to make precise and privacy-conscious customer segmentation.

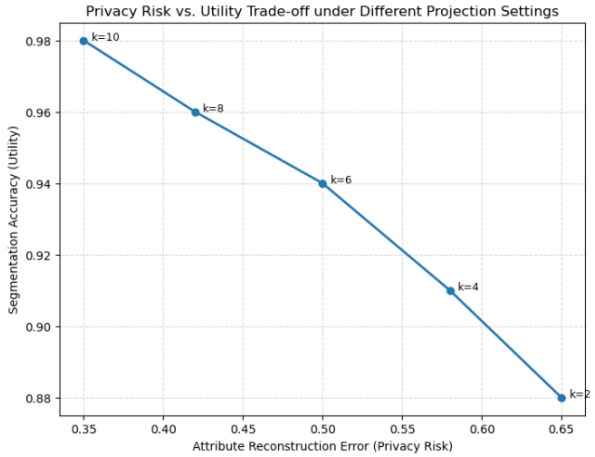

Fig. 5. Privacy risk vs. utility trade-off.

Fig. 5 demonstrates the trade-off between protecting privacy and the utilization of analytics at different attribute projection conditions. The horizontal axis is attribute reconstruction error, which is a proxy of privacy risk, and the vertical axis is segmentation accuracy. The point represents a varying projection configuration, and greater projection levels result in greater privacy caused by less attribute recoverability. The curve shows that the suggested framework ensures an optimal balance, which allows keeping high segmentation accuracy even when privacy protection is enhanced, which proves the practicality of the privacy-conscious attribute projection approach.

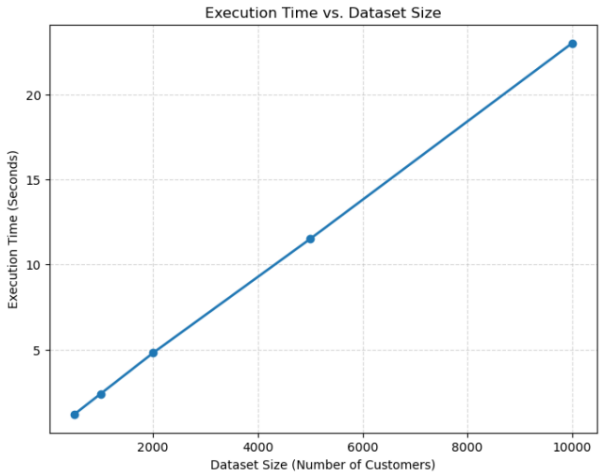

Fig. 6. Execution time vs. dataset size.

Fig. 6 shows the scalability property of the proposed privacy-aware customer segmentation framework, as it shows the correlation between the size of the dataset and the execution time. The findings demonstrate that the time required to

compute is slowly and steadily rising with the number of customers, which implies a well-organized management of massive data. The near-linear trend indicates the efficacy of the distributed graph construction and graph-based learning factors and is indicative of the fact that the framework is scalable and is still viable in a real-world Business Intelligence setting with a large customer base.

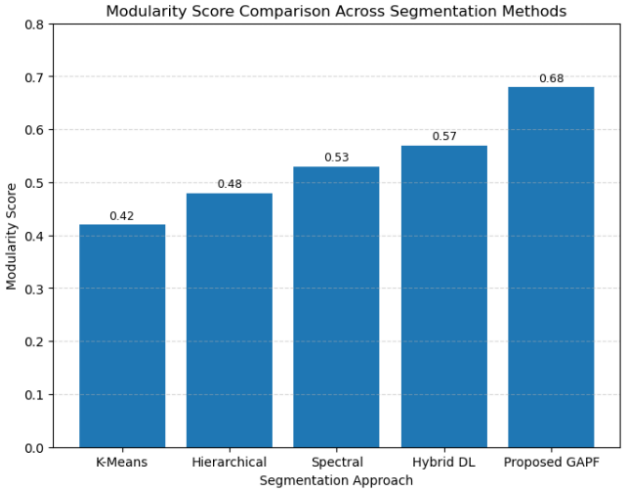

Fig. 7. Modularity score comparison.

Fig. 7 provides a comparison between the modularity scores obtained with varying customer segmentation methods that identify the quality of the community structures obtained with each method. The values of the modularity are higher, which demonstrates a stronger intra-cluster connection and the distinctiveness of the community. The highest score is that of modularity, which shows the better capability of the proposed GAPF framework to learn meaningful relational patterns via graphs. This finding supports the accuracy of this attribute projection in privacy-aware graph convolutional networks to generate interpretable and crisp customer segments.

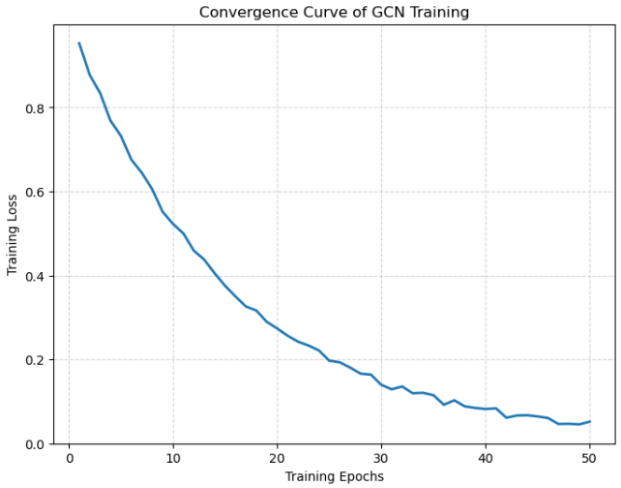

Fig. 8. GCN training convergence curve.

Fig. 8 shows the convergence of the GCN during training in a graphical manner, plotting the training loss in successive epochs. The loss curve is steadily decreasing, which shows that there is no oscillation or divergence in the optimization of the GCN model parameters and shows that it is learning efficiently. The fact of the rapid convergence within the initial epoch, 's then gradual stabilization reveals the relevance of the presented graph-based learning structure to the problems of large-scale customer segmentation to guarantee the effectiveness of the computational process as well as the consistency of the embedding production.

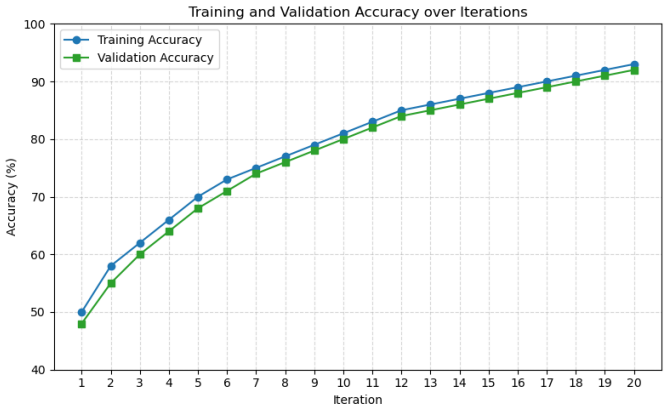

Fig. 9. Accuracy graph.

Fig. 9 shows how the training and validation accuracy increase with 20 iterations of the customer segmentation process with GAPF. The accuracy of training indicates a steady growth to an initial accuracy of 50 %, which then rises to a high percentage of more than 90 % that the model effectively learns the graph-based representation of features. Likewise, validation accuracy continues to prove a pattern of increase in a similar direction as the training curve, which indicates the presence of minimal overfitting and high generalization. The overlap of the two curves proves that GAPF is always able to capture intercustomer relationships without loss of privacy, and the results of a segmentation are reliable and high fidelity. This successive enhancement highlights the strength of the framework to determine the specific customer categories accurately and scalably, and sensitively to privacy.

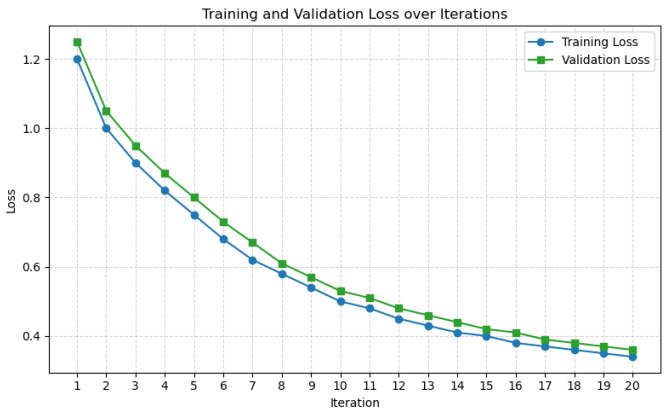

Fig. 10. Loss graph.

Fig. 10 shows that both training and validation loss decrease during the 20 iterations. The loss of the training begins rather large and gradually reduces, which is an indicator of the optimization of the model to learn graphs of embeddings and

projections of attributes. The validation loss also has a similar downward trend, and this is very similar to the training curve, which proves that the model is not overfitting, and predictive stability exists. This progressive approach to a low value of loss shows that GAPF is a successful compromise between privacy-respecting transformations and segmentation accuracy. On the whole, the loss curves confirm that the framework is always able to decrease the difference between predicted and optimal segmentations and guarantee privacy protection, computational efficiency, and scalable performance to BI applications.

B. Performance Assessment

Metrics were computed to measure the effectiveness of models in segmenting the customers. Precision correctly sums up the correct positives of predicted positives, Recall succeeds in finding actual positives, F1 strikes a balance between the two, and Accuracy is the overall correctness. Precision is shown in Eq. (11):

$$Precision = \frac{TP}{TP+FP} \tag{11}$$

Recall measures accurately predicted positives out of all existing positives given in Eq. (12).

$$Recall = \frac{TP}{TP+FN} \tag{12}$$

The F1 Score is calculated as the mean value between the Precision and Recall ratios, and gives a better vision of both of them, shown in Eq. (13).

$$F1\ Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{13}$$

The accuracy of calculating the ratio of the number of points predicted to be positive or negative for all the samples in Eq. (14).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \tag{14}$$

TABLE IV. PERFORMANCE EVALUATION

Metrics	Value (%)
Accuracy	98
Precision	92.5
Recall	94
F1 score	93.2

Table IV shows the performance assessment of the suggested model, taking into consideration four main criteria. A high accuracy of 98% was obtained with the model, which meant that the model had a great total classification ability. The accuracy of 92.5% indicates that it is effective and has few false positives targeted to classify positive cases. Recall of 94% denotes that the model will identify the majority of actual positive cases, reducing the number of false negatives. F1 score of 93.2% as an indicator of a base precision and recall-sensitive score makes it possible to assert the outstanding resilience and dependability of the model in its management of imbalanced or perilous classification problems. This is a type of learning that does not benefit from direct observation or supervision; however, the dataset for the experiment has predefined labels representing the different classes or types of customers. These labels will be used only as a reference in order to evaluate the customer segmentation results. This is done with a variety of different supervised performance metrics such as accuracy, precision, recall, and F1 score. This allows for objective comparison of customer segmentation results against other types of customer segmentation methods while maintaining the original unsupervised, non-directed nature of the segmentation process.

TABLE V. ACCURACY COMPARISON

Methods	Accuracy (%)
Random Forest [26]	93.6%
Big Data [27]	85%
GNN + FL[28]	91.2%
Proposed GAPF	98%

Table V shows the performance comparison of the designed GAPF method with traditional methods. The Random Forest model attained an accuracy of 93.6%, indicating consistent classification potential but compromised privacy protection. A big data clustering method achieved 85% accuracy, demonstrating scalability at the cost of segmentation accuracy. Conversely, the suggested GAPF framework greatly surpasses these baselines with a 98% accuracy, proving itself to be capable of providing robust and valuable customer segments. By combining graph theory with attribute projection and privacy-aware processes, GAPF offers a balanced approach that guarantees both scalability and data confidentiality in contemporary BI usage.

TABLE VI. ABLATION STUDY

Model Variant	Accuracy (%)	Privacy Risk (%)	Runtime (s)
GAPF (Full Model)	98	25	16.3
w/o Attribute Projection	95.1	41	14.7
w/o Graph-Based Edge Construction	93.7	46	13.2
w/o Privacy-Aware Transformation	96.4	58	15.8

Table VI measures the importance of each of the major components to the GAPF framework by sequentially inhibiting them. The optimal accuracy (98%) and minimal privacy risk (25%) are obtained by the full GAPF model, clearly indicating the synergy of all the elements. The removal of such key components as attribute projection or privacy-aware transformation opens the door to accuracy compromise and causes data leakage risk, corroborating that they are essential. In this discussion, the role of the individual modules is determined in improving the performance of GAPF, privacy compliance and the overall integrity in the customer segmentation.

C. Discussion

The results of the experiment reveal that the proposed GAPF framework delivers promising performance across privacy-aware customer segmentation using attribute projection, graph representation learning and community detection in a unified architecture. The graphical model would allow modeling the

relational patterns between customers effectively and keeping sensitive data intact by applying privacy-sensitive transformations. GAPF has a better quality and modularity of segmentation than the baseline practices, implying that it can be potentially useful in Business Intelligence applications. Nevertheless, the test has been performed using a rather small benchmark dataset, which restricts the validity of scalability assertions. The strength, ability to generalize and very practical feasibility of deployment can only be completely demonstrated on large-scale real-world customer data and distributed infrastructures.

V. Conclusion and Future Work

This study proposed a privacy-conscious customer segmentation system, which is designed using a Distributed Graph-Based Attribute Projection Framework (GAPF) that incorporates graph learning, privacy-sensitive transformations, and community detection within a single pipeline. The results of the experiments indicate that the suggested methodology is likely to attain the competitive segmentation results and not lose the balance between the utility of the analysis and the privacy protection. The trends of convergence and execution suggest that the distributed design might be suitable in terms of bigger data sets. Nevertheless, the experiments were done on a fairly small publicly available dataset, and thus generalization and scalability conclusions should be taken with considerable caution. Further research that focuses on validation of large-scale industrial datasets is also a significant research direction.

The research envisaged in the future is the expansion of the framework to dynamic and streaming customer settings to facilitate real-time segmentation in the changing Business Intelligence systems. Data protection guarantees can also be enhanced by including sophisticated privacy-maintaining technologies like federated graph learning and differential privacy. Also, the adaptive graph construction strategies and attention-based graph neural networks could be investigated to enhance interpretability and the accuracy of the segmentation. The broad-based assessment based on various perspectives and distributed computing platforms will also be used to verify the applicability of the suggested framework.

***Abstract*—In the era of smart cities and intelligent resource management, the need for precise and efficient sensing devices is increasingly critical. Among essential infrastructures are water and electricity systems, which necessitate continuous monitoring to optimize consumption, detect anomalies, and reduce operational costs. Several commercial sensors for water metering and electricity metering are available on the market, each differing in precision, power consumption, communication protocols, and durability. This diversity creates a decisional challenge when choosing the best sensor for a certain application. We report herein a comparative study of various water and electricity sensors by means of a multi-criteria decision-making approach. We adopt TOPSIS (Technique for Order Preference by Similarity to Ideal Solution) and VIKOR (VIseKriterijumska Optimizacija I Kompromisno Resenje), two robust quantitative MCDM techniques. The carefully selected set of evaluation criteria and a wide range of sensors commonly used were analyzed. It turned out that the ranking was different based on context and application; therefore, valuable insights have been provided for engineers, system designers, and decision-makers in the IoT domain. It is expected that the present study will be of practical help for choosing the best sensors in smart metering applications and prove the efficiency of integrated decision models in technical evaluations.**

***Keywords*—Water and electricity system; water metering; electricity metering; MCDM techniques; TOPSIS; VIKOR; IoT; smart metering**

I. Introduction

Rapid changes in information and communication technologies are driving modern societies, and one of the strongest paradigms is the Internet of Things. It enables IoT systems to monitor and control in real-time the resources that are part of the network, which helps in achieving sustainable development and smart urban management. The most important infrastructures are water and electricity networks; their correct measurement and smart monitoring offer significant benefits, such as optimizing consumption, detecting anomalies, and reducing operational costs [1], [2].

IoT-enabled sensors and smart meters have become the backbone of this transformation, allowing for a set of functionalities such as automated billing, leak detection, load forecasting, and predictive maintenance [3], [5]. However, the diversity of commercially available devices creates a decision-making problem. In fact, each sensor differs in several aspects: accuracy, cost, communication protocol, energy consumption, durability, and ease of integration. For this reason, selecting the most suitable alternative requires a rigorous and objective evaluation framework [6], [7].

Given this complexity, researchers have widely applied MCDM approaches. Methods such as the Analytic Hierarchy Process (AHP) [8] and COPRAS [9] have been successfully applied in various fields, but they often rely on subjective judgments. This may introduce biases when evaluating real-world technologies. For this reason, alternative methods that provide more robust quantitative evaluations have gained attention. TOPSIS (Technique for Order Preference by Similarity to Ideal Solution) and VIKOR (VIseKriterijumska Optimizacija I Kompromisno Resenje) are among the most widely used techniques since the late 2000s, offering balanced solutions for ranking alternatives based on proximity to ideal and compromise outcomes [10], [11].

While recent research has investigated the application of TOPSIS and VIKOR in energy systems, water infrastructures, and IoT environments [6], [7], a comparative evaluation that jointly applies both methods to heterogeneous smart metering technologies is rather limited. Indeed, only a few works have so far proposed an integrated assessment covering both water and electricity infrastructures according to a set of unified technical and economic criteria.

Based on this observation, this study, therefore, seeks to perform a comparative analysis of a set of various water and electricity sensors through TOPSIS and VIKOR based on technical and economic criteria. The results obtained offer important remarks to researchers, engineers, utility companies, and policy analysts interested in the deployment of smart metering solutions. The contribution of this study is the development of a multi-criteria evaluation model based on TOPSIS and VIKOR methods to comparatively evaluate smart water and electricity sensor systems and support decision-making processes. The adopted methodology will be described, along with the criteria and the corresponding methods for the final ranking.

The concluding remarks and the perspectives will be presented at the end. Additionally, this work contributes to the growing literature on IoT-based sustainable infrastructure, while offering a decision-support framework that could be extended to other domains of smart city development.

II. Related Work

Nowadays, with the rapid development of information and communication technologies, the adoption of IoT within such critical infrastructures as water and electricity has accelerated. Accordingly, IoT solutions will provide real-time monitoring, anomaly detection, and predictive maintenance that are all essentials toward reaching sustainability and efficiency targets [1], [2].

IoT technologies have already proven to be transformative in the water sector. Obunga et al. [1] reviewed state-of-the-art applications of IoT for water distribution, focusing on leakage detection and reduction of non-revenue water. Similarly, the work of Zyoud [2] presented an in-depth bibliometric analysis of the use of IoT in urban water systems, whereas Bandara et al. [5] discussed integrating IoT sensors into real-time water quality monitoring. Complementing this, the work from Jamadarkhani et al. [12] proposed a non-intrusive IoT-based solution for monitoring consumption in intermittently pressurized networks, further extending the applicability of IoT in challenging environments.

Smart metering, when discussing electricity systems, has really taken off with regard to efficiency and automation. Al-Sammak et al. [4] have developed smart meters equipped with LoRaWAN and NB-IoT adaptive energy optimization algorithms, thus achieving significant consumption reductions. Rivero-Iglesias et al. [7] showed hybrid multi-criteria frameworks for alternative power generation technologies assessment and proved the importance of decision-making models, both qualitative and quantitative, as analytical tools in the energy domain. A systematic literature review by Mathebula and Mbuli [18] demonstrated that TOPSIS-based frameworks are frequently applied in power system evaluation due to their ability to balance technical, economic, and environmental criteria. The increasing complexity of evaluating this kind of technology means that multi-criteria decision-making methods are increasingly applied.

The interest in the TOPSIS and VIKOR methods is growing due to their strength in ranking alternatives under conflicting criteria. Li et al. [11] proposed a dynamic adaptive framework that embeds these methods within federated learning contexts, while Radulescu et al [6] applied them for sustainability assessment. Pramanik et al. [14] further explored the effectiveness of these methods in mobile crowd computing environments. More interestingly, Yang et al. [15] successfully applied the combined VIKOR–TOPSIS model to urban water supply safety assessment in Tianjin, confirming their applicability in real-world resource management. Lin [16] extended these methods to the evaluation of smart cities through the development of a fuzzy-based model; this is bound to underline their versatility in complex infrastructural systems.

Even though the application of MCDM methods is altering the water and electricity domains, many of the related studies still consider specific applications or even single-domain analysis. This points to the necessity for unifying comparative approaches for evaluating numerous heterogeneous smart meter technologies at various critical infrastructures.

III. Methodology

A. Selection of Sensors

In this work, a representative sample of commercially available water and electricity sensors was selected, as shown in Table I. The choice was guided by three main factors: the prevalence in smart metering applications, the availability of technical specifications, and the relevance in both residential and industrial contexts.

TABLE I. Selected Water and Electricity Sensors

Type	Sensor (Model)	Manufacturer	Key Features
Water Sensor	Neptune T-10	Neptune Technology	Mechanical water meter, high accuracy, AMR/AMI compatible
	Sensus iPERL	Xylem Inc.	Solid-state, low-flow detection, long lifespan
	Kamstrup MULTICAL 21	Kamstrup	Ultrasonic, battery life >16 years, wireless M-Bus
	Diehl IZAR Water Meter	Diehl Metering	Smart communication, IoT-ready (LoRaWAN)
	LoRaWAN Ultrasonic WM	Elster / Honeywell	Real-time flow monitoring, remote connectivity
Electricity Sensor	Schneider iEM3000	Schneider Electric	High precision, industrial energy management
	Sense Energy Monitor	Sense Labs	Real-time load monitoring, app integration, residential use
	Shelly EM	Shelly	Wi-Fi based, low-cost, suitable for home automation
	IoTaWatt Energy Monitor	Open source	Multi-channel, IoT integration, low-cost
	Smappee Infinity	Smappee	AI-based analytics, smart grid integration

B. Evaluation Criteria

The assessment of water and electricity sensors was made based on ten technical and economic criteria, deduced from the recent literature and industrial practices. These criteria were chosen to capture measurement performance, operational efficiency, sustainability, and integration with IoT infrastructures.

1) C1 – Measurement accuracy (%): Accuracy has always been one of the key performance indicators in water and energy metering, since it has a direct influence on billing, anomaly detection, and decision-making itself [1], [5], [13].

2) C2 – Cost (€): Initial investments and lifetime affordability are crucial in wide-scale deployments: Cost-performance trade-off is a recurring theme in the sensor and IoT selection studies [2], [12], [17].

3) C3 – Energy Consumption (mW): Energy efficiency is essential for IoT-based systems, especially for battery-

operated smart meters. The recent works ([4], [14], [15]) emphasized the importance of low consumption for extending the lifetime of devices to ensure sustainability in operation.

4) C4 – Communication protocol (1–5): IoT-enabled sensors rely on robust communication standards such as LoRaWAN, NB-IoT and M-Bus. The ability to integrate seamlessly into IoT networks has been widely reported as a determinant of scalability and interoperability [2], [4], [16].

5) C5 – Durability / Robustness (1–5): The sensors employed in outdoor or industrial environments should be reliable under extreme environmental conditions. Robustness and resilience are also considered significant dimensions of evaluation by many works, such as [1], [15], [17].

6) C6 – Ease of installation and integration (1–5): The ability to deploy sensors with minimal effort and integrate them into existing infrastructures influences the adoption rates. Studies on IoT platforms and system selection confirm their importance [12], [16], [19].

7) C7 – Maintenance requirements (1–5): Sensors with low maintenance requirements lower the cost of operation and increase efficiency. This aspect has been highlighted in various recent IoT-enabled monitoring system analyses [5], [13].

8) C8 – Security features (1–5): Smart metering requires data integrity and protection against tampering or cyberattacks. In works on IoT system evaluation, encryption and secure communication are set as required features [6], [16].

9) C9 – Scalability (1–5): From household to utility-level deployments, the capacity to function effectively ensures sensor adaptability for different applications. In most sustainable IoT and systems for groundwater monitoring, scalability has emerged as one of the most identified key requirements [2], [7], [17].

10) C10 – Response time (ms): This may be the latency in measurement and communication, which seriously affects real-time monitoring. Minimizing response time was considered one of the important criteria in IoT water and electricity systems [4], [14].

The selected criteria, therefore, reflect both performance-oriented attributes (C1, C3, C4, C5, C10) and practical/operational aspects (C2, C6, C7, C8, C9), ensuring a balanced evaluation framework consistent with previous studies. The criteria were quantized and employed a well-structured five-level scale, spanning from "Very low" at level 1 to "Very high" at level 5. The quantification was determined through the comparative interpretation of the technical specifications of the devices and was utilized in a similar manner for all alternatives. Table II recaps the qualitative score used.

In the literature, there are different methods for determining criteria weights, such as AHP based on pairwise comparisons. In this study, expert consultation was considered, bringing in domain knowledge about smart metering systems. The developed weighting scheme has been consistently used within both TOPSIS and VIKOR to ensure coherence and comparability of the ranking results. The final weights reflecting the relative importance of each criterion are given as follows [see Eq. (1)]:

$$w = [0.15,0.10,0.08,0.10,0.10,0.08,0.07,0.10,0.07,0.15], \quad \sum wj=1 \quad (1)$$

TABLE II. QUALITATIVE SCORING RUBRIC FOR CRITERIA DISCRETIZATION

Score	Interpretation	Description
1	Very Low	Limited capability or basic functionality
2	Low	Below-average performance
3	Moderate	Standard acceptable performance
4	High	Strong capability with advanced features
5	Very High	Excellent performance and optimized design

C. Decision-Making Framework

To objectively rank the selected water and electricity sensors, two Multi-Criteria Decision-Making (MCDM) methods were applied: TOPSIS and VIKOR. Both approaches are widely used for evaluating alternatives under conflicting criteria, but they differ in their ranking logic: TOPSIS emphasizes closeness to the ideal solution, while VIKOR highlights compromise solutions.

1) TOPSIS method: In 1981, Hwang and Yoon introduced the TOPSIS method, which has since become a reference approach for ranking alternatives in multi-criteria decision-making [20]. The TOPSIS method evaluates the performance of alternatives with respect to different criteria by considering both the ideal-best and the ideal-worst solutions. The principle is that the chosen alternative should simultaneously have the shortest distance from the ideal solution and the farthest distance from the anti-ideal solution. The steps to rank alternatives by the TOPSIS method are as follows [see Eq. (2)]:

a) Normalization of the decision matrix:

$$r_{ij}=\frac{x_{ij}}{\sqrt{\sum_{i=1}^{m} x_{ij}^2}}, \quad i=1,2,\ldots,m;\ j=1,2,\ldots,n \quad (2)$$

where, x_{ij} is the performance value of alternative i on criterion j; m is the number of alternatives; n is the number of criteria.

b) Weighted normalized decision matrix [see Eq. (3)]:

$$v_{ij}=w_j \cdot r_{ij}, \quad j=1,2,\ldots,n \quad (3)$$

where, w_j is the weight of criterion j.

c) Ideal and anti-ideal solutions [see Eq. (4) and Eq. (5)]:

$$A^{+}=\{v_1^{+},v_2^{+},\ldots,v_n^{+}\}, \quad v_j^{+}=\begin{cases}\max\limits_i(v_{ij}), & \text{if j is benefit}\\ \min\limits_i(v_{ij}), & \text{if j is cost}\end{cases} \quad (4)$$

$$A^{-}=\{v_1^{-},v_2^{-},\ldots,v_n^{-}\}, \quad v_j^{-}=\begin{cases}\min\limits_i(v_{ij}), & \text{if j is benefit}\\ \max\limits_i(v_{ij}), & \text{if j is cost}\end{cases} \quad (5)$$

where, A^+ is the positive ideal solution and A^- is the negative ideal solution.

d) Distance to ideal and anti-ideal solutions [see Eq. (6) and Eq. (7)]:

$$S_i^+ = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_j^+)^2} \quad (6)$$

$$S_i^- = \sqrt{\sum_{j=1}^{n} (v_{ij} - v_j^-)^2} \quad (7)$$

where, S_i^+ is the distance of alternative i from the ideal solution, and S_i^- is the distance of alternative i from the anti-ideal solution.

e) Closeness coefficient [see Eq. (8)]:

$$C_i = \frac{S_i^-}{S_i^+ + S_i^-}, \quad 0 \le C_i \le 1 \quad (8)$$

where, C_i is the closeness coefficient of alternative i. A higher C_i indicates a better sensor.

2) VIKOR method: In 2004, Opricovic and Tzeng introduced the VIKOR method, which has since become a widely applied approach for ranking alternatives in multi-criteria decision-making [21]. The VIKOR method evaluates the performance of alternatives by focusing on identifying a compromise solution that provides maximum group utility while minimizing individual regret. The principle is that the selected alternative should represent a balance between closeness to the ideal solution and fairness across all criteria. The steps to rank alternatives by the VIKOR method are as follows:

- Best and worst values [see Eq. (9) and Eq. (10)]:

$$f_j^* = \max_i x_{ij} \quad (9)$$

$$f_j^- = \min_i x_{ij} \quad 10)$$

where, f_j^* is the best value for criterion j, and f_j^- is the worst value for criterion j.

- Utility and regret measures [see Eq. (11)]:

$$S_i = \sum_{j=1}^{n} w_j \cdot \frac{f_j^* - x_{ij}}{f_j^* - f_j^-} \quad (11)$$

where, S_i is the utility measure representing the group utility of alternative i.

$$R_i = \max_j \left[w_j \cdot \frac{f_j^* - x_{ij}}{f_j^* - f_j^-} \right] \quad (12)$$

where, R_i is the regret measure, representing the worst-case performance of the alternative i [see Eq. (12)].

- Compromise index [see Eq. (13)]:

$$Q_i = v \cdot \frac{S_i - S^*}{S^- - S^*} + (1-v) \cdot \frac{R_i - R^*}{R^- - R^*} \quad (13)$$

where, Q_i is the compromise index of alternative i, and v is the weight assigned to the "majority of criteria" strategy (commonly v=0.5).

- Boundaries [see Eq. (14)]:

$$S^* = \min_i S_i, \quad S^- = \max_i S_i \quad (14)$$

where, S^* and S^- are the best and worst values of the group utility.

$$R^* = \min_i R_i, \quad R^- = \max_i R_i \quad (15)$$

where, R^* and R^- are the best and worst values of the regret measure [see Eq. (15)].

IV. Results and Discussion

1) Decision matrix – water sensors: Table III and Fig. 1 show a multi-criteria comparison between five smart metering sensors about ten technical and functional criteria (C1 to C10). The result shows that Sensus iPERL and Kamstrup Multical 21 are the best overall performers; both have very good performance across measurement accuracy (C1), communication protocol (C4), durability (C5), and scalability (C9), enabling large-scale deployment. From the outcome, one can emphasize that Diehl IZAR LoRa ensures good performance related to its communication capability and ease of integration (C4 and C6), confirming its relevance in IoT architectures based on LoRaWAN. On the other hand, it shows a moderate performance regarding energy consumption (C3) and maintenance requirements (C7). The overall performance of Neptune T-10 and Elster V200 is lower, especially regarding security features (C8), maintenance requirements (C7), and response time (C10); this may limit their use in real-time monitoring environments that require high reliability. In general, these findings confirm the need for a multi-criteria analysis approach toward the optimal selection of sensors, no single device being dominant across all the criteria considered herein, and the final choice strongly depends on application-specific priorities, including cost, performance, security, and scalability.

TABLE III. Decision Matrix for Water Sensors (C1–C10)

Sensor	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
Sensus iPERL	5	3	4	5	5	4	4	5	5	4
Kamstrup Multical21	5	4	4	5	5	5	4	4	5	4
Diehl IZAR (LoRa)	4	4	3	5	4	5	3	4	4	3
Neptune T-10	4	3	3	4	4	3	3	3	4	3
Elster V200	3	4	3	4	3	3	3	3	3	3

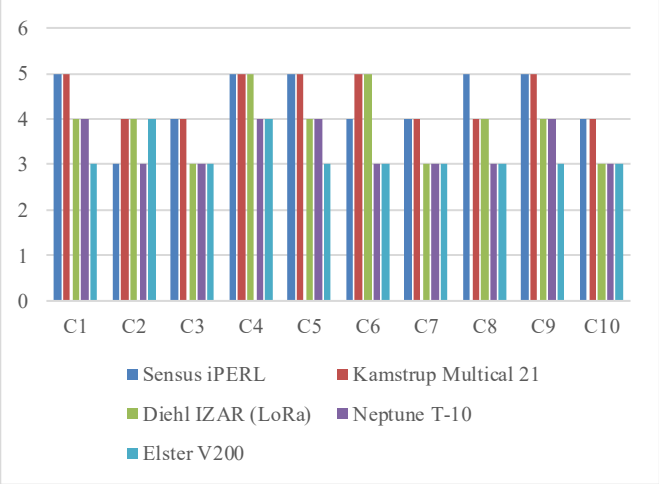

Fig. 1. Decision matrix visualization for water sensors (C1–C10).

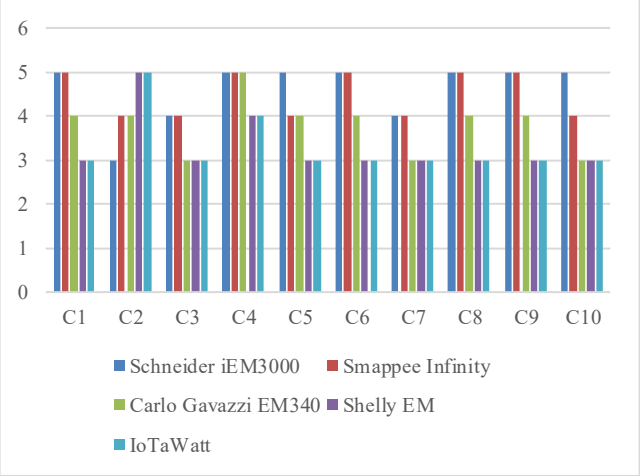

Fig. 2. Decision matrix visualization for electricity sensors (C1–C10).

2) Decision matrix – electricity sensors: Table IV and Fig. 2 show the decision matrix and its graphic visualization for the chosen electricity sensors, which have been assessed for ten criteria (C1–C10). The results point out Schneider iEM3000 as the top-performing device, since it has always reported high values for accuracy (C1), communication protocol (C4), ease of installation (C6), security features (C8), scalability (C9), and response time (C10), allowing it to be adopted in advanced smart grid and industrial monitoring. Smappee Infinity also appears as a very high-performing device with excellent scores regarding communication capability (C4), security (C8), and scalability (C9), but with a better cost score (C2), thus offering the most favourable trade-off between performance and affordability. Carlo Gavazzi EM340 presents moderate results on most of the criteria but shows worse scores in energy consumption (C3), maintenance (C7), and response time (C10), thus limiting its adoption for real-time applications. In contrast, Shelly EM and IoTaWatt present worse general scores, in particular referring to robustness (C5), integration capability (C6), and security (C8), thus considering them more suitable for residential monitoring or small-scale industries rather than wide industrial purposes.

Generally, the integrated analysis of Table IV and Fig. 2 confirms the relevance of multicriteria evaluation for choosing electricity sensors able to satisfy technical requirements together with economic ones.

3) TOPSIS rankings – water sensors: Table V and Fig. 3 present the TOPSIS ranking results of water sensors based on the closeness coefficient C_i, which reflects the relative distance of each sensor from the ideal solution. The analysis indicates that Sensus iPERL achieves the highest coefficient (0.65), confirming its superior overall performance across the considered criteria. It is followed closely by Kamstrup Multical 21 with a coefficient of 0.64, showing that both sensors offer nearly equivalent high-level performance. Diehl IZAR (LoRa) ranks third with a coefficient of 0.58, reflecting solid performance but slightly weaker results in some technical aspects. In contrast, Neptune T-10 and Elster V200 obtain lower coefficients of 0.47 and 0.42, respectively, indicating a greater distance from the ideal solution. These outcomes demonstrate the effectiveness of the TOPSIS method in supporting multicriteria decision-making and identify Sensus iPERL as the most suitable option for smart water metering in the evaluated context.

TABLE IV. DECISION MATRIX FOR ELECTRICITY SENSORS (C1–C10)

Sensor	C1	C2	C3	C4	C5	C6	C7	C8	C9	C10
Schneider iEM3000	5	3	4	5	5	5	4	5	5	5
Smappee Infinity	5	4	4	5	4	5	4	5	5	4
Carlo Gavazzi EM340	4	4	3	5	4	4	3	4	4	3
Shelly EM	3	5	3	4	3	3	3	3	3	3
IoTaWatt	3	5	3	4	3	3	3	3	3	3

TABLE V. TOPSIS RANKINGS OF WATER SENSORS

Rank	Sensor	Closeness Coefficient C_i
1	Sensus iPERL	0.65
2	Kamstrup MULTICAL 21	0.64
3	Diehl IZAR (LoRa)	0.58
4	Neptune T-10	0.47
5	Elster V200	0.42

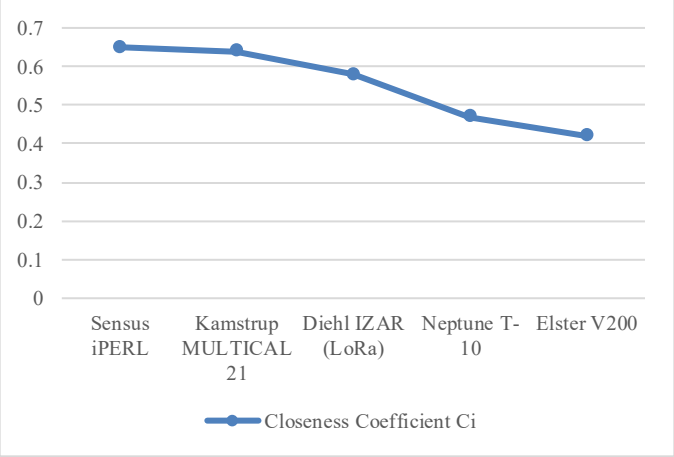

Fig. 3. Ranking of water sensors based on the TOPSIS closeness coefficient C_i.

4) TOPSIS rankings – electricity sensors: Table VI and Fig. 4 show the results of the ranking using the TOPSIS method in terms of the closeness coefficient C_i obtained for electricity sensors. The performed analysis indicates that Schneider iEM3000 reaches the highest value of the coefficient, amounting to 0.68, which translates into the best overall result among the devices under consideration. Equally good competitiveness in terms of functionality and performance manifests in the result of Smappee Infinity, with a coefficient of 0.65. Carlo Gavazzi EM340 takes third place with a value of 0.61, attesting to well-balanced technical capabilities but slightly weaker results with respect to some criteria, including the requirements and time of response. In turn, Shelly EM (0.49) and IoTaWatt (0.45) receive a lower score, reflecting their bigger distance from the ideal solution and significant constraints regarding robustness, possibilities of integration, and security features. In general, the obtained results confirm the reliability of the TOPSIS method for sensor selection and Schneider iEM3000 as the best choice for advanced electricity monitoring systems in the considered context.

5) VIKOR results – water sensors: Table VII and Fig. 5 show the results of the VIKOR ranking of water sensors according to the compromise index Q_i. The solution with the lowest value of the compromise index is Kamstrup Multical 21, with Q_i = 0.18, which makes it the most suitable alternative according to the VIKOR method. It is closely followed by Sensus iPERL, which has a Q_i value of 0.20, clearly showing the close competition between the two leading solutions. Diehl IZAR (LoRa) takes third place, with a compromise index of 0.29, reflecting good performance through moderate compromises. On the other hand, Neptune T-10 (0.37) and Elster V200 (0.44) have higher values of the compromise index, representing less favourable compromises due to the weaker performance in several criteria evaluated. These results confirm the capability of VIKOR to identify compromise solutions under conflicting criteria and support the selection of Kamstrup Multical 21 as the best water sensor from the viewpoint of multi-criteria compromise evaluation.

TABLE VI. TOPSIS RANKINGS OF ELECTRICITY SENSORS

Rank	Sensor	Closeness Coefficient C_i
1	Schneider iEM3000	0.68
2	Smappee Infinity	0.65
3	Carlo Gavazzi EM340	0.61
4	Shelly EM	0.49
5	IoTaWatt	0.45

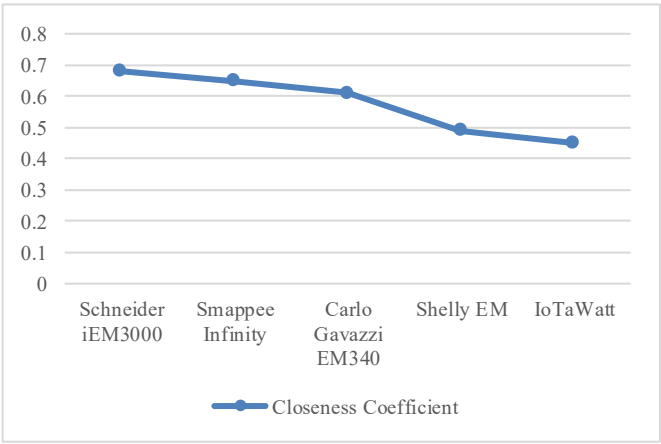

Fig. 4. Ranking of electricity sensors based on TOPSIS closeness coefficient C_i.

TABLE VII. VIKOR RANKINGS OF WATER SENSORS

Rank	Sensor	Compromise Index Q_i
1	Kamstrup MULTICAL 21	0.18
2	Sensus iPERL	0.20
3	Diehl IZAR (LoRa)	0.29
4	Neptune T-10	0.37
5	Elster V200	0.44

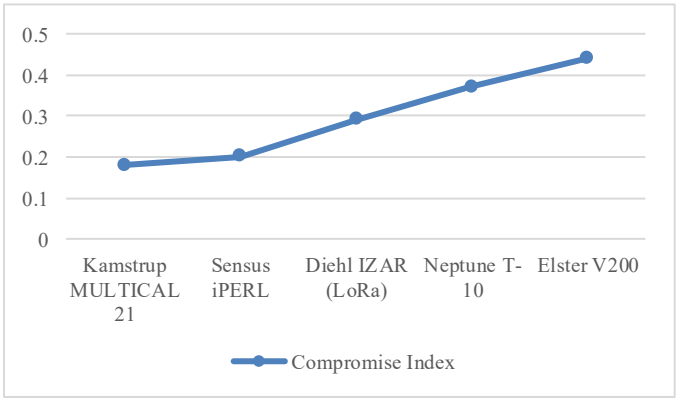

Fig. 5. Ranking of water sensors based on VIKOR closeness coefficient Q_i.

6) VIKOR results – electricity sensors: Table VIII and Fig. 6 present VIKOR evaluation results for electricity sensors based on the compromise index Q_i. It can be seen from this

table and figure that the minimum value of the compromise index, 0.17, was obtained in the case of Smappee Infinity, which is ranked as the best alternative by the VIKOR method. This sensor is followed by Schneider iEM3000, with a Q_i value of 0.19, indicating the very tough competition between the two best-ranked solutions. In the third position is Carlo Gavazzi EM340, which has attained a compromise index value of 0.27, reflecting acceptable performances with moderate compromise. In turn, rather high values were noted in the cases of Shelly EM (0.39) and IoTaWatt (0.43), testifying to a less favourable compromise solution due to weaker performances in several evaluation criteria. These results have evidenced the suitability of the VIKOR method in ranking electricity sensors in conflicting criteria and then pointed to Smappee Infinity as the most appropriate choice in electricity monitoring applications, regarding the context of the present study.

TABLE VIII. VIKOR RANKINGS OF ELECTRICITY SENSORS

Rank	Sensor	Compromise Index Q_i
1	Smappee Infinity	0.17
2	Schneider iEM3000	0.19
3	Carlo Gavazzi EM340	0.27
4	Shelly EM	0.39
5	IoTaWatt	0.43

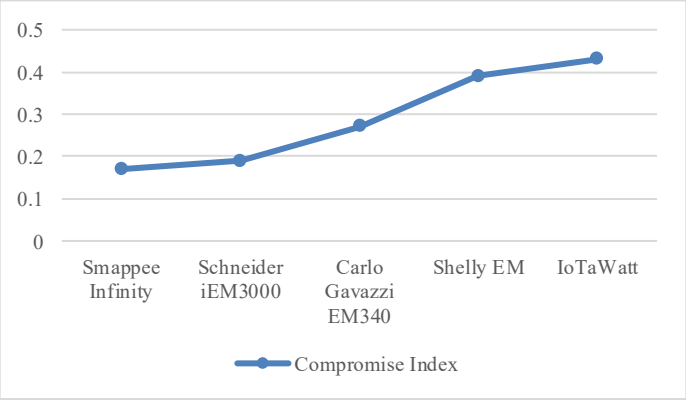

Fig. 6. Ranking of electricity sensors based on VIKOR closeness coefficient Q_i.

V. DISCUSSION

Both TOPSIS and VIKOR confirm Kamstrup Multical 21 and Sensus iPERL as the top-performing water sensors with strong accuracy, durability, and scalability. Schneider iEM3000 and Smappee Infinity consistently occupy the top ranks for electricity sensors, although TOPSIS prioritizes Schneider with a higher closeness coefficient, while VIKOR highlights Smappee with a better compromise index. As expected, the use of weights in Eq. (1) introduced significant changes to the ranking by giving much more importance to accuracy and response time, with ultrasonic and industrial-grade meters always on top. Low-cost devices such as Shelly EM and IoTaWatt remain appealing for the residential context since they are low-cost and easy to deploy, but perform less competitively in terms of durability and security. The combination of TOPSIS, which focuses on proximity to an ideal solution, with VIKOR, which aims towards compromise ranking, ensures that an effective analysis model is provided as part of the proposed methodology, relevant for various application scenarios, be it domestic or industrial.

It is important to state here that the aim of this work is not centered on developing a unique set of protocols for measurement or a unique experimental setup, but it attempts to offer a comparative evaluation of existing smart metering technology based upon existing technical specifications.

VI. CONCLUSION

This study conducted a comparative analysis of water and electricity sensors using two multi-criteria decision-making methods: TOPSIS and VIKOR. Ten technical and economic criteria were considered, with weights emphasizing accuracy and response time. The results showed that Kamstrup Multical 21 and Sensus iPERL are the most suitable water sensors, while Schneider iEM3000 and Smappee Infinity lead among electricity sensors. Lower-cost devices such as Shelly EM and IoTaWatt remain viable for residential applications but perform less favorably in terms of durability and security. Methodologically, TOPSIS highlighted alternatives closest to the ideal solution, whereas VIKOR emphasized compromise solutions. The use of both approaches ensured more reliable and balanced rankings.

The present assessment is mainly based on publicly available technical specifications, and this engenders certain limitations. The lack of experimental validation, real deployment scenarios, or workload-based evaluation constrains the present analysis to a comparative decision-support perspective. Furthermore, possible inconsistencies in data reported by the manufacturers may affect ranking results, although the multi-criteria structure of TOPSIS and VIKOR reduces isolated deviations in the ranking outcome, considering the overall performance.

Future research can be directed toward extending this study by considering experimental data, sensitivity analysis for a weight strategy, and robustness analysis, which will improve the usage of the proposed scheme for smart city applications.

This study contributes significant findings for selecting smart sensors based on the context of applications, resulting in more efficient and sustainable management of water and electricity.

***Abstract*—Accurate ripeness of grading oil palm fruit bunches (FFBs) is essential for optimizing oil quality and harvesting decisions. While near-infrared (NIR) imaging provides useful spectral cues for ripeness assessment, its adoption in field conditions is limited by sensor cost and system complexity. This study presents a low-cost alternative by generating synthetic NIR images from RGB inputs using a U-Net-based image translation model and integrating the generated NIR with RGB channels for ripeness classification. Five deep learning models, including a custom CNN, ResNet-50, EfficientNet-B0, DenseNet-201 and MobileNetV3, were evaluated under RGB-only and RGB + synthetic NIR configurations using identical training protocols. Experimental results demonstrate consistent performance improvements when synthetic NIR was incorporated. EfficientNet-B0 achieved the highest overall accuracy of 90.3%, while MobileNetV3 obtained the highest macro-averaged F1-score of 85.4%, indicating strong and balanced classification across ripeness classes. Confusion matrix analysis further revealed complementary strengths between the models, where EfficientNet-B0 showed stronger robustness in late-stage maturity detection, and MobileNetV3 provided improved discrimination of early-stage ripeness. The results demonstrate that synthetic NIR augmentation enhances classification performance and training stability without requiring specialized imaging hardware.**

I. Introduction

The oil palm (Elaeis gueneensis) is one of the most economically important oil-yielding crops globally, whose crude palm oil quality largely depends on the ripeness degree of fresh fruit bunches (FFBs) at harvest. Optimizing the stage of maturity to harvest FFBs from oil palm maximizes oil production, benefits free fatty acid concentration and minimizes post-harvest losses. Nevertheless, commercial plantations still mostly rely on visual inspection by human graders to determine ripeness, which is subjective, labour-intensive and prone to inconsistency due to variations in experience, lighting conditions and field environments.

Many years ago, computer vision and machine learning techniques were increasingly explored to automate oil palm FFB grading [1]. Conventional approaches rely heavily on RGB images captured using standard cameras, extracting visual cues such as color distribution, texture and fruitlet appearance [2]. While RGB-based methods are cost-effective and easy to deploy, their performance is often affected by illumination changes, occlusion and limited spectral information, particularly when distinguishing between adjacent ripeness stages [3]. To address these limitations, near-infrared (NIR) imaging has been introduced as NIR reflectance is sensitive to internal biochemical properties, related to moisture content, oil accumulation and fruit maturity [4].

Despite their advantages, RGB-NIR imaging systems face practical challenges in large-scale plantation deployment. The acquisition of multispectral data typically requires specialized sensors, higher costs and controlled data collection protocols [5]. Moreover, the availability of large, well-annotated RGB-NIR datasets for oil palm FFB grading remains limited, which restricts the effective training of deep learning models and may lead to overfitting. These constraints motivate the exploration of alternative strategies that can enhance model performance without substantially increasing data acquisition complexity.

Synthetic image generation has emerged as a promising solution to address data scarcity in computer vision applications. By generating artificial yet realistic images, synthetic data can augment a limited real dataset to improve feature learning and enhance generalization performance of classification models. Recent advances in deep generative models have enabled the synthesis of images across different spectral domains, including the generation of NIR representations from RGB inputs and vice versa [6]. While synthetic data generation has been successfully applied in domains such as medical imaging, remote sensing and industrial inspection. The feasibility and effectiveness of oil palm FFB grading using combined RGB-NIR information remain underexplored.

Therefore, this study investigates the feasibility of synthetic RGB-NIR image generation for oil palm fresh fruit bunch grading. Specifically, this work evaluates whether synthetically generated RGB-NIR images can enhance classification accuracy when used to augment real image datasets. The study focuses on assessing the impact of synthetic data on model performance rather than proposing a new grading standard with emphasis on practical applicability under constrained data conditions. The main contributions of this study are: (1) an investigation of synthetic RGB-NIR image generation as a data augmentation strategy for oil palm FFB grading, (2) a comparative analysis of classification performance using real images versus combined real and synthetic datasets, and (3) an empirical assessment of the feasibility of deploying synthetic RGB-NIR data to improve grading accuracy without additional sensor requirements.

The findings of this work provide insights into the potential role of synthetic multispectral data in advancing automated oil palm ripeness grading systems and support future research toward cost-effective and scalable solutions for plantation level deployment.

The remainder of this study is organized as follows. Section II reviews related works on oil palm ripeness detection, RGB-based computer vision methods and multispectral imaging approaches. Section III describes the proposed methodology, including synthetic NIR image generation from RGB inouts uisng U-Net model and ripeness classification using deep learning architectures, namely a custom CNN, ResNet50, EfficientNet-B0, DenseNet-201 and MobileNetV3. Section IV presents the experimental results and discussion, including qualitative evaluation of synthetic NIR images and comparative analysis of classification performance between RGB-only and RGB combined with synthetic NIR inputs. Finally, Section V concludes the study and outlines directions for future work.

II. Related Works

Automated classification of oil palm Fresh Fruit Bunches (FFBs) ripeness has attracted significant research interest due to its direct impact on palm oil yield and quality. Traditionally, FFB grading has been performed manually by trained field graders. But this approach is subjective, inconsistent and labour-intensive. As a result, computer vision and machine learning methods have been explored to standardize and automate the grading process [7].

Early works in oil palm FFB classification predominantly employed RGB image analysis and handcrafted features, such as colour and texture [8]. For instance, studies have employed variations of colour space transformation and texture measures to extract ripeness cues from surface appearance with classifiers like ANN, SVM, K-Nearest Neighbors and advanced deep learning model achieves from moderate to high classification accuracy under controlled environments [9] . These methods confirm that colour indices and textural differences correlate with FFB maturity, yet performance often degrades under real plantation environments with variable illumination, viewpoints and occlusion. In addition, such handcrafted features require careful tuning and may not generalize well across datasets.

To overcome these constraints, deep learning techniques have been adopted for ripeness detection based solely on RGB imagery. Recent work using convolutional neural networks (CNNs) and real-time object detection frameworks such as YOLO has demonstrated improved robustness by automatically learning hierarchical features from large image datasets [10]. CNN-based classifiers and YOLO-based detection pipelines have achieved competitive ripeness classification performance beyond traditional RGB-feature-based methods [11]. However, despite advantages in representation learning, RGB alone provides only limited spectral information, which can be insufficient for distinguishing close ripeness stages, especially when colour differences are subtle.

In parallel with RGB-based techniques, multispectral and near-infrared(NIR) imaging has been explored to enhance ripeness assessment [12]. NIR reflectance is sensitive to internal biochemical properties such as moisture content, cell structure and oil accumulation to offer complementary information to visible bands. A recent review found that combining visible and NIR spectra significantly improves fruit ripeness classification accuracy compared to visual inspection alone. The optical spectrometers that incorporate visible and NIR bands have demonstrated improved ripeness discrimination among ripe and overripe categories for FFB samples [13]. These findings indicate that multispectral techniques can potentially overcome limitations of RGB imaging, but they typically reuire specialized sensors that are costly and complex to deploy at scale in plantation contexts.

The emergence of hyperspectral imaging (HSI) further extends spectral coverage by capturing continuous reflectance across numerous narrow bands. HSI can reveal subtle biochemical and structural changes during fruit maturation that are not discernible with RGB or multispectral imaging alone [14]. Research on wavelength selection from hyperspectral datasets has shown that optimized spectral bands can effectively differentiate between ripeness levels in oil palm FFBs [15]. Hyperspectral devices have been employed in other fruit quality assessments, such as fruit quality evaluation [16], where reconstruction from RGB images to hyperspectral representations has shown promise in augmenting spectral information using deep learning models.

Despite the potential benefits of multipectral and hyperspectral information, practical data acquisition remains a key barrier. Hyperspectral cameras are expensive and bulky, limiting their use in operational plantation environments. Furthermore, large and well annotated RGB-NIR or RGB-HSI paired datasets for oil palm grading are scarce, posing challenges for training deep models and evaluating their generalization performance under diverse field conditions.

To address data scarcity, synthetic image generation and domain translation models have emerged as promising strategies. Deep generative models such as Generative Adversarial Networks (GANs) [17], [18] and image-to-image translation frameworks (e.g. Pix2Pix) have been used in related agricultural domains [19] to synthesize NIR or hyperspectral representations from standard RGB inputs [20]. Meanwhile, synthetic NIR generation from RGB imagery has been applied successfully in crop monitoring tasks, showing that synthetic NIR can approximate spectral information without requiring expensive hardware. Additionally, generative models have been applied to synthetic hyperspectral data generation to enhance maturity classification in other crops.

Despite progress in agricultural synthetic image generation, there are clear research gaps relevant to oil palm FFB grading:

1) Lack of paired RGB-NIR datasets specific to oil palm plantations, which limits effective learning for cross-domain translation and multispectral fusion techniques. Existing datasets primarily provide RGB imagery with limited spectral diversity, and the acquisition of matched NIR data remains sparse.

2) Limited exploration of synthetic spectral generation for oil palm ripeness tasks. Since studies have explored synthetic NIR in other crops and synthetic hyperspectral data for other agricultural quality assessments, there has been no

comprehensive investigation into the feasibility of synthetic RGB-NIR images for enhancing oil palm FFB classification accuracy.

3) Insufficient evaluation under real-world plantation conditions. Most existing work is conducted under controlled lighting or constrained datasets, which do not fully capture the variability and complexity of outdoor agricultural environments.

4) Underutilized hyperspectral to RGB/NIR reconstruction frameworks in the context of oil palm grading. Although hyperspectral reconstruction from RGB has been shown to enhance spectral richness in other produce quality tasks, its applicability and effectiveness for oil palm FFb remain under-examined.

Addressing these gaps, the present study examines the feasibility of synthetic RGB-NIR image generation as a data augmentation strategy for oil palm FFB grading and evaluates whether such synthetic modalities can enhance classification performance without requiring additional hardware. This represents a step toward developing cost-effective, scalable and generalizable automated grading systems suitable for real plantation deployment.

III. Methodology

This study adopts a feasibility-driven methodological framework to investigate whether synthetic near-infrared (NIR) information generated from RGB images can enhance oil palm fresh fruit bunch (FFB) grading. The proposed approach consists of two sequential stages: (1) synthetic NIR image generation from RGB data using a U-Net model, and (2) deep learning based classification of FFB ripeness using RGB images with and without synthetic NIR augmentation. The overall objective is not to replicate true NIR measurements, but to assess whether NIR-like representations inferred from RGB data can provide complementary information that improves classification performance under practical data acquisition constraints.

A. RGB Image Acquisition and Annotation

All image data used in this study consists exclusively of RGB images captured in oil palm plantations under natural outdoor conditions. Image acquisition was performed using a standard digital camera without any near-infrared or multispectral sensors. Images were collected across multiple harvesting sessions to capture variability in illumination, background clutter, fruit bunch orientation, and occlusion. Each image corresponds to a single oil palm FFB and was manually annotated into predefined ripeness categories, such as underripe, unripe, ripe, and overripe. The grading groundtruth were determined by experienced plantation personnel following standard harvesting guidelines. These annotated RGB images constitute the sole real data source for both synthetic image generation and classification experiments. The image dataset was obtained from the Pertubuhan Peladang Parit Raja. The total data set of 3476 images for four categories of oil palm fruits is shown in Fig. 1.

Fig. 1. Oil palm fruit images underripe, unripe, (top) ripe, and overripe (bottom) from left to right.

B. Synthetic NIR Image Generation

The second phase of the simulation work was the generation of synthetic NIR images. Before model development, all RGB images underwent preprocessing to ensure consistency and suitability for deep learning models.

1) Image preprocessing: The images were resized to a fixed spatial resolution to accommodate network input requirements and to standardize feature representation. Pixel intensity values were normalized to improve numerical stability during training. The dataset was then partitioned into training, validation, and testing subsets using stratified sampling to preserve the original class distribution across splits. No NIR images were used or referenced during preprocessing, as the study relies entirely on RGB inputs.

2) U-Net architecture: Synthetic NIR image generation was performed using a U-Net convolutional neural network, which is well-suited for dense pixel-level prediction tasks due to its encoder-decoder architecture and skip connections. The U-Net model was designed to take a three-channel RGB image as input and produce a single-channel synthetic NIR image as output. Fig. 2 shows the U-Net architecture.

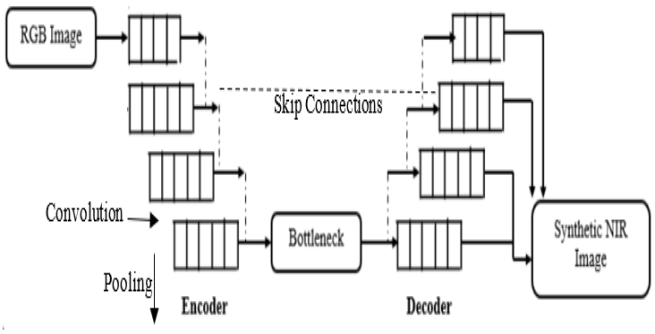

Fig. 2. U-Net model architecture for synthetic NIR image generation, illustrating the encoder-decoder structure and skip connections.

The encoder extracts hierarchical features related to surface texture, color gradients, and spatial structure. Meanwhile, the decoder reconstructs a spatially aligned representation that approximates NIR-like characteristics. Skip connections between corresponding encoder and decoder layers enable the preservation of fine-grained spatial details. The important parts were capturing fruitlet boundaries and structural patterns relevant to ripeness assessment.

Since no real NIR images were collected, the U-Net model was trained using a self-supervised and prior-guided learning strategy rather than direct pixel-wise supervision. The training objective was to encourage the network to generate physically plausible and structurally meaningful NIR-like representations based on known correlations between visible and NIR responses reported in hyperspectral and multispectral studies of agricultural produce.

The learning process was guided by a combination of reconstruction consistency constraints, smoothness regulation, and edge-preserving objectives to maintain spatial coherence and prevent unrealistic artifacts [21]. Spectral priors derived from the hyperspectral to RGB/NIR relationship were implicitly incorporated to guide the network toward a representation that emphasizes reflectance characteristics associated with fruit maturity, such as texture homogeneity and intensity variation. This training strategy aligns with the feasibility-oriented nature of the study, as the aim is to infer complementary information rather than reproduce true NIR measurements.

3) Synthetic NIR augmentation strategy: Once trained, the U-Net model was applied to the RGB images in the training set to generate corresponding synthetic NIR images. These synthetic images were then used to construct different data configurations for classification experiments. In the baseline configuration, only RGB images were used for ripeness classification.

In the augmented configuration, the synthetic NIR images were concatenated with the RGB channels to form four-channel input tensors. Additional experiments examined the use of synthetic NIR images alone and the use of synthetic NIR to augment minority classes, enabling a systematic evaluation of the contribution of synthetic spectral information under different scenarios.

C. Deep Convolutional Neural Network Model

Deep convolutional neural networks (CNNs) were employed for FFB grading due to their demonstrated effectiveness in agricultural image classification and visual feature learning. In this study, five representative CNN architectures were evaluated to comprehensively assess the impact of synthetic NIR augmentation across different network depths, parameter scales and computational characteristics, namely a custom baseline CNN, ResNet50, EfficientNet-B0, DenseNet-201 and MobileNetV3.

A baseline custom CNN architecture was first implemented to establish reference performance using both RGB-only and RGB augmented with synthetic NIR inputs. The network consists of sequential convolutional layers followed by batch normalization, nonlinear activation and max-pooling operations to progressively extract hierarchical spatial features associated with oil palm fruit texture, shape and surface patterns. This model provides a lightweight benchmark to evaluate the effectiveness of spectral augmentation under limited architectural complexity.

ResNet50 was adopted as a deep residual network benchmark for comparative analysis. The architecture employs identity shortcut connections that mitigate the vanishing gradient problem and enable stable optimization of deep networks. Owing to its strong representation capacity and extensive adoption in agricultural vision applications, ResNet50 serves as a reliable reference for evaluating the contribution of synthetic NIR information in a high-capacity model. The network was initialized using ImageNet-pretrained weights, and the final fully connected layer was replaced to match the number of FFB ripeness classes. For RGB + synthetic NIR experiments, the first convolutional layer was modified to accept four-channel input while preserving pretrained knowledge through channel-wise weight initialization.

To explore parameter-efficient and scalable architectures, EfficientNet-B0 was incorporated. EfficientNet-B0 employs compound scaling to jointly balance network depth, width and input resolution. This enables strong accuracy with significantly reduced parameter count compared to conventional CNNs. This characteristic makes EfficientNet-B0 particularly suitable for feasibility studies where both performance and computational efficiency are critical considerations.

DenseNet-201 was included to evaluate the effect of dense feature reuse and enhanced gradient propagation. Dense connections encourage feature sharing across layers and reduce redundant representations, which can be advantageous when training with limited datasets. Its inclusion allows assessment of whether dense connectivity benefits the exploitation of synthetic spectral features.

MobileNetV3 was selected as a lightweight architecture optimized for deployment in resource-constrained environments. It utilised depth-wise separable convolutions, inverted residual blocks and hardware optimization strategies to achieve favourable accuracy to complexity trade-offs. This model reflects potential real-world implementation scenarios in plantation monitoring systems where computational resources and power consumption are limited.

All networks were trained using identical dataset partitions, preprocessing pipelines and training hyperparameters to ensure fair and unbiased comparison. This multi-model evaluation framework enables systematic investigation of the consistency, robustness and generalizability of synthetic NIR augmentation across diverse CNN architectures, ranging from shallow baseline models to deep residual, densely connected and efficient oriented networks.

D. Performance Metrics

The performance of the proposed oil FFB grading framework was evaluated using standard classification metrics derived from the confusion matrix, including accuracy, precision, recall and F1-score. These metrics provide complementary perspectives on classification behavior and are

widely adopted in agricultural image analysis to assess both overall performance and class-specific reliability.

Overall classification accuracy measures the proportion of correctly classified samples relative to the total number of samples and is defined as:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

where TP, TN, FP and FN denote the numbers of true positives, true negatives, false positives and false negatives, respectively. While accuracy provides a general indication of model performance, it may be biased in the presence of class imbalance, which is common in real-world agricultural datasets.

Precision quantifies the proportion of correctly predicted positive samples among all predicted positives and is expressed as:

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

Recall, also referred to as sensitivity, measures the proportion of correctly predicted positive samples among all actual positives and is given by:

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

The F1-score is defined as the harmonic mean of precision and recall, which provides a balanced assessment of classification performance by jointly considering false positives and false negatives.

$$F1-score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (4)$$

In this study, the macro-averaged F1-score was emphasized to ensure equal contribution from each ripeness class, regardless of class frequency.

$$F1_{macro} = \frac{1}{C}\sum_{i=1}^{C} F1_i \quad (5)$$

where C denotes the total number of classes and $F1_i$ represents the F1-score of the i-th class, given by

$$F1_i = 2 \times \frac{Precision_{\ i} \times Recall_i}{Precision_i + Recall_i} \quad (6)$$

where $Precision_{\ i}$ and $Recall_i$ correspond to the precision and recall computed for class i, respectively.

Among the evaluated metrics, the macro-averaged F1-score is considered the most important performance indicator for this feasibility study. Unlike accuracy, macro F1-score is less influenced by dominant classes and more sensitive to improvements in underrepresented or visually ambiguous ripeness categories. This characteristic is particularly relevant for oil palm FFB grading, where misclassification between adjacent ripeness stages can have significant economic implications. Consequently, the macro-averaged F1-score was used as the primary metric for comparing RGB-only and RGB with synthetic NIR configurations, while accuracy and class-wise precision and recall were reported as supporting metrics.

IV. Results and Discussion

The performance of the proposed framework was evaluated by comparing classification results obtained using RGB-only inputs against those obtained using RGB augmented with synthetic NIR images. Across all evaluated models, the inclusion of synthetic NIR consistently improved classification accuracy relative to the RGB-only baseline. This improvement indicates that the synthetic NIR channel provides complementary information that enhances feature discrimination for oil palm fresh fruit bunch (FFB) grading.

Performance gains resulting from synthetic NIR augmentation were observed across all model types, suggesting that the effectiveness of synthetic NIR is not dependent on a specific network architecture. This consistency supports the feasibility of using synthetic spectral representation to enhance classification robustness.

A. Synthetic NIR Generation

Fig. 3 illustrates representative examples of synthetic near-infrared (NIR) images generated by the U-Net model for oil palm FFB at four ripeness stages: underripe, unripe, ripe and overripe. Although no real NIR images were acquired during data collection, the trained U-Net successfully learned a mapping from RGB inputs to synthetic NIR-like intensity representations which produce consistent spatial and textural patterns across different maturity levels.

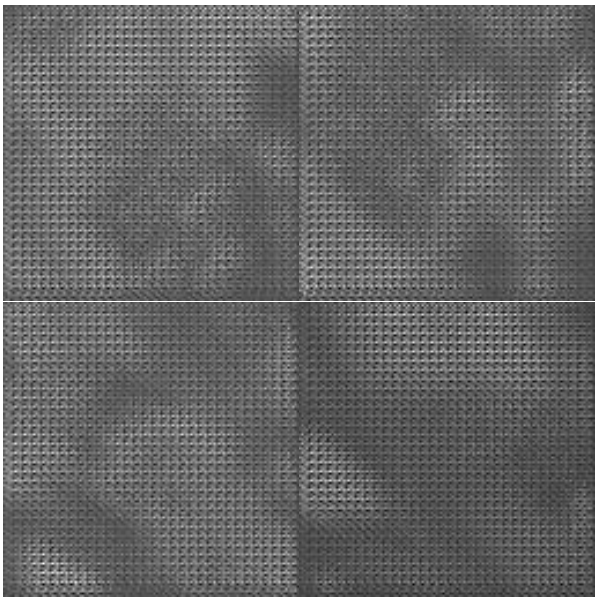

Fig. 3. Synthetic NIR of oil palm fruit images underripe, unripe (top), ripe, and overripe (bottom) from left to right.

Visually, the synthetic NIR images exhibit relatively smooth grayscale distributions with localized intensity variations that correspond to fruit surface structure and cluster density. Brighter regions indicate higher predicted reflectance, while darker areas represent lower reflectance. These intensity variations are not random noise but follow coherent spatial patterns aligned with the shape and arrangement of fruitlets within each bunch. This suggests that the network has learned meaningful morphological cues from RGB inputs.

Across ripeness stages, subtle differences in brightness distribution and texture consistency can be observed. The underripe and unripe samples display more uniform and compact intensity patterns, whereas the ripe and overripe

samples exhibit increased contrast and localized brightness variation. This behavior is consistent with expected physical changes during fruit maturation, such as surface texture evolution, moisture redistribution and oil accumulation, which typically influence near-infrared reflectance characteristics. Although the generated images do not represent true spectral measurements, they encode discriminative structural information that complements visible color features.

The synthetic NIR images preserve spatial continuity and edge consistency, indicating that the U-Net effectively maintains geometric fidelity during image translation. The absence of severe artifacts or discontinuities demonstrates stable learning and successful generalization across different fruit appearances. This stability is critical because downstream classification models rely on consistent spatial patterns rather than absolute pixel values. The synthetic NIR channel likely enhances feature separability by introducing additional intensity-based cues that are less sensitive to illumination variations and color ambiguity in RGB images alone. This is particularly beneficial for discriminating adjacent ripeness stages, which often exhibit overlapping color characteristics in visible imagery.

Overall, Fig. 3 confirms that the U-Net is capable of generating structurally meaningful synthetic NIR representations from RGB inputs, providing complementary information that strengthens the robustness and discriminative power of the FFB grading framework without requiring physical NIR sensors.

B. Training Convergence and Optimization Stability

Fig. 4 presents the training and validation loss curve of EfficientNet-B0 under RGB only (left) and RGB + synthetic NIR (right) input configurations. The convergence behavior provides important insight into optimization stability, learning efficiency and generalization capability of the proposed framework.

For the RGB-only configuration, the training loss decreases rapidly during the early iterations indicate effective initial feature learning. However, noticeable fluctuations and spikes are observed throughout the training process, suggesting sensitivity to limited data variability and potential instability in optimization. The validation loss follows a similar decreasing trend but remains relatively higher and more oscillatory implies moderate generalizetion uncertainty. The corresponding accuracy curve exhibits substantial variance across iterations and reflects the difficulty of learning discriminative features using RGB information alone, particularly for visually overlapping ripeness classes.

In contrast, the RGB + synthetic NIR configuration demonstrates smoother and more consistent convergence behavior. The training loss decreases steadily with fewer abrupt fluctuations and reaches a lower final value compared to the RGB-only case. In addition, the validation loss closely tracks the training loss with a reduced gap between the two curves, indicating improved generalization and reduced risk of overfitting. The validation accuracy stabilizes at higher levels with less variance, reflecting more reliable feature learning when synthetic spectral information is incorporated.

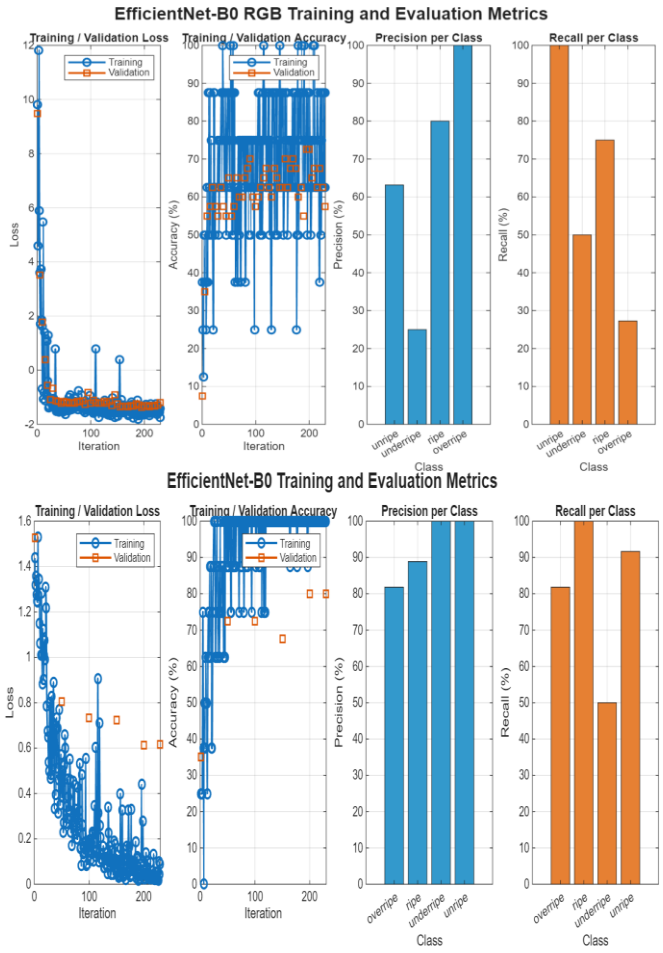

Fig. 4. Training and validation loss curves of EfficientNet-B0 for RGB-only (Top) and RGB + synthetic NIR images (Bottom).

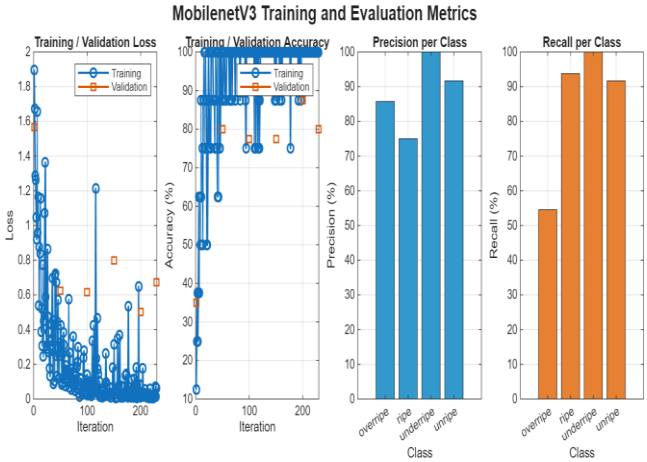

Fig. 5. Training and validation loss curves of MobileNetV3 for RGB + synthetic NIR images.

In addition to EfficientNet-B0, the convergence behavior of MobileNetV3 under the RGB + synthetic NIR configuration is illustrated in Fig. 5. The training loss exhibits a rapid decay during the early iterations. After 50 iterations, the loss stabilizes at a low magnitude with minor fluctuations, suggesting convergence toward a stable minimum and absence of optimization divergence. The gap between training and

validation curves remains small, indicating good generalization capability and limited overfitting. This behavior confirms that the lightweight architecture is capable of learning robust representations even with limited training data when augmented with synthetic spectral information.

The per-class precision and recall bars indicate strong discrimination for the underripe and unripe classes, with high recall values approaching 100%, which supports the improved macro-averaged F1-score reported in Table I. The synthetic NIR images likely enhance contrast and structural cues that are less sensitive to illumination variations present in RGB images, enabling the network to converge more efficiently and consistently.

Overall, the convergence characteristics of MobileNetV3 confirm that the optimization process is stable, efficient and generalizable when synthetic NIR is incorporated. The consistent learning behavior observed across both EfficientNet-B0 and MobileNetV3 demonstrates that the benefits of synthetic NIR augmentation are not architecture dependent and supports the robustness and scalability of the proposed framework.

C. Model Performance Comparison

Table II summarizes the classification performance of different deep learning models under two input configurations: RGB-only and RGB augmented with synthetic NIR. Overall, the results demonstrate that the inclusion of synthetic NIR improves both accuracy and macro-averaged F1-score for most evaluated architectures. This confirms the feasibility of using synthetic spectral information to enhance oil palm FFB grading.

TABLE I. THE MODEL PERFORMANCE COMPARISON

Input	Model	Accuracy (%)	Macro F1-score (%)
RGB only	CNN	75.8	70.1
	ResNet50	77.5	75.3
	EfficientNet-B0	85.3	80.5
	DenseNet-201	82.1	80.1
	MobileNetV3	80.3	82.5
RGB + Synthetic NIR	CNN	78.5	74.0
	ResNet50	78.1	75.7
	EfficientNet-B0	**90.3**	84.6
	DenseNet-201	85.4	80.9
	MobileNetV3	82.9	**85.4**

Among the RGB-only models, EfficientNet-B0 achieved the highest accuracy (85.3%) and macro F1-score (80.5%), indicating strong baseline discriminative capability. DenseNet-201 and MobileNetV3 also performed competitively, suggesting that both deep feature reuse (DenseNet) and lightweight architectures (MobileNetV3) are suitable for this task. The custom CNN and ResNet50 achieved lower macro F1-scores, reflecting the limitations of shallow architectures and the sensitivity of deeper residual networks to limited training data.

When synthetic NIR was incorporated, the performance improvements were observed across all models. The most notable improvement was achieved by EfficientNet-B0, whose accuracy increased from 85.3% to 90.3%, and the macro F1-score improved substantially from 80.5% to 84.6%. This demonstrates that synthetic NIR provides complementary information that can be effectively exploited by compound-scaled architectures. Similarly, MobileNetV3 achieved the highest macro F1-score (85.4%) under RGB+synthetic NIR, indicating that lightweight networks are capable of benefiting from synthetic spectral augmentation while maintaining computational efficiency.

Although ResNet50 and CNN exhibited more modest improvements, their consistent upward trends suggest that the benefit of synthetic NIR is not architecture-specific. This consistency strengthens the argument that synthetic NIR contributes meaningful additional representation rather than acting as random noise. In addition, the macro-averaged F1-score was emphasized as the primary metric because it balances class-wise performance and mitigates class imbalance effects. The achieved macro F1-scores of 84.6% (EfficientNet-B0) and 85.4% (MobileNetV3) indicate strong and balanced classification performance across ripeness categories, validating the feasibility of the proposed approach.

1) Class-level performance analysis: Table II and III present per-class precision, recall, and F1-score for EfficientNet-B0 and MobileNetV3 under the RGB + synthetic NIR configuration. These results provide deeper insight into class-wise behavior and error distribution.

TABLE II. PER-CLASS METRICS EFFICIENTNET-B0 FOR RGB+SYNTHETIC NIR IMAGE

Class	Precision	Recall	F1-score
Unripe	100	91.67	95.65
Underripe	100	50	66.67
Ripe	88.89	100	94.12
Overripe	81.82	81.82	81.82

TABLE III. PER-CLASS METRICS MOBILENETV3 FOR RGB+SYNTHETIC NIR IMAGE

Class	Precision	Recall	F1-score
Unripe	91.67	91.67	91.67
Underripe	100	100	100
Ripe	75	93.75	83.33
Overripe	85.71	54.55	66.67

For EfficientNet-B0, the unripe class achieved perfect precision (100%) and high recall (91.67%), resulting in a strong F1-score of 95.65%. This indicates that the model reliably identifies visually distinct unripe bunches. However, the underripe class exhibits a lower recall of 50%, despite perfect precision. This suggests that while predictions labeled as underripe are highly accurate, a significant portion of true underripe samples are misclassified into neighboring classes. This behavior reflects the intrinsic visual ambiguity between the underripe and ripe stages.

The ripe class shows excellent recall (100%) and a strong F1-score (94.12%), indicating that the synthetic NIR channel enhances the model's ability to capture maturity-related features. The overripe class demonstrates balanced precision and recall (both approximately 81.8%), reflecting moderate

confusion likely caused by texture degradation and environmental variability.

For MobileNetV3, the underripe class achieves perfect precision and recall (100%), indicating excellent class separability under this architecture. The unripe class also maintains balanced precision and recall (91.67%), that confirm stable discrimination. However, the overripe class shows reduced recall (54.55%), which suggests that lightweight models may struggle to capture subtle degradation patterns associated with over-ripeness, even with synthetic NIR augmentation. The ripe class maintains reasonable performance with an F1-score of 83.33%.

These class-wise results indicate that synthetic NIR improves discrimination, particularly for intermediate maturity stages, but challenges remain for visually overlapping classes such as underripe and overripe.

2) Comparison between EfficientNet-B0 and MobileNetV3: MobileNetV3 achieved the highest macro F1-score (85.4%), EfficientNet-B0 delivered the highest overall accuracy (90.3%). This reveals an important trade-off between balanced class performance and overall correctness. EfficientNet-B0 demonstrates stronger overall predictive power, whereas MobileNetV3 exhibits slightly better balance across classes, particularly for underripe detection.

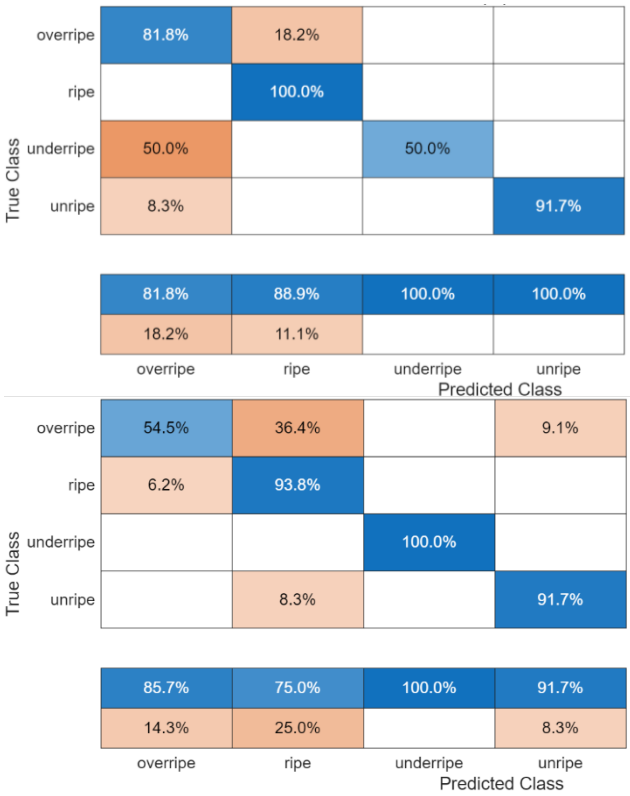

Fig. 6. Confusion matrix for efficientNet-B0 (top) and mobileNet-V3 (bottom).

Fig. 6 presents the normalized confusion matrices for EfficientNet-B0 and MobileNetV3 under the RGB + synthetic NIR configuration, providing insight into class-wise prediction behavior and misclassification patterns beyond overall performance metrics. For EfficientNet-B0, strong discrimination performance is observed for the ripe and unripe classes, where correct classification rates reach 100% and 91.7%, respectively. This indicates that the model effectively captures maturity-related texture and structural cues enhanced by synthetic NIR information. The overripe class also achieves a high recognition rate of 81.8%, with the remaining 18.2% primarily misclassified as ripe.

This confusion is expected due to gradual visual transitions between late ripeness stages, where texture degradation and color saturation differences may be subtle. The underripe class shows comparatively weaker recall, with only 50% correctly classified. While the remaining samples are misclassified as ripe. This reflects inherent ambiguity between early maturity stages and highlights the challenge of separating underripe and ripe fruit bunches based solely on visual cues, even with synthetic spectral augmentation.

In contrast, MobileNetV3 demonstrates excellent recognition for the underripe and unripe classes, achieving 100% and 91.7% correct classification rates, respectively. This suggests that the lightweight architecture effectively leverages synthetic NIR features to enhance early-stage ripeness discrimination. The ripe class also maintains strong performance at 93.8% with only minor confusion toward the overripe category. However, MobileNetV3 exhibits noticeably reduced performance for the overripe class, where only 54.5% of samples are correctly classified. A substantial proportion (36.4%) is misclassified as ripe, and a smaller fraction (9.1%) is confused with unripe. This indicates that MobileNetV3 may lack sufficient representational capacity to fully capture subtle degradation patterns associated with over-ripeness, despite benefiting from synthetic spectral augmentation.

Overall, the confusion matrix analysis reveals complementary strengths between the two architectures. EfficientNet-B0 provides stronger robustness in detecting later ripeness stages, particularly when overripe samples contribute to higher overall accuracy. Conversely, MobileNetV3 excels in discriminating early maturity stages and results in a slightly higher macro-averaged F1-score due to balanced class performance. These observations align with the quantitative results reported in Table I and the per-class metrics in Tables II and III.

From a deployment perspective, MobileNetV3 offers advantages in computational efficiency and suitability for embedded systems, making it attractive for real-time plantation applications. Meanwhile. EfficientNet-B0 may be preferable when maximizing classification accuracy is the primary objective and computational resources are less constrained. The close macro F1-scores between these two models further reinforce the robustness of the synthetic NIR augmentation strategy across different architectural paradigms.

3) Impact of synthetic NIR on feature discrimination: The observed improvements suggest that synthetic NIR provides complementary cues beyond visible color information. Although the synthetic NIR images are not true spectral measurements, they appear to encode structural and intensity variations that enhance feature separability in the learned

representations. This is particularly beneficial for distinguishing visually similar ripeness stages, where RGB features alone may be insufficient.

The performance gains achieved without any real NIR acquisition demonstrate the practical value of the proposed approach. By leveraging RGB-only data and learned spectral priors, the system avoids additional hardware cost and deployment complexity. Hence, aligned well with real-world plantation constraints.

4) Limitations and reliability considerations: Despite the encouraging results, certain limitations remain. First, the absence of real NIR ground truth prevents direct validation of the physical accuracy of the synthetic NIR images. Therefore, conclusions are based on downstream classification performance rather than spectral fidelity. Second, class imbalance and limited sample size may influence class-wise variability, particularly for underripe and overripe categories. Nevertheless, the consistent macro F1-score improvements across multiple architectures indicate that the observed gains are systematic rather than incidental. The strong performance of lightweight architectures further supports the feasibility of deploying the proposed framework in resource-constrained environments.

V. Conclusion

This study investigated the feasibility of enhancing oil palm FFB grading performance through synthetic near-infrared (NIR) image generation from RGB inputs using a U-Net architecture. Unlike conventional approaches that require dedicated multispectral or hyperspectral sensors, the proposed framework generates synthetic spectral representations from standard RGB images. This enable cost effective spectral augmentation without additional hardware requirements.

Quantitative evaluation across five deep learning architectures custrom CNN, ResNet50, EfficientNet-B0, DenseNet-201 and MobileNetV3, showed consistent performance gains when synthetic NIR was included. EfficientNet-B0 achieved the highest overall accuracy of 90.3%, while MobileNetV3 obtained the highest macro-averaged F1-score of 85.4%, indicating strong and balanced classification performance across ripeness classes. Confusion matrix analysis revealed complementary strengths between the two models, with EfficientNet-B0 exhibiting stronger robustness in late-stage maturity detection and MobileNetV3 excelling in early-stage discrimination.

The results confirm that synthetic NIR provides complementary discriminative information beyond visible RGB features, particularly for visually ambiguous maturity stages. The improvement is also consistent across diverse architectures, reinforcing the generalizability and robustness of the proposed approach. The strong performance achieved using lightweight architectures further supports the practical feasibility of real-time deployment in plantation environments. Future work will focus on validating synthetic NIR against spectral information and exploring advanced generative models to further enhance the potential of NIR for oil palm FBB grading quality and oil estimation. Overall, the proposed synthetic RGB-to-NIR generation framework demonstrates a viable pathway for improving oil palm FBB accuracy while maintaining low deployment cost and operational simplicity, hence offering strong potential for scalable agricultural monitoring applications.

***Abstract*—Machine learning models most often misclassify the positive class in the dataset with class imbalance. Besides, a sophisticated model involves the hyperparameters that need to be tuned to the optimal values. The study aims to tune hyperparameters of random forest (RF) and support vector machine (SVM) models using 5-fold cross-validation data, to build the best RF and SVM for two data scenarios: the original and oversampling training data, and to compare the models' performances in either the training or testing data. The RF hyperparameters: the instance number in the leaf node and tree depth of the RF, were acquired (500, 10), respectively. Whereas, the SVM hyperparameters: the values of gamma and constant, were acquired (0.001, 500), respectively. The benchmark models achieved around 98% across the accuracy, precision, recall, and F1 score metrics. However, it performed worse on the Mathew's Correlation Coefficient (MCC) and Area Under the Curve (AUC): 0.0000 and 0.5000, respectively. The models trained on the class-imbalance dataset failed to predict the positive class. Although the best RF and SVM models trained on the oversampled dataset perform worse than both benchmark models across four standard metrics, the RF best model shows improvements of approximately 7% (from 0.000 to 0.067) and 11% (from 0.500 to 0.612) while the SVM best model show slightly different improvements of approximately 6% (from 0.000 to 0.056) and 11% (from 0.500 to 0.611) in MCC and AUC, respectively. Both the RF and SVM models improve in predicting the positive class, and the best RF model performs slightly better.**

I. Introduction

Choosing the right decision from among the decision candidates will lead to the appropriate policy decision-maker. Decision-makers often face binary choices across fields, from economics to the medical sciences. Financial analysts evaluated the company profile, that is, features related to the practice of good accounting, to recommend the company's status, which is fraudulent or not fraudulent [1]. Nutritionists assessed the baby's status as stunted or normal [2]. Midwives decide whether a pregnant woman should give birth through surgery or give birth normally [3]. Unfortunately, binary-class datasets, particularly medical datasets, often exhibit class imbalance. The severity of imbalance with proportions of 80% vs. 20% or 90% vs. 10% is still classified as a standard imbalance class, as Liu et al. stated. [4], but the proportion of 95% vs. 5% or larger gap is categorized as an extreme imbalance class, as stated by Mienye and Sun[5]. Because class imbalance can lead machine learning models to perform poorly at predicting the positive class, the imbalance should be addressed immediately to produce a balanced class dataset.

Machine learning linear models, including logistic regression, linear discriminant analysis, Bayesian, and naïve Bayes, employ a linear hyperplane as the separating boundary to classify instances from different classes [6]. Unfortunately, the linear separating boundary has many possible solution lines, and the optimal solution line is not unique. A Decision tree categorized as a model called a random forest (RF), is a choice for better performance than a decision tree classification model [8]. Some studies have reported satisfactory performance of the RF model, including Speiser et al. [9], Alam et al. [10], and El-Sappagh et al. [11]. Although RF models are relatively resistant to overfitting, some hyperparameters, such as the tree depth and the minimum number of instances required to split a leaf, strongly influence the optimal RF model. Tuning RF hyperparameters should receive significant attention to obtain the best RF model. Another classification model type, the support vector machine (SVM), is a popular model with superior performance on nonlinear hyperplane boundaries [12]. Nevertheless, determining an optimal SVM model is difficult [13]. The SVM with a radial basis function (RBF) kernel has two hyperparameters: a constant term, which is the inverse of the regularization term in the SVM objective function, and a gamma parameter, which controls the width of the RBF kernel [14]. As with RF modeling, tuning the SVM hyperparameters should receive significant attention. The works conducted by Kumar et al. [15], Bektaş [16], and Ganaie et al. [17] are some examples of applications of the SVM classification model. Again, both hyperparameters of the SVM with the RBF kernel must be tuned systematically to obtain the optimal SVM model. The performance evaluation metric is another critical factor in determining the best model [18]. A confusion matrix was used to compute performance metrics [19]. Using different metrics for model performance evaluation can lead to different best models, particularly in imbalanced-class classification.

*Corresponding author.

There are three central issues encountered in developing the best RF and SVM models: oversampling to address class imbalance, tuning the model's hyperparameters using 5-fold cross-validation, and evaluating model performance using six metrics. The imbalanced-class problem is addressed using oversampling, as employed by Kovács [20] and Xu et al. [21], which can significantly improve model performance in classifying instances from the positive class. The hyperparameters of both models were tuned systematically using k-fold cross-validation, as in Passos and Mishra [22] and Nematzadeh et al. [23]. They randomly partitioned the training set into k folds, yielding k pairs of training and validation sets. The performance of both the optimal RF and SVM models will be evaluated by not only four famous metrics, that is, accuracy, precision, recall, and F1 score [24], but also MCC and AUC metrics that should measure the shifting prediction of models to the positive class[25].

The research goals are to develop the best RF and SVM models by oversampling for class imbalance and tuning the models' hyperparameters using cross-validation data. The RF's optimal hyperparameters (minimum number of instances per tree leaf and tree depth) and the SVM's optimal hyperparameters (constant and gamma values) were determined by averaging the k-fold validation accuracies obtained via grid search. The models with optimal hyperparameters of both RF and SVM were trained using either the training set or the oversampled training set. The best model's performance is evaluated on the training and test data using six metrics. Furthermore, the important features of the best RF model are explored. The rest of the sections are organized as follows: reviewing the related works given in Section two, the material data and proposed methods are explored and explained in Section three, the results consisting of the hyperparameter tuning, the model's performance, and the discussion presented in Section four, and finally, Section five presents the conclusion.

II. Related Works

The dataset characteristics, such as high dimensionality and imbalanced classes, tend to influence the machine learning model's performance. In fact, two issues can arise across all aspects of human life, including business (e.g., predicting fraudulent firms [26]), industry (e.g., manufacturing quality prediction [27]), and public health (e.g., cancer classification [28]). Fraud business, unusual products, and cancer patients are minority groups that control the class imbalance in the dataset. Some efforts have been made to handle class imbalance to improve classifier performance. The techniques range from simple methods with basic principles to creating a balanced class through random sampling without replacement, employing oversampling or under sampling methods [29] to sophisticated techniques that were innovated either by hybridization between simulated annealing algorithm for under-sampling and machine learning model [30] or ensemble techniques that concern on combining individual techniques such as under sampling technique, Real Ada-boost, cost-sensitive weight modification, and adaptive boundary decision strategy to acquire classifier models with better performance[31].

The deployment of artificial intelligence across most aspects of human life has made machine learning methods a popular approach and a challenging area of research. In general, machine learning techniques are grouped into unsupervised and supervised methods based on whether a target feature is available [32]. A popular method in unsupervised learning is clustering, which groups similar instances into the same group [33]. The other unsupervised method, namely the ranking method (e.g., the Analytic Hierarchy Process), is often used in decision support systems [34]. When the target feature has a numerical scale, the appropriate model is called a regression model, which can be used to predict [35] or forecast future value [36]. The supervised predictive modeling technique that uses the target feature category is known as a classification model [37]. The categorical target features can be binary [38] or multiclass [39].

Classification models for binary classification can have either a linear decision boundary, such as logistic regression [40] and linear discriminant analysis [41], or a nonlinear one, such as a decision tree [42] and a support vector machine [43]. The decision tree implemented in various fields outperformed the other machine learning models. The ensemble of decision tree models creates a random forest (RF) model that not only mitigates the disadvantages of the decision tree model, such as reducing the risk of overfitting, but also achieves higher performance than the DT model [44]. The RF classifier performed very satisfactorily for the brain-stroke classification by Subudhi et al. [45] and for Arabic sentiment analysis of social media related to COVID-19 conspiracy theories by Al-Hashedi et al. [46]. Nevertheless, similar to the DT model, the RF model also has hyperparameters that should be tuned systematically.

Another classification model with a different approach is the support vector machine (SVM), which uses a hyperplane as the decision boundary [47]. When the decision boundary is complex and nonlinear, SVMs outperform logistic regression [48] and k-means clustering [49]. It also performs comparably to neural network ensembles and boosted shallow trees [50]. The superior performance of both RF and SVM has prompted numerous researchers to compare them, including fraud detection in credit card transactions by Hussain et al. [51], classification of invasive and expansive species by Sabat-Tomala et al. [52], and optimization modeling of callus growth and development in Cannabis sativa done by Hesami and Jones [53]. Based on the above-cited research, RF and SVM show comparable performance, with the difference between the two models not significant. The model's hyperparameters should be adequately tuned to improve the model's performance. Efforts to find the RF-optimal hyperparameters were carried out using various approaches, including the grid search technique [54], Bayesian optimization [55], and an RF model hybridized with a genetic algorithm [56]. On the other hand, the SVM/s hyperparameters, i.e., gamma value and kernel parameter, became the focus of SVM's hyperparameter tuning. Al-Mejibli et al. [57] investigated SVM performance across hyperparameters (e.g., gamma values) and kernel parameters. Wainer and Fonseca [58] employed grid search, random search, Bayesian optimization, simulated annealing, particle swarm optimization, Nelder Mead, and others as methods for SVM tuning hyperparameters.

High-dimensional features and class imbalance are not only common challenges in building machine learning models but can also lead to poor classifier performance. The

implementation of artificial intelligence across most aspects of modern human life has brought machine learning to the forefront as a popular method and a central challenge in the field. It assumes that both RF and SVM will perform satisfactorily, high-performing classifiers for predicting instances with an unknown label when trained with optimal model hyperparameters, so their hyperparameters must be tuned systematically. Comparing the optimal RF and SVM performance remains a challenging research topic, especially for class-imbalanced datasets.

III. The Material and Proposed Method

The dataset containing 52159 patient records for joint replacement surgery is a preprocessed subset of a data mining project. The original data were published as public data and were collected from a Taiwanese hospital in 2021. The target feature, the outcome, had binary classes (infected or uninfected) and should be influenced by 29 predictors consisting of categorical and numerical features. Table I presents the categorical features and their associated label distributions. Table II presents the numerical features and their corresponding basic statistics, i.e., the minimum, maximum, and variance for each feature.

Table I presents all features followed by their class distribution. The target feature (outcome) has two labels: not infected (class_0) or infected (class_1), with a label distribution of [51280, 879], indicating that the target feature is highly class-imbalanced. The not-infected class dominated the infected class, accounting for 98% of the dataset. This means that simply guessing an unknown instance label, without using a classifier, will achieve 98% accuracy. There are 17 categorical predictors in the dataset. where their distribution is 11 features with two classes, two features with three classes, and the remaining features with 4, 6, 14, and 16 classes. Predictors with two classes dominate the others, and their class frequencies are heterogeneous. Nevertheless, the predictor features have a more balanced class distribution than the target feature.

The predictors with numerical scales and their simple summaries are displayed in Table II. There seems to be a clear issue with a commensurate measure. Among the features, there are not only significant gaps in the range statistic but also very heterogeneous variances. In addition, the incomparable unit scales are resolved by converting them into standardized normal scores. Finally, all numerical predictors have an N (0,1) distribution and the range of [-3, 3].

The study builds the best RF and SVM classifiers, with the model development stages covering 4 main processes sequentially: addressing the class imbalance with oversampling, using cross-validation data in the hyperparameters tuned, training the model candidates employing the obtained hyperparameters, and assessing the model's performance on six performance metrics for both the training and testing data. Before splitting the dataset into training and testing data. The preprocessing step converts the original scale to Z-scores to ensure a commensurate measure is obtained. Fig. 1 displays the steps for building the SVM classifier model; the steps for building the RF classifier model are similar, except for performing PCA and using both standardized and categorical data as inputs.

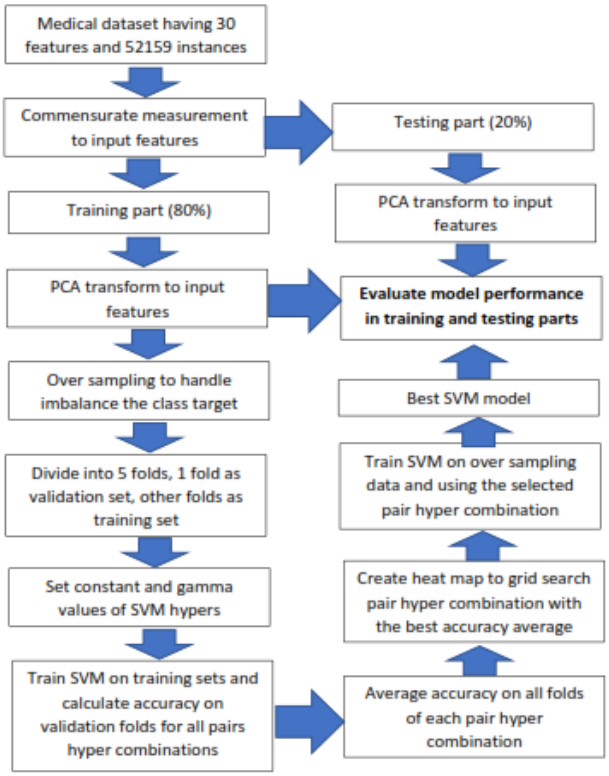

Fig. 1. The steps of the building SVM classifier.

A. The K-Folds Cross-validation to Create Pairs of Training and Validation Sets

Splitting a dataset into training and test data is a fundamental step in machine learning modeling, as the test data is needed to assess how well the model performs. Usually, the dataset is randomly split into 80% for training and 20% for testing. Most machine-learning models involve hyperparameters that should be carefully tuned [59]. The k-fold cross-validation method is a popular approach that requires substantial computational effort to obtain the optimal hyperparameters of machine learning models [60]. Fig. 2 describes splitting the dataset into training and test sets, dividing the training set into 5 folds, and finally creating pairs of training and validation sets. In detail, the stages in producing the training and validation sets are as follows.

- The validation set was the first fold, and all succeeding folds were the training set.
- The validation set was the second fold, and the other folds were the training set.
- The validation set was the third fold, and the other folds were the training set.
- Finally, the validation set was the k-fold, and all preceding folds were the training set.

After the domain values of the hyperparameters that cover the optional ones are determined, the model's candidate with a hyperparameter pair is trained on the training set, and performance is evaluated on the validation set using the accuracy metric. The trained model with the highest average accuracy was selected via grid search [61].

Training part					Testing part
fold_1	fold_2	fold_3	. . .	fold_k	
val_1	Training set_1

B. Random Forest Classifier Model

The Random Forests (RF) method was proposed by Leo Breiman in 2001. It is an ensemble method designed explicitly for decision tree classifiers. There are two sources of randomness: bagging and a random input vector. Bagging means that each tree was grown using a bootstrapped sample of the data. A random input vector was used at each decision node, where the best split was chosen from a random sample of m features or a subset of attributes instead of all attributes [62].

Fig. 3 depicts the steps for building the RF model. They include selecting the M-dimensional predictors from the dataset, setting m < M, randomly selecting the m predictors, and calculating the information gains (IG). Furthermore, determine the splitting feature with the highest IG value. The RF algorithm was presented as follows[63]:

for $b = 1$ to B,

- Take the bootstrapped dataset (Db) with size N from the D dataset.
- Grow the decision tree (Tb) based on Db, and repeat the steps for each decision node until the leaf node.
  - Select m of M features randomly with (m < M)
  - Compute the IG of the m features
  - Select the best splitting feature and the IG
  - Divide the node into two child nodes
- The RF output was yielded by the majority vote.

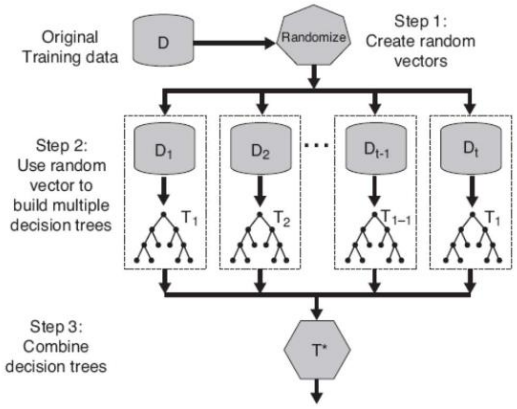

Fig. 3. The concept of developing the RF model.

The RF's hyperparameters, including the tree depth and the number of instances per tree leaf node, should be determined fairly. The grid search method selects the hyperparameter pair with the highest average accuracy obtained from evaluating the trained RF on 5-fold validation data.

C. Modeling Support Vector Classifier Model

The conventional classifier models, namely logistic regression (LR) and Fisher linear discriminant (FDL), do not have a unique decision boundary due to their lack of well-definedness. An example of a well-defined classifier model is a support vector machine (SVM). The decision boundary of the SVM is produced by maximizing the distance between the boundary and the nearest instances. The SVM model is known as the maximum-margin classifier.

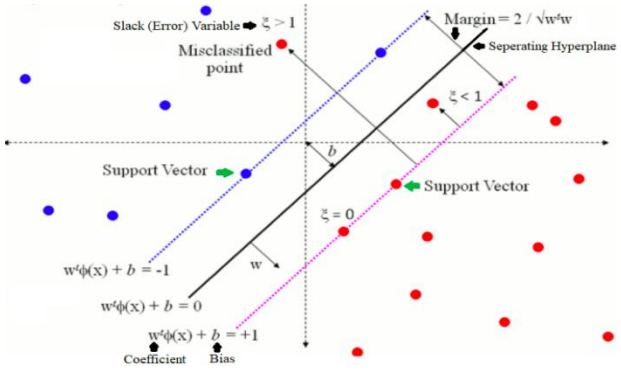

Fig. 4. The SVM model including the decision boundary and support vectors.

The margin of an SVM classifier is the smallest distance between the decision boundary and any training instance, called a support vector[64]. Fig. 4 describes the relationship among the components of an SVM model, including the decision boundary (separating hyperplane), decision margin, and support vectors. A support vector is a training point that lies on the decision-margin line. The SVM concept involves finding support vectors that minimize the distance between the two decision-margin lines. In other words, the SVM task is the same as maximizing the vectors of x nearest to the decision boundary[65].

Fig. 4 depicts three kinds of points in the SVM modeling: points well-classified are $(y_i(w^T \cdot x + w_0) \geq 1)$, points lying within the margin are $(0 < y_i(w^T \cdot x + w_0) < 1)$, and misclassified points are $(y_i(w^T \cdot x + w_0) < 0)$. Eq. (1) describes the three types of points in the SVM model.

$$y_i(w^T \cdot x + w_0) \geq 1 - \xi_i \quad (1)$$

where $\xi_i \geq 0$, is the slack variable. The problem formulation in SVM modeling maximizes the margin and minimizes the slack variable. Mathematically, the formulation is presented by Eq. (2) as follows:

$$\text{minimize } J(\boldsymbol{w}, w_0, \xi) = \frac{1}{2}||w||^2 + C\sum \xi_i \quad (2)$$

Subject to

$$y_i(w^T \cdot x_i + w_0) \geq 1 - \xi_i \; \alpha\nu\delta \; \xi_i \geq 0$$

Consider Eq. (2) and rewrite it by adding the Lagrange multiplier to produce Eq. (3) as follows:

$$\mathcal{L}(w, b, \alpha, \xi) = \frac{1}{2}w^T w + C\sum_i \xi_i - \sum_i \alpha_i(y_i(w^T x_i + b) - 1 + \xi_i) - \sum_i \beta_i \xi_i \quad (3)$$

Where are $\alpha_i \geq 0$, and $\beta_i \geq 0, \forall i = 1,2,3,\ldots,N$. Minimize $\mathcal{L}(w, b, \alpha, \xi)$ through setting $\nabla \mathcal{L}(w, b, \alpha, \xi) = 0$. Furthermore, by rewriting the dual problem formulation given in Eq. (4) as follows [66]:

$$\mathcal{L}(\boldsymbol{w}, b, \alpha) = \sum_i \alpha_i - \frac{1}{2}\sum_i \sum_j \alpha_i \alpha_j y_i y_j x_i x_j \quad (4)$$

Subject to:

$$\sum_i \alpha_i y_i = 0 \; and \; 0 \leq \alpha_i \leq C \quad \forall i = 1,2,3,\ldots,N$$

The inverse of the regularization (C constant) is a crucial hyperparameter for the SVM. The C value describes the behavior as follows: as C increases, the model overfits. In contrast, as C decreases, the model underfits.

Consider the last term of Eq. (4) that can be replaced with a kernel function that serves as a nonlinear mapping from a low-dimensional to a high-dimensional feature space, thereby resulting in a simple form of the optimization problem. The method is known as the kernel trick. Furthermore, the formula for a kernel function is given as follows:

$k(x_1, x_2) = \langle \varphi(x_1), \varphi(x_2) \rangle$ where k and φ respectively are the kernel and the feature map. The decision function of the SVM model in the space of feature-map is stated as follows:

$$y(x) = w^T \emptyset(x) + b \;\; \omega\eta\varepsilon\rho\varepsilon \;\; w = \sum_{n=1}^{N} a_n t_n \emptyset(x_n)$$

An instance x with unknown class is classified by involving a kernel with the formula as follows:

$y(x) = \sum_{n=1}^{N} a_n t_n k(x, x_n) + b$ where t_n is the target class, and the bias b is calculated by the formula as follows:

$$b = \frac{1}{N_{\mathcal{M}}} \sum_{n \in \mathcal{M}} (t_n - \sum_{m \in S} a_m t_m k(x_n, x_m))$$

Both formulas of w and b are obtained by satisfying the constraints of the Karush Kuhn Tucker (KKT).

Whereas the Radial Basis Function (RBF) kernel is presented as follows:

$$k(x, x^l) = exp\left(-\frac{||x - x^l||^2}{2\sigma^2}\right) \quad (5)$$

The denominator in Eq. (5) is referred to as the gamma value only for the RBF kernel. Gamma is a model hyperparameter for the RBF kernel. The gamma value has a behavior: when gamma increases, the SVM overfits, and when gamma decreases, the SVM underfits.

D. Classifier Model Performance Metrics

The metrics for evaluating the classifier's performance are calculated using a confusion matrix. The confusion matrix elements are presented in Eq. (6) as follows:

$$confusion\ matrix = \begin{bmatrix} TN & FN \\ FP & TP \end{bmatrix} \quad (6)$$

Where are TN, FN, FP, and TP representing true negatives, false negatives, false positives, and true positives, respectively

[67]. The study employs the six metrics to evaluate the classifier model's performance, presented in Eq. (7) as follows:

$$\begin{aligned} Accuracy &= \frac{(TP+TN)}{(TP+TN+FP+FN)} \\ Precision &= \frac{TP}{(TP+FP)} \\ Recall &= \frac{TP}{(TP+FN)} \\ F1\ score &= \frac{2\times Recall\times Precision}{(Recall+Precision)} \\ MCC &= \frac{TP\times TN-FP\times FN}{\sqrt{(TP+FP)\times(TP+FN)\times(TN+FP)\times(TN+FN)}} \\ AUC &= \int_0^1 ROC(x)dx \end{aligned} \tag{7}$$

Performance metrics, including accuracy, precision, recall, and F1 score, are widely used to evaluate classifier models in binary classification with balanced classes. Two other metrics, namely Matthews Correlation Coefficient (MCC) and Area Under the ROC Curve (AUC), were employed to evaluate the classifier's performance more comprehensively [68].

The MCC metric is widely used to evaluate the performance of classifier models in biomedical research. Both MCC and AUC are elective metrics for reaching a consensus on the best practices for the development and validation of predictive models for personalized medicine[69]. The AUC value ranges from 0.0 to 1.0, describing the capability of the binary classifier to separate instances of the positive class (class_1) from instances of the negative class (class_0).

IV. Performance Metrics of Classification Model

A commensurate measure of the dataset's numerical features is the first issue encountered during preprocessing. The numerical predictors with the heterogeneous unit scale are converted to standardized Z-scores with a mean of zero and a variance of one. The advantage of standardized data is that it is straightforward to identify the extreme values. The value of a feature of an instance is considered an outlier when the absolute Z-score exceeds 3 in the instance where an outlier value of any feature is dropped from the dataset. Although the action entails a risk of dropping an instance from the minority class, further observation to identify the factors underlying the occurrence of extreme features was not straightforward. The former version of the dataset used an incomparable unit scale, and there were no outliers in either the training or testing data.

A. Do Over Sampling and Format the Training and Validation Subsets

The dataset with all predictor features was randomly split into training (80%) and testing (20%) sets. The random forest (RF) and support vector machine (SVM) models were developed using a training set and five pairs of training and validation subsets for hyperparameter tuning. The test set serves as out-of-sample data to evaluate the performance of the best model, i.e., the one with the optimal hyperparameters. Because the dataset is imbalanced, the issue must be addressed by oversampling. For simplicity, the research oversampled the training data only once before dividing the training set randomly into five cross-validation folds. The target feature has a class-label distribution of [class_0, class_1] = [36155, 611], indicating an imbalance. Oversampling was performed on the lower-frequency class (class_1) until its frequency matched that of class_0. Fig. 5 shows that both classes had the same frequency.

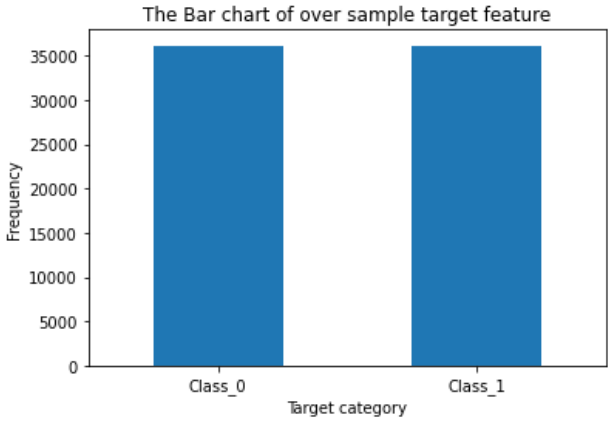

Fig. 5. The class distribution after oversampling.

By applying oversampling, the class_1 frequency increased from 611 to 36155, bringing the total number of instances in the oversampled training set to 72310. Oversampling introduces a trade-off in model training, and hyperparameter tuning requires longer processing time. Furthermore, the oversampled training set was randomly split into five folds, producing five pairs of the training and validation subsets. The number of instances in each validation subset was 14462. The training subset was used to train model candidates with a given associated hyperparameter pair, whereas the validation subset was used to calculate the model's accuracy. Each pair of hyperparameters was used to train a model candidate on five training subsets, producing five accuracy values on five validation subsets. The average accuracy indicates the model's performance on the pair of hyperparameters.

B. Tuning Hyperparameters of Random Forest Classifier

The research builds an RF classifier model that considers not only tree depth but also the number of instances per leaf node as hyperparameters. Both are expected to affect the RF's performance significantly. Their ranges are first determined by trial and error to cover the optimal value. Furthermore, the first hyperparameter was set to [300, 500, 700, 1000, 1200], and the second one to [7, 8, 9, 10, 12, 14]. The RF model candidate was trained by evaluating each hyperparameter pair on four folds of training data, then calculating the accuracy metric on the remaining fold as validation data. There are not only five pairs of training and validation data but also five pairs of hyperparameters; as a result, each pair of training and validation data is used 5 times to train an RF model. The accuracy metric of each trained RF model is calculated on its corresponding validation data. The model's accuracy for a pair of hyperparameters was calculated and recorded. The average accuracy represents the RF model's performance across the pair of hyperparameters. Fig. 6 is a heatmap of the average accuracy across 30 cells.

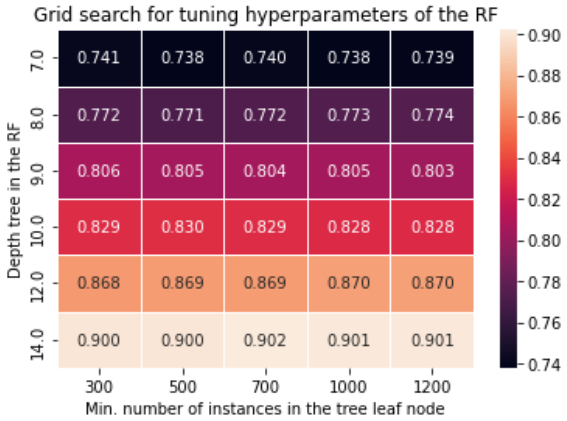

Fig. 6. The average accuracy presented in a heatmap.

Fig. 6 shows the RF's performance: average accuracy increases with tree depth. For example, at a tree depth of 10, the average accuracy increases by around 6% when the tree depth increases by around two points. On the other hand, a different pattern emerges when the tree depth exceeds 10, with the RF's performance increasing less than at the preceding depth level. There is only a marginal increase in the RF's performance of approximately 4% as the tree depth increases from 10 to 12 points. The phenomenon indicates that the model overfits when the RF tree depth exceeds 10. The number of instances per leaf node does not significantly affect the shift in mean accuracy. RF performance at a tree depth of 10 is in the range [0.828, 0.830]. The highest mean accuracy occurs with the cell hyperparameter pair (500, 10). The obtained hyperparameter pair is used to train the RF model on the oversampled training data. The confusion matrix of the optimal RF model is presented for the training and testing data, as presented in Table III:

TABLE III. THE OPTIMAL RF MODEL CONFUSION MATRIX

Actual value	Prediction training		Prediction testing	
	Class_0	Class_1	Class_0	Class_1
Class_0	26329	9826	6512	2511
Class_1	36	575	84	85

Table III displays the confusion matrices for the optimal RF model on both the training and test data with the hyperparameter pair (500, 10). The best RF incorrectly classified 9826 of 36155 instances in the negative class (class_0) on the training data and incorrectly classified 2511 of 9023 instances in class_0 on the testing data. On the other side, the best RF incorrectly classified 36 of 611 instances in the positive class (class_1) in the training data and incorrectly classified 84 of 169 instances in class_1 in the testing data.

C. Tuning Hyperparameter of the Support Vector Classifier Model

In developing the support vector machine (SVM) classifier, the constant and gamma hyperparameters are tuned using cross-validation. The optimal hyperparameter range was determined carefully. First, the SVM model candidate was trained with a given constant value and various gamma values to identify the gamma value with the highest accuracy, and select it as the selected gamma value. Furthermore, the SVM model was retrained with the selected gamma and various constant values. Finally, the sets of gamma and constant values are obtained as [0.0001, 0.0005, 0.001, 0.005, 0.01] and [100, 500, 1000, 3000, 5000, 10000]. For each hyperparameter combination (30 pairs), an SVM model candidate was trained on the training set (the union of the four folds), and the accuracy on the associated validation set (the remaining fold) was calculated. The average accuracy across all folds and gamma-constant pairs is presented as a heat map in Fig. 7.

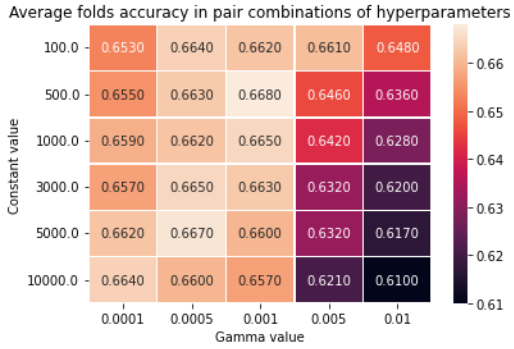

Fig. 7. The heat map of the SVM average accuracy.

Fig. 7 shows the average accuracy of the SVM model candidates in gamma coordinates and constant hyperparameter coordinates. They appear to be randomly distributed and compete tightly with one another. The highest accuracy was achieved with the pair [0.001, 500] for the gamma and constant values, respectively. The hyperparameter pair for the SVM model achieved an average accuracy of 0.668. Furthermore, the hyperparameter pair (0.001, 500) was used to train an SVM candidate model on the oversampled training data, and the confusion matrices for both the training and test sets are presented in Table IV.

TABLE IV. THE SVM MODEL CONFUSION

Actual value	Prediction training		Prediction testing	
	Class_0	Class_1	Class_0	Class_1
Class_0	22813	13342	5461	3562
Class_1	192	419	65	104

Table IV displays the confusion matrix of the best SVM, in which the classifier model incorrectly classified 13342 of 36155 instances of the negative class (class_0) in the training data and incorrectly classified 3562 of 9023 instances of class_0 in the testing data. In addition, the best SVM model incorrectly classified 192 of 611 instances of the positive class (class_1) in the training data and incorrectly classified 65 of 169 instances of class_1 in the testing data. The best SVM model performs better in classifying the class_1 instance in the testing data than the best RF model does. Nevertheless, the best RF outperformed the best SVM on the training data. The best SVM model's average accuracy, displayed in the heat map, showed a random distribution, suggesting it has no evidence of overfitting. Nevertheless, it should be noted that training the SVM model on the 5-fold validation data took longer than training the RF model.

D. The Models' Performance Comparison and the Important Features

The comparison of the best RF and SVM models was conducted in the six performance metrics, i.e., accuracy, precision, recall, F1 score, MCC, and AUC, on both the training and testing data. In addition, the acquired optimal hyperparameters were employed to train both models, using the original training data (rather than the oversampled training data) as the benchmark. Table V displays the benchmark and the best model's performance on both the training and testing data. Table V consists of two primary columns: the first presents RF performance, and the second presents SVM performance. Each primary column contains four columns: the first and second columns present the benchmark model performance, and the two remaining columns display the best model's performance.

TABLE V. THE BEST RF AND SVM PERFORMANCE COMPARISON METRICS

Performance measures	Random Forest (RF)				Support Vector Machine (SVM)			
	Benchmark		*Best model*		Benchmark		Best model	
	Training	*Testing*	*Training*	*Testing*	Training	Testing	Training	Testing
Accuracy	0.984	0.982	0.732	0.718	0.983	0.982	0.632	0.605
Precision	0.980	0.960	0.980	0.970	0.970	0.970	0.970	0.980
Recall	0.980	0.980	0.730	0.720	0.980	0.980	0.630	0.610
F1-score	0.980	0.970	0.830	0.820	0.970	0.980	0.760	0.740
MCC	0.150	0.000	0.190	0.067	0.000	0.000	0.085	0.056
AUC	0.512	0.500	0.835	0.612	0.500	0.500	0.658	0.611

On the training data, the RF benchmark model achieved 98% across four metrics: accuracy, precision, recall, and F1 score. Furthermore, it achieved the MCC and AUC metrics of 15% and 51.2%, respectively. The best RF model performs worse than the RF benchmark across four metrics. However, it achieves the same precision as the RF benchmark and improves by 4% and 32.3% in MCC and AUC metrics, respectively.

The RF model's performance is assessed on the test data; the RF benchmark outperforms the best RF in three metrics, namely accuracy, recall, and F1 score, by 26.4%, 26%, and 15%, respectively. However, the best RF outperforms the RF benchmark in precision, MCC, and AUC, with improvements of 1%, 6.7%, and 11.2%, respectively. The RF benchmark achieves an MCC of 0% and an AUC of 50%, which is equivalent to a coin toss; thus, the RF benchmark model has no performance. Mathematically, an MCC of 0% is obtained when the numerator in the MCC formula equals 0, i.e., when both the true positives (TP) and false positives (FP) are 0. Although the best RF model performed below the RF benchmark on three standard metrics, it significantly outperformed MCC and AUC, which were 6.7% and 61.2%, respectively. Oversampling increased the MCC and AUC by 6.7% and 11.2%, respectively.

When evaluated on the training set, the benchmark SVM model achieved the same precision (97%) as the best SVM model, and the two models showed a performance difference of 35.1%, 35%, and 21% for accuracy, recall, and F1 score, respectively. Furthermore, the best SVM outperformed the benchmark by 8.5% and 15.8% in MCC and AUC, respectively. When evaluating the SVM models on the test set, the benchmark SVM model outperformed the best SVM by 37.7%, 37%, and 24% in accuracy, recall, and F1 score, respectively. In contrast, the best SVM outperformed the benchmark model in precision, MCC, and AUC, with improvements of 1%, 5.6%, and 11.1%, respectively.

The SVM benchmark's performance on the test set is nearly identical to that of the RF benchmark. Both benchmark models perform poorly, as demonstrated by an MCC of 0 and an AUC of 0.5. This explains why they cannot correctly predict labels for unknown positive-class instances on the test set. Extensive attempts have been made to add hyperparameters to produce a well-performing classifier, but to no avail. The best-performing RF model is similar to the best SVM model on both the training and test sets. On the training set, the best RF performs slightly better than the best SVM, with differences of 10%, 1%, 10%, 7%, 10.5%, and 17.7% for accuracy, precision, recall, F1 score, MCC, and AUC, respectively. On the test dataset, the best RF achieves slightly higher accuracy, recall, F1 score, MCC, and AUC than the best SVM, with differences of 11.3%, 11%, 8%, 1.1%, and 0.1%, respectively. The best SVM outperforms the best RF on all five metrics, except precision, by 1%.

The results confirmed that oversampling to address class imbalance during machine learning model training does not always improve model performance. This is similar to the work done by [20], [29], and [30]. The MCC or AUC metrics clearly explain performance improvements. The MCC values increased by 6.7% and 5.6% for the best RF and SVM models, respectively, whereas the AUC values for both models were approximately 11%. Although the best RF model performs slightly better than the best SVM model, hyperparameter optimization for the RF model requires careful attention. Otherwise, there is a potential for overfitting problems[55]. Additionally, the benchmark model identified other findings warranting significant attention. The benchmark model achieves approximately 98% performance across both the training and test sets in four metrics: accuracy, precision, recall, and F1 score. However, both benchmark models performed poorly in the test set, as indicated by an MCC value of 0 and an AUC value of 0.5, where their performance was only equal to the probability of a

balanced coin toss[25]. The event implicitly suggests that using four widely used metrics to evaluate model performance on imbalanced binary classes is misguided.

In machine learning modeling, assessing model performance on test data is crucial because it confirms the model's ability to classify out-of-sample data. This study presents model performance assessments on both training and test data to explicitly demonstrate that assessing model performance based on training data can lead to biased conclusions. The model performed worse on the test data, but the pattern of performance metrics was similar when it did not overfit [52]. Optimally fitting an RF model is constrained by the difficulty in determining the hyperparameter domain that covers optimal values. However, training the RF model on cross-validation data requires less time. On the other hand, the hyperparameter space of an SVM model is straightforward to determine, but training it on cross-validation data is more time-consuming.

Another advantage of building an RF model is that it is a key feature that warrants exploration. The degree of importance of each feature can be used to determine the dominant features or for dimension reduction[10]. Developing a model that involves a few predictor features is preferable because the system mechanism underlying the model can be explained and interpreted well[42]. Fig. 8 presents the degree of essential features produced by the best RF model.

The bar chart in Fig. 8 presents the ranking of important features in increasing order. The numerical features appear to dominate the importance measure, serving as the splitting features in developing the RF model. The first five important features are CBC_Platelet, AGE, K, GOT, and LOS, with importance levels of approximately 10%, 9%, 8%, 8%, and 8%, respectively. This indicates that the five features account for approximately 43% of the RF model's development. The next group comprises four features, each with a degree of importance of approximately 6%, followed by Na and GPT features with approximately 5%. There were five features with a degree of importance of roughly 3%. The importance of the first 16 critical features is approximately 92%. From a dimension-reduction perspective, 16 features account for approximately 92% of the dataset's total variance. The variance explained by feature importance represents the contribution of the original features to the RF model. On the other hand, the variance explained by the PCA transformation is the sum of the variances of the principal components, which are mutually orthogonal and account for the dataset's variance. Note that all 12 numerical features are considered important.

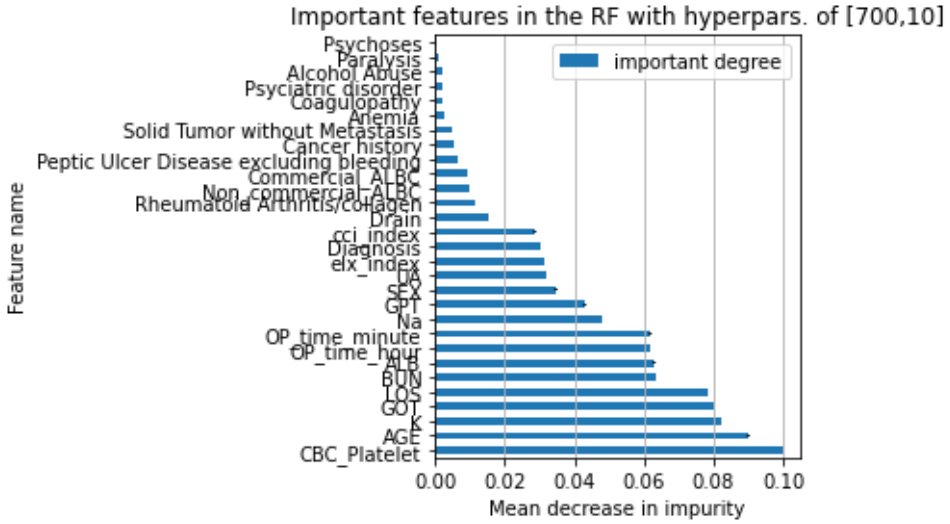

Fig. 8. The best RF model's important features.

V. Conclusion

Oversampling significantly increases the size of the training data, doubling it. This consumes substantial time, particularly when training the SVM model on cross-validation data for hyperparameter tuning. The optimal hyperparameters acquired for the RF model are (500, 10) for the number of instances per tree leaf and the tree depth, respectively. The optimal hyperparameters acquired for the SVM model are (0.001, 500) for the gamma and the constant, respectively. Both RF and SVM benchmarks achieve satisfactory performance on 4 metrics: accuracy, precision, recall, and F1 score, all at 98%. However, they perform worse on 2 metrics: MCC and AUC, with 0% and 50%, respectively. In contrast, the best RF and SVM performed similarly on 6 metrics. Oversampling reduces both the best models across four metrics: accuracy, precision, recall, and F1 score, but it increases on two metrics, namely MCC and AUC. The best RF and SVM outperformed the benchmark on the MCC and AUC metrics. The performance gaps between the best RF and the RF benchmark are (6.7% and 11.2%) for the MCC and AUC metrics, respectively. Whereas the performance gaps between the best SVM and the SVM benchmark are (5.6% and 11.1%) for the MCC and AUC metrics, respectively. In addition, the best RF produces important features that can serve as predictors for other models. In the future, the challenging research topics should focus on building an RF model using the original feature scale, employing MCC or AUC as selection criteria to obtain optimal hyperparameters, and conducting oversampling on the cross-

validation data. They are expected to significantly improve model performance.

K-Nearest Neighbors Algorithm for Short-to-Medium Term Directional Stock Price Forecasting: An Analysis of Thailand's Banking Sector

Passawan Noppakaew*, Parit Wanitchatchawan, Kanchana Phuhoy, Natthasorn Seubwong
Faculty of Science-Department of Mathematics, Silpakorn University, Nakhon Pathom, 73000, Thailand

***Abstract*—This research explores the efficacy of a parsimonious K-Nearest Neighbors (KNN) framework for short-to-medium term stock direction forecasting, focusing specifically on the banking sector within Thailand's SET50 index. Prior preliminary analysis, aimed at determining the optimal prediction horizon, indicated that a 60-day forecast yielded the most effective results, establishing the scope of this study as medium-term prediction. The objective of this analysis is to determine if a 60-day directional movement can be effectively captured using a minimalist feature set limited to the current day's Opening Price and the previous day's 14-day Simple and Exponential Moving Averages. Employing a rolling-window validation methodology on seven key banking stocks during H1 2025, the KNN model demonstrated significant predictive capability. The average accuracy across the selected banking stocks reached 82.0%, with standout performance for TISCO and SCB. While results varied across stocks, our findings substantiate the theoretical and practical sufficiency of a simplicity-first approach. The research demonstrates that in high-noise emerging markets, feature sparsity and instance-based logic serve as an essential defense against overfitting, providing institutional practitioners with a transparent and robust alternative to complex methodologies.**

***Keywords*—Stock trend prediction; K-Nearest Neighbors; technical analysis**

I. Introduction

The intricate, volatile, and non-linear nature of financial markets presents a formidable and long-standing challenge [1]. Accurately forecasting stock price movements has been a desirable objective for both investors and academics [2], [3], as marginal improvements in predictive accuracy can offer significant financial advantages. Based on the limitations of traditional linear models for forecasting stock movements, alternative approaches have been explored. Machine learning (ML) which is a sub-field of artificial intelligence (AI) has emerged as a powerful paradigm for identifying the complex latent structures within financial time-series data [4], [5], [6]. See also [7], [8], [9], [10] for alternative approaches using deep learning techniques.

Unlike conventional models, ML algorithms excel at identifying non-linear patterns and hidden correlations within high-dimensional datasets [11]. This capability has led to widespread applications across various domains, from natural language processing and computer vision to intelligent recommendation engines [12]. The research efforts within ML-based financial forecasting can be broadly divided into two main approaches: one focusing on price prediction and the other on market directional forecasting. The first approach treats the problem as a regression task, attempting to forecast the exact future value or closing price of a stock. While academically rigorous, this method encounters significant challenges due to the high level of stochastic noise in market data. The second approach, which is the focus of this study, frames the problem as a classification task, predicting the directional movement, such as upward or downward trends, of the stock price. This classification approach offers distinct practical advantages. For a trader or investor, their decision is often binary, i.e., buy or sell, not the prediction of an exact price point. A model that correctly classifies the direction of a trend, even if it misses the magnitude, provides a clearer and more actionable signal for formulating trading strategies. The focus on direction rather than price is often more robust and less susceptible to the noise that plagues regression models.

Among the suite of ML tools, the K-Nearest Neighbors (KNN) algorithm, a non-parametric and instance-based learning method, has attracted significant attention due to its simplicity, transparency, and effectiveness [13]. KNN operates on the principle of feature similarity, classifying a new data point based on the majority class of its k nearest neighbors in the feature space. Due to its reliance on local similarity rather than global parameter estimation, KNN-based frameworks are effectively utilized to mitigate overfitting in noisy financial time series, particularly when coupled with strategic feature selection [14]. Its utility has been validated in diverse fields, such as the trading system proposed by Teixeira and de Oliveira [15], who utilized a high-dimensional feature space of 22 technical indicators to achieve significant results. However, recent advancements in emerging market research suggest a strategic shift toward binary directional classification as a more robust objective than point-based price estimation [6]. Specifically, in the context of the Stock Exchange of Thailand (SET), evidence indicates that focusing on market direction allows for higher predictive stability despite the inherent volatility of the Thai banking sector [6].

Consequently, this study diverges from the feature-rich precedent by investigating a minimalist, direction-oriented hypothesis. Rather than adopting the extensive 22-indicator framework, the current research examines whether effective directional forecasting for the Thai banking sector is achievable through a deliberately restricted feature set, thereby enhancing both model transparency and practical interpretability. This study investigates the hypothesis that a simple KNN classifier can effectively perform directional forecasting even with minimal input data. The analytical focus is narrowed specifically to

*Corresponding author.

stocks within the Banking sector, as listed in Thailand's SET50 Index for the H1 2025 period, namely BBL, KBANK, KTB, KTC, SCB, TISCO, and TTB. This sector presents a particularly interesting case for study due to several factors: bank stocks often exhibit a degree of sensitivity to macroeconomic indicators, their performance can be interrelated, reflecting broader economic health, and they represent a significant component of the overall market index, making their predictability valuable for investors. Within this focused scope, the objective is to predict whether the closing price 60 days in the future will be up (higher) or down (lower) relative to the current day's opening price. This prediction utilizes a deliberately minimalist feature set consisting of: 1) the current day's Opening Price, 2) the 14-day Simple Moving Average (SMA) from the previous day, and 3) the 14-day Exponential Moving Average (EMA) also from the previous day. The use of opening prices serves to enhance economic realism by simulating decision-making at the start of the trading session. By evaluating this model specifically on these key banking stocks, this research aims to determine if the minimalist KNN approach provides a practical and effective basis for directional forecasting within this vital market sector. To distinguish the unique contributions of this study from existing KNN-based forecasting literature, this study pivots toward a parsimonious framework that challenges the prevailing necessity of model complexity in high-noise environments. Methodologically, this study demonstrates that a minimalist feature set can maintain high predictive accuracy by prioritizing robustness over complexity. Such an approach serves as a strategic defense against the overfitting typically encountered in algorithmically dense architectures within high-noise environments. Beyond its empirical setting, the choice of the Thai banking sector serves as a strategic economic bellwether. Grounded in the theoretical consensus that financial systems are primary engines of national stability [16], [17], this research leverages the heightened sensitivity of these securities to macroeconomic shifts as a rigorous stress test for model reliability [18]. Finally, the research offers significant practical utility by providing a transparent, instance-based logic for institutional practitioners. Unlike complex models, the KNN framework offers superior interpretability, allowing users to substantiate forecasts through historical analogies–a vital requirement for real-world trading deployment.

The remainder of this study is organized into four primary sections to provide a comprehensive overview of the research framework: Section II details the research methodology, specifically focusing on the data selection process within the Thai banking sector and the implementation of the deliberately minimalist feature set. Section III reports the empirical results and predictive performance across the selected constituents. Finally, Section IV provides a synthesis of key findings, summarizing the practical utility of the parsimonious model and offering strategic recommendations for subsequent research directions.

II. Methodology

This study employs a quantitative methodology to ascertain the effectiveness of a KNN model for financial market classification. The process involves data acquisition from a major emerging market index, precise variable features, and a model training and validation process.

A. Dataset and Scope

Instead of serving as a nominal constraint for this study, the focus on the Thai banking sector represents a strategic decision to test the proposed model within a pivotal economic bellwether [17]. In an emerging market such as Thailand, the banking industry acts as a direct proxy for broader national stability, characterized by its acute sensitivity to monetary policy shifts, interest rate volatility, and macroeconomic fluctuations [16], [18]. This inherent sensitivity creates a high-variance and information-rich environment which is an ideal test for evaluating whether medium-term technical indicators can maintain predictive reliability under shifting conditions. To uphold the analytical reliability of this research and shield the model from the stochastic noise inherent in low-volume securities, this study deliberately focuses on banking constituents within the SET50 Index. This approach ensures the study is grounded in the market's most liquid and institutionally significant securities.

For this study, the banking constituents were identified from the official SET50 list [19] for the H1 2025 period starting from January 1, 2025, to June 30, 2025, namely BBL, KBANK, KTB, KTC, SCB, TISCO, and TTB, as shown in Table I. Concentrating on this sector allows a focused examination of the model's performance within a group of stocks often influenced by similar macroeconomic factors.

TABLE I. The Banking Sector in SET50 Index (H1 2025: Jan 1 - Jun 30, 2025)

No.	Symbol	Company Name
1	BBL	BANGKOK BANK PUBLIC COMPANY LIMITED
2	KBANK	KASIKORNBANK PUBLIC COMPANY LIMITED
3	KTB	KRUNG THAI BANK PUBLIC COMPANY LIMITED
4	KTC	KRUNGTHAI CARD PUBLIC COMPANY LIMITED
5	SCB	SCB X PUBLIC COMPANY LIMITED
6	TISCO	TISCO FINANCIAL GROUP PUBLIC COMPANY LIMITED
7	TTB	TMBTHANACHART BANK PUBLIC COMPANY LIMITED

All necessary historical time-series data (including daily Open, High, Low, Close, and Volume) for these selected banking stocks were programmatically retrieved using the Yahoo Finance (yfinance) library. To establish an appropriate prediction horizon for the main study, a preliminary experiment was conducted. This involved evaluating the KNN model's average prediction accuracy across various forward-looking horizons (n days), ranging from 3 to 120 days, while keeping the feature set constant. The results of this sensitivity analysis indicated that model balances between achieving near-maximal predictive performance and maintaining a forecast window appropriate for short-to-medium-term trading strategies at $n = 60$ days (details in Appendix A, Appendix B, and Appendix C). Therefore, a 60-day prediction horizon was adopted for the final evaluation. The final out-of-sample prediction (testing) phase, using this 60-day target, was conducted on data from January 1, 2025, to June 30, 2025.

B. Study Design and Variable Engineering

This research is designed as a binary classification task. The objective is to predict the directional movement of a stock's price over a fixed, 60-day forward-looking horizon.

1) Target variable (dependent variable): For any given trading day t, the target variable $Y(t)$ is defined as the future price direction. It is assigned a binary value based on a comparison between the closing price on day t and the closing price 60 days later ($t + 60$):

- Class 1 (Up) if $Close_{t+60} > Close_t$,
- Class 0 (Down) if $Close_{t+60} \leq Close_t$,

where, $Close_t$ represents the closing price on the prediction day (day t) and $Close_{t+60}$ is the closing price 60 days later. This definition is designed to directly model the practical trading decision of determining whether buying a stock at today's closing price will yield a higher closing price 60 days from now.

2) Feature set: Unlike models that rely on a high-dimensional feature space, this study adopts a deliberately minimal approach. Intricate feature engineering is sidestepped in favor of utilizing fundamental and widely recognized technical indicators common in financial analysis. Specifically, the feature set is constructed solely from the current day's Opening Price, alongside the previous day's 14-day Simple Moving Average (SMA) and 14-day Exponential Moving Average (EMA). Further details on these moving averages are provided in [20]. This deliberate simplicity allows for a focused evaluation of the core predictive power inherent in these basic trend metrics.

The resulting feature set $X(t)$, used to predict the outcome for day t consists of only three variables:

- Open Price ($Open_t$) is the opening price on the day of prediction.
- SMA-14 ($SMA_{14(t-1)}$) is the 14-day Simple Moving Average, calculated using closing prices up to the previous trading day ($t - 1$).
- EMA-14 ($EMA_{14(t-1)}$) is the 14-day Exponential Moving Average, also calculated using data up to the previous trading day ($t - 1$).

The 14-day lookback period for the moving averages was selected to align with the empirically determined optimal prediction horizon (see Appendix A, Appendix B, and Appendix C) and reflects common practice in short-to-medium-term technical analysis. Fine-tuning the moving average periods was considered beyond the scope of this study, which focuses on the effectiveness of the chosen minimalist feature types. This specific feature construction is critical, as it ensures that only information known at the time of prediction (the morning of day t) is used, thereby preventing any lookahead bias.

3) Model training and validation: The KNN algorithm was selected as the core classifier. To simulate realistic market conditions and ensure model robustness, a rolling-window validation procedure was implemented.

For each of the 7 stocks, and for each day in the test period (Jan-Jun 2025), the model was trained as follows:

- Data Window: A historical data window of approximately 1 year was retrieved relative to the prediction day (e.g., for a prediction on June 1, 2025, data from June 1, 2024, to May 31, 2025, will be used).
- K-Value Optimization: This historical window was split into a training set and a testing (validation) set (3:1 ratio). The KNN model was run iteratively to find the optimal hyperparameter k (the number of neighbors) that yielded the highest accuracy on this validation set.
- Prediction: The full historical window was then used as the training set, and the optimized k and the model created by the historical data window ($\approx$ 1 year) was used to make the single directional prediction, which is class 0 or 1, for the target day.

This process was repeated for every trading day in the test period, ensuring the model was always retrained on the most recent data available before making a new prediction. The final accuracy, precision and recall were calculated as the percentage of correctly predicted days over the entire 6-month test period. Minimalist approach provides a practical and effective basis for KNN-based directional forecasting.

III. Results

This section presents the empirical findings from applying the KNN classification model, configured with the minimalist feature set and a 60-day prediction horizon, to the selected banking stocks within Thailand's SET50 Index (H1 2025). The model's performance is evaluated on a per-stock basis using standard classification metrics, focusing primarily on prediction accuracy, recall, and precision, over the designated test period. The predictive performance of the KNN model across the selected banking stocks is detailed in Table II and visualized in Fig. 1. Overall, the model demonstrates considerable effectiveness for most stocks within this sector, although performance varies significantly between individual securities.

TABLE II. KNN Model Performance Metrics for SET50 Banking Stocks (H1 2025).

Stock Symbol	Accuracy (%)	Precision (%)	Recall (%)
BBL	61.0	40.5	44.7
KBANK	83.9	93.4	86.7
KTB	80.5	84.9	92.8
KTC	84.7	72.3	100.0
SCB	89.8	93.7	95.4
TISCO	94.9	96.3	98.1
TTB	78.8	91.3	80.2
Average	**82.0**	**81.8**	**85.4**

Both SCB and TISCO exhibit strong performance with high accuracy, precision and recall. Especially, TISCO emerges as the top performer, achieving exceptionally high scores across all metrics. This suggests that the model is highly reliable and effective at predicting the 60-day directional movement for these specific stocks. Whereas, several other banks, including KBANK, KTB, and KTC, also show robust results, generally achieving accuracies above 80%. Especially, KTC displays a perfect recall score, indicating the model successfully identified all actual upward movements within the test period for this stock. However, this comes with a lower precision compared to KBANK and SCB, implying a higher rate of false positives. KTB also shows a strong recall paired with moderate precision. TTB presents good precision, but

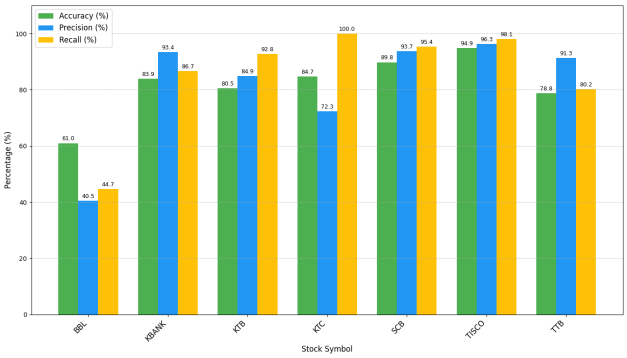

Fig. 1. Bar chart of KNN performance metrics for banking stocks.

lowers recall compared to the top performers. In contrast, BBL shows significantly weaker results across all aspects of the performance metrics. The model struggles considerably with predicting this stock's movement compared to the others in the sector.

Considering the average performance across the seven banking stocks, the KNN model with the selected features appears generally proficient for this sector. The high average recall suggests the model is good at capturing upward trends, while the respectable average precision indicates that when it predicts an upward movement, it is correct about 82% of the time on average.

IV. Conclusion

This research set out to explore the viability of a simplified approach to predict stock price direction within the Thai financial market. The study specifically investigated whether a KNN classifier, equipped with a deliberately minimalist set of technical indicators (Opening Price, 14-day SMA, 14-day EMA), could effectively forecast medium-term (60-day) upward and downward movements for stocks in the SET50 banking sector. The selection of the 60-day horizon was itself informed by a preliminary sensitivity analysis aiming for a balance between predictive power and practical trading relevance.

The study showed that the KNN model demonstrated considerable predictive capability, achieving an average accuracy of 82.0% across the sector. Performance was particularly strong for certain stocks like TISCO (94.9% accuracy) and SCB (89.8% accuracy), suggesting the model can be highly effective in specific cases. The findings indicate that even without complex feature engineering or computationally intensive algorithms, a basic KNN approach can capture meaningful predictive signals for medium-term directional changes, at least within this homogeneous sector. The high average recall (85.4%) further suggests a particular aptitude for identifying potential upward trends. However, the results were not uniform. The model's significantly lower performance for BBL underscores that predictive success, even with a consistent methodology, can be highly stock-specific.

The robust accuracy achieved through this minimalist framework underscores the theoretical and practical sufficiency of a simplified KNN approach, even in the absence of complex algorithmic benchmarks. These findings suggest that in high-noise environments like the SET50 banking sector, feature sparsity and low model complexity may actually serve as a primary defense against the overfitting typically observed in more elaborate architectures. By demonstrating that significant market signals can be effectively captured without the inherent computational overhead of complex models, this study provides a compelling case for a parsimonious modeling framework. Furthermore, the instance-based logic of KNN offers superior interpretability—a vital requirement for practitioners who prioritize understanding the historical analogies driving a prediction as much as the forecast itself.

Future research could productively expand upon this work by comparing the minimalist KNN approach against other classifiers (e.g., Logistic Regression, Naive Bayes) and applying the methodology to diverse market sectors and international markets. In addition, future research will investigate adaptive methods for selecting the optimal prediction horizon and moving average periods. Despite its limitations, this study affirms the potential utility of simple, interpretable models like KNN in the challenging domain of financial market prediction.

APPENDIX

Before proceeding with the main analysis, it was crucial to empirically justify the selection of the prediction horizon (n). An arbitrary choice could weaken the study's validity. Therefore, a sensitivity analysis was conducted to evaluate the KNN model's performance across various forward-looking timeframes.

A. Methodology

The core experimental setup mirrored the main study's design, with only the prediction horizon (n) being varied.

- Horizons Tested: A range of plausible short-to-medium-term horizons was selected for comparison. The parameter n was defined using the following intervals: $3, 5, 7, 10, 14, 21, 30, 45, 60, 90, 120$ days.
- Target Variable Definition: For each tested horizon n, the binary target variable $Y(t)$ was redefined as:
  - Class 1 (Up) if $Close_{t+n} > Close_t$,
  - Class 0 (Down) if $Close_{t+n} \leq Close_t$.
- Constant Factors: The minimalist feature set (current Open Price, previous day's SMA-14, previous day's EMA-14) and the KNN algorithm remained constant across all tests.
- Optimal k Selection: For each stock and each prediction day, the optimal number of neighbors (k) was determined. This involved:
  - Splitting the 1-year historical data starting from January 1, 2024, to December 31, 2024 into a 3:1 training/validation set.
  - Iterating through k values from 1 to 30.
  - Selecting the k that yielded the highest accuracy on the validation set for that specific stock and that specific training window.
- Performance Evaluation: Using the optimized k, predictions were made for the target day within the rolling window procedure. This entire process was repeated for all 50 stocks across the full test period (October 1, 2024, to December 31, 2024) for each of the selected horizons ($n = 3, 5, ..., 120$). The performance metric was the average prediction accuracy, precision and recall calculated across all 50 stocks for each horizon.

B. Results

The key metrics tracked were average accuracy, precision, and recall. The results are presented in Table III and visualized in Fig. 2.

TABLE III. AVERAGE PERFORMANCE METRICS VS. PREDICTION HORIZON (n DAYS).

Prediction	Average Metrics (%)		
Horizon (n days)	Accuracy	Precision	Recall
3	61.0	56.0	47.0
5	65.0	65.0	54.0
7	68.0	67.0	66.0

120	79.0	80.0	80.0

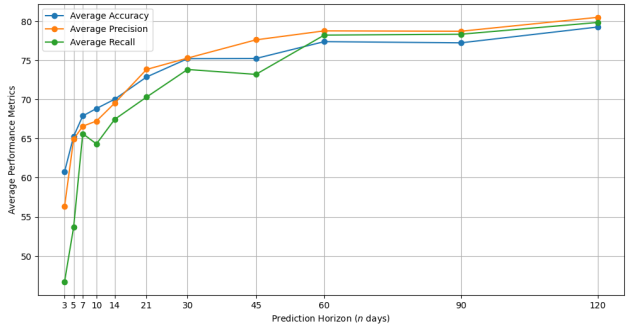

Fig. 2. Average performance metrics vs. prediction horizon (n days) up to 120 days.

As depicted in Fig. 2, all three performance metrics generally exhibit an upward trend across the entire tested range. Notably, the rate of improvement decelerates considerably after approximately $n = 45$ days. Average Precision, in particular, begins to plateau around $n = 60$ days, showing only marginal increases thereafter up to $n = 120$. While the highest average accuracy $\approx 79\%$ was observed at $n = 120$, the gain compared to $n = 60$ which has the average accuracy $\approx 77\%$ is relatively small, especially considering the doubling of the forecast period from approximately two months to four months. Moreover, $n = 120$ is beyond the typical scope of short-to-medium-term trading. Therefore, a horizon of $n = 60$ days (approximately two months) was chosen for this study. This decision represents a deliberate trade-off. It captures the vast majority of the predictive performance achievable while maintaining a forecast window that remains relevant and actionable for medium-term position adjustments.

C. Conclusion

Based on this empirical evidence, the 60-day prediction horizon ($n = 60$) was selected as the most suitable timeframe for the main classification task in this study. The sensitivity analysis in Fig. 2 supports this choice, indicating significantly diminishing improvement rates in performance gains for horizons substantially longer than 60 days.

Multi-Criteria Methodology for Selecting Communication Protocols in M2M Environments

Oleg Iliev
Institute of Mathematics and Informatics, Bulgarian Academy of Sciences, Sofia, Bulgaria

***Abstract*—The continuous expansion of Machine-to-Machine (M2M) communication and Internet of Things (IoT) ecosystems has significantly increased the complexity of selecting appropriate communication protocols and data flow management systems. Contemporary M2M deployments operate across heterogeneous functional domains, including sensor networks, transactional systems, and real-time streaming environments, each imposing distinct and often conflicting non-functional requirements such as latency, reliability, scalability, and resource efficiency. This study proposes a domain-oriented multi-criteria decision-making methodology for structured protocol selection in M2M environments. The framework integrates the Analytic Hierarchy Process (AHP) for context-dependent weighting of evaluation criteria with the Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) for quantitative ranking of alternative technologies. A structured domain taxonomy is introduced to dynamically align evaluation priorities with functional deployment characteristics, and 99th percentile latency (L_{p99}) is incorporated as a primary performance indicator to capture tail-behavior effects critical for M2M reliability. Beyond ranking computation, the methodology formalizes a reproducible analytical workflow linking empirical measurements to domain-specific decision outcomes and incorporates a sensitivity-analysis perspective to assess ranking robustness under variations in criterion weights. The proposed framework establishes a transparent and adaptable decision-theoretic foundation for context-aware communication protocol selection in heterogeneous M2M scenarios.**

Keywords*—Machine-to-Machine communication; Internet of Things; multi-criteria decision making; AHP; TOPSIS; communication protocol selection; non-functional requirements

I. Introduction

Machine-to-Machine (M2M) communication has evolved from a specialized industrial paradigm into a foundational architectural component of modern cyber-physical systems, smart infrastructures, and large-scale Internet of Things (IoT) deployments. The rapid growth of connected devices, heterogeneous hardware platforms, and distributed data-processing architectures has significantly increased the complexity of communication design decisions. Contemporary M2M environments operate under diverse functional constraints, including energy efficiency, transactional consistency, ultra-low latency, and high-throughput streaming, each imposing distinct non-functional requirements.

The proliferation of communication technologies-ranging from request–response protocols such as HTTP/1.1 and HTTP/2 [1] to broker-oriented systems such as MQTT and AMQP, and high-throughput distributed streaming platforms such as Apache Kafka-has transformed protocol selection into a multi-dimensional engineering problem. Each protocol is optimized for specific design assumptions, transport-layer characteristics, and performance objectives. However, when deployed outside their intended operational domain, these technologies may exhibit significant degradation in latency, reliability, or scalability [2].

The protocol selection problem is further complicated by the conflicting nature of non-functional requirements (NFRs). Minimizing latency may increase resource consumption; maximizing reliability may reduce throughput; and optimizing scalability may introduce architectural complexity. In practice, many M2M deployments rely on protocol benchmarking studies that compare isolated performance metrics without embedding them into a unified analytical framework [3]. As a result, architectural decisions are frequently driven by ad hoc evaluations rather than systematic, reproducible methodologies.

This study addresses this gap by proposing a structured, domain-oriented decision-making methodology grounded in Multiple-Criteria Decision-Making (MCDM) theory. The proposed framework integrates the Analytic Hierarchy Process (AHP) [4] for domain-specific weighting of evaluation criteria with the Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) [5] for quantitative ranking of alternative technologies.

The present work formalizes a reproducible methodological workflow that can be systematically applied across heterogeneous M2M scenarios. Its primary contribution lies in the definition of a consistent analytical framework in which heterogeneous communication protocols can be evaluated, compared, and ranked according to domain-specific priorities.

While the current study focuses on the conceptual structure, mathematical formulation, and decision-theoretic foundations of the model, its empirical application to concrete deployment scenarios constitutes a complementary line of research that extends the methodology toward domain-specific validation.

The objective is not to identify a universally optimal protocol, but rather to determine the most suitable communication solution for a given functional context. By explicitly linking domain taxonomy, measurable evaluation criteria, and structured multi-criteria analysis, this study provides a reproducible foundation for systematic protocol selection in M2M environments.

The remainder of this study is organized as follows: Section II reviews related work and identifies the main research gaps. Section III introduces the conceptual architecture and the domain taxonomy. Section IV formalizes the evaluation criteria and details the integrated AHP–TOPSIS workflow. Section V discusses the implications of the methodology, including a

sensitivity perspective. Finally, Section VI concludes the study and outlines directions for future research.

The main contributions of this study can be summarized as follows:

- Domain-Oriented Formalization: A structured taxonomy of three representative M2M domains (Sensor Networks, Transactional Systems, and Real-Time Streaming) is defined, explicitly linking functional requirements to measurable non-functional criteria.
- Integrated AHP–TOPSIS Methodology: A reproducible multi-stage computational framework is developed, combining domain-aware subjective weighting (AHP) with objective distance-based ranking (TOPSIS).
- Tail-Latency-Centric Evaluation: The explicit inclusion of 99th percentile latency (L_{p99}) as a primary evaluation criterion addresses a critical yet frequently underrepresented performance dimension in M2M systems.
- Hybrid-Architecture Compatibility: The methodology supports evaluation of both standalone and hybrid communication architectures, reflecting contemporary deployment practices.
- Sensitivity-Aware Decision Framework: A structured sensitivity-analysis perspective is incorporated, enabling evaluation of ranking stability under variations in domain-specific weight configurations.
- Reproducible Analytical Model: The proposed framework establishes a transparent mathematical workflow linking empirical performance metrics to domain-specific decision outcomes.

II. Literature Review and Related Work

The scientific discourse regarding communication protocols in M2M and IoT environments has historically been divided into two separate silos: empirical performance evaluation and theoretical decision science. This section explores the convergence of these fields and identifies the prevailing research gaps.

A. Comparative Analysis of Communication Protocols

Extensive surveys have established a baseline for understanding protocol behavior. Al-Fuqaha et al. [2] provided one of the most comprehensive classifications of IoT technologies, mapping protocols to the OSI model and highlighting the trade-offs between RESTful architectures and broker-based systems. Their work emphasized that the choice of protocol is tightly coupled with the transport layer (TCP vs. UDP), which dictates the underlying reliability and congestion control mechanisms.

Empirical studies, such as those by Thangavel et al. [6], have utilized specialized testbeds to compare MQTT and CoAP. Their findings demonstrated that MQTT's TCP-based nature provides superior reliability in stable networks, whereas CoAP's UDP-based approach offers lower overhead in constrained environments. However, these studies typically focus on a narrow set of criteria, such as latency or throughput, often ignoring the "tail latency" (L_{p99}) or the impact of message ordering violations on transactional integrity.

More recent experimental studies extend these comparisons by incorporating security mechanisms and realistic deployment constraints. Seoane et al. [7] evaluate the performance impact of security layers on CoAP and MQTT in IoT environments, highlighting non-negligible latency overhead under encryption. Similarly, Wytrebowicz et al. [8] provide a pragmatic comparison of messaging protocols that considers not only raw performance metrics but also implementation complexity and deployment characteristics.

B. Architectural Middleware and Data Flow Management

The role of Message-Oriented Middleware (MOM) has been critically examined by Curry [3], who identified persistence, delivery guarantees, and asynchronous decoupling as the three pillars of modern M2M communication. As systems scale, the focus shifts from individual device connectivity to the management of large-scale data streams. Platforms like Apache Kafka have introduced a paradigm shift towards "log-based" communication, which offers high durability but introduces significant complexity in terms of client-side resource consumption.

The literature highlights a clear trade-off: lightweight protocols (MQTT, CoAP) lack the robust data management features of heavy-duty streaming platforms (Kafka, Pulsar). Yet, performance-oriented studies rarely provide a mechanism for translating these qualitative architectural benefits into a structured decision-making framework.

C. Multi-Criteria Decision-Making (MCDM) in IoT

The application of MCDM methods to solve complex engineering trade-offs has gained significant traction. The Analytic Hierarchy Process (AHP), developed by Thomas Saaty, has been used to determine information priorities in resource allocation [4]. In the IoT context, AHP has been successfully applied to select routing protocols and cloud service providers. However, AHP alone is often criticized for its susceptibility to human subjectivity and the "rank reversal" phenomenon when many alternatives are added.

To address these limitations, researchers have explored hybrid models. The integration of AHP with TOPSIS [5] has been identified as a robust solution. Sharifian et al. [9] applied this combination to evaluate reactive routing protocols, while Durão et al. [10] used it for process selection in industrial IoT. These frameworks demonstrate that while AHP captures expert knowledge, TOPSIS provides a mathematically stable ranking based on the Euclidean distance to an "ideal solution" [11].

Recent literature reviews further demonstrate the growing adoption of MADM methodologies in Industry 4.0 decision problems. Zayat et al. [12] synthesize contemporary applications of MADM techniques across industrial systems, confirming their relevance for complex multi-criteria technological selection scenarios similar to M2M communication environments.

Table I summarizes representative studies across protocol surveys, empirical evaluations, and MCDM-based selection approaches, highlighting the absence of dynamic domain weighting and hybrid support in most prior work.

TABLE I. COMPACT SUMMARY OF RELATED WORK CHARACTERISTICS

Reference	Type	Domain Weights	Hybrid
Al-Fuqaha et al. [2]	Survey	No	No
Thangavel et al. [6]	Empirical	No	No
Seoane et al. [7]	Empirical	No	No
Wytrebowicz et al. [8]	Empirical	No	No
Sharifian et al. [9]	MCDM	Partial	No
Durão et al. [10]	MCDM	Static	No
Zayat et al. [12]	Review	N/A	No
Proposed work	MCDM	Yes (Dynamic)	Yes

D. Discussion and Identification of Research Gaps

Despite the richness of the existing literature, two major structural limitations can be identified. First, most MCDM-based approaches in IoT assume static criterion importance, implicitly treating evaluation weights as context-independent. Such an assumption neglects the fact that distinct M2M domains, such as sensor networks and real-time streaming systems, impose fundamentally different non-functional priorities. Second, existing studies typically evaluate communication protocols as mutually exclusive alternatives, without systematically considering hybrid architectural configurations.

The proposed methodology addresses these limitations by introducing a domain-oriented formalization of the decision space. Criterion weights are dynamically derived through AHP in accordance with functional context, thereby embedding domain specificity directly into the ranking process. Furthermore, the integration of tail latency (L_{p99}) as a primary evaluation parameter extends traditional benchmarking approaches that rely predominantly on average metrics. Finally, the formalized AHP–TOPSIS workflow establishes a reproducible mathematical bridge between empirical measurements and domain-aware decision outcomes.

III. DEFINING THE METHODOLOGICAL ARCHITECTURE

Selecting a communication protocol in an M2M environment is inherently a multi-criteria problem. It involves balancing throughput, latency, reliability, scalability, and resource efficiency [5]. The proposed architecture integrates domain-oriented reasoning with quantitative evaluation.

A. Three-Layer Decision-Making Process

The framework in Fig. 1 defines an iterative, three-layer process.

- The Contextual Layer (Domain & Criteria Definition): The process begins by identifying the functional domain and the specific non-functional requirements. This layer defines the “Goal” and the “Criteria” of the AHP hierarchy.
- The Analytical Layer (Evaluation via AHP-TOPSIS): At this stage, weights are calculated using AHP [4] to reflect domain priorities. These weights are then applied to normalized empirical data within the TOPSIS model [9].
- The Strategic Layer (Selection & Hybridization): The output is a closeness coefficient C_i. This value is used to rank technologies or to identify complementary protocols for a hybrid solution.

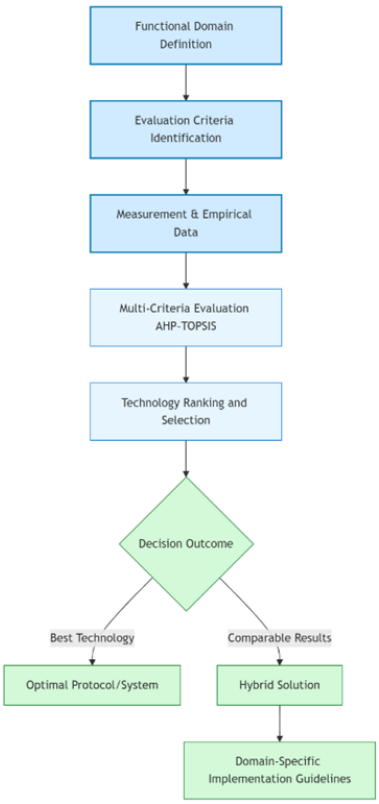

Fig. 1. Conceptual framework for selecting communication protocols and data flow management systems in M2M environments.

B. Core Design Principles

The methodology is guided by four fundamental principles:

- Domain Orientation: Priorities are not fixed but derived from the functional needs of the domain (e.g., Sensor vs. Real-Time).
- Quantitative Measurability: Every criterion must be expressed in a measurable unit (ms, msg/s, $\%$ loss).
- Mathematical Consistency: The use of the Consistency Ratio (CR) in AHP ensures that expert judgments are logical [4].
- Euclidean Distance Optimization: TOPSIS ensures that the chosen technology is not just ”the best” in one category, but the closest to the multidimensional “Ideal Solution” [11].

C. Taxonomy of M2M Domains

To enable dynamic weighting, we classify M2M environments into three domains:

- Sensor Networks: Focus on energy efficiency and aggregate reliability. Latency is secondary.
- Transactional Systems: Focus on strict message ordering, idempotency, and low tail latency to ensure system consistency.

- Real-Time Streaming: Focus on high throughput and minimal L_{p99} latency. Minimal loss is acceptable to maintain "freshness".

IV. Evaluation Criteria and Integrated Methodology

A. Formalization of Evaluation Criteria

A critical aspect of this methodology is the rigorous definition of criteria [13]. The selection process relies on multiple empirically measurable criteria, grouped into two main categories, as in Table II:

TABLE II. Formalized Evaluation Criteria for Protocol Selection.

Criterion	Description	Unit	Type
L_{avg}	Average message transmission latency	ms	Cost
L_{p99}	Latency at 99th percentile	ms	Cost
$Loss$	Share of lost messages	%	Cost
$Ordering$	Message ordering violations	%	Cost
$Reliability$	Successfully delivered messages	%	Benefit
$Throughput$	Channel throughput	msg/s	Benefit
$Scalability$	Behavior with increasing client count	-	Benefit
$Efficiency$	Efficiency in network and computational resource usage	-	Benefit

The relationship between domain and criteria is non-uniform: for instance, in sensor networks L_{avg} and $Reliability$ are prioritized, while in real-time systems L_{p99} and $Tput$ carry higher weights. This dependency is modeled via AHP-derived weights.

We categorize criteria into "Cost" (to be minimized) and "Benefit" (to be maximized), as given in Table III.

TABLE III. Mathematical Definitions of Selection Criteria

Criterion	Mathematical Definition	Type
L_{avg}	$\frac{1}{N}\sum_{i=1}^{N}(t_{recv,i} - t_{send,i})$	Cost
L_{p99}	$P(L \leq x) = 0.99$	Cost
$Loss$	$(1 - \frac{N_{recv}}{N_{sent}}) \times 100$	Cost
$Ordering$	$\frac{N_{out_of_order}}{N_{recv}} \times 100$	Cost
$Reliability$	$\frac{N_{ack}}{N_{sent}} \times 100$	Benefit
$Throughput$	$\frac{Total_Bytes}{Total_Time}$	Benefit
$Scalability$	$\frac{Perf_{N_clients}}{Perf_{1_client}}$	Benefit
$Efficiency$	$\frac{Payload_Size}{Total_Packet_Size}$	Benefit

This categorization ensures that during the normalization phase of TOPSIS, the mathematical direction of each variable is correctly handled [5].

B. The Integrated AHP-TOPSIS Computational Workflow

The core of the proposed methodology lies in the synergy between the subjective prioritization of AHP and the objective, distance-based ranking of TOPSIS. The synergy between AHP and TOPSIS is illustrated in Fig. 2. This dual-layered approach mitigates the inherent weaknesses of using either method in isolation. While AHP can be prone to inconsistencies in human judgment, TOPSIS provides a stable mathematical anchor. Conversely, while TOPSIS requires predefined weights, AHP provides a rigorous mechanism for deriving them based on domain-specific expertise.

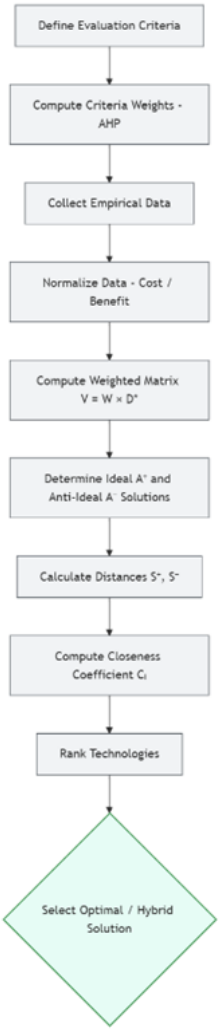

Fig. 2. Integrated AHP–TOPSIS evaluation process for technology selection.

1) Weight determination via the Analytic Hierarchy Process (AHP): The AHP phase begins with the decomposition of the decision problem into a hierarchy. At the summit is the objective (optimal protocol selection), followed by the criteria (latency, throughput, etc.), and finally the alternatives (HTTP/2, Kafka, MQTT).

The fundamental tool of AHP is the pairwise comparison matrix A. For a set of n criteria, the matrix $A = [a_{ij}]$ is a square $n \times n$ matrix where each element represents the relative importance of criterion i compared to criterion j based on the Saaty Fundamental Scale (ranging from 1 to 9) [4]. The matrix is reciprocal, such that $a_{ji} = 1/a_{ij}$ and $a_{ii} = 1$.

To derive the weight vector W, we solve the eigenvalue problem:

$$A \cdot w = \lambda_{max} \cdot w \tag{1}$$

where, λ_{max} is the principal eigenvalue. In practice, the geometric mean method is often used to approximate the weight vector:

$$w_j = \frac{\left(\prod_{j=1}^{n} a_{ij}\right)^{1/n}}{\sum_{i=1}^{n}\left(\prod_{j=1}^{n} a_{ij}\right)^{1/n}} \tag{2}$$

A critical requirement for the validity of AHP is the consistency check [4]. Since human judgment is stochastic and potentially contradictory (e.g., if $A > B$ and $B > C$, a human might mistakenly say $C > A$), we must calculate the Consistency Index (CI):

$$CI = \frac{\lambda_{max} - n}{n - 1} \tag{3}$$

The final validation is the consistency ratio ($CR = CI/RI$), where RI is the Random Index for a matrix of size n. If $CR \leq 0.1$, the weights are considered robust and logically consistent [4]. If not, the pairwise comparisons must be re-evaluated. This rigor is essential in M2M systems where a misaligned weight (e.g., underestimating the importance of tail latency in a transactional domain) could lead to catastrophic system failure.

2) Normalization and the construction of the decision space: Once the weights $W = (w_1, w_2, \ldots, w_n)$ are established, we move to the empirical evaluation of technologies. Let D be the decision matrix containing the raw performance data for m alternatives and n criteria. Because the criteria are measured in heterogeneous units (milliseconds, percentages, messages per second), they cannot be compared directly.

Non-linear normalization is employed [5] to transform all values into a dimensionless space $[0, 1]$. Unlike simple linear scaling, this approach preserves the relative significance of extreme values, which is vital for capturing the performance gaps between protocols like Kafka and HTTP/2.

For benefit criteria (e.g., Throughput, Reliability):

$$r_{ij} = \frac{x_{ij}}{\max_i(x_{ij})} \tag{4}$$

For cost criteria (e.g., Latency, Loss):

$$r_{ij} = \frac{\min_i(x_{ij})}{x_{ij}} \tag{5}$$

This transformation ensures that for all r_{ij}, a value closer to 1 always represents superior performance, regardless of whether the original metric was a "cost" or a "benefit".

3) The TOPSIS ranking algorithm: The Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) is based on the geometric principle that the chosen alternative should have the shortest Euclidean distance from the positive ideal solution (A^+) and the farthest distance from the negative ideal solution (A^-) [11].

First, we construct the weighted normalized decision matrix V:

$$v_{ij} = w_j \cdot r_{ij} \tag{6}$$

Next, we identify the ideal coordinates:

- Positive Ideal Solution (A^+): $A^+ = (v_1^+, v_2^+, \ldots, v_n^+)$, where $v_j^+ = \max_i(v_{ij})$.
- Negative Ideal Solution (A^-): $A^- = (v_1^-, v_2^-, \ldots, v_n^-)$, where $v_j^- = \min_i(v_{ij})$.

The separation measures for each alternative i are calculated using the n-dimensional Euclidean distance:

$$S_i^+ = \sqrt{\sum_{j=1}^{n}(v_{ij} - v_j^+)^2}, \quad S_i^- = \sqrt{\sum_{j=1}^{n}(v_{ij} - v_j^-)^2} \tag{7}$$

Finally, we compute the closeness coefficient (C_i):

$$C_i = \frac{S_i^-}{S_i^+ + S_i^-} \tag{8}$$

The value C_i serves as a universal performance index [5]. An alternative with $C_i = 1$ would represent a hypothetical "perfect" protocol, while $C_i = 0$ would represent the worst possible performer across all criteria.

C. Methodology Summary

For clarity and reproducibility, the complete methodological workflow can be summarized in the following sequential stages:

- Definition of functional domain.
- Identification of measurable evaluation criteria.
- Construction of AHP pairwise comparison matrix.
- Consistency validation of weight configuration.
- Normalization of empirical performance metrics.
- Computation of TOPSIS separation measures.
- Ranking via closeness coefficient C_i.

D. Illustrative Example

To demonstrate the operational logic of the proposed framework, consider a simplified scenario involving three communication alternatives: HTTP/2, MQTT, and Apache Kafka. Let the evaluation criteria be latency (L_{p99}), throughput, and reliability.

Assume that the AHP phase produces the following domain-specific weights:

$$W = (0.4, 0.35, 0.25)$$

After normalization and TOPSIS computation, assume the resulting closeness coefficients are:

$$C_{HTTP/2} = 0.62, \quad C_{MQTT} = 0.71, \quad C_{Kafka} = 0.84$$

In this illustrative scenario, Apache Kafka ranks first due to its superior throughput and reliability characteristics under the assigned domain priorities.

This example does not represent empirical validation, but serves to clarify the computational mechanics of the integrated AHP–TOPSIS workflow.

V. Discussion and Sensitivity Analysis

The results generated by the integrated AHP-TOPSIS methodology provide more than just a simple ranking; they offer a profound insight into the architectural trade-offs inherent in M2M communication. This section delves into the interpretation of the closeness coefficient and the stability of the model.

A. Conceptual Sensitivity Analysis

In multi-criteria decision-making frameworks, ranking stability is inherently dependent on the configuration of criterion weights. Since the AHP phase introduces domain-specific weighting derived from expert judgment, it is necessary to examine the structural robustness of the resulting ranking with respect to controlled perturbations of the weight vector.

Let w_k denote the weight of criterion k. A perturbation Δw_k modifies the weighted normalized matrix V, and consequently affects the separation measures S_i^+ and S_i^-. The perturbed closeness coefficient can be expressed as:

$$C_i' = \frac{S_i^-(\Delta w_k)}{S_i^+(\Delta w_k) + S_i^-(\Delta w_k)}.$$

Conceptually, three stability regimes may be distinguished:

- Dominant-Criterion Regime: Small perturbations in w_k induce ranking shifts, indicating high sensitivity to specific criteria.
- Balanced Regime: Moderate perturbations lead to proportional changes in C_i without rank reversal.
- Robust Regime: The ranking remains invariant under admissible perturbations, demonstrating structural stability of the decision space.

The explicit incorporation of a sensitivity-analysis perspective enhances the methodological credibility of the framework and provides decision-makers with insight into ranking resilience under evolving domain priorities.

B. Architectural Implications of the Closeness Coefficient

A high C_i value suggests that a protocol occupies a "sweet spot" in the multi-criteria space for a specific domain. For instance, in the real-time streaming domain, a protocol like Apache Kafka might achieve a high C_i not necessarily because it has the lowest latency, but because its superior throughput and scalability outweigh its latency costs when weighted through the AHP process.

Conversely, the model often reveals the limitations of "general-purpose" protocols. HTTP/2, while highly efficient for request-response cycles, frequently shows a declining C_i as the number of concurrent M2M connections increases, due to the overhead of its frame-management and the Head-of-Line (HoL) blocking issues at the application layer.

C. The Role of Hybridization in M2M Systems

One of the most significant findings of our methodology is that no single protocol is universally optimal. This supports the move towards hybrid communication architectures. By analyzing the distances S_i^+ and S_i^-, architects can identify protocols that are "specialists". If Protocol A has the best S^+ for reliability and Protocol B has the best S^+ for latency, a hybrid system can be designed where Protocol A handles control signaling and Protocol B handles the raw data payload.

D. Sensitivity Analysis: Testing Model Robustness

In any MCDM model, the final ranking is sensitive to the weights assigned in the AHP phase. To assess robustness, an OAT sensitivity-analysis procedure can be applied by varying the weight of a single criterion (e.g., Latency) by $\pm 20\%$ and examining the resulting changes in the C_i ranking [5]. This procedure can be used to identify stability zones in which the ranking remains invariant and regimes in which rank reversal occurs.

Conceptually, the methodology implies that: 1) Dominant Criteria: In the Transactional domain, the ranking is highly sensitive to the $Ordering$ and $Reliability$ weights. Even a small reduction in these weights can shift the preference from Kafka to a more traditional RDBMS-backed broker. 2) Resilient Criteria: $Throughput$ weights tend to have a more linear and less volatile impact on the final ranking, suggesting that most modern protocols are sufficiently optimized for volume, making other NFRs the true differentiators.

E. Practical Implementation Challenges

Implementing this methodology in a real-world industrial environment requires addressing the stochastic nature of empirical data. Network latency is rarely a constant; it is affected by "micro-bursts", background traffic, and hardware-level interrupts. Therefore, the input data for the decision matrix D should be derived from statistical distributions (e.g., 99th percentile values) rather than simple arithmetic means. Furthermore, the computational overhead of the AHP-TOPSIS process itself is negligible, meaning it can be integrated into "self-adaptive" M2M systems that dynamically switch protocols as network conditions change.

VI. Conclusion and Future Research Directions

This study has presented a domain-oriented, multi-criteria methodology for structured communication protocol selection in Machine-to-Machine (M2M) environments. By integrating the Analytic Hierarchy Process (AHP) with the Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), the proposed framework establishes a transparent and reproducible analytical workflow linking domain requirements to measurable performance criteria.

The primary contribution of this study is methodological. Rather than focusing on isolated protocol benchmarks, the framework defines a consistent decision-theoretic space in

which heterogeneous communication technologies can be evaluated according to domain-specific priorities. The explicit incorporation of functional taxonomy, measurable non-functional criteria, and tail-latency–centric evaluation enhances the rigor and interpretability of protocol selection decisions.

The proposed approach is not intended to identify a universally optimal communication protocol. Instead, it formalizes a structured mechanism for determining context-dependent suitability. By supporting dynamic weighting of criteria and accommodating hybrid architectures, the model reflects the practical realities of contemporary M2M deployments.

Limitations: The current study focuses on the conceptual and methodological formalization of the decision workflow. The empirical population of the decision matrix with domain-specific measurements, and the evaluation of ranking outcomes against deployment objectives, are treated as complementary research activities and will be reported separately.

Future research will focus on large-scale empirical validation of the framework across representative deployment scenarios and on extending the methodology toward adaptive decision models capable of responding to dynamic environmental conditions. The integration of uncertainty-aware extensions, such as Fuzzy-AHP and stochastic sensitivity modeling, constitutes a promising direction for further methodological refinement.

***Abstract*—Interoperability across heterogeneous information systems remains a persistent challenge, particularly in resource constrained contexts where infrastructures are fragmented and data formats remain incompatible. This study introduces a novel methodology that integrates generative Artificial Intelligence (AI) with the urbanization of information systems to enable scalable and seamless interoperability. The approach employs AutoGen AI, an open-source orchestration framework powered by Large Language Models (LLMs), specifically GPT-4o, to coordinate task-specific intelligent agents for data extraction, transformation, and harmonization. By converting disparate data into a standardized JSON representation, the architecture resolves both syntactic and semantic inconsistencies while simultaneously emphasizing multi-agent concurrency, distributed orchestration, and computational scalability, resulting in improved throughput, reduced latency, and enhanced robustness. A real-world healthcare case study is presented to illustrate the framework's effectiveness: heterogeneous clinical datasets were unified into a coherent JSON structure, enabling accurate health indicator generation and reliable decision support. Experimental results demonstrate substantial improvements in system connectivity, processing efficiency, and integration reliability, with potential to generalize far beyond the medical sector. Moreover, the methodology incorporates advanced prompt engineering and context-aware dialogue design, minimizing model hallucinations and ensuring trustworthy outputs in LLM-driven processes. Overall, the study positions generative AI not only as a promising solution for interoperability in health informatics, but also as a transformative paradigm for intelligent system integration across diverse domains characterized by distributed, heterogeneous environments.**

***Keywords*—Decision support systems; interoperability; generative Artificial Intelligence; Large Language Model (LLM); heterogeneous data sources; information system**

I. Introduction

The integration and interoperability of Health Information Systems (HIS) remain pressing challenges, particularly in developing countries where infrastructures are fragmented and data ecosystems are heterogeneous. As healthcare organizations increasingly adopt diverse digital platforms, the demand for seamless system communication and reliable data exchange becomes more urgent. Effective interoperability is not only important for consistent and accurate information sharing, but also for enhancing patient care, optimizing clinical workflows, and strengthening evidence-based decision-making [1]. However, the prevalence of autonomous, distributed, and technologically diverse data sources exacerbates these challenges, often resulting in inconsistent health indicators, organizational misalignments, and limited decision-making capacity [2].

To address these limitations, innovative and flexible approaches are required that can connect fragmented infrastructures while adapting to evolving requirements. In this study, we propose a novel methodology that leverages generative AI, specifically LLMs, to achieve interoperability across distributed medical data sources. Central to this approach is the concept of urbanization of information systems, a strategic framework for modernizing legacy infrastructures incrementally. By reducing the reliance on costly system replacements, this strategy supports the sustainable integration of cutting-edge AI-driven technologies into existing health ecosystems.

The proposed solution is operationalized through AutoGen AI, an open-source orchestration framework for LLM powered applications, implemented via AutoGen Studio and GPT-4o. It employs a network of intelligent agents to collect, transform, and harmonize heterogeneous datasets, thereby constructing a unified and machine-compatible platform. The normalized data is integrated into a central repository, enabling real-time analytics, computationally efficient processing, and reliable decision support.

This study proposes a scalable generative AI-driven interoperability methodology for fragmented healthcare information systems in developing countries, grounded in an urbanization information system strategy and implemented through AutoGen AI and GPT-4o. The contributions include a modular multi-agent harmonization workflow, a canonical JSON standardization layer for KPI-oriented decision support, and a real-world validation using precision, recall, and record-consistency metrics.

This methodology has been validated through a comprehensive real-world healthcare case study, which demonstrates its effectiveness in addressing interoperability challenges at scale. The findings highlight the role of generative AI as a catalyst for dynamic, scalable, and adaptive integration, yielding substantial improvements in data exchange, analytics efficiency, and healthcare service delivery. More broadly, this work underscores the potential of intelligent multi-agent orchestration as a generalizable paradigm for system interoperability in heterogeneous and distributed environments.

The remainder of this study is structured as follows: Section II provides a literature review covering heterogeneous data interoperability, generative AI in healthcare, and urbanization strategies for HIS. Section III details the proposed architectural framework and its technical components. Section IV discusses the results of the case study, presenting validation outcomes and key insights. Finally, Section V concludes by summarizing the contributions and outlining directions for future research.

II. Literature Review

This section presents related studies in the literature on interoperability approaches for heterogeneous data sources, the interoperability of medical data sources, and the urbanization of information systems.

A. Interoperability of Data Sources

With the rise of the Internet and Intranet, the exchange and sharing of information from distributed, autonomous, and heterogeneous data sources have become a fundamental requirement [2]. In such scenario, simultaneous access to multiple sources is often necessary, as they contain relevant and complementary information, emphasizing the importance of interoperability among these systems. Consequently, achieving interoperability and integrating data sources to provide users with a unified access interface is a significant challenge. This challenge encompasses three main aspects: data heterogeneity, source autonomy, and the evolving nature of sources [3].

Integrating disparate information systems requires addressing interoperability issues stemming from various forms of heterogeneity, including hardware platforms, software systems, and especially semantic differences. According to [4], interoperability entails collaboration between applications, specifically referring to the ability of independently developed tools to cooperate and function together. Interoperability means that source A can request and receive services from source B and use their features, thereby establishing interoperability between sources A and B. Data exchange represents a limited form of interoperation, where system A periodically transfers data to system B. Generally, two information systems are considered interoperable if they meet certain criteria: the ability to exchange messages and requests or the ability to work together as a single unit to accomplish a common task [4].

As noted by [5], two information systems are interoperable if: 1) they can exchange messages and requests; 2) they can function as a unit to achieve a shared task. These conditions imply that interoperable systems can leverage each other's functions, act as both clients and servers, and communicate effectively even if their internal components are incompatible. In [4], the authors outline several levels of interoperability:

- The most internal level within the architecture of data management systems, facilitated by specialized gateways programs that establish connections between systems, enabling one system (A) to access data from another (B). Such gateways are already available for many database management systems (DBMS).
- The intermediate level, which involves deploying a multi-database system. This software layer allows users to define their persistent views or perspectives on a set of databases. These systems ensure appropriate connections based on defined views, enabling distributed data access but not managing consistency constraints across different data sources.
- The highest level, where a global system is developed atop existing systems, ensuring overall coherence among them and providing the desired level of integration for a set of data sources.

Interoperability aims to enable effective communication between heterogeneous data models, ensure the integration of functionalities from distinct applications, and support coordination, data dissemination, training, and process validation. However, achieving interoperability is often hindered by three core challenges: conceptual, technological, and organizational barriers. To address these challenges and establish interoperability across multiple data sources, three main strategies can be utilized: the integrated approach, the unified approach, and the federated approach (see Fig. 1).

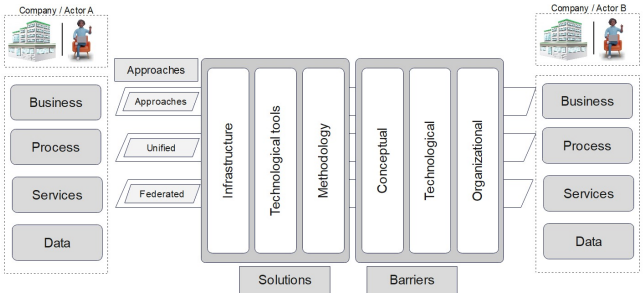

Fig. 1. Interoperability: Levels, barriers, approaches, and solutions.

B. Interoperability and Decision Support

Decision support information systems are a solution to the problems of integration and interoperability of heterogeneous information systems [6]. A decision support system is a truly integrated system that leverages a wide range of tools from various origins, such as specialized software, powerful machines, query tools, DBMS, etc., [7]. It is an information system dedicated to decision-making applications. These applications provide a set of information and tools made available to decision-makers to effectively support the decision-making process. Thus, it is a decision support system aimed at facilitating decision-making based on a wealth of heterogeneous data sources. Implementing such a system is a complex task that involves numerous challenges [8]. Its rigorous design is complicated by the multiplicity of data sources and the so-called complex data that may appear in non-numerical or non-symbolic [9].

A decision support system cannot be built independently of existing systems. Its development process requires a comprehensive vision of operational information systems. Two major phases characterize this process: the information extraction phase and the exploitation phase of the aggregated data from the warehouse.

The first phase involves extracting information from the original data sources, which are often heterogeneous and even distributed. This phase culminates in the construction of a data

warehouse. The integration module addresses the heterogeneity issues of various sources by incorporating them into a global source (GS). This global source is virtual, as the data used for decision-making remains stored in the original data sources and is only extracted during the warehouse update process. The construction module extracts relevant decision-making data and transfers it to the data warehouse while retaining, if necessary, changes in data states. The data warehouse consolidates extracts from source databases that are useful to decision-makers. It serves as a centralized collection of data, a specifically designed database, or a repository for Decision Support Information System (DSIS) applications.

The exploitation phase is handled by database experts. Their role involves restructuring the data in the warehouse to meet the needs of decision-makers. The reorganization module produces data marts. This reorganization aims to efficiently support data query and/or analysis processes. These data marts can be used by online analytical processing (OLAP) applications. To achieve this, the data imported into the marts is organized in a multidimensional manner. Data marts are derived from the warehouse and are tailored to specific analytical needs. The query module manipulates multidimensional data to analyse past trends and support decision-making. The data is represented in forms that facilitate comprehension and manipulation by non-technical decision-makers (tables, charts, maps, etc.).

A viable decision support system requires a specific and scalable data model. Its architecture demonstrates the management of two distinct configurations: the data repository (DW and DM) on the storage side (server), which allows access to all information, and the transactional side (client), which comprises analytical tools that ensure document presentation via graphical interfaces.

C. Generative AI and LLMs for Interoperability

Interoperability across heterogeneous data sources remains a major challenge, especially when information is embedded in unstructured formats or spread across distributed environments. Traditional approaches, ETL pipelines, ontology-based mappings, middleware, and decision support tools, require substantial human effort and often deliver limited scalability. Generative AI, and more specifically LLMs, has emerged as a promising solution to simplify multi-step processes, harmonize diverse inputs, and enable semantic alignment across systems.

Recent literature highlights the growing role of LLMs in data integration. In [10], the authors demonstrate their ability to facilitate entity extraction and resolution from heterogeneous sources by combining automation with human expertise in semi-autonomous pipelines. Similarly, [11] and [12] underline that, despite contextualization and reformulation capabilities, LLMs still struggle with private data access, discrimination between multiple sources, and scalability challenges. In the field of system interoperability, [13] investigates the translation of API calls into natural language.

Schema alignment and ontology matching also benefit from LLMs. In [14], the authors employ LLMs combined with Retrieval-Augmented Generation (RAG) to semi-automate schema harmonization, while [15] introduce Harmonia, an interactive framework integrating LLM reasoning with harmonization primitives. More recently, [16] evaluated LLMs4OM for ontology matching, showing mixed performance compared to traditional methods. In [17], the authors highlight that LLMs can generate Common Data Elements (CDEs) for biomedical research, though with modest interoperability scores. Additionally, [18] present TeaBERT, a knowledge-infused model improving medical entity normalization in multilingual contexts.

In healthcare, several studies demonstrate the effectiveness of LLMs for transforming clinical texts into standardized formats such as HL7 FHIR. In [19], [20], and [21], the authors show that, by using prompts, annotations, clustering, or RAG, LLMs can achieve high accuracy in generating structured FHIR resources, sometimes surpassing traditional NLP. Complementary work by [22] illustrates their potential for transforming laboratory results and mapping diagnostic codes, while [23] show how they can analyze echocardiogram reports to support natural language querying. These applications demonstrate the potential of LLMs to simplify data exchange, improve decision-making, and reduce the need for overly complex standardization.

Beyond clinical texts, [24] and [25] emphasize the importance of common type systems and ontologies to ensure semantic interoperability across biomedical terminologies. In [26], the authors propose retrieval architectures combining NLP with database technologies, while [27] show how ETL, NLP, and semantic web methods can achieve technical, syntactic, and semantic integration across healthcare institutions. Challenges remain in multilingual interoperability and ontology alignment, requiring closer collaboration between NLP and applied ontology [25].

Practical implementations further confirm these insights. In [28], the authors explore FHIR-enabled machine learning systems for improved interoperability and analysis, while [29] proposes a middleware to integrate structured sensor data with unstructured indigenous knowledge for environmental monitoring. Generative AI also shows strong potential in automating workflows and improving patient care [30][31], creating new data forms including text, images, and music [32], and advancing areas such as medical imaging, protein prediction, clinical documentation, and drug design [33][34].

Noteworthy generative models include GPT-4 [35], Claude [36], and PaLM2 [37], which have significantly advanced natural language processing and interoperability applications. Research by [38] shows the widespread adoption of ChatGPT among medical students in Nigeria, underscoring its accessibility and perceived utility. Furthermore, [39] highlight its ability to improve patient understanding and adherence to treatment.

Finally, new AI-driven methods are extending beyond data integration into clinical applications. In [40], the authors propose a privacy-preserving system for abnormal gait detection using encrypted video capture and ML classification. In [41], the authors develop a gait-based analysis model for Parkinson's disease with high accuracy, while [42] survey intelligent models combining NLP, deep learning, and speech recognition for neurological disease interpretation.

Overall, LLMs and generative AI represent a transformative force. They address computational challenges of interoperability in heterogeneous data environments and demonstrate

strong potential in healthcare applications, from clinical documentation to advanced diagnostics. The remaining challenges include prompt dependency, token limits, privacy preservation, and standardization, but evidence consistently shows their ability to bridge gaps between complex informatics infrastructures and practical use of healthcare.

1) Critical synthesis and research gap: Overall, the literature shows that interoperability is commonly addressed through three major directions: i) engineering-based solutions such as ETL pipelines and middleware, ii) semantic approaches relying on ontologies and mapping rules, and iii) decision support architectures built on data warehouses. These methods can be effective in stable and well resourced environments, yet they often require substantial manual effort, rigid schema assumptions, and continuous maintenance, which limits their scalability in rapidly evolving and resource constrained settings. More recently, LLM-based approaches have introduced promising flexibility by enabling semantic reasoning and dynamic transformation; however, they remain sensitive to prompt quality, context limitations, privacy constraints, and the risk of hallucinated outputs. Taken together, these limitations motivate the need for a framework that combines the adaptability of generative AI with a structured modernization strategy, enabling scalable harmonization without requiring disruptive infrastructure replacement.

D. The Urbanization Approach in Health Information Systems

The Urbanization of Health Information Systems is a strategic method designed to enhance the interoperability, agility, and efficiency of health information systems, particularly in developing countries such as Cameroon. According to the World Health Organization (WHO), health information systems must align with public health strategies to ensure their effectiveness. However, the systems currently deployed in contexts like Cameroon are often inadequate, poorly adapted to strategic goals, and suffer from limited interoperability [43]. These systems are fragmented, unstable in the face of organizational and regulatory changes, and difficult to use in collaborative processes [2].

Health systems in developing countries lack coherent digitization. They are characterized by the absence of reliable and accessible data, as well as fragmented and unsecured information systems [44]. These challenges hinder coordination among healthcare institutions, thus impeding the effective implementation of public health policies.

Inspired by urban city planning, the urbanization of information systems aims to modernize existing systems by aligning organizational objectives with technological opportunities while adhering to common rules to ensure quality and consistency [45]. This approach promotes an open, scalable, and adaptable architecture, avoiding costly system overhauls [46].

In the context of health information systems, urbanization entails the development of a national urbanization strategy, supported by general rules for interoperability, accessibility, and security. Such a strategy facilitates information exchange and collaboration among public, private, and non-governmental actors [43]. It also supports the integration of technological innovations such as the Internet of Medical Things (IoMT) and cyber-physical systems [47].

By combining top-down and bottom-up approaches, the urbanization of health systems can improve the quality of care, enhance professional practices, and foster patient engagement in managing their health. Achieving this requires an open architecture, semantic data management, and the integration of decision-support tools [48].

1) Positioning of the proposed approach: The urbanization of information systems offers a well-established strategy for incrementally modernizing healthcare infrastructures, particularly in developing countries. However, existing studies provide limited operational mechanisms for automating semantic harmonization across heterogeneous and autonomous data sources. In this work, generative AI is introduced as the enabling layer that translates urbanization principles into practice through intelligent multi-agent orchestration, thereby connecting strategic modernization goals with concrete interoperability execution.

E. Comprehensive Summary of Key Articles on Interoperability with Generative AI

To make the comparison across existing studies more explicit, Table I synthesizes representative works and highlights not only their contributions, but also recurring limitations, particularly in terms of scalability, semantic consistency, and feasibility in low-resource environments.

The main goal of this study is to design an intelligent tool based on AutoGen AI and GPT-4o, capable of producing reliable outputs with high accuracy and reduced error rates in interoperability driven tasks. Achieving this performance relies on optimized prompts, structured multi-agent workflows, and validation mechanisms designed to mitigate hallucinations and ensure consistent transformations.

III. Proposed Architectural Framework

The methodology presented in this study leverages generative Artificial Intelligence, particularly large language models, to address challenges related to the interoperability and integration of heterogeneous and distributed medical data sources in developing countries.

AutoGen AI, an open-source framework by Microsoft, enables collaborative multi-agent systems using large language models to solve complex tasks. It integrates customizable agents, tools, and human input, supporting scalable deployment and research innovation.

The main goal of this study is to demonstrate how generative AI, specifically through Microsoft's Autogen AI, can be applied to overcome interoperability issues associated with disparate medical data. This approach facilitates the seamless integration of information from diverse sources into a centralized environment while ensuring the consistency and quality of processed data.

The methodology is primarily based on generative AI technologies, notably Autogen AI, structured around an agent-based approach for each phase of data processing. These agents are specifically configured to perform various tasks, ranging

TABLE I. COMPREHENSIVE SUMMARY OF KEY ARTICLES ON INTEROPERABILITY WITH GENERATIVE AI

Citation Key	Description	Limitations
[26]	Proposes architectures that integrate NLP with databases for querying heterogeneous clinical data sources.	Limited adaptability to evolving data formats and semantic inconsistencies.
[25]	Discusses linguistic challenges in biomedical ontologies and emphasizes semantic alignment.	Persistent misconceptions in ontologies and difficulty in integrating multiple terminologies.
[27]	Uses ETL, NLP, and semantic web technologies to improve syntactic and semantic interoperability.	Lack of standard clinical representation and issues with multi-language support.
[28]	Explores machine learning systems leveraging FHIR for clinical interoperability.	Challenges include scalability and lack of robust clinical validation.
[29]	Proposes middleware architecture to unify structured and unstructured environmental data using semantic tools.	Limited scalability and potential domain specificity.
[22]	LLMs used to extract structured insights from unstructured clinical records like lab results and diagnosis codes.	Complexity in mapping across coding systems.
[23]	Uses LLMs to query echocardiogram histories with natural language.	Focused on specific report types.
[10]	Applied LLMs for entity extraction and resolution from heterogeneous sources in higher education; designed semi-autonomous pipelines combining automation and human expertise.	Manual integration remains time-consuming; success highly dependent on prior modeling decisions.
[11]	Drew lessons from data integration research; explored LLMs for contextualization and reformulation in multi-source access.	Difficulty handling private data, discriminating between multiple sources, and achieving scalability.
[19][20]	Used multiple prompts and manual annotations (3,671 clinical text excerpts) to transform clinical texts into FHIR resources with GPT-4, Llama-2-70B, and Falcon-180B; compared with existing NLP tools.	High dependency on prompt design; token limitations; incomplete medical terminologies; risk of hallucinations.
[21]	Employed clustering, prompt engineering, and RAG to transform structured clinical data into HL7 FHIR format.	Difficulty linking complex resources; limited scalability; lack of user-friendly interfaces.
[14]	Applied LLMs and RAG to semi-automate schema alignment in healthcare data integration.	Preliminary research; limited efficiency and scalability.
[15]	Proposed an interactive harmonization system combining LLM reasoning, harmonization primitives, and a user interface.	Process remains complex and time-intensive; further research required.
[16]	Developed an ontology matching framework using RAG + LLM, including confidence filtering and post-processing.	Limited context length; risk of hallucinations; underperformed traditional methods on Bio-ML tasks.
[17]	Leveraged LLMs with human-in-the-loop (HITL) to generate Common Data Elements (CDEs) from biomedical ontologies and corpora.	Low mapping efficiency (32.4%); modest interoperability score (53.8/100); manual revisions still required.

from converting data into uniform formats to managing interoperability within a data warehouse. This structure not only optimizes the flow of information but also ensures efficient data harmonization, thereby enabling in-depth analyses and informed decision-making.

By integrating these advanced technologies, our methodology aims to establish an interoperable data ecosystem that meets the specific needs of healthcare systems in developing countries. It also provides a framework for continuous innovation and the improvement of medical care practices, thereby contributing to enhanced healthcare quality and better patient outcomes.

A. An Approach Based on the Urbanization of Information Systems

The aim of medical data interoperability is to federate data sources for effective decision-making. To achieve this, the Urbanization of Information Systems methodology is adopted, focusing on four levels of concern: business, functional, application, and technical. It balances organizational strategy implementation, system consistency, efficiency, and cost-effective integration of new technologies.

This structured approach involves key steps, including study planning, strategic axis review, current situation analysis, strategy definition, convergence planning, strategy publication, and updates. Applied to medical data interoperability, this methodology results in a framework (Fig. 2) tailored to the integration of distributed and heterogeneous data sources.

The proposed model consolidates consistent medical data into a decision-support-oriented data warehouse. It features: i) Environmentally Open Architecture (Facilitates sharing and integration of distributed data across healthcare stakeholders), ii) Integrated Architecture (Unifies data from autonomous sources into a flexible ecosystem), and iii) Decision-Support Architecture (Provides tools like indicators and statistical analyzis for informed decision-making). This system serves as a monitoring tool, offering valuable insights into medical phenomena while supporting strategic healthcare programs.

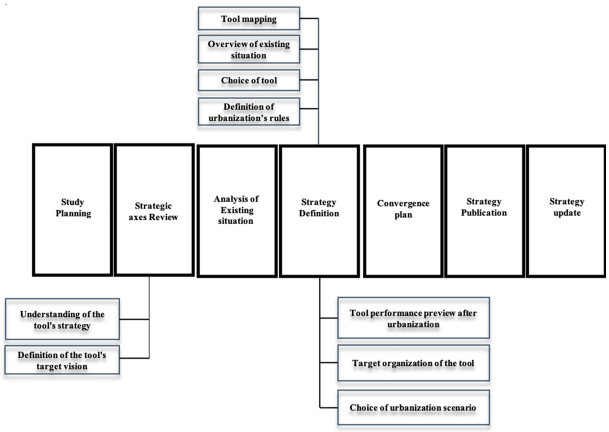

Fig. 2. Implementation of the proposed methodology for information system urbanization, supporting interoperability across heterogeneous data sources.

B. Proposed Architectural Framework

This section addresses the overall architecture of the interoperability methodology for medical data sources, applicable in urban areas of developing countries. Fig. 3 given below provides an overview of our methodological approach.

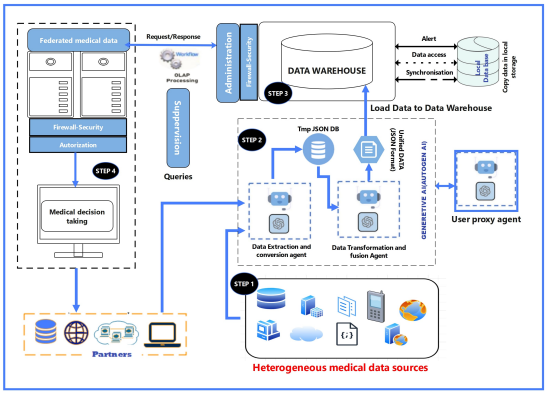

Fig. 3. Interoperability architecture for medical data sources based on the use of generative AI (AutoGen AI framework).

This architecture outlines a complex and structured process to manage the interoperability of heterogeneous medical data, ensuring its transformation, unification, and security with the help of generative AI. The ultimate goal is to create a federated and secure system capable of supporting precise and rapid medical decision-making by using unified and reliable data.

AutoGen AI, an open-source framework developed by Microsoft, streamlines the development of applications leveraging large language models through a multi-agent approach designed to collaboratively tackle complex tasks. These customizable agents, inspired by human teamwork dynamics, integrate LLMs, diverse tools, and human contributions to optimize their performance. AutoGen supports local development of multi-agent systems before deploying them in distributed cloud environments. This innovative platform establishes a synergistic framework where the collective capabilities of agents surpass those of any individual agent, thereby facilitating advanced research and development in artificial intelligence.

The AutoGen AI Framework leverages specialized agents and GPT-4o language models to automate the extraction, transformation, and integration of heterogeneous medical data into a unified platform. These agents perform specific tasks, such as data normalization, semantic mapping, and error correction, while the LLMs ensure contextual understanding and conversion of diverse formats. The system operates through orchestrated workflows with real-time feedback, enabling scalable and efficient data harmonization. This approach ensures compliance with regulatory standards and supports decision-making in healthcare systems.

1) Architectural design rationale: The architecture adopts a multi-agent design because interoperability is inherently a multi-step process that benefits from task specialization (extraction, normalization, semantic alignment, and validation). AutoGen AI was selected as it natively supports agent orchestration, tool integration, and human supervision, which are essential for controlled execution in sensitive healthcare contexts. A canonical JSON representation was chosen as the primary interoperability layer due to its lightweight structure, ease of validation, and direct compatibility with downstream decision-support pipelines. Finally, the data warehouse component ensures long-term consistency and enables systematic KPI computation without disrupting operational source systems, in line with information-system urbanization principles.

a) Step 1. Data extraction and conversion: In this initial step, data is extracted from multiple heterogeneous and distributed medical sources. These sources may include databases, medical records management systems, connected devices, or even local files. The extracted data can be in various formats (e.g., XML, CSV).

The Data Extraction and conversion Agent is responsible for collecting the necessary and relevant data for interoperability. It verifies the formats of the extracted data and converts non-JSON formats into a standardized JSON format. The converted data is stored in a temporary database, TMP JSON DB, for further processing. The conversions are performed without any data loss or alteration.

b) Step 2. Data transformation and fusion: This phase is managed by the Data Transformation and Fusion Agent, which is responsible for data transformation, the handling of heterogeneity issues, and the fusion of multiple JSON files into a single coherent JSON file. The agent reads all JSON files stored in the TMP JSON DB and applies transformation rules provided via the prompt and the tool, including: i) identifying inconsistencies across files (e.g., variations in keys, data types, structures, etc.); ii) resolving these inconsistencies to ensure uniform, consistent, and interoperable outputs; iii) performing any additional operations required by the transformation rules.

Once the transformation is complete, the agent merges all files into a single JSON file, removing redundancies, null values, and non-pertinent data to produce a clear and unambiguous result. Owing to the quality of the preceding transformation, the fusion process is seamless and coherent. The merged file is stored in the Unified Data database and subsequently transferred to the Data Warehouse, which may be performed using a dedicated data-loading tool.

c) Step 3. Storage and administration: The unified data is transferred to a Data Warehouse for centralized and secure storage. Additionally, some data is saved in a local database for faster access or specific processing needs. This step also includes: Data Security (Access to the data is controlled through firewalls and authorization mechanisms); Monitoring (Continuous supervision ensures data integrity); Administration (Administrators manage data, configure access rules, and address user requests);

d) Step 4. Data utilization for decision-making: In this step, federated data is leveraged to support medical decision-making. ETL (Extraction, Transformation, Loading) tools are employed to extract the necessary indicators and convert them into actionable insights for clinical decisions. Health partners can also access the data for analysis or to offer additional services.

AutoGen AI plays a central role in steps 1, 2, and 3

by orchestrating the agents responsible for data extraction, verification, transformation, and unification. Meanwhile, ETL tools take over in step 4, preparing the necessary indicators to facilitate decision-making. ETL tools can also intervene between steps 2 and 3 by assisting in loading unified files into the Data Warehouse.

User Proxy Agent: The User Proxy Agent is pivotal in coordinating and supervising interactions among the various agents within the AutoGen AI system, acting as a human interface within the data interoperability process.

By bridging AI and human expertise, the User Proxy Agent ensures that the AutoGen AI framework remains adaptive, reliable, and aligned with the intricate requirements of medical workflows.

C. Workflow Design for Interoperable Medical Data Architecture

Fig. 4 below provides a simplified representation of the architecture's functionality.

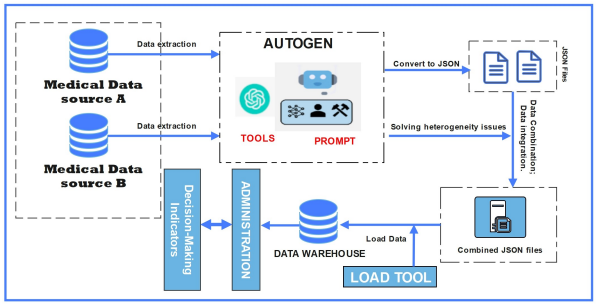

Fig. 4. Workflow of the interoperability architecture for medical data sources based on the use of generative AI (AutoGen AI framework).

1) Conceptual vs. implementation perspective: Conceptually, the proposed framework is organized into four layers: i) heterogeneous medical data sources, ii) AI-driven harmonization and interoperability management, iii) canonical JSON integration and centralized storage, and iv) analytics and decision support services for KPI generation. Implementation wise, these layers are operationalized through AutoGen AI agents, GPT-4o prompting strategies, and dedicated tools for extraction, transformation, validation, and loading. This separation clarifies the methodological principles independently of the technical deployment choices.

This workflow outlines the various steps and processes involved in addressing the challenges of interoperability, integration, and merging of medical data from multiple sources. Its goal is to centralize information and facilitate decision-making. The LLM plays a important role at each key step by using "Tools" (capabilities) and "prompts" (specific instructions) to manage data extraction, transformation, integration, and storage.

a) Tool: A tool represents a specific block of code or script, typically written in Python, that allows AutoGen AI Agents to perform concrete actions or interact with external systems. A tool acts as a "toolkit" for AutoGen AI agents, enabling them to perform complex operations they would not be able to execute without explicit guidance. Each tool is designed to accomplish a specific task and is executed by an agent whenever a prompt triggers its use.

b) Prompt: A prompt is an instruction or request directed to an AutoGen AI agent to perform a specific task. Unlike a tool, which is a piece of code, a prompt is a sentence or query that guides an AutoGen AI agent on what it needs to accomplish. The agent interprets this instruction and, as needed, uses one or more Tools to complete the requested task.

c) Workflow explanation: The workflow encompasses a series of steps designed to address the challenges of interoperability, integration, and unification of medical data from multiple sources. Below is a detailed explanation of the process:

- Data extraction from sources: The Data Extraction and conversion Agent is instrumental in retrieving essential data from medical databases (Data Sources A and B in the diagram) and preparing it for further processing. It begins by connecting to the data sources using predefined Tools to extract only the relevant information needed. To ensure data standardization, the agent analyzes the format of the extracted data, retaining it as JSON if already compliant or converting it to JSON when necessary, thus creating a uniform structure for subsequent stages. Finally, the prepared JSON files are systematically stored in a dedicated repository called the JSON File DB.
- Management of heterogeneities: The Data transformation and fusion Agent processes raw JSON files from the JSON File DB, addressing differences in data formats to ensure interoperability. The process begins with reading the JSON files from the repository, followed by schema standardization to ensure data consistency. This involves unifying key names and types, maintaining data type consistency for values, and resolving semantic variations and structural discrepancies. Once standardized, the are ready to be merged. The rules, requirements, and constraints of the transformation and merging are provided by the tool called **Transform**.
- Combination or merging of prepared JSON files: The Data transformation and fusion Agent consolidates all prepared JSON files into a single, coherent dataset, ready for storage in the Data Warehouse. The agent merges the JSON files into a unified dataset by eliminating duplicates to enhance data clarity and efficiency, processing or removing fields with null values to prevent inconsistencies, and applying a homogeneous schema to create a consolidated file.
- Storage in the data warehouse: The finalized dataset is prepared for long-term storage and use. The merged JSON file is stored in a centralized Data Warehouse, which serves as a repository for federated data and provides an integrated, ready-to-use version of the data suitable for decision-making, analysis, or reporting.
- Administration and decision support indicators: Structured in two complementary components: data gov-

ernance and security, and analytical decision support. The governance layer establishes strict access controls and privacy safeguards within the Data Warehouse, ensuring that only authorized users handle sensitive information while upholding confidentiality and data integrity, which is important in healthcare. Decision support indicators are derived through systematic analysis of stored data, enabling the identification of health trends, forecasting of treatment demands, and generation of actionable recommendations. Together, these processes empower healthcare professionals and administrators to enhance care quality, allocate resources efficiently, and strengthen data-driven strategic planning.

The workflow ensures the seamless integration, transformation, and utilization of medical data, delivering a robust and secure system for healthcare decision-making. Interoperability management is achieved through the coordination of two AutoGen AI agents: The Data Extraction and conversion Agent is responsible for retrieving raw data from various sources and conversion of each data in JSON file. The Data transformation and fusion Agent standardizes, harmonizes diverse datasets, combines and consolidates data into a unified format. All these agents are orchestrated by the User Proxy to ensure efficiency and consistency across the workflow.

IV. Results and Discussion

In order to validate the proposed methodology, this section describes the different case studies and the results obtained.

A. Context of the Case Study

To test and validate our interoperability model, we used three heterogeneous medical data sources from three Central African countries. These data, sourced from MSSQLSERVER (Cameroon), MySQL (DR Congo), and Excel (Gabon), contain information on diseases diagnosed over a year, prescribed treatments, and patient progress.

1) Reproducibility and data availability: The datasets used in this case study correspond to real clinical records and cannot be publicly released due to privacy and institutional restrictions. To support experimental reproducibility, we provide the complete data schema, record volumes per source, field-level statistics (missingness and value distributions), and anonymized examples illustrating structural and semantic heterogeneity. We also document the harmonization rules (key mapping, normalization, deduplication, and validation) and describe a synthetic data generation procedure that preserves the original schema characteristics, enabling independent replication of the end to end workflow under equivalent conditions. Table II presents dataset summary for the case study.

TABLE II. Dataset Summary for the Case Study

Dataset	Country	Format / DB	Records
DS_1	Cameroon	SQL Server (DIAG table)	2000
DS_2	DR Congo	MySQL (detect table)	1997
DS_3	Gabon	Excel (gabon_patients.xlsx)	1978
Unified dataset (canonical JSON)			5975

Table III presents the various fields from each data source.

Interoperability management was entrusted to two AutoGen Studio agents using the GPT-4-o model, yielding promising results.

2) Data extraction and verification: The first agent, responsible for extraction, verification and conversion, retrieved data from the three sources and converted them into JSON files.

The Data Extraction and conversion Agent relies on specific tools, including connection parameters for databases, directories where extracted data is stored, retrieving data from external sources.

To optimize the agent's guidance and ensure its proper functioning, four dedicated tools are provided. The tool *sqlservercon* defines the connection parameters, enables data extraction from the SQL Server database, and performs task verification; its implementation script is available on GitHub (not yet deployed for public use). Similarly, the tool *mysqlcon* establishes the connection parameters, supports data retrieval from the MySQL database, and ensures task validation, with its corresponding implementation script also accessible on GitHub (not yet deployed for public use). Finally, the tool *excelcon* specifies the connection settings, facilitates data extraction from Excel files, and provides task verification, with the related implementation script likewise available on GitHub (not yet deployed for public use).

The data extraction and conversion prompt providing instructions to the agent is as follows:

```
You are a data extraction agent. Your mission: read raw data
↪  from three sources and write them to JSON with no
↪  alteration whatsoever.
AVAILABLE TOOLS
sqlservercon: SQL Server (table DIAG) → produces ca.json
mysqlcon: MySQL (table detect) → produces rdc.json
excelcon: Local Excel (path handled by the tool) → produces
↪  ga.json
Common output folder: D:\AUTOGEN\EXTRACTFILES
OBJECTIVES (for EACH source)
Read 100% of the data.
Convert to standard JSON, strictly identical to the source
↪  values.
Write to D:\AUTOGEN\EXTRACTFILES, overwriting existing
↪  files.
Enforced file names: ca.json (SQL Server), rdc.json (MySQL),
↪  ga.json (Excel).
CONSTRAINTS
No processing/normalization/sorting/typing. Zero alteration.
JSON must be valid and parsable.
VERIFICATION / EVALUATION
Verify the existence of all three generated files.
Check integrity: source_count == json_count (and values
↪  unmodified).
Produce small audit charts/diagrams (without modifying the
↪  data).
Produce Acccuracy, precision, lost
EARLY STOP CONDITION
If all three tasks are completed successfully and integrity
↪  is confirmed for each source, then produce a concise
↪  final report (status, file paths, integrity metrics) and
↪  stop immediately with no further actions.
EXPECTED OUTPUTS
Files: D:\AUTOGEN\EXTRACTFILES\ca.json, rdc.json, ga.json
Final report: for each source → success/failure, file path,
↪  source_count, json_count, integrity_ok,
↪  warnings/anomalies. Produce Acccuracy, precision, lost
```

This prompt defines a data extraction agent that retrieves raw data from SQL Server, MySQL, and Excel, exporting them into JSON files with no alteration. It enforces strict file naming, location, and integrity checks to guarantee one-to-one correspondence between source and output. Audit metrics

TABLE III. VARIOUS FIELDS FROM EACH DATA SOURCE

COUNTRY	CAMEROON (SQL Server)	DR CONGO (MySQL)	GABON (Excel)
FIELD	• PATIENT_ID • COUNTRY • AGE • DIAGNOSIS • TREATMENT • CONSULTATION_YEAR • STATUS	• p_code • Country_code • Year_of_Birth • Disease • Medication • Year_of_Diagnosis • Outcome	• PatientID • Country • Date_of_birth • Condition • Medication • VisitYear • Status

(accuracy, precision, loss) and charts ensure transparency of the process. Finally, a concise report validates completeness and correctness before termination.

3) Data transformation and fusion: The second agent(Data Transformation and Fusion Agent), specializing in data transformation, the handling of heterogeneity issues, and the fusion of multiple JSON files into a single coherent JSON file. To accomplish this task, it relies on the following elements:

a) Tool called Transform: This tool enables the agent to manage file reading and access paths, normalize fields and values, address heterogeneity issues, compute derived attributes (such as age), enforce data quality controls, apply processing and merging constraints, and generate detailed execution reports.

The implementation code of the **Transform** tool is available on github (not yet deployed for public use).

After the transformations, the various files are merged into a single structured file. The text below presents the prompt for the transformation and unification agent:

```
ROLE
Unify three JSON sources into one standardized file using
↪  the tool "transform" only.
TOOL
- Use "transform" for ALL steps (load, map, compute AGE,
↪  dedupe, normalize, write, report). Do not implement
↪  logic outside the tool.
INPUTS
- D:\AUTOGEN\EXTRACTFILES\ca.json   (SQL Server)
- D:\AUTOGEN\EXTRACTFILES\rdc.json  (MySQL)
- D:\AUTOGEN\EXTRACTFILES\ga.json   (Excel; may be {Sheet:
↪  [rows]}; concatenate all rows)
TARGET SCHEMA
IDPATIENT (string), COUNTRY (string), AGE (int), DIAGNOSIS
↪  (string), TREATMENT (string), CONSULTATION_YEAR (int),
↪  STATUS (string)
KEY MAPPING (case/underscore/space-insensitive)
IDPATIENT ← p_code, PATIENT_ID, PatientID, id, ID, IdPatient
COUNTRY ← Country_code, COUNTRY, Country
AGE ← AGE
DIAGNOSIS ← Disease, Condition
TREATMENT ← Medication, drug
CONSULTATION_YEAR ← VisitYear, Year_of_Diagnosis,
↪  YearOfDiagnosis
STATUS ← Outcome, Status
Birth fields for AGE: Year_of_Birth, Date_of_birth (and
↪  variants)
AGE RULES
- If AGE missing/invalid and birth year/date available:
  - If CONSULTATION_YEAR present: AGE = CONSULTATION_YEAR -
  ↪  Year_of_Birth (or year(Date_of_birth))
  - Else: AGE = (current year) - Year_of_Birth
- If result <0 or >120 → AGE = null
LIGHT NORMALIZATION
- Cast AGE, CONSULTATION_YEAR to int when possible; else
↪  null
- Trim spaces for COUNTRY/DIAGNOSIS/TREATMENT/STATUS (do not
↪  change case)
- COUNTRY codes → canonical: {CD,RDC→"DR Congo";
↪  CM,CMR→"Cameroon"; GA,GAB→"Gabon"}; otherwise keep as-is
- Do not rewrite DIAGNOSIS/TREATMENT/STATUS semantically
DEDUPLICATION
- Composite key: (IDPATIENT, COUNTRY, DIAGNOSIS,
↪  CONSULTATION_YEAR)
- Keep the most complete record (most non-null fields);
↪  count conflicts/removed duplicates
OUTPUT
- Write: D:\AUTOGEN\EXTRACTFILES\unifiedMedicalData.json
↪  (overwrite if exists)
VERIFY & REPORT
- Report: N_ca, N_rdc, N_ga, N_in (sum), N_out, duplicates
↪  removed, conflicts resolved
- % rows with computed AGE; simple COUNTRY distribution
- Confirm JSON written and parsable
Produce small audit charts/diagrams (without modifying the
↪  data).
Produce Acccuracy, precision, lost
EARLY STOP
- On success (file written + checks done): output concise
↪  final report and stop immediately.
```

This prompt defines a transformation workflow to merge three heterogeneous JSON sources into a single standardized schema. All operations mapping, age computation, normalization, deduplication, and reporting are delegated to the tool transform. It ensures data consistency, enforces validation rules, and resolves duplicates transparently. Final output is a unified JSON file plus integrity metrics and audit charts, ensuring reliability and reproducibility.

B. Results

The case study highlights the effectiveness of generative Artificial Intelligence(the use of AutoGen Studio and the GPT-4o model) in enhancing interoperability across distributed and heterogeneous healthcare systems. The proposed approach is built upon an architecture of intelligent agents capable of autonomously extracting, transforming, and harmonizing medical data from multiple sources, while accounting for the specific constraints of clinical environments. This is achieved through a strategy based on the urbanization of information systems, which enables rapid and flexible integration without requiring substantial restructuring of existing infrastructures. The process demonstrates a very low error rate and strong performance in interpreting medical data. Hallucination risks were substantially reduced through constrained prompting, tool-based execution, and systematic validation, even when processing noisy or non-standardized records, thereby ensuring reliable normalization and consistent outputs for both information systems and end users. Moreover, unified access to harmonized data improves real-time medical decision-making, while the modular architecture supports scalability and adaptability across diverse clinical settings.

Step by step, the obtained results are as follows:

1) Data extraction and conversion: This section produced the following results:

a) Successful extraction: Data were successfully extracted and converted from multiple sources without errors or data loss. The DIAG table from MSSQLSERVER and the detect table from MySQL were both converted without issues, while the Excel file gabon medical gabon_patients.xlsx was transformed into JSON with data integrity fully preserved.

b) Verification and encoding management: All JSON files were validated and encoded in UTF-8, with any potential encoding issues addressed by employing alternative character sets such as Latin1, ISO-8859-1, and Windows-1252.

c) Overall results: No data was lost or altered during extraction, and a "SUCCESS" message appeared for each completed task. The same number of rows for all three sources when comparing input and output. The same number of columns for all three sources when comparing input and output. No data loss for any of the three sources, with 97% to 99% of accuracy.

Table IV given below presents a comparative summary of record counts from the external sources (SQL Server, MySQL, Excel) and from the JSON files extracted and converted by the agent.

According to the table, all input records match exactly with the output records in terms of the number of rows. Accuracy and Precision prove that Data was extracted and converted without loss or alteration.

The diagram below (Fig. 5) illustrates the success of the data extraction and conversion process.

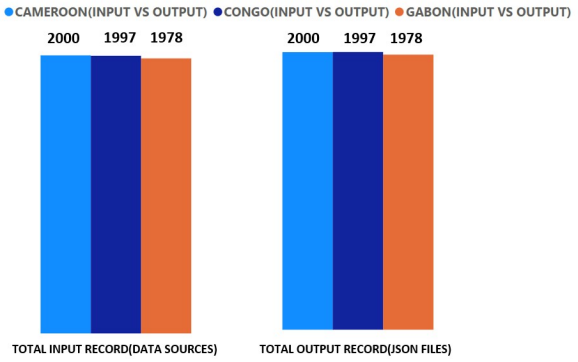

Fig. 5. This figure shows that all records are matched for each country. The correspondence is perfect, as the values for INPUT RECORDS are equal to the values for OUTPUT RECORDS.

2) Data verification and fusion:

a) The result is as follows: The unified JSON file called **unifiedMedicalData.json** was generated correctly with no errors or ambiguities as a direct result of rigorous transformation and careful resolution of data heterogeneity as follows.

b) Key standardization: A standard key-value mapping (**KEY_MAPPING**) was applied to harmonize field names across the three JSON inputs. Heterogeneous fields (e.g., Year_of_Birth, Date_of_birth) were consolidated under the single canonical key **AGE**; diagnostic fields (Disease, Condition) under **DIAGNOSIS**; and visit fields (VisitYear, Year_of_Diagnosis) under **CONSULTATION_YEAR**. Country codes were normalized to canonical labels (e.g., CM/CMR → Cameroon, CD/RDC → DR Congo, GA/GAB → Gabon).

Problematic files with non-UTF8 encodings were automatically re-decoded and validated.

Numeric casts were enforced for **AGE** and **CONSULTATION_YEAR** when possible. Leading and trailing spaces were trimmed from **COUNTRY**, **DIAGNOSIS**, **TREATMENT**, and **STATUS**, without semantic modification.

All three sources were successfully unified into a single standardized JSON with uniform keys and validated numeric types. Encoding issues were auto-corrected. Deduplication preserved all unique information while eliminating redundant entries.

c) Overall outcome: No information was lost, and the resulting dataset offers a homogeneous, coherent structure ready for use in decision-support systems.

Table V below summarizes the results of the transformation and unification agent.

The table shows a very good accuracy, precision, and recall of 0,97%, confirming that all data from the various files are accurately reflected in the unified file.

The table confirms that all heterogeneity issues were successfully resolved, and all transformed files maintain the same key names and types. The identified common keys are: **IDPATIENT**, **COUNTRY**, **AGE**, **DIAGNOSIS**, **TREATMENT**, **CONSULTATION_YEAR**, **STATUS**.

The diagram below (Fig. 6) illustrates the success of the data transformation and fusion process. A bar chart of the final result is given.

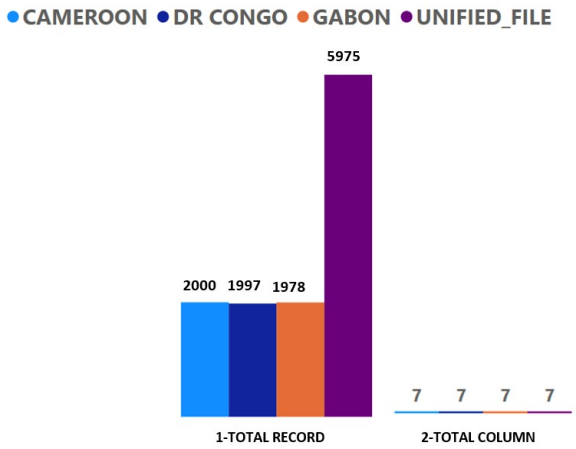

Fig. 6. Final result comparison diagram.

The unified file consolidates all records from the three countries (2000 + 1997 + 1978 = 5975), confirming that the data merging process, in terms of the number of rows, is a success.

All entities (Cameroon, DR Congo, Gabon, and Unified_File) have the same number of columns (7). This indicates

TABLE IV. DATA EXTRACTION AND CONVERSION RESULTS TABLE

MEASURES	CAMEROON(SQL SERVER)	DR CONGO(MYSQL)	GABON(EXCEL)
1-TOTAL RECORD(SOURCES)	2000	1997	1978
2-TOTAL RECORD(JSON FILES)	2000	1997	1978
3-ACCURACY	0,97	0,97	0,98
4-PRECISION	0,98	0,98	0,99

TABLE V. THE RESULTS OF THE UNIFICATION AGENT

MEASURES	CAMEROON	DR CONGO	GABON	UNIFIED_FILE
1-TOTAL RECORD	2000	1997	1978	5975
2-TOTAL COLUMN (KEYS)	7	7	7	7,00
3-ACCURACY	0,96	0,96	0,98	0,97
4-PRECISION	0,98	0,98	0,99	0,97
5-RECALL MATCHED	0,98	0,98	0,99	0,97

that the merging of the various files was also successfully executed in terms of column consistency.

This chart demonstrates the successful integration of individual data into a consolidated file (Unified_File).

The results are consistent with the defined methodology.

- Sensured complete extraction of heterogeneous medical data (Cameroon, DR Congo, Gabon) without alteration.
- Verified integrity, showing identical record counts between sources and JSON outputs.
- Unified the datasets into a standardized schema, producing 5,975 records across 7 columns. Normalization and deduplication rules were respected, preserving data quality and consistency.
- Integrated the unified file into the data warehouse, enabling OLAP analysis and medical decision support.

The proposed framework primarily standardizes heterogeneous inputs into a canonical JSON representation, which serves as the core interoperability layer for unified integration. This standardized JSON is directly consumed by a decision-support system to generate reliable healthcare KPIs and enable evidence-based analytics. When required, an additional mapping layer can align the canonical JSON with widely adopted standards such as HL7 FHIR (e.g., Patient, Observation, Condition, Encounter), ensuring compatibility with external clinical systems without constraining the harmonization process.

C. Discussion and Future Directions

The proposed methodology, which integrates generative AI through the AutoGen AI framework and GPT-4o, represents a significant advancement in addressing the challenge of interoperability in health information systems. The findings highlight the feasibility of harmonizing data from heterogeneous sources, such as SQL Server, MySQL, and Excel, into a unified and interoperable platform. The results hold theoretical importance as they demonstrate how modular, multi-agent architectures can address both syntactic and structural inconsistencies in medical data. For researchers in other countries, these findings emphasize the adaptability of generative AI to modernize fragmented health infrastructures, offering valuable insights into achieving scalable and sustainable interoperability. Lessons learned include the critical importance of modularity and the integration of advanced AI to optimize workflows and decision-making.

The study's results validate the initial hypotheses by confirming that generative AI, when combined with a modular multi-agent system, can achieve seamless interoperability. The high precision and recall rates achieved underscore the robustness of the methodology. The deployment of specialized agents and the capabilities of GPT-4o ensure efficient workflow optimization and reliable data harmonization. This supports the study's objectives and demonstrates the value of an AI-driven approach in overcoming the fragmentation challenges inherent in many healthcare systems, particularly in resource-constrained settings.

1) Biases and generalizability: Although the results are encouraging, they may be influenced by dataset-specific factors such as local coding practices, missing values, and differences in clinical documentation across countries. The proposed framework is expected to generalize to other healthcare environments as long as a minimal overlap of clinical concepts and metadata is available. However, performance may degrade in settings with highly ambiguous schemas, inconsistent terminologies, or extremely noisy records, highlighting the need for stronger semantic validation and domain-specific constraints.

External comparisons reveal the methodology's novelty and its advantages over existing approaches. In many developed countries, interoperability solutions often rely on centralized systems that necessitate costly infrastructure overhauls. In contrast, the modular and incremental integration demonstrated in this study proves more adaptable to resource-constrained environments. Previous studies have identified issues with semantic ambiguities and scalability in AI-driven interoperability frameworks. This methodology effectively addresses those challenges, positioning it as a superior alternative. Differences in results across studies are often attributed to variations in infrastructure and data availability, further underscoring the flexibility of this approach to diverse healthcare settings.

2) Comparison with existing approaches: Compared to classical ETL- or middleware-driven interoperability solutions, the proposed methodology reduces manual schema engineering by delegating normalization and semantic consolidation to LLM-orchestrated agents. In contrast to purely ontology-based mappings, which often require extensive expert maintenance, the multi-agent workflow enables adaptive harmonization under evolving schemas. Relative to recent LLM-to-FHIR transformation studies, our approach differs by emphasizing a canonical JSON interoperability layer designed for direct KPI-oriented decision support, while keeping FHIR alignment as an optional compatibility extension.

The study's contributions are both conceptual and methodological, representing a significant leap forward in the field of health informatics. Conceptually, it introduces the urbanization of HIS as a progressive strategy for modernization. This approach emphasizes gradual, sustainable improvements rather than disruptive overhauls, offering a scalable model for developing healthcare systems. Methodologically, the integration of generative AI with a multi-agent framework offers a novel and practical approach to addressing data interoperability. While generative AI has been explored in various domains, this study is among the first to demonstrate its potential for harmonizing diverse medical data, presenting a new perspective for health informatics research.

Security risks associated with LLM-driven code generation and execution over sensitive medical databases must be explicitly addressed. In our framework, the LLM is not granted direct execution privileges on production systems. Instead, all generated queries and transformation scripts are treated as untrusted outputs and are routed through a policy-enforcement layer that validates requests, restricts operations to an allow list, and blocks destructive commands. Execution is performed in an isolated environment using least-privilege service accounts, thereby limiting potential damage and preventing uncontrolled access to personally identifiable information. In addition, prompt-injection threats originating from untrusted clinical text are mitigated through strict data–instruction separation and input sanitization. Finally, all interactions are logged to support traceability, auditing, and compliance, while future work will investigate privacy-preserving extensions such as federated learning and stronger governance mechanisms.

Despite its strengths, the study is not without limitations. The reliance on high-quality prompts for GPT-4o operations introduces variability, which could be addressed through the development of standardized prompt templates. Additionally, concerns about data privacy and security, especially when processing sensitive medical information in cloud environments, remain a significant challenge. Implementing encryption, data anonymization, and on-premises or federated learning models could mitigate these risks. Furthermore, the need for human oversight to manage semantic ambiguities suggests a need for future research into domain-specific contextual dictionaries and training modules. Testing the framework in diverse healthcare environments would also help identify potential gaps in its adaptability.

Building on these findings, several avenues for future research emerge. Integrating Federated Learning (FL) could enhance privacy and security while maintaining interoperability by enabling collaborative model training without direct data sharing. Additionally, incorporating adaptive learning mechanisms into the AI framework could improve its ability to autonomously handle semantic inconsistencies. Cross-country validations would further establish the framework's global applicability and scalability. Lastly, the development of international ethical guidelines for the use of generative AI in healthcare would ensure equitable and responsible implementation. These future directions provide a pathway for refining and expanding this methodology, making it a critical tool for advancing global health information systems.

V. Conclusion

This study addressed the challenges of interoperability in heterogeneous information systems, with a particular focus on resource constrained healthcare environments. By combining generative Artificial Intelligence, notably GPT-4o, with the AutoGen AI orchestration framework, the proposed methodology demonstrated that a modular multi-agent workflow can effectively harmonize distributed and incompatible medical data sources into a unified, machine compatible representation.

The experimental findings support the feasibility of the approach and confirm that AI-driven harmonization can reduce fragmentation while improving integration reliability and analytics readiness. Importantly, embedding the methodology within an information-system urbanization strategy strengthens its practical relevance for developing regions by enabling incremental modernization without disruptive infrastructure replacement.

Nevertheless, the validity of the proposed framework depends on several conditions. Its performance is strongest when heterogeneous sources share minimal overlapping clinical concepts, when basic metadata is available, and when transformation rules can be constrained through well-defined prompts and validation mechanisms. Conversely, highly ambiguous schemas, inconsistent terminologies, and extreme noise in clinical records may reduce alignment quality and increase the need for human oversight. These limitations highlight the importance of systematic validation, governance, and careful deployment in sensitive environments.

Future work will focus on improving reproducibility through the release of synthetic datasets and structured schemas, strengthening privacy guarantees through federated and privacy-preserving mechanisms, and extending the methodology to broader domains characterized by heterogeneous and distributed data ecosystems. Establishing ethical and governance guidelines will also remain essential for responsible adoption.

Finally, in adherence to ethical guidelines and to protect patient confidentiality, all datasets used in this study were anonymized prior to analysis.
