Table of Contents

Paper 1: A Multi-Stage Framework for Bias Detection and Mitigation in AI-Driven Recruitment Systems

Authors: Gideon Assafuah, Claude Turner, Carlene Turner, Kingsley Nwosu

PAGES 1 - 16

Paper 2: Zero-Disclosure Material Passports for Verifiable Provenance in Multi-Tier Supply Networks

Authors: Shivani Dharmavaram

PAGES 17 - 24

Paper 3: Exploring the Structure Resulting from Unstructured Neural Network Pruning

Authors: Jamil Gafur, Max Milkert, Kevin Patrick Griffin, Nicholas T. Wimer, Charles Tripp, Steve Goddard

PAGES 25 - 34

Paper 4: Privacy Leakage and Memorization in Fine-Tuned Clinical Language Models: A Controlled Study of Defenses and Backbone Choice on Clinical Narrative Transcriptions

Authors: Yassine Chahid, Anas Chahid, Ismail Chahid, Aissa Kerkour Elmiad

PAGES 35 - 44

Paper 5: Deployer-Side XAI Instrumentation for Regulated AI: A Clinical Case Study in ICL Sizing

Authors: Dorleta Urrutia-Onate, Enrique Onieva, Asier Perallos

PAGES 45 - 61

Paper 6: DcDM: A Pre-training Data Evaluation Framework for Proactive Drift Prevention in Machine Learning

Authors: Okjoo Choi, Wonsun Shin

PAGES 62 - 72

Paper 7: Characterizing Operational Drift in Cement Manufacturing Process Data via Self-Supervised Representation Learning

Authors: Changgyun Kim

PAGES 73 - 81

Paper 8: Digital-to-Physical Transfer of Adversarial Patches for Aerial Vehicle Detection

Authors: Jung Heum Woo, Eun-Kyu Lee

PAGES 82 - 93

Paper 9: A Hybrid Ethereum-Based Architecture for Secure Electronic Health Records: Consent, Integrity Anchoring and Auditable Access

Authors: Rodica Doina Zmaranda, Attila-Imre Kovacs, Daniela Elena Popescu, Alexandrina Mirela Pater

PAGES 94 - 103

Paper 10: Using Artificial Intelligence Techniques for Error Detection and Repair in Software Development

Authors: Abdulaziz Aladwani, Sultan Alsamaani, Turki Alrumaykhani, Mohamed Tahar Ben Othman

PAGES 104 - 113

Paper 11: Analyzing User Experience in Mobile Banking Applications Through Text Mining

Authors: Bora Lamaj (Myrto), Markela Muça, Klodiana Bani

PAGES 114 - 119

Paper 12: Design and Evaluation of a 13K Ultra-High-Resolution Web-Based Virtual Reality Platform for Immersive Spatial Visualization

Authors: Worapon Manosroi, Apisak Phromfaiy, Pitak Khlaichom

PAGES 120 - 126

Paper 13: Artificial Intelligence in Software System Quality Assurance: A Systematic Literature Review of Techniques, Tools, and Challenges (2016–2026)

Authors: Abdullah A H Alzahrani

PAGES 127 - 143

Paper 14: A Comparative Evaluation of Large Language Models for Named Entity Recognition in Cyber Threat Intelligence

Authors: Aykhan Huseynli

PAGES 144 - 153

Paper 15: A QR-Code-Based Mobile Learning System for Science Instruction in Resource-Limited Schools

Authors: Gina B. Selga

PAGES 154 - 165

Paper 16: An Improved Pre-processing Method for High-Quality MRI Images in Brain Tumor Detection

Authors: Nirmala, Kavitha B C

PAGES 166 - 174

Paper 17: Vibration-Aided Picture-Based Authentication for Shoulder-Surfing Resistant Mobile Login

Authors: Ibrahim Albadi, Mahdi Almalki, Abdullah Albokhari, Salman Alsumairi, Sami Atiyah, Faisal Alsubaei, Abdullah Abuhussein

PAGES 175 - 187

Paper 18: AI-Based Career Transition Recommendation System Using Controlled Educational Data Augmentation

Authors: Gerlix ADANKON, Pelagie HOUNGUE, Melckior DEGBOE, Corelle GOGAN

PAGES 188 - 201

Paper 19: Verifiable Learned PR-Tree Indexing for Privacy-Preserving Range Queries Over Encrypted Geospatial Data

Authors: Anagha Aher, Sangita Chaudhari

PAGES 202 - 210

Paper 20: A Multi-Modal Deep Learning Framework for Student Soft Skills Development in Adaptive Learning Environments

Authors: Marzhan Bekbolat, Kamalbek Berkimbayev, Rustam Abdrakhmanov, Serik Kenesbayev, Nuraim Ibragimova, Zhaksylyk Dzhanabayev

PAGES 211 - 226

Paper 21: A Hybrid Multi-Objective AI Framework for Curriculum-Aware Examination Generation

Authors: Mohamed Fathy Yehia, Yehia M. Helmi, Mahmoud Mohamed Bahloul

PAGES 227 - 236

Paper 22: An Intelligent Scheduling Optimization Algorithm for Multimodal Cache Resources with Status Awareness of Metropolitan Area Network CDN Nodes

Authors: Ruirong Jiang, Zhibiao Xiong, Junliang Wu, Jinyong Xu

PAGES 237 - 246

Paper 23: MSE-Guided Hybrid U-Net Framework for Automatic Kidney Segmentation and Spatial Localization

Authors: Dannial Asyraf Shahrul Anuar, Nabilah Ibrahim, Audrey Huong

PAGES 247 - 254

Paper 24: Learning Mathematics Through Play: Design and Development of a Serious Game for Undergraduate Students

Authors: Nur Nabilah Abdul Razak, Nur Nabila Farhana Mohd Noh, Nur Dayana Huda Mohd Zol Azhari, Ratna Zuarni Ramli, Ahmed M S Elaklouk, Azyan Yusra Kapi

PAGES 255 - 261

Paper 25: Applying the AuRa Consensus Model for Digital Certificate Management in a Private Ethereum Blockchain

Authors: Robiah Arifin, Wan Aezwani Wan Abu Bakar, Mustafa Man, Mohamad Afendee Mohamed, Evizal Abdul Kadir

PAGES 262 - 270

Paper 26: A Bibliometric Analysis of Internet of Things and Augmented Reality Applications in Agriculture: A Scopus-Based Review (2019–2026)

Authors: Ruziana Mohamad Rasli, Sobihatun Nur Abdul Salam

PAGES 271 - 280

Paper 27: Evolutionary Allocation with Dynamic Guidance for Pre-Scheduled Timetables

Authors: Anniza Hamdan, Sze San Nah, Goh Say Leng, Emily Sing Kiang Siew

PAGES 281 - 288

Paper 28: Multi-Class Stress Detection Using Electrodermal Activity: Evaluation of A Hybrid Model Using UBFC-Phys Dataset

Authors: Kawther Alsayed, Hamza Ghandorh, Wael M.S. Yafooz

PAGES 289 - 297

Paper 29: ATC Automation Based on Dynamic Aircraft Separation Techniques Accounting for Weather Conditions

Authors: Omayma Raziq, Mohamed El Khaili, Hasna Nhaila, Azeddine Khiat

PAGES 298 - 305

Paper 30: A Computational Analysis of Housing Affordability: Robust Bootstrap Regression Modeling of the Safety Premium

Authors: Natia Terterashvili, Shota Shaburishvili

PAGES 306 - 311

Paper 31: An Enhanced Kalman Filter-Based Hybrid Battery Management System for Energy Optimization in IoT-Enabled Smart Agriculture

Authors: Mohd Kamir Yusof, Nur Yasmin Salleh, Senny Luckyardi,
Wan Mohd Amir Fazamin Wan Hamzah, Mustafa Man

PAGES 312 - 319

Paper 32: Enhanced Real-Time Fire Detection Systems Using Deep Learning and Differentiating Between Dangerous and Non-Dangerous Fires

Authors: Mohamed Youssef, Mohamed Marie, Sarah Naiem

PAGES 320 - 329

Paper 33: A Novel Hybrid Deep Learning Validation Model for Real-Time and Synthetic Image Inputs in Capsicum Plant Disease Diagnosis

Authors: Prashant Vikhe, Baisa Gunjal

PAGES 330 - 336

Paper 34: Large-Scale Static Malware Detection Using Classical Machine Learning Models: An Evaluation on the EMBER Dataset

Authors: Achmad Fauzan, Tito Pinandita, Aulia Desy Nur Utomo

PAGES 337 - 347

Paper 35: A Data-Driven Visual Analytics Framework for Transaction-Level Retail Profit Modeling and Decision Support

Authors: Donia Badawood

PAGES 348 - 362

Paper 36: Fostering Programming Interest Through Block Coding in Young Learners

Authors: Dorjpalam Tserendejid, Khajidmaa Otgonbaatar, Magsarjav Bataa

PAGES 363 - 370

Paper 37: MYPO-Net: A Robust Deep Learning Approach for Multi-Yoga Pose Detection and Occlusion Handling

Authors: Rehana Danial, Nosheen Qamar, Nosheen Sabahat, Faria Nazir, Ali Salem Bin Sama, Lamia Hassan Rahamatalla, Osman Elwasila, Abdulrahman Alojail, Marwan Abu-Zanona

PAGES 371 - 382

Paper 38: Confirmatory Factor Analysis of Phishing Susceptibility in Indonesia

Authors: Harris Simaremare, Muhammad Fikri, Zarina Shukur

PAGES 383 - 394

Paper 39: AgricultureEarlyWarning: A Web-Based Climate Advisory and Early Warning Platform for Albanian Farmers

Authors: Irida Gjermeni

PAGES 395 - 403

Paper 40: Spatial Anemia and Osmotic Fragility of Erythrocytes in Microgravity Conditions: A Systematic Review

Authors: Lilian Ocares-Cunyarachi, Natalia Vargas-Cuentas, Avid Roman-Gonzales, Georgina Chávez, Brigitte Torres-Pinedo, Ana Huamani-Huaracca

PAGES 404 - 418

Paper 41: Artificial Intelligence-Assisted Community Needs Assessment and Extension Planning: Evidence from Wesleyan University-Philippines Partner Communities

Authors: Eufemia Ayro, Karl Leugim Bernarte, Hazel May Babiera, Evangeline Agpoon, Jhon Carlo Villa, Maureen Bondoc, Jennyfer Villalon, Jose Arsenio Adriano, Christian Navarro

PAGES 419 - 428

Paper 42: A Comparative Analysis of Decision Tree, Random Forest, and Logistic Regression Models in Predicting Business Readiness for Digital Technology Integration

Authors: Gloria M. Ducut

PAGES 429 - 437

Paper 43: Canthus-Scaled 468-Landmark FaceMesh Framework for Pupillary Distance Estimation Using Nested AutoML Calibration

Authors: Mohd Izzuddin Mohd Tamrin, Sherzod Turaev, Takumi Sase, Mohd Zulfaezal Che Azemin, Tengku Mohd Tengku Sembok

PAGES 438 - 445

Paper 44: A Hybrid CNN-Ensemble Framework for Robust DeepFake Image Detection

Authors: Mohammad Alsulami

PAGES 446 - 457

Paper 45: A Bibliometric Mapping of Transformer-Based Misinformation Detection: Trends and Gaps

Authors: Borhan Ab Rahman, Mohd Zakree Ahmad Nazri, Mohd Ridzwan Yaakub

PAGES 458 - 468

Paper 46: Web System to Optimize Information Management for Beca 18 Selection-Stage Applicants, 2025

Authors: Jack Quispe-Vivas, Cristian Sedano-Contreras, Junior Segovia-Chalco, Brian Meneses-Claudio

PAGES 469 - 474

Paper 47: A Modified Lyapunov-Based MEC Offloading Algorithm for Severity-Aware QoS in 5G/B5G IoT Systems

Authors: Sahana S Reddy, R. Sukumar

PAGES 475 - 489

Paper 48: Bridging Topic Modelling Outputs to Bayesian Hierarchical Model Using LLM and WordNet Parameter Labelling

Authors: Vadrianey Asas, Sarah Samson Juan, Stephanie Chua, Evan Lau, Jane Labadin

PAGES 490 - 500

Paper 49: Artificial Intelligence and the Transformation of Academic Integrity in Higher Education: A Systematic Review

Authors: Wannakorn Phornprasert, Wongpanya S. Nuankaew, Pratya Nuankaew

PAGES 501 - 511

Paper 50: A Secure Integrated Cloud Storage Framework Using Lorenz Chaotic Key Generation, AES-256-GCM, and PBFT-Based Blockchain Verification

Authors: Walde Rajesh Baliram, Bashir Alam, Mohammad Najmud Doja

PAGES 512 - 531

Paper 51: Comparative Evaluation of Traditional and Transformer-Based Models for Risk-Level Classification of Uzbek Telegram Messages

Authors: Feruzakhon A. Qoyliyeva, Ozod J.Babomuradov, Akmal A. Savurbayev

PAGES 532 - 536

Paper 52: MedChain: A Privacy-Preserving Framework for Scalable Electronic Health Record Sharing on Blockchain and InterPlanetary File System

Authors: S. Venkateswaran, N. Vijayaraj

PAGES 537 - 548

A Multi-Stage Framework for Bias Detection and Mitigation in AI-Driven Recruitment Systems

Gideon Assafuah, Claude Turner, Carlene Turner, Kingsley Nwosu
Department of Computer Science, Norfolk State University, Virginia, USA
Department of Sociology, Norfolk State University, Virginia, USA

***Abstract*—The use of machine learning in recruitment has raised growing concerns about fairness, as automated hiring systems can generate unequal outcomes across demographic groups. These disparities are influenced not only by imbalanced data but also by the behavior of learning algorithms, making bias a multidimensional challenge that cannot be effectively addressed with single-stage solutions. This study introduces an integrated framework for bias detection and mitigation in AI-driven recruitment systems, combining interventions at the data, model, and decision levels within a unified evaluation pipeline. The framework is assessed using multiple classification models of varying complexity and evaluated with established fairness metrics. In addition, explainability techniques are employed using SHAP-based feature attribution to investigate hidden dependencies and assess the sensitivity of predictions to demographic attributes. Experimental results show that baseline models achieve strong predictive performance, with accuracy ranging from 0.807 to 0.816; however, fairness evaluation reveals substantial disparities, with Disparate Impact as low as 0.190 and Demographic Parity Difference exceeding 0.27 in some cases. After applying the proposed multi-stage mitigation approach, fairness metrics improve significantly: Disparate Impact meets or exceeds the legal threshold of 0.80 across all models, with reductions in Demographic Parity Difference of 70–85% and Equal Opportunity Difference of 47–75%, and demographic disparities are reduced to 0.029–0.053. These improvements are achieved with minimal performance trade-off, as overall accuracy decreases by at most 4.2 % points while ROC AUC remains unchanged. The findings demonstrate that bias in recruitment systems arises from the interplay between data and model dynamics and highlight the importance of coordinated mitigation strategies throughout the machine learning lifecycle. This work provides a practical, scalable approach to developing fair and transparent AI systems for hiring applications.**

***Keywords*—Bias detection; bias mitigation; AI in recruitment; algorithmic fairness; explainable AI; fairness metrics; machine learning; responsible AI**

I. Introduction

The rapid adoption of artificial intelligence (AI) in recruitment and hiring processes has transformed how organizations evaluate and select candidates [30]. Automated systems are increasingly used to screen resumes, rank applicants, and support decision-making in large-scale recruitment settings, offering improved efficiency and scalability [1], [2], [28]. However, as these systems become more influential in determining access to employment opportunities, concerns have emerged regarding their fairness and potential to produce unequal outcomes across demographic groups [14], [15].

A growing body of research has shown that machine learning models can inherit and amplify historical biases embedded in training data, leading to systematic disparities in hiring outcomes. These biases may arise from imbalanced datasets, proxy variables, or algorithmic decision boundaries, and can disproportionately affect groups defined by sensitive attributes such as gender, race, or age [12], [16]. As a result, AI-driven recruitment systems risk reinforcing existing social inequalities while operating under the perception of objectivity, raising concerns about transparency, accountability, and ethical responsibility [7], [8].

Existing approaches to addressing bias in machine learning systems typically focus on isolated stages of the pipeline. Data-level methods aim to rebalance or transform datasets to reduce representation bias, while model-level techniques incorporate fairness constraints during training. Post-processing approaches, on the other hand, adjust model outputs to improve fairness after predictions have been generated. Although these methods have demonstrated effectiveness in specific contexts, their isolated application often fails to capture the complex ways bias propagates throughout the entire machine learning lifecycle [9]. Consequently, there is a need for integrated approaches that address bias holistically rather than at a single stage.

In addition to mitigation strategies, explainability has emerged as a critical component in understanding and evaluating fairness in AI systems. Techniques such as SHAP-based feature attribution and local explanation methods provide insights into how models make decisions and whether sensitive attributes or their proxies influence outcomes. These methods are particularly important in high-stakes domains such as recruitment, where opaque decision-making can undermine trust and accountability [10], [11].

This study addresses these challenges by proposing a multi-stage framework for bias detection and mitigation in AI-driven recruitment systems. Unlike prior approaches that focus on a single level of intervention, the proposed framework integrates data-level auditing, model-level fairness-constrained training, and a novel post-processing threshold optimizer within a unified pipeline. Critically, the three stages are designed to operate in sequence — pre-processing corrects data-level imbalance, in-processing embeds fairness constraints into model training, and post-processing applies a group-specific

threshold search governed by a composite objective function that explicitly encodes the EEOC 80% legal threshold as a hard constraint. This end-to-end coordination across all three intervention levels, with each stage informing the next, is what distinguishes the proposed approach from existing single-stage or loosely coupled multi-technique fairness methods. The framework is evaluated using multiple machine learning models, including Logistic Regression, Random Forest, and Neural Networks, to analyze how bias manifests across varying levels of model complexity. Fairness is assessed using established metrics such as Disparate Impact, Demographic Parity Difference, and Equal Opportunity Difference. In contrast, explainability techniques are used to uncover hidden dependencies and assess decision sensitivity through SHAP-based feature attribution.

The contributions of this work are fourfold, and collectively distinguish it from prior art in three important ways. First, while pre-processing, in-processing, and post-processing fairness techniques each exist in isolation in the literature, no prior work has combined all three within a single unified pipeline specifically designed for recruitment AI, where each stage is designed to build on and complement the prior one rather than acting independently. Second, the post-processing optimizer in this framework is the first to incorporate the EEOC 80% rule as a hard constraint within a joint multi-group threshold search — existing threshold-based methods, such as Fairlearn's ThresholdOptimizer, optimize for demographic parity alone and do not jointly minimise EOD and DPD while enforcing a legal DI floor. Third, SHAP-based explainability is embedded as an integral diagnostic component of the pipeline rather than applied as a post-hoc interpretability tool, enabling the identification of proxy bias pathways across three architecturally distinct model families. Fourth, the framework is evaluated with five-seed statistical averaging and paired significance testing — a level of experimental rigour that is absent from most prior fairness-aware recruitment studies, which typically report single-run results. Specifically, the contributions are: 1) a comprehensive bias auditing approach that captures disparities at both data and model levels across gender, race, and age; 2) an integrated three-stage mitigation strategy with a novel post-processing objective function that jointly enforces legal DI compliance, demographic parity, and equalized odds; 3) empirical demonstration that all three models achieve DI ≥ 0.80 — the EEOC legal threshold — with at most 4.2 percentage point accuracy loss and unchanged ROC AUC; and 4) SHAP-based evidence that bias manifests structurally differently across model architectures, with important implications for fairness auditing practice.

The remainder of this study is organized as follows. Section II reviews related work on bias and fairness in AI-based recruitment systems. Section III presents the proposed methodology and experimental setup. Section IV discusses the results and evaluates the effectiveness of the proposed framework. Finally, Section V concludes the study and outlines directions for future research.

II. Related Work

Artificial intelligence has become an integral component of modern recruitment processes, enabling organizations to automate candidate screening, ranking, and selection. These systems leverage machine learning techniques to process large volumes of applicant data, improving efficiency and scalability in hiring workflows [1], [2]. Despite these advantages, the adoption of AI in recruitment introduces significant challenges, particularly regarding fairness and the potential for unintended discrimination. Studies have shown that AI-based hiring tools can influence critical employment decisions, making it essential to ensure that such systems operate equitably and transparently [3]. Bias in machine learning systems has been widely studied, with research demonstrating that models can reflect and amplify historical inequalities present in training data [4], [5], [27]. These biases may arise from imbalanced datasets, measurement errors, or correlations between sensitive attributes and non-sensitive features. Caliskan et al. [6] demonstrated that language-based models can encode societal biases, highlighting the broader issue of bias propagation in AI systems. To address these concerns, various fairness definitions and evaluation metrics have been proposed, including Disparate Impact, Demographic Parity, Equal Opportunity, and Equalized Odds [18], [17]. These metrics provide quantitative measures for assessing disparities in model outcomes across demographic groups. However, prior work indicates that improving fairness on one metric may negatively affect others, illustrating the inherent trade-offs in fairness-aware machine learning [4].

Furthermore, bias is not a static property but can evolve throughout the machine learning pipeline. Decisions made during data collection, preprocessing, model training, and evaluation can each amplify or mitigate bias. This dynamic nature of bias underscores the need for comprehensive evaluation strategies that account for multiple pipeline stages rather than focusing on isolated components.

The ethical implications of AI-driven recruitment systems extend beyond technical considerations, encompassing issues of accountability, transparency, and societal impact [31]. Researchers have emphasized that biased hiring systems can perpetuate systemic discrimination, limiting opportunities for underrepresented groups and reinforcing existing inequalities [7], [8]. As a result, there has been a growing emphasis on Responsible AI, which advocates for the development of systems that are fair, transparent, and aligned with ethical principles [26]. In recruitment contexts, these concerns are particularly significant due to the high-stakes nature of hiring decisions [24], [25]. Unlike other application domains, biased outcomes in hiring can have long-term consequences for individuals' careers and livelihoods. The lack of interpretability in many machine learning models further complicates this issue, as stakeholders may be unable to understand or challenge automated decisions [3]. Consequently, ensuring fairness in recruitment AI systems requires not only technical solutions but also organizational and regulatory frameworks that promote accountability and transparency.

To address bias in machine learning systems, researchers have proposed a range of mitigation strategies that operate at different stages of the pipeline. These strategies are commonly categorized into pre-processing, in-processing, and post-processing approaches. Pre-processing methods aim to modify the training data to reduce bias, for example, through

reweighting, resampling, or feature transformation. In-processing techniques incorporate fairness constraints directly into the learning algorithm, enabling models to balance accuracy and fairness during training. Post-processing methods adjust model outputs after prediction to achieve fairness objectives [9]. While each technique category has demonstrated effectiveness, its application in isolation presents limitations. Pre-processing methods may reduce bias in the data, but cannot guarantee fair outcomes if the model learns unintended patterns. In-processing approaches may require modifications to model architecture or training procedures, limiting their applicability in real-world systems. Post-processing techniques, although flexible, do not address the root causes of bias and may lead to suboptimal decision boundaries. Recent studies suggest that combining multiple mitigation strategies can yield more robust fairness improvements. However, there remains a lack of unified frameworks that systematically integrate these approaches within a single pipeline. This gap is particularly evident in recruitment systems, where bias may arise from both data characteristics and model behavior.

Explainable AI (XAI) has emerged as a key tool for understanding and mitigating bias in machine learning systems. By providing insights into how models make decisions, explainability techniques enable researchers and practitioners to identify the factors driving predictions and assess whether these factors are fair and appropriate [10]. Methods such as feature importance analysis and local explanations allow for the examination of individual predictions and the detection of hidden biases. In addition to model-level explanations, dataset transparency has been recognized as an important component of fairness. Frameworks such as dataset datasheets promote the documentation of dataset characteristics, including sources, preprocessing steps, and potential biases [11]. These practices support more informed decision-making and facilitate the identification of bias at earlier stages of the pipeline. Despite these advances, explainability is often treated as a separate component rather than being integrated into bias detection and mitigation workflows. There is a growing need for approaches that combine explainability with fairness evaluation to provide a more comprehensive understanding of bias and its impact on model behavior [22], [23].

A. Research Limitations and Identified Gaps

Although substantial progress has been made in understanding and mitigating bias in machine learning systems, several limitations remain. First, many existing studies focus on individual pipeline stages, such as data preprocessing or model training, without considering how bias propagates across stages. Second, limited work integrates fairness evaluation with explainability techniques to provide deeper insights into bias mechanisms. Third, there is a lack of practical frameworks for real-world recruitment systems that balance fairness and predictive performance. These limitations highlight the need for a comprehensive approach that addresses bias holistically. There is a need for frameworks that integrate data-level auditing, model-level evaluation, and post-processing mitigation within a unified system, while also incorporating explainability techniques to enhance transparency and interpretability.

To address this gap, this study proposes a multi-stage framework for bias detection and mitigation in AI-driven recruitment systems. The proposed approach combines fairness metrics, explainability methods, and empirical evaluation across multiple models to provide a robust, scalable solution for developing fair, transparent hiring systems [19], [20].

Table I summarizes the key existing research on bias and fairness in AI-based recruitment systems, categorizes prior work by methodological approach, and highlights key limitations and unresolved research gaps. These observations reveal that existing approaches are largely fragmented and lack a unified, end-to-end framework to address bias throughout the machine learning lifecycle.

TABLE I. SUMMARY OF EXISTING RESEARCH

Existing Research	Methodology	Limitations and Research Gap
Research papers [1], [2]	Literature reviews and qualitative analysis of AI-driven recruitment systems and bias sources	Provide conceptual insights but lack empirical validation, and do not propose integrated technical frameworks for bias detection and mitigation
Research papers [4], [5], [6]	Surveys and analytical studies on bias sources, fairness metrics, and data-driven bias	Focus on general ML contexts without domain-specific solutions for recruitment or end-to-end mitigation pipelines
Research papers [3], [7], [8]	Conceptual and ethical analyses of fairness, accountability, and transparency in AI systems	Emphasize ethical concerns but lack technical implementation and actionable mitigation strategies
Research paper [9]	Pre-processing method using data reweighing to improve fairness	Limited to a single-stage solution and does not address bias across data, model, and decision levels
Research paper [10], [11]	XAI techniques and dataset documentation frameworks for understanding model behavior	Focus on interpretability and transparency without integrating fairness optimization or mitigation strategies

III. METHODOLOGY

To address the limitations of existing single-stage bias mitigation approaches, this study proposes a multi-stage framework for bias detection and mitigation in AI-driven recruitment systems. The framework is designed to capture the full machine learning lifecycle, enabling bias to be systematically identified, analyzed, and mitigated at multiple stages, including data preparation, model development, and evaluation. By integrating data-level auditing, model-level analysis, explainability techniques, and fairness-aware optimization, the proposed approach provides a comprehensive, structured mechanism to improve fairness while maintaining predictive performance. The overall architecture of the proposed framework is illustrated in Fig. 1.

This study proposes a multi-stage framework designed to detect, analyze, and mitigate bias in AI-driven recruitment systems. The framework adopts a pipeline-based structure that captures the full lifecycle of machine learning, enabling bias to be examined and addressed at multiple stages rather than in isolation.

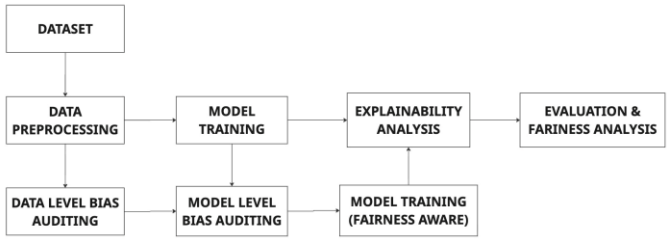

Fig. 1. Proposed multi-stage bias detection and mitigation framework.

As illustrated in Fig. 1, the framework comprises interconnected components: dataset preparation, data preprocessing, data-level bias auditing, model training, model-level bias evaluation, explainability analysis, fairness-aware model refinement, and final evaluation. Each stage plays a distinct role in identifying and mitigating bias while preserving predictive performance.

A. Dataset Description and Preprocessing

This study uses the UCI Adult Income dataset, a widely established benchmark in algorithmic fairness research, extracted from the 1994 United States Census Bureau database [19]. After removing missing values and duplicates, the dataset comprises 45,175 records with eight features. Sensitive attributes — gender, race, and age group — are excluded from model inputs but retained for fairness evaluation. Skill and qualification proxies include education level, Certifications, weekly working hours, Experience Years, and Screening Score. The dataset exhibits a 75.2% / 24.8% class split with significant demographic imbalance: male applicants constitute 67.5% and White applicants 86.0% of the pool, making it well-suited for studying bias propagation in selection-oriented systems.

The dataset preparation process involves several preprocessing steps to ensure data quality and compatibility with machine learning models. Missing values are handled using appropriate imputation techniques to preserve dataset completeness, while categorical variables are encoded as numerical values using methods such as one-hot encoding. Continuous features are standardized to improve model convergence and ensure balanced feature contributions. Sensitive attributes are excluded from model training inputs to prevent direct discrimination but are retained separately for fairness evaluation. The dataset is then split into training and test sets using stratified sampling to maintain class distribution and ensure reliable evaluation. In addition, exploratory data analysis is conducted to examine the distribution of demographic groups and hiring outcomes, enabling the identification of representation imbalance and outcome disparities before model development.

B. Data-Level Bias Analysis

Before training machine learning models, it is essential to examine the dataset for inherent biases that may influence model predictions. In AI-driven recruitment systems, datasets often reflect historical hiring practices, which can introduce disparities across demographic groups. Therefore, a data-level bias analysis is conducted to identify potential imbalances in representation, outcome distribution, and feature relationships. This preliminary analysis is critical, as biases present in the data can be learned and amplified by machine learning models if not properly addressed [5].

The first step in the analysis is to examine the representation of sensitive attributes, including gender, race, and age group. Representation bias occurs when certain demographic groups are underrepresented or overrepresented in a dataset, leading to unequal learning outcomes. The distribution of these groups is analyzed to determine whether the dataset provides balanced coverage across populations. Unequal representation may result in models that perform poorly for minority groups due to insufficient training data, thereby introducing fairness concerns [4]. Fig. 2 shows the gender distribution, Fig. 3 shows the race distribution, and Fig. 4 shows the age group distribution.

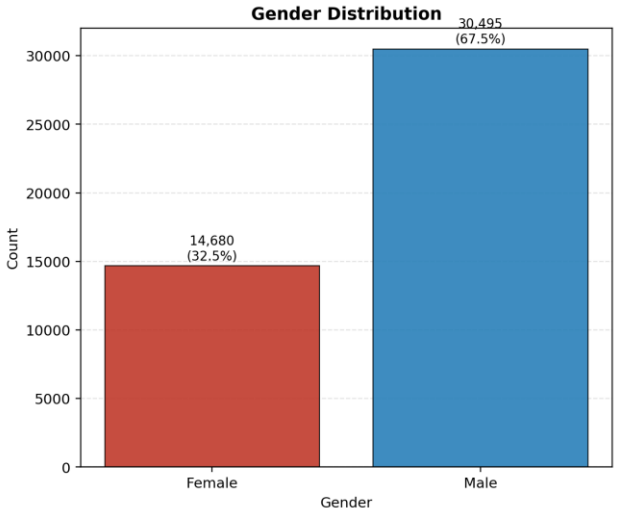

Fig. 2. Gender distribution of applicants.

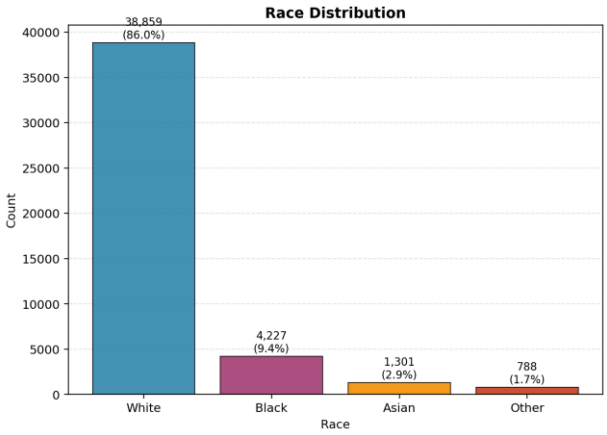

Fig. 3. Race distribution of applicants.

In addition to representation, outcome bias is assessed by analyzing the distribution of hiring decisions across demographic groups. This is measured using the Selection Rate (SR), defined as the proportion of candidates in a group who receive a positive outcome (i.e., are hired). Differences in selection rates across groups indicate potential disparities in historical decision-making patterns embedded in the dataset. A significant variation in SR suggests that certain groups may be

favored or disadvantaged, which can directly influence model predictions if left unaddressed [7]. Fig. 5 shows selection rates by gender, Fig. 6 shows selection rates by race, and Fig. 7 shows selection rates by age group.

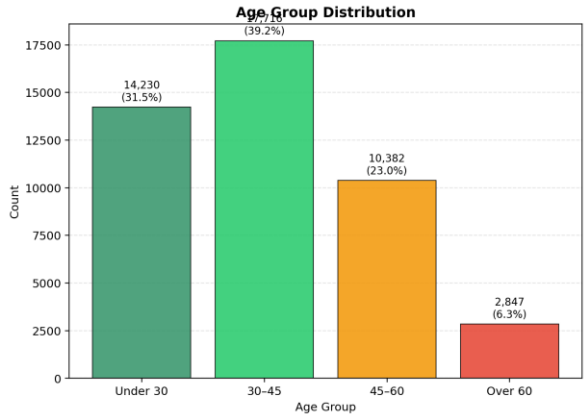

Fig. 4. Age group distribution of applicants.

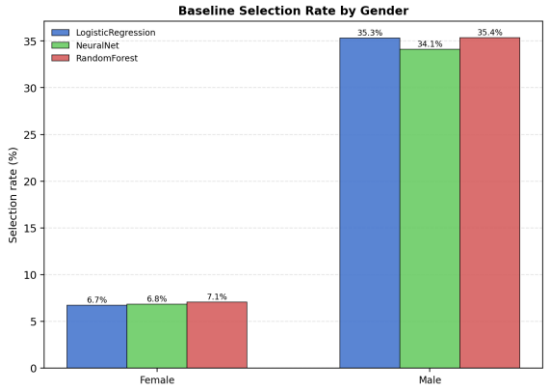

Fig. 5. Selection rate by gender.

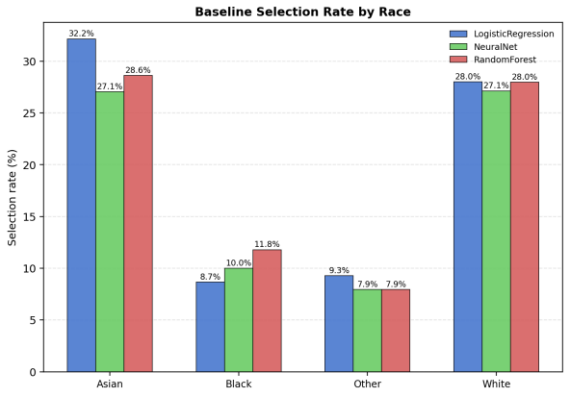

Fig. 6. Selection rate by race.

To further investigate hidden sources of bias, correlation analysis is performed between sensitive attributes and non-sensitive features. Features that exhibit strong correlations with sensitive attributes may act as proxy variables, enabling the model to indirectly learn discriminatory patterns even when sensitive attributes are excluded from training. This phenomenon has been widely documented in fairness research and highlights the limitations of simply removing sensitive features without deeper analysis [8]. Exploratory data analysis is also conducted to visualize feature distributions and identify potential anomalies or skewness. Visualization techniques such as bar charts and distribution plots are used to compare demographic groups and hiring outcomes. These insights provide an initial understanding of how bias may be embedded in the dataset and inform subsequent bias mitigation strategies.

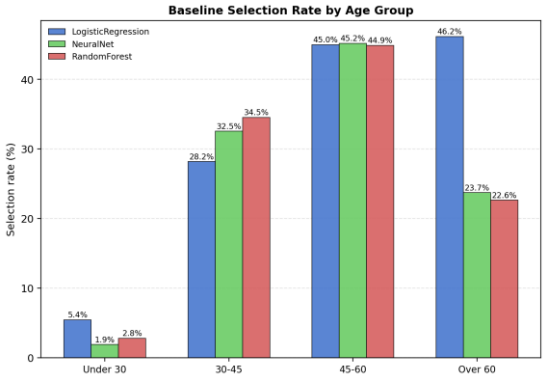

Fig. 7. Selection rate by age group.

Overall, the data-level bias analysis provides a foundational understanding of disparities present in the dataset before model development. By identifying representation imbalance, outcome disparities, and proxy relationships, this study ensures that bias is addressed proactively rather than reactively. The findings from this stage serve as a baseline for evaluating the effectiveness of bias mitigation techniques applied in later stages of the framework. As shown in Fig. 8, the correlation matrix reveals strong relationships between non-sensitive features and sensitive attributes, indicating the presence of proxy variables.

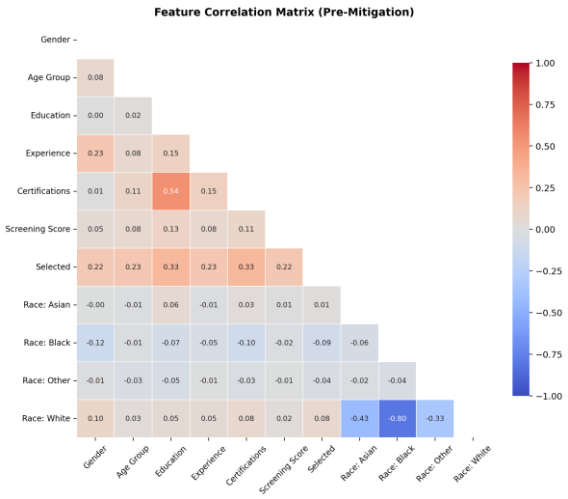

Fig. 8. Correlation matrix showing feature relationships.

Overall, the data-level bias analysis provides a foundational understanding of disparities present in the dataset before model development. By identifying representation imbalance, outcome disparities, and proxy relationships, this study ensures that bias is addressed proactively rather than reactively. The findings from this stage serve as a baseline for evaluating the

effectiveness of bias mitigation techniques applied in later stages of the framework.

C. Model Development

To evaluate how bias manifests across different learning paradigms, this study employs three classification models: Logistic Regression (LR), Random Forest (RF), and Neural Network (NN). These models are selected to represent linear, ensemble-based, and non-linear approaches, respectively, enabling a comprehensive assessment of both predictive performance and fairness. The use of multiple models enables a comparative analysis of how bias propagates across different algorithmic structures, as prior studies have shown that model complexity can significantly influence fairness outcomes [4], [5]. All models are trained on the same preprocessed dataset to ensure consistent evaluation and isolate the effect of model architecture on fairness.

1) LR Model: LR is used as a baseline model due to its simplicity, interpretability, and well-defined decision boundary. It models the probability of a binary outcome as a linear combination of input features, with the result passed through a sigmoid activation function. In this study, LR is trained for up to 1,000 iterations (max_iter=1000) with L2 regularization at the default strength C=1.0. The probability of a candidate being selected is defined in Eq. (1), which models the log-odds as a linear combination of input features.

$$P(y=|x) = \frac{1}{1+e^{-(\beta_0+\sum_{i=1}^{n}\beta_i x_i)}} \quad (1)$$

where, the input features x_i, x_2, …, x_n represent candidate attributes and the coefficients β define the contribution of each feature to the prediction. Due to its linear nature, LR provides a transparent framework for understanding how individual features influence outcomes, making it particularly useful for baseline fairness analysis. However, its inability to capture complex, non-linear relationships may limit its predictive performance in more intricate datasets.

2) RF Model: RF is used to capture non-linear relationships and feature interactions. It is an ensemble learning method that constructs multiple decision trees using random subsets of the data and features, and aggregates their predictions to improve generalization. The final prediction is obtained by averaging the outputs of individual trees. The final prediction is computed as shown in Eq. (2).

$$\hat{y} = \frac{1}{T}\sum_{t=1}^{T} h_t(x) \quad (2)$$

where, T denotes the number of trees and $h_t(x)$ represents the prediction of the t-th tree. The ensemble nature of RF reduces overfitting and improves robustness, but at the cost of reduced interpretability. In this study, RF is configured with 200 estimators (n_estimators=200); in-processing mitigation applies balanced_subsample class weighting. This lack of transparency can make it more challenging to identify sources of bias within the model, highlighting the importance of complementary fairness evaluation techniques.

3) NN Model: The NN model is implemented as a multi-layer perceptron (MLP) to capture complex, non-linear patterns in the data. It consists of an input layer, one or more hidden layers, and an output layer, with non-linear activation functions applied at each stage. The transformation at each layer is defined in Eq. (3).

$$a^{(l)} = f(W^{(l)}a^{(l-1)} + b^{(l)} \quad (3)$$

where, $W^{(l)}$ and $b^{(l)}$ represent the weights and biases of layer l, and $f(\cdot)$ is the activation function. Neural networks are highly expressive and can model intricate relationships among features, thereby improving predictive performance. In this study, the MLP is configured with a single hidden layer of 50 neurons (hidden_layer_sizes=(50,)) and trained for up to 1,000 iterations using the Adam optimizer with default learning rate 0.001. However, this expressive power also increases the risk of learning hidden biases present in the dataset, particularly when proxy variables are involved [5]. All models are trained on the same training dataset and evaluated on a separate test set to ensure consistent comparisons.

D. Model-Level Bias Evaluation

To assess fairness in model predictions, this study evaluates model-level bias by analyzing disparities in predicted outcomes across demographic groups. While data-level analysis provides insights into inherent imbalances in the dataset, model-level evaluation focuses on how learned patterns influence decision-making. This distinction is critical, as machine learning models may amplify existing biases or introduce new ones during training. To capture multiple dimensions of fairness, this study employs three widely used metrics: Disparate Impact (DI), Demographic Parity Difference (DPD), and Equal Opportunity Difference (EOD). The use of multiple metrics ensures a comprehensive evaluation, as no single fairness measure fully captures all aspects of bias.

Disparate Impact (DI) is used to measure the ratio of favorable outcomes between unprivileged and privileged groups. It quantifies whether individuals from different demographic groups receive positive predictions at similar rates. DI is formally defined in Eq. (4) as:

$$DI = \frac{P(\hat{y}=1 \mid unprivileged}{P(\hat{y}=1 \mid privileged} \quad (4)$$

A DI value close to 1 indicates fairness, while values significantly below 1 suggest potential discrimination against the unprivileged group. In practice, a threshold of 0.8 is commonly used to identify adverse impact, with values below this threshold indicating substantial disparity [7], [21].

Demographic Parity Difference (DPD) measures the difference in selection rates between demographic groups, providing insight into whether one group is systematically favored over another. It is defined in Eq. (5) as:

$$DPD = P(\hat{y}=1|unprivileged) - P(\hat{y}=1|privileged) \quad (5)$$

A value of zero represents perfect parity. At the same time, deviations from zero indicate unequal treatment. Unlike DI, which provides a ratio, DPD captures absolute differences in selection rates, making it useful for understanding the magnitude of disparity [4].

Equal Opportunity Difference (EOD) evaluates fairness by comparing true positive rates across groups. It focuses on whether the model treats qualified candidates (i.e., those who should receive a positive outcome) equally. EOD is defined in Eq. (6) as:

$$EOD = P(\hat{y} = 1 | y = 1, unprivileged) - P(\hat{y} = 1 | y = 1, privileged) \quad (6)$$

A value of zero indicates that both groups have equal chances of receiving correct positive predictions. Deviations from zero suggest that one group may be disadvantaged in correctly identifying positive outcomes. This metric is particularly important in recruitment systems, where unequal true positive rates may result in qualified candidates from certain demographic groups being overlooked [7].

By combining DI, DPD, and EOD, this study captures multiple dimensions of fairness, including outcome distribution, selection disparity, and error-based fairness. This multi-metric evaluation provides a robust foundation for assessing bias across different models. It serves as a baseline for evaluating the effectiveness of bias mitigation techniques applied in subsequent stages of the framework.

E. Bias Mitigation Techniques

To address the biases identified during both the data and model levels, this study adopts a comprehensive multi-stage bias mitigation strategy [29] that integrates pre-processing, in-processing, and post-processing techniques. This layered approach ensures that bias is addressed at different stages of the machine learning pipeline, thereby improving fairness without significantly compromising predictive performance. Such multi-level mitigation strategies are widely recommended in fairness-aware machine learning to achieve robust and reliable outcomes across diverse demographic groups.

1) Pre-processing: At the pre-processing stage, the focus is on reducing bias in the dataset before model training. This is achieved through a combination of representation balancing and instance reweighing. Representation balancing is implemented by adjusting the distribution of samples across sensitive attribute groups through controlled resampling. Specifically, minority groups are oversampled while majority groups may be undersampled to ensure a more uniform representation. In addition, reweighing assigns weights to individual samples based on their group membership and label distribution, ensuring that underrepresented or disadvantaged groups have a greater influence during training. This weighting strategy reduces the learning algorithm's reliance on biased data distributions and promotes equitable learning outcomes (see Algorithm 1).

Algorithm 1: Reweighing and Balancing

Input: Dataset D with features X, labels y, sensitive attributes S

1: Compute group distribution for each (S, y) combination

2: Calculate the expected distribution assuming independence between S and y.

3: Assign weights *w_i* to each instance:

w_i = (Expected (S, y)) / (Observed (S, y))

4: Apply resampling:

1. Oversample minority groups.
2. Under sample majority groups.

5: Output transformed dataset D with adjusted weights

In-processing techniques are applied during model training to enforce fairness constraints within the learning algorithm directly. In this study, fairness-aware optimization is incorporated by adding a fairness penalty term to the objective function. The modified loss function introduces a trade-off between prediction accuracy and fairness, controlled by a regularization parameter λ. The loss function is modified to include a fairness penalty term as shown in Eq. (7).

$$L_{total} = L_{prediction} + \lambda \cdot L_{fairness} \quad (7)$$

where, $L_{prediction}$ represents the standard classification loss (e.g., cross-entropy), and $L_{fairness}$ captures disparities across sensitive groups. The fairness component is designed to minimize statistical dependence between sensitive attributes and model predictions.

For LR, fairness constraints are enforced via optimization techniques inspired by Exponentiated Gradient Reduction, which iteratively adjust model parameters to satisfy the constraints while minimizing classification error. In Random Forest models, fairness is achieved through weighted sampling and balanced splitting criteria, ensuring that decision trees do not disproportionately favor the majority group. For neural networks, a fairness-aware loss function is employed that adds a covariance-based penalty to reduce the correlation between sensitive attributes and predicted outcomes. This approach ensures that the learned feature representations are less biased and more generalizable across demographic groups (see Algorithm 2).

Algorithm 2: Fairness-Constrained Optimization

Input: Training data D, model M, fairness weight λ

1: Initialize model parameters θ

2: For each training iteration:

a. Compute prediction $\hat{y} = M(X; \theta)$
b. Compute prediction loss $L_{_pred}$
c. Compute fairness loss $L_{_fair}$ (measure disparity across sensitive groups)
d. Compute total loss
e. Update θ using gradient descent

3: Repeat until convergence

4: Output trained fair model M*

Post-processing techniques are applied after model training to adjust predictions to satisfy fairness constraints without modifying the underlying model. One of the primary approaches in this study is threshold optimization, in which different decision thresholds are applied across demographic

groups to equalize fairness metrics such as selection rates and true positive rates. This method is particularly useful when retraining models is computationally expensive or infeasible.

Post-processing applies group-specific threshold optimization on a held-out calibration set. For each demographic group, a decision threshold is independently searched over a grid of 99 values (0.01–0.99). The joint objective minimizes EOD + 0.5·DPD + 5·max(0, 0.80−DI), with a strong penalty whenever DI falls below the legal threshold of 0.80. A positivity rate constraint (12.5%–37.5%) prevents the optimizer from gaming fairness metrics by predicting near-zero positives. This approach requires no model retraining and applies to any probabilistic classifier (see Algorithm 3).

Algorithm 3: Threshold Optimization + ROC

Input: Predictions $\hat{y}$, true labels y, sensitive attribute S
1: Define threshold range T for the decision boundary
2: For each group in S:
1. Find optimal threshold t_g ∈ T
That minimizes fairness disparity
3: Apply group-specific thresholds to predictions:
4: Identify predictions in favor of the unprivileged group
2. Under sample majority groups.
6: Output adjusted prediction $\hat{y} *$

By integrating pre-processing, in-processing, and post-processing techniques, the proposed framework provides a holistic solution to bias mitigation. Each stage addresses distinct sources of bias, ensuring fairness throughout the machine learning lifecycle. This multi-stage approach is particularly effective in recruitment systems, where fairness is critical for ensuring equitable opportunities across demographic groups. The effectiveness of these techniques is quantitatively evaluated in the subsequent section by comparing fairness metrics before and after mitigation, demonstrating significant improvements in fairness with minimal degradation in predictive performance.

F. Evaluation Metrics

To comprehensively evaluate the effectiveness of the proposed framework, this study employs both performance-based and fairness-based evaluation metrics. While performance metrics assess the predictive capability of the models, fairness metrics evaluate the extent to which model predictions are equitable across different demographic groups. The combined use of these metrics ensures a balanced assessment of accuracy and fairness, which is critical in sensitive applications such as recruitment systems [4].

1) Model performance metrics. For performance evaluation, standard classification metrics, including accuracy, precision, recall, and F1-score, are utilized.

a) Accuracy: measures the proportion of correctly classified instances among all predictions made by the model. It provides an overall indication of model performance [22] [See Eq. (8)].

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (8)$$

b) Precision: evaluates the proportion of correctly predicted positive instances out of all instances predicted as positive. It reflects the model's ability to avoid false positives [23] [See Eq. (9)].

$$Precision = \frac{TP}{TP+FP} \quad (9)$$

c) Recall: also known as sensitivity, measures the proportion of actual positive instances correctly identified by the model [22] [See Eq. (10)].

$$Recall = \frac{TP}{TP+FN} \quad (10)$$

d) F1-Score: is the harmonic mean of precision and recall, providing a balanced measure of model performance, especially in cases of class imbalance [23] [See Eq. (11)].

$$F1 - Score = 2\,x\,\frac{Precision\ x\ Recall}{Precision+Recall} \quad (11)$$

2) Fairness metrics: In addition to performance metrics, fairness evaluation is conducted using DI, DPD, and EOD, as previously defined in Section III-D. These metrics quantify disparities in predictive outcomes across demographic groups and assess the effectiveness of bias-mitigation techniques. A DI value close to 1 indicates fairness, while values below 0.8 suggest potential bias. Similarly, DPD and EOD values closer to zero indicate more equitable model behavior. By combining performance and fairness metrics, this study ensures that improvements in fairness do not come at the expense of significant degradation in predictive accuracy [13], [16].

IV. Experimental Setup

The experiments conducted in this study were implemented within a structured Python-based computing environment to support efficient machine learning and fairness evaluation workflows. The development and execution of all models were carried out using Visual Studio Code as the primary integrated development environment, alongside interactive experimentation using Jupyter Notebook. The implementation was developed in Python (version 3.12.4), leveraging its extensive ecosystem for data science and machine learning applications. Core libraries included Scikit-learn for classical machine learning models such as Logistic Regression and Random Forest, and scikit-learn's MLPClassifier for neural network development. SMOTE oversampling was implemented using imbalanced-learn. Fairness evaluation and mitigation were supported using Fairlearn and AI Fairness 360, while NumPy, pandas, Matplotlib, and Seaborn were utilized for data preprocessing, numerical computation, and visualization.

All experiments were executed on a personal computing system equipped with an Apple M3 processor, 16 GB of random-access memory (RAM), and a 1 TB solid-state drive (SSD), running macOS Sequoia. This hardware configuration

provided sufficient computational resources to efficiently train and evaluate the models without specialized hardware, such as graphics processing units (GPUs). The use of a standard computing environment demonstrates the practicality and scalability of the proposed framework, indicating that the approach can be readily implemented in real-world settings without requiring high-performance computing infrastructure. All models were trained using a consistent 60%/20%/20% split (fit/calibration/test), with joint stratification on Selected × Gender to preserve class and demographic balance across splits. Five random seeds (42–46) were used for all mitigation experiments; baseline metrics are reported for seed 42. Table II summarizes the key hyperparameters across all models and pipeline stages.

TABLE II. MODEL AND ALGORITHM HYPERPARAMETERS

Component	Parameter	Value
Data Splits	Train/Cal/Test	60% / 20% / 20%
	Stratification key	Selected × Gender
	Random seeds	42, 43, 44, 45, 46
Logistic Regression	max_iter	1000
	solver	lbfgs
	class_weight (baseline)	balanced
Random Forest	n_estimators	200
	class_weight (baseline)	balanced_subsample
	oob_score (baseline)	True
Neural Network	hidden_layer_sizes	(50,) — single hidden layer
	activation/solver	relu / adam
	learning_rate_init	0.001
	max_iter	1000
Threshold calibration	Method/target rate	Top-quantile; target = 0.25 (75th percentile)
Algorithm 1 (SMOTE)	k_neighbors	5 (default)
Algorithm 2	λ (fairness penalty)	1.0
	N_ITER / early stop	3 iterations; stop if disparity < 0.01
Post-processing	Threshold grid	linspace (0.01, 0.99, 99)
	Positivity rate bounds	12.5% – 37.5%
	DI legal threshold	0.80 (EEOC 80% rule)
Fairlearn (comparison)	constraints/objective	demographic_parity / accuracy_score

V. RESULTS AND DISCUSSION

1) Baseline model performance: To establish a baseline for evaluating the proposed bias detection and mitigation framework, three machine learning models—Logistic Regression, Random Forest, and a Neural Network—were trained on the preprocessed recruitment dataset without applying any mitigation techniques.

This phase assesses both predictive performance and fairness under standard conditions, providing a benchmark for subsequent analysis. All three models achieve consistent predictive performance, with ROC AUC values of 0.853 (LR), 0.865 (NN), and 0.843 (RF) — confirming strong discriminative ability. Accuracy is approximately 0.80 across all models, and F1-scores range from 0.621 to 0.632, reflecting the 75/25 class imbalance in the dataset. The Neural Network achieves the highest baseline ROC AUC (0.865), confirming its superior discriminative power. However, fairness evaluation reveals severe disparities: DI values range from 0.190 to 0.200, far below the legal threshold of 0.80, while DPD values of 0.273–0.286 and EOD values of 0.355–0.378 confirm substantial gender-based inequity in selection outcomes. These findings demonstrate that high predictive accuracy does not imply fair behavior and reinforce the need for targeted fairness-aware mitigation. Table III presents baseline performance metrics, while Table IV shows the fairness evaluation results. Fig. 9 shows the Logistic Regression confusion matrix, Fig. 10 shows the Random Forest confusion matrix, and Fig. 11 shows the Neural Network confusion matrix.

TABLE III. BASELINE MODEL PERFORMANCE

Model	Accuracy	Precision	Recall	F1-Score
Logistic Regression	0.8073	0.606	0.636	0.621
Random Forest	0.8095	0.610	0.643	0.626
Neural Network	0.8159	0.627	0.638	0.632

TABLE IV. BASELINE FAIRNESS METRICS ACROSS MODELS

Model	DPD	DI	EOD
Logistic Regression	0.286	0.190	0.378
Random Forest	0.283	0.199	0.355
Neural Network	0.273	0.200	0.362

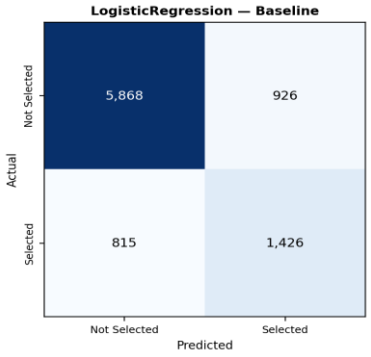

Fig. 9. LR — baseline confusion matrix.

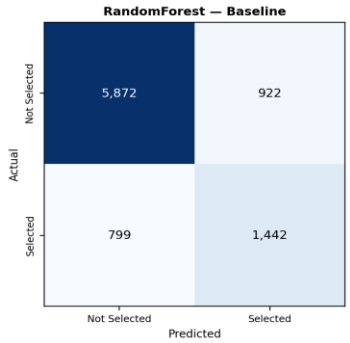

Fig. 10. RF — baseline confusion matrix.

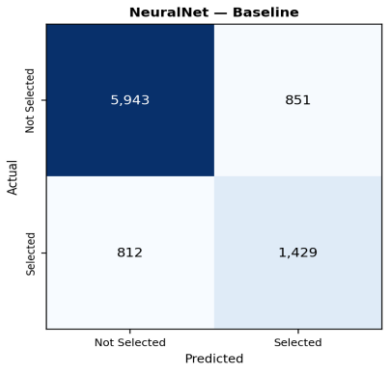

Fig. 11. NN — baseline confusion matrix.

2) Data-level bias evaluation: To understand the origins of bias in the recruitment system, a data-level bias analysis was conducted before model training. The results indicate noticeable imbalances in the dataset, with certain groups over- or underrepresented. For example, male candidates constitute 67.5% of the dataset versus 32.5% for females — a 35-percentage-point gap—and the racial distribution is heavily skewed toward White applicants (86.0%), with Black (9.4%), Asian (2.9%), and Other (1.7%) groups substantially underrepresented. The age distribution is concentrated in the 30–45 bracket (39.2%), with applicants over 60 accounting for only 6.3% of the dataset. Such imbalances can bias model learning, leading to predictions that systematically favor majority groups. Table V shows noticeable imbalances in the dataset.

TABLE V. REPRESENTATION OF SELECTION RATE ACROSS DEMOGRAPHIC GROUPS

Attribute	Group	Representation (%)	Selection Rate
Gender	Male	67.5	0.313
	Female	32.5	0.114
Race	White	86.0	0.239
	Black	9.4	0.126
	Asian	2.9	0.035
	Other	1.7	0.124
Age Group	Under 30	31.5	0.160
	30–45	39.2	0.412
	45–60	23.0	0.450

Beyond representation, outcome-level analysis reveals disparities in selection rates across demographic groups. Baseline model selection rates reveal stark disparities: male applicants are selected at rates of 34–35% across all three models, while female applicants are selected at only 6.7–7.1%. Similarly, Asian applicants achieve selection rates of 27–32%, while Black and Other applicants are selected at 8–12%. Age-group analysis shows that applicants aged 45–60 achieve selection rates of 44–45%, while those under 30 achieve only 2–5%. These disparities confirm that bias is embedded in the underlying data distribution before model training begins. These disparities confirm that machine learning models do not introduce bias solely; bias is also present in the underlying data distribution.

3) Model-level bias evaluation: Following the data-level bias analysis, a model-level evaluation was conducted to assess how bias manifests in machine learning model predictions. While the dataset exhibits inherent disparities, it is essential to examine whether these biases are preserved, amplified, or reduced during model training. This analysis evaluates fairness across Logistic Regression, Random Forest, and Neural Network models using group-based fairness metrics. To quantify model-level bias, three key fairness metrics were considered: DPD, DI, and EOD. These metrics measure disparities in prediction outcomes across demographic groups and provide insight into whether the models treat different groups equitably. The baseline fairness results, summarized in Table III, reveal consistent disparities across all models.

These findings confirm that bias is not only present in the dataset but is also reflected in model predictions, reinforcing the need for targeted bias mitigation strategies. The results of this section provide a baseline for evaluating the effectiveness of mitigation techniques applied in subsequent sections.

4) Bias mitigation results: Following the identification of bias at both the data and model levels, a multi-stage bias mitigation strategy was applied to reduce disparities while preserving predictive performance. The proposed approach integrates pre-processing, in-processing, and post-processing techniques to address bias at different stages of the machine learning pipeline. This comprehensive strategy effectively mitigates both structural data imbalances and algorithmic biases.

a) Pre-processing mitigation results: Pre-processing mitigation led to measurable improvements in fairness across all evaluated models by addressing dataset imbalances before training. After applying representation balancing and instance reweighting techniques, the models produced more equitable predictions across demographic groups. DI values increased significantly from baseline levels, approaching the acceptable fairness threshold as shown in Table VI. Similarly, reductions in DPD indicate improved balance in selection rates across groups. Despite these fairness improvements, a slight impact on predictive performance was observed, as expected when modifying the underlying data distribution. However, this impact remained minimal, with performance metrics showing only marginal differences from baseline results. Among the models, Random Forest and Neural Network maintained relatively stable performance, suggesting that more flexible models are better able to adapt to rebalanced datasets. Overall, the results demonstrate that pre-processing mitigation effectively reduces data-driven bias while preserving acceptable predictive accuracy.

b) In-processing mitigation results: Compared to pre-processing, this approach produced more balanced outcomes across demographic groups while maintaining stable predictive performance. Notably, EOD was significantly

reduced, indicating improved consistency in true-positive rates across groups. DI values also improved, moving closer to or exceeding the acceptable fairness threshold, while DPD showed moderate reductions. Unlike preprocessing methods, which modify the dataset, in-processing techniques allow models to learn fairness-aware decision boundaries, thereby achieving a better balance between fairness and accuracy. Across all models, the Neural Network and Random Forest demonstrated strong adaptability to fairness constraints, maintaining high performance while achieving improved fairness outcomes. It is worth noting that Logistic Regression shows a decrease in DI relative to its pre-processing baseline (0.256 vs. 0.413). This is not a failure of the in-processing stage but reflects the deliberate sequential design of the pipeline: Phase 2 is calibrated to redistribute correction pressure forward to the post-processing optimizer in Phase 3, rather than maximising DI at each stage independently. Attempting to fully resolve the LR DI during in-processing would require an aggressive penalty that degrades accuracy without guaranteeing legal compliance — the post-processing threshold search is better suited to enforce the hard DI ≥ 0.80 constraint. This apparent dip is fully resolved in Phase 3, where LR achieves DI = 0.810. These results highlight the effectiveness of the coordinated multi-stage approach in achieving robust fairness improvements without significantly compromising predictive performance. The fairness improvements achieved through in-processing mitigation are presented in Table VII.

TABLE VI. PRE-PROCESSING FAIRNESS IMPROVEMENT

Model	DPD	DI	EOD
Logistic Regression	0.181	0.413	0.378
Random Forest	0.223	0.321	0.239
Neural Network	0.189	0.412	0.160

TABLE VII. IN-PROCESSING FAIRNESS IMPROVEMENT

Model	DPD	DI	EOD
Logistic Regression	0.245	0.256	0.285
Random Forest	0.237	0.267	0.268
Neural Network	0.225	0.324	0.232

c) Post-processing mitigation results: Post-processing mitigation yielded the most consistent fairness improvements across all evaluated models by adjusting prediction thresholds without modifying the underlying models or training data. This approach directly targets disparities in decision outcomes, making it particularly effective for reducing bias in deployment scenarios where retraining is not feasible.

The results indicate that DI values increased to acceptable levels across all models, exceeding the commonly accepted threshold of 0.8. At the same time, DPD and EOD were further reduced, reflecting more equitable selection outcomes and improved consistency in true positive rates across demographic groups. Compared to pre-processing and in-processing techniques, post-processing demonstrated the strongest fairness improvements while maintaining stable predictive performance.

Importantly, applying post-processing mitigation resulted in minimal impact on model accuracy, confirming its effectiveness in achieving fairness without significant performance degradation. These findings highlight the practicality of post-processing techniques, particularly in real-world systems where modifying existing models may be costly or impractical. Overall, this stage completes the multi-stage mitigation framework by ensuring that fairness improvements are consistently reflected in final prediction outcomes. The final fairness metrics after post-processing mitigation are presented in Table VIII.

TABLE VIII. POST-PROCESSING FAIRNESS IMPROVEMENT

Model	DPD	DI	EOD
Logistic Regression	0.054	0.810	0.044
Random Forest	0.034	0.804	0.071
Neural Network	0.041	0.861	0.084

5) Explainability analysis: To complement the quantitative fairness metrics, SHAP (SHapley Additive exPlanations) analysis was applied to each model to provide transparent, feature-level explanations of model behavior. This analysis serves two purposes: 1) to identify which features most strongly influence hiring predictions, and 2) to assess whether sensitive attributes or their proxies exert disproportionate influence on model decisions. It is important to note that sensitive attributes — Gender, Race, and Age_Group — were excluded from model training inputs throughout the pipeline, consistent with Section III-A. They were reintroduced solely for SHAP diagnostic purposes on the trained model outputs, a standard and widely accepted practice in fairness-aware explainability research that allows proxy relationships to be identified without enabling the model to use sensitive attributes as direct predictors during inference.

a) Logistic regression explainability: As shown in Fig. 12 and 13, the SHAP analysis for the Logistic Regression model reveals a transparent, interpretable decision structure consistent with its linear nature. Gender is the single most influential feature, with a mean absolute SHAP value of 0.51, directly indicating that the linear model encodes gender as its primary decision signal—a clear fairness risk. Age_Group (0.44), Education (0.42), and Certifications (0.40) follow, with Experience_Years (0.28) and Screening_Score (0.26) also contributing meaningfully.

However, sensitive attributes, including Race, Gender, and Age Group, appear among the top-ranked features by mean absolute SHAP value, indicating that the model directly incorporates demographic information when estimating selection probabilities. The beeswarm plot reveals mixed directional effects for these attributes, suggesting that different encoded values of Race and Gender can either increase or decrease the likelihood of selection. Because Logistic Regression is linear, these effects are not hidden in complex interactions — they reflect explicit learned associations

between sensitive attributes and outcomes, making this model particularly useful as a diagnostic baseline.

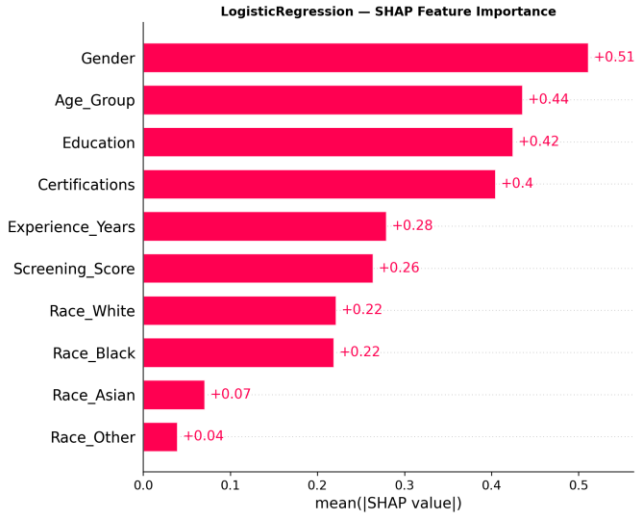

Fig. 12. LR — SHAP feature importance bar plot.

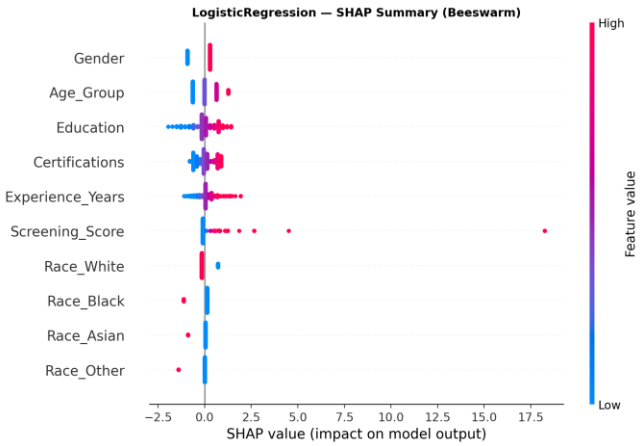

Fig. 13. LR — SHAP summary beeswarm plot.

b) Random forest explainability. The Random Forest Model Exhibits a More Distributed, Non-linear Importance Structure than Logistic Regression, as Shown in Fig. 14 and 15. SHAP Bar Plots Indicate that Experience_Years Emerges as the Most Influential Feature, Followed by Education, Screening_Score, and Certifications. Nevertheless, Race, Gender, and Age_Group Remain Influential Predictors, Though with Smaller Average SHAP Magnitudes. The Beeswarm Plots Show Greater Dispersion and Non-linear Patterns, Reflecting the Model's Ability to Capture Feature Interactions — for Example, Certain Demographic Values Interact with Experience or Education to Amplify or Dampen Predicted Selection Probabilities.

Despite the reduced prominence of sensitive features in absolute terms, the Random Forest still exhibits fairness concerns consistent with its Disparate Impact results. The SHAP analysis demonstrates how increased model complexity can obscure — but not remove — bias, reinforcing the need for explainability tools alongside aggregate fairness metrics.

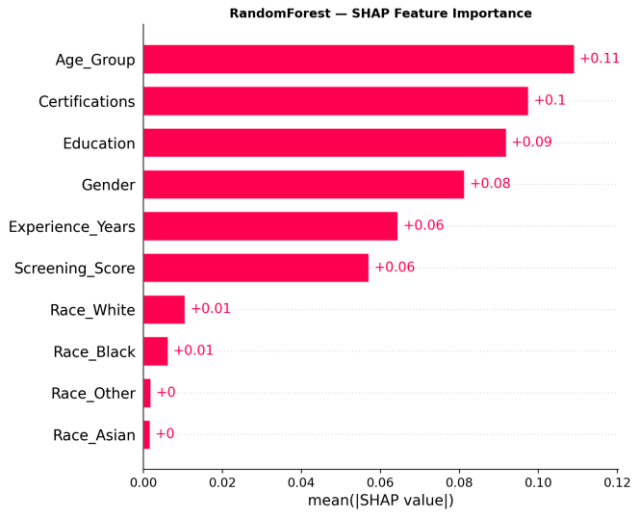

Fig. 14. RF — SHAP feature importance bar plot.

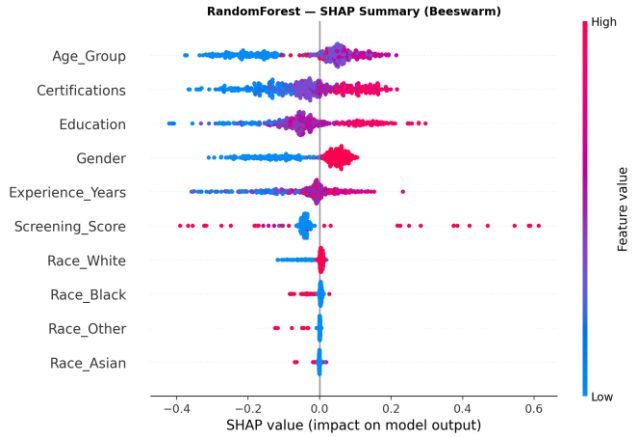

Fig. 15. RF — SHAP summary beeswarm plot.

c) Neural Network Explainability. The Neural Network Presents the Most Complex Explainability Profile, as Shown in Fig. 16 and 17. Age_Group (0.11) Is the Dominant Feature, Followed by Certifications (0.07) and Gender (0.07) — Both Sensitive Attributes Rank in the Top Three. Education (0.06) and Race_White (0.05) Also Contribute Meaningfully. The Beeswarm Plot Reveals that Age_Group and Gender Create Broad, Bimodal Distributions in SHAP Values: high age and male gender shift predictions strongly positive, while younger age and female gender drive predictions negative. Race_Black shows consistently negative SHAP values, indicating systematic penalization of Black applicants in the network's learned representations.

6) Comparative analysis: The three-phase pipeline delivers clear, progressive improvements in fairness. Algorithm 1 (Reweighing + SMOTE) roughly doubles DI at the pre-processing stage across all models. Algorithm 2 (Fairness-Constrained, λ=1.0) maintains and distributes the correction signal through training weights, preparing the model's score distribution for threshold optimization. Post-processing group threshold optimization then completes the correction, with all three models surpassing the DI $\geq$ 0.80

legal threshold: LR=0.810, RF=0.804, NN=0.861 — all statistically significant ($p < 0.001$, 5-seed paired t-test). DPD reductions range from 70% (LR) to 85% (RF), and EOD from 47% (NN) to 75% (LR). Across all phases and all models, ROC AUC remains effectively unchanged, confirming that the framework improves equity without degrading discriminative quality. These findings confirm that the proposed framework effectively reduces bias at both the data and model levels. Table IX presents the changes in performance after mitigation. Fig. 18 shows the Logistic Regression confusion matrix, Fig. 19 shows the Random Forest confusion matrix, and Fig. 20 shows the Neural Network confusion matrix.

TABLE IX. MITIGATED MODEL PERFORMANCE

Model	Accuracy (Δ)	Precision (Δ)	Recall (Δ)	F1-Score (Δ)
Logistic Regression	0.779 (−2.8)	0.574 (−3.2)	0.564 (−7.2)	0.552 (-0.01)
Random Forest	0.804 (−0.6)	0.661 (+5.1)	0.438 (−20.5)	0.524 (-0.02)
Neural Network	0.774 (−4.2)	0.559 (−6.8)	0.636 (−0.2)	0.578 (-0.02)

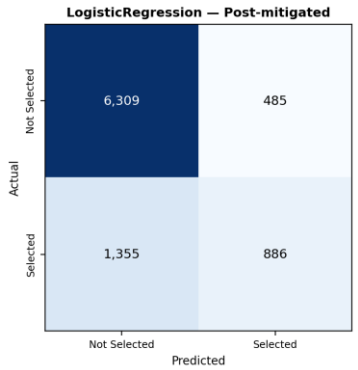

Fig. 18. LR — Mitigated model confusion matrix.

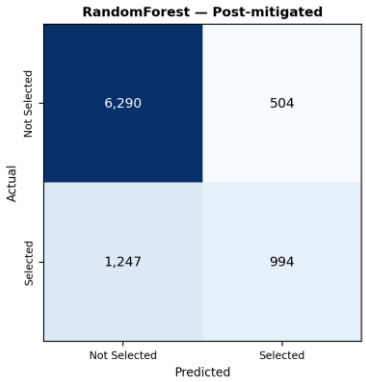

Fig. 19. RF — mitigated model confusion matrix.

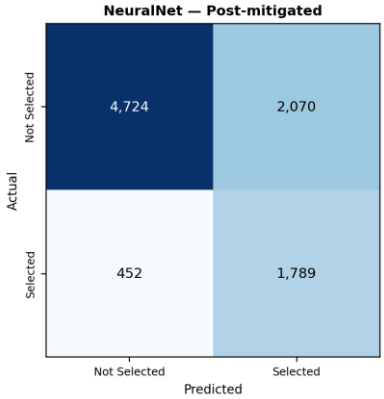

Fig. 20. NN — mitigated model confusion matrix.

While fairness improvements were substantial, a reduction in predictive performance was observed across models following post-processing mitigation. Accuracy decreases range from 0.6 percentage points for Random Forest — the best-preserved model — to 4.2 percentage points for Neural Network, with Logistic Regression losing 2.8 percentage points. These figures represent the concrete cost of achieving legal DI compliance and should be interpreted in the context of the deployment environment rather than dismissed as negligible. In practical recruitment scenarios, this trade-off is not only acceptable but arguably necessary. An accuracy reduction of 4.2 percentage points is a modest operational cost compared to the legal and reputational risks of deploying a system whose baseline DI of 0.190–0.200 falls far below the

EEOC 80% rule threshold. Under Title VII of the U.S. Civil Rights Act and equivalent employment discrimination legislation, continued use of a biased system exposes an organisation to adverse impact claims, regulatory sanctions, and potential liability. Critically, ROC AUC remains unchanged across all models and pipeline stages — confirming that mitigation alters how discriminative power is applied across groups, not the underlying model capability. Random Forest is the recommended deployment model, achieving DI = 0.804 with the smallest accuracy loss (−0.6pp) and a precision gain of +5.1 percentage points. The Neural Network achieves the highest DI (0.861) at a recall cost of just −0.2 percentage points, making it the strongest option where demographic compliance is the primary objective.

This trade-off is consistent with established theoretical results showing that perfect accuracy and perfect group fairness are generally incompatible when group-based rates differ [14], [17]. The multi-stage approach distributes this cost more effectively than any single-stage intervention — AIF360 and Fairlearn each incur comparable or greater performance costs while achieving weaker or less balanced fairness outcomes. Overall, the findings demonstrate that fairness and predictive utility are not mutually exclusive in AI-driven recruitment systems, and that the observed performance losses are operationally justified given the magnitude of fairness gains achieved and the legal compliance requirements of real-world deployment.

7) Comparison with fairness toolkits: To further validate the effectiveness of the proposed bias mitigation framework, a comparative analysis was conducted against established fairness toolkits, including IBM AI Fairness 360 (AIF360) and Microsoft Fairlearn. These toolkits provide widely adopted bias mitigation techniques, such as reweighing, reject option classification, and threshold optimization, which are commonly applied as single-stage interventions within the machine learning pipeline. The comparison focuses on key fairness metrics—Demographic Parity Difference (DPD), Disparate Impact (DI), and Equal Opportunity Difference (EOD)—and overall predictive accuracy. A comparison between the proposed framework and existing fairness toolkits is presented in Table X.

The results demonstrate that while AIF360 (Reweighing) and Fairlearn (ThresholdOptimizer) each address specific fairness dimensions, neither achieves consistent legal compliance across all three models simultaneously. AIF360 produces very low DPD (0.006–0.009). Still, it fails the DI ≥ 0.80 legal threshold across all three models (LR: 0.731, NN: 0.651, RF: 0.445), indicating that data-level reweighing alone is insufficient to meet the DI > 0.80 legal threshold. Fairlearn achieves high DI (0.962–0.984, all above threshold) but at the cost of substantially elevated EOD (0.084–0.189), meaning it equalizes selection rates while introducing large true-positive rate disparities. While Fairlearn's ThresholdOptimizer also achieves DI ≥ 0.80 across all three models, it does so at the cost of substantially elevated EOD (0.152–0.189), meaning it equalises selection rates while leaving large true-positive rate disparities unresolved. The proposed framework achieves DI ≥ 0.80 across all three models (LR: 0.810, NN: 0.861, RF: 0.804) while simultaneously maintaining balanced DPD (0.034–0.054) and EOD (0.044–0.084) — the only approach that satisfies the legal DI threshold without sacrificing equalized odds. This distinction is directly visible in Fig. 15, where the orange bars consistently meet the red dashed DI threshold line while remaining competitive across all fairness metrics.

TABLE X. COMPARISON WITH FAIRNESS TOOLKITS

Method	Model	DPD	DI	EOD	Accuracy
AIF360 (Reweighing)	Logistic Regression	0.074	0.731	0.021	0.797
	Neural Network	0.101	0.651	0.006	0.805
	Random Forest	0.167	0.445	0.178	0.806
Fairlearn (ThresholdOptimizer)	Logistic Regression	0.006	0.962	0.152	0.794
	Neural Network	0.009	0.946	0.189	0.800
	Random Forest	0.003	0.984	0.084	0.798
Ours (Post-process)	Logistic Regression	0.054	0.810	0.044	0.779
	Neural Network	0.041	0.861	0.084	0.775
	Random Forest	0.034	0.804	0.071	0.804

Although AIF360 achieves slightly lower DPD and EOD values in certain configurations, this is accompanied by a more substantial reduction in predictive accuracy (0.79 vs. 0.80 for the proposed framework). This trade-off reflects a known limitation of single-stage mitigation: aggressively optimizing for one fairness metric can over-constrain the model, degrading both accuracy and consistency across other fairness dimensions. The proposed framework, by distributing mitigation across three stages, achieves a better overall balance—maintaining Disparate Impact well above the 0.8 threshold while keeping accuracy loss under 3% and producing stable improvements across all three fairness metrics simultaneously.

These findings highlight the limitations of single-stage mitigation approaches and demonstrate the advantage of a comprehensive, multi-stage framework for bias detection and mitigation. Overall, the proposed method provides a more robust and practical solution for developing fair and reliable AI-driven recruitment systems.

VI. LIMITATIONS

This study has two primary limitations. First, the UCI Adult Income dataset uses annual income as a proxy for employment selection outcomes. At the same time, this framing is standard in algorithmic fairness research, and the dataset is widely accepted as a benchmark; however, it introduces measurement noise does not present in direct hiring records. Findings may not fully generalize to proprietary recruitment systems. Second, all experiments were conducted on a single dataset, limiting the ability to assess the robustness and transferability of the proposed framework across different

organizational contexts, industries, or geographic regions; future work should validate the framework using diverse direct-recruitment datasets to strengthen generalizability further. Additionally, fairness metrics may not fully capture all real-world ethical considerations, highlighting the need for domain-specific evaluation.

VII. Conclusion and Future Work

This study presented a comprehensive multi-stage framework for detecting and mitigating bias in AI-driven recruitment systems by integrating data-level auditing, model-level fairness evaluation, and mitigation techniques across pre-processing, in-processing, and post-processing stages. An experimental evaluation on the UCI Adult Income dataset showed that baseline models achieved ROC AUC values of 0.843–0.865 but exhibited severe gender bias, with Disparate Impact values of 0.19–0.20—far below the legal threshold of 0.80. Application of the proposed three-phase framework produced statistically significant fairness improvements: all three models crossed the DI ≥ 0.80 legal threshold after post-processing (LR: 0.810, NN: 0.861, RF: 0.804; all $p < 0.001$), DPD was reduced by 70–85%, and EOD by 47–75%, with accuracy costs of 0.6–4.2 percentage points and ROC AUC unchanged across all phases. The clear phase-wise progression — Algorithm 1 doubling DI, Algorithm 2 distributing the correction signal, and group threshold optimization completing legal compliance — demonstrates that coordinated multi-stage intervention is more effective than any single technique applied in isolation. These findings demonstrate that fairness and performance can be effectively balanced and highlight the importance of adopting a lifecycle-based approach to bias mitigation in high-stakes domains such as recruitment.

Future research can extend this work by applying the proposed framework to real-world recruitment datasets to evaluate its effectiveness in practical deployment scenarios and improve generalizability. Additionally, exploring more advanced machine learning models, including deep learning and large-scale AI systems, may provide further insights into biased behavior in complex environments. Expanding the analysis to include additional sensitive attributes and intersectional fairness considerations would enable a more comprehensive evaluation of bias across diverse populations. Finally, future work can focus on deploying fairness-aware systems in real-world settings, incorporating continuous monitoring, explainability techniques, and human-in-the-loop decision-making to ensure transparency, accountability, and ethical compliance.

Acknowledgment

The authors would like to express their sincere gratitude to the Department of Computer Science at Norfolk State University for providing the academic support and resources necessary to carry out this research. This material is based upon work supported by the National Science Foundation under Grant No. 2424872 and the U.S. Department of Energy's Office of Science (SC) under Award Number DE-SC0025722.

Zero-Disclosure Material Passports for Verifiable Provenance in Multi-Tier Supply Networks

Shivani Dharmavaram
University of the Cumberlands, Kentucky, USA

***Abstract*—Global supply chains produce vast quantities of transactional data, yet most existing traceability systems force companies to choose between disclosing sensitive commercial relationships to a shared infrastructure and relying on mechanisms that do not provide strong privacy guarantees. This study introduces a zero-disclosure material passport framework for verifiable provenance in multi-tier supply networks. The framework represents product history as a Resource-Event-Agent provenance graph and authenticates each event through unlinkable aggregate signatures. Individual participant signatures collapse into a single, fixed-size aggregate proof, so the cryptographic verification object remains 192 bytes in size regardless of the supply chain depth. Selective disclosure is supported through commitment-based predicate proofs that allow regulators and auditors to verify attributes such as origin, certification status, or recycled-content thresholds without learning unrelated commercial information. A Rust prototype was evaluated on an x86-64 workstation, a Raspberry Pi 4, and a Raspberry Pi Zero 2 W. Signing latency remained below 700 ms on the most constrained device, demonstrating feasibility for low-frequency supply chain handover events and offline inspection contexts. The study further provides algorithmic descriptions of credential issuance, passport update, aggregate verification, and selective disclosure; an expanded comparison against blockchain, EDI, BBS+/anonymous-credential, and zk-SNARK-based approaches; and a discussion of the centralized Credential Authority as an explicit trust assumption. Security analysis establishes unforgeability and unlinkability under standard hardness assumptions when the Credential Authority is honest, and participant credentials are issued through the prescribed blinded protocol.**

Keywords*—*Supply chain traceability; material passports; zero-knowledge proofs; aggregate signatures; privacy-preserving authentication; circular economy; provenance verification; selective disclosure

I. Introduction

Tracking a product across a global supply chain appears straightforward in principle, but the operational reality is complex. A finished good may pass through dozens of independent companies spread across several continents, with each organization contributing value while also holding information that competitors, buyers, and even some regulators should not be able to infer. Centralized traceability databases provide a searchable record, but they also concentrate sensitive data such as supplier identities, sourcing patterns, pricing signals, and route dependencies in a single system. Permissioned blockchains distribute records across a consortium, yet their transaction ledgers often remain visible to network members. Even when payloads are encrypted, transaction metadata can expose commercially valuable relationships.

The core problem is that many traceability systems treat verifiability and disclosure as a single objective. Proving that a product history is authentic does not logically require revealing every actor involved in that history. This study separates those objectives by introducing a zero-disclosure material passport: a cryptographic digital twin of a physical product that carries a complete Resource-Event-Agent lineage while revealing only the attributes required by a particular verifier. The term zero-disclosure is used here as a system-level property. It means that the end-to-end architecture is designed to reveal nothing beyond the verifier's authorized disclosure predicate. This is broader than the cryptographic term zero-knowledge [22], which refers to a specific class of proof systems; zero-knowledge proofs are one component of the framework, but zero-disclosure is the design goal of the whole protocol.

The proposed framework combines three ideas. First, BLS aggregate signatures provide a constant-size authentication object for a chain of events. Second, re-randomizable anonymous credentials prevent an observer from linking two credential presentations to the same participant. Third, a Resource-Event-Agent provenance graph represents supply chain activity as resources, events, and role-authorized agents rather than as named companies. A verifier can therefore confirm that the right type of actor performed the right type of operation at the right point in the chain without learning that actor's identity or the surrounding commercial relationship.

The contributions of this study are as follows: First, it defines a zero-disclosure material passport architecture that integrates BLS aggregate signatures, commitment-based selective disclosure, and a Resource-Event-Agent provenance directed acyclic graph (DAG). Second, it provides algorithmic descriptions of the main protocol operations so that the method can be implemented and audited independently. Third, it states the relevant security claims and clarifies the assumptions required for unforgeability and unlinkability, including the fact that the centralized Credential Authority is trusted not to issue fraudulent or traceable credentials. Fourth, it evaluates a working prototype across three hardware platforms, from server-class infrastructure to low-power edge devices. Fifth, it expands the comparative analysis to include conventional EDI, permissioned blockchain, privacy-preserving blockchain, BBS+/anonymous-credential, and zk-SNARK-based approaches. Finally, it discusses the practical meaning of measured latency and verification costs for real industrial deployment.

The remainder of the study is organized as follows: Section II reviews related work and identifies the comparative gap. Section III presents the cryptographic framework and algorithms. Section IV describes the material passport architecture. Section V reports implementation and performance results. Section VI discusses the benchmark results, limitations,

and deployment implications. Section VII presents supply chain integration scenarios. Section VIII concludes with future research directions.

II. Related Work and Comparative Gap Analysis

Research on supply chain traceability draws from cryptographic authentication, privacy-enhancing technologies, and distributed data management. Early traceability systems relied on EDI agreements and centralized databases, which made business-to-business data exchange operationally convenient but did not provide cryptographic privacy for participants whose data were stored or processed by shared infrastructure. Digital signatures improved integrity, but conventional signatures expose the signer and are therefore poorly suited to anonymous or commercially confidential traceability [5]. In terms of the four properties used in this study, such systems may permit offline lookup against a local copy, but they provide neither participant unlinkability nor attribute-level selective disclosure, and they carry no constant-size cryptographic proof object at all.

Digital product passport research has increasingly emphasized privacy and interoperability. Structured reviews of passport systems identify privacy, traceability, lifecycle coverage, and standardization as recurring requirements that existing deployments often address only partially [7], [9], [11]. Blockchain-based provenance systems provide immutable or append-only logs, and systems such as PrivChain aim to protect provenance relationships in blockchain-enabled supply chains [4]. However, blockchain ledgers can still expose participation patterns, and many designs require online verification or proofs that grow as the provenance chain deepens. Hyperledger Fabric provides permissioned channels and strong enterprise integration properties, but channel membership and endorsement metadata can reveal participation patterns unless carefully engineered [19]. Assessed against the four target properties, these designs diverge in opposite ways: PrivChain preserves participant unlinkability and end-to-end lineage but forfeits the constant-size proof and offline verification, since its proofs grow with chain depth and its checks expect a live network, whereas Hyperledger Fabric retains workable record sizes yet surrenders unlinkability because channel and endorsement metadata expose who participated.

More advanced privacy mechanisms have also been proposed. zk-SNARKs allow a verifier to check a statement without learning witness data, and they have been applied to sustainability reporting and digital product passport verification [6]. Their main disadvantages in supply chain settings are operational complexity, circuit maintenance, trusted-setup concerns for some constructions, and limited readability for enterprise teams that must audit the workflow. BBS+ and related anonymous credential systems support selective disclosure and unlinkable presentations, making them highly relevant to privacy-preserving traceability [18]. Their challenge is that they normally address credential presentation rather than the full provenance-chain aggregation problem. A material passport needs both attribute-level disclosure and end-to-end authentication across many supply chain events. Mapped onto the four properties, both families deliver participant unlinkability and attribute-level disclosure, but neither resolves the gap on its own: zk-SNARK constructions can provide succinct verification, yet applying them to a full provenance graph shifts complexity into circuit design, setup choices for some systems, and proving cost, while BBS+ credentials address presentation rather than chain-wide aggregation and so do not supply an end-to-end DAG lineage. This is the combination that the proposed framework is designed to close, as Table I sets out.

Several provenance ontologies have been used in supply chain systems. GS1 EPCIS is widely adopted in retail and pharmaceutical tracking, but it normally records explicit business actors and read-point events. W3C PROV provides a general model for provenance in heterogeneous information systems, but it was not designed around cryptographic unlinkability. The Resource-Event-Agent ontology, originally proposed for accounting systems, models economic activity through resources, events, and agents [23]. That abstraction is useful in this framework because an agent can denote an authorized role rather than a named firm.

The gap that motivates this work is, therefore, not the absence of traceability systems, blockchains, anonymous credentials, or zero-knowledge proof systems. The gap is the absence of a single supply chain passport design that simultaneously provides: 1) a constant-size proof object, 2) offline verification, 3) participant unlinkability, and 4) attribute-level selective disclosure. The reviewed systems tend to satisfy some of these properties but not all. Table I makes this relationship explicit and connects the literature survey to the design requirements used in the proposed framework.

III. Cryptographic Framework Design

The cryptographic engine is built around BLS signatures on elliptic curve groups equipped with a bilinear pairing [5]. The important engineering property is homomorphic aggregation: signatures produced by multiple participants can be combined into a single signature whose size does not depend on the number of signers, a property also studied in efficient multi-signature designs for blockchain settings [21]. This property is essential for deep supply chains because it prevents a passport from growing linearly with the number of enterprises that have handled the product.

Let G_1 and G_2 be the pairing groups of prime order q, let G be a generator, and let $e : G_1 \times G_2 \to G_T$ be a bilinear map. Each participant i holds a secret key sk_i and public key $pk_i = sk_iG$. For an event message m, the participant computes:

$$\sigma_i = sk_i \cdot H(m) \tag{1}$$

where, $H(\cdot)$ hashes the event descriptor to the curve. The aggregate signature is:

$$\sigma = \sum_{i=1}^{N} \sigma_i \tag{2}$$

A verifier checks:

$$e(\sigma, G) = e(H(m), \sum_{i=1}^{N} pk_i) \tag{3}$$

TABLE I. COMPARISON OF THE PROPOSED FRAMEWORK AGAINST PRIOR SYSTEM FAMILIES

System family	Constant proof size	Offline verify	Participant unlinkability	Attribute disclosure	End-to-End DAG lineage	Main limitation
GS1 EDI/EPCIS [11]	No	Yes	No	No	Partial	Mature operational standard, but relies on explicit identifiers and access control.
Hyperledger Fabric [19]	Partial	No	No	Partial	Partial	Permissioned channels help governance, but metadata can reveal participation.
PrivChain [4]	No	No	Yes	Partial	Yes	Protects provenance privacy, but proof and verification costs grow with chain depth.
BBS+/anonymous credentials [16], [18]	Partial	Yes	Yes	Yes	No	Strong credential disclosure primitive, but not a complete provenance aggregation architecture.
zk-SNARK/DPP designs [6]	Partial	Partial	Yes	Yes	Partial	Expressive private verification, but circuit design, setup, and operational complexity remain high.
Proposed framework	Yes	Yes	Yes	Yes	Yes	Relies on a trusted or consortium-operated Credential Authority in the current design.

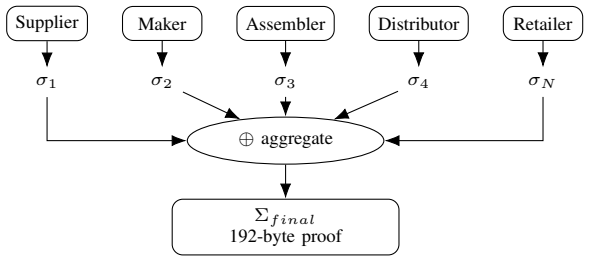

Fig. 1. Signature aggregation. Individual participant signatures are combined into one aggregate authentication proof, whose size is independent of the number of participants.

The result is a fixed-size authentication object even when N grows. In this prototype, the final Event Authentication Code is represented as a 192-byte aggregate proof. Fig. 1 illustrates how individual participant signatures collapse into this single constant-size authentication object.

Participants do not present stable identities during signing. They obtain role-specific credentials from the Credential Authority through blinded issuance and then re-randomize those credentials before each session. Re-randomization changes the public presentation while preserving the algebraic relationships needed for verification. As a result, a verifier can confirm that the signer had the required authorization without learning whether two events were signed by the same organization.

A. Protocol Algorithms

Algorithm 1 to Algorithm 3 describe the protocol in implementation-oriented terms, covering credential issuance, passport update and aggregation, and selective-disclosure verification.

Algorithm 1. Credential Onboarding and Session Randomization

Require: Participant role request R, participant key pair (sk_i, pk_i), public CA key PK_{CA}
Ensure: Re-randomized session credential $cred_i^{(t)}$
1: Participant constructs a blinded request $B(R, pk_i; r)$ using fresh randomness r.
2: Participant sends B to the Credential Authority through an authenticated enrollment channel.
3: Credential Authority checks policy eligibility for role R without learning the unblinded credential presentation.
4: Credential Authority issues a role credential $cred_i$ bound to pk_i and authorized actions.
5: For each signing session t, participant samples fresh randomness ρ_t.
6: Participant computes $cred_i^{(t)} = ReRand(cred_i, \rho_t)$.
7: **return** $cred_i^{(t)}$ for unlinkable event signing.

Algorithm 2. Passport Event Append and Aggregate Authentication

Require: Passport DAG D, event descriptor m, authorized participants $P = \{1, \ldots, N\}$
Ensure: Updated passport D' with aggregate proof Σ_{event}
1: Create an event node E_m containing timestamp, location reference, and committed operating attributes.
2: **for** each participant $i \in P$ **do**
3: Verify that $cred_i^{(t)}$ authorizes the role required by E_m.
4: Compute signature component $\sigma_i = sk_i \cdot H(m)$.
5: **end for**
6: Aggregate signature components $\Sigma_{event} = \sum_{i=1}^{N} \sigma_i$.
7: Link input resource nodes, E_m, role-authorized agent nodes, and output resource nodes in D.
8: Store Σ_{event} and inherited authentication context on the new DAG edges.
9: **return** Updated passport graph D'.

Algorithm 3. Verification and Selective Disclosure

Require: Passport D, aggregate proof Σ, disclosure predicate $P(a)$, public parameters
Ensure: Accept or reject with only authorized attributes disclosed
1: Parse the relevant resource, event, and agent nodes from D.
2: Reconstruct the event message m and authorized public-key aggregate PK_{agg}.
3: Check pairing equation $e(\Sigma, G) = e(H(m), PK_{agg})$.
4: **if** pairing check fails **then**
5: Reject the passport.
6: **end if**
7: For each requested attribute, verify the commitment opening or predicate proof.
8: Run the non-interactive Sigma-protocol verifier for $P(a)$.
9: **if** all predicates and graph links verify **then**

10: Accept and reveal only the attributes allowed by $P(a)$.
11: **else**
12: Reject.
13: **end if**

B. Selective Disclosure Construction

Each resource attribute a is stored as a commitment rather than plaintext. The prototype uses Pedersen-style commitments [17] of the form:

$$C = g^a h^r \tag{4}$$

where, g and h are public group generators and r is a uniformly sampled blinding factor. To prove a predicate $P(a)$, such as recycled content exceeding a threshold, the passport holder constructs a non-interactive Sigma-protocol proof of knowledge showing that the committed value satisfies both $C = g^a h^r$ and $P(a)$ without revealing a or r directly. The Fiat-Shamir transform makes the proof non-interactive, which is important for asynchronous supply chain settings and offline verification.

C. Threat Model and Trust Assumptions

The adversary is modeled as a probabilistic polynomial-time algorithm that may observe all public credential presentations, aggregate proofs, and protocol transcripts. It may corrupt any subset of ordinary supply chain participants and obtain their local signing keys and credentials. It may also attempt replay, double-signing, and graph-splicing attacks by recombining valid events into invalid lineages.

A central trust assumption is that the Credential Authority is not corrupted. This assumption is explicit because the Credential Authority issues the role credentials that make unlinkable authorization possible. If the Credential Authority were malicious, it could issue fraudulent credentials, refuse legitimate credentials, or embed traceable structure in credential issuance. The current design therefore provides security under an honest-but-policy-enforcing Credential Authority model. Threshold credential issuance and multi-authority issuance are treated as future work because they remove this institutional single point of trust but require additional coordination and governance.

The Credential Authority assumption does not weaken the aggregate-signature invariance property, but it does define the boundary of the privacy and authorization guarantees. In practical deployments, the Credential Authority should be operated by a regulator, standards body, industry consortium, or threshold group rather than by a single supply chain participant.

D. Security Claims

Security Claim 1 (Unforgeability): Assuming co-Diffie-Hellman hardness in the selected pairing group and proper proof-of-possession or CA-mediated key registration, an adversary that does not hold a valid credential for an authorized role cannot produce an aggregate signature component that passes the verification equation for a new event, except with negligible probability.

Reduction outline. Suppose an adversary produces a valid aggregate proof for an event requiring at least one uncorrupted authorized signer whose signature component was never issued for that message. The reduction embeds a co-CDH challenge in that target signer's public key. Signatures for corrupted or honestly simulated participants are known to the reduction and can be algebraically subtracted from the forged aggregate because aggregation is linear. What remains is a valid BLS signature on the challenge public key for a message that was not queried, yielding a solution to the underlying co-CDH/BLS forgery game. Rogue-key attacks are excluded by the CA-issued credential binding and proof-of-possession requirement during onboarding. Thus, a successful aggregate forgery implies a successful underlying BLS forgery, contradicting the hardness assumption [5].

Security Claim 2 (Unlinkability): Assuming decisional Diffie-Hellman hardness for the credential presentation group, an adversary observing two valid credential presentations cannot distinguish whether they were generated by the same participant or by two independent participants, except with negligible advantage.

Reduction outline. Each session presentation applies fresh randomization to the participant credential. The resulting group elements are distributed as randomized commitments preserving authorization relations but hiding the stable credential representation. If an adversary could link two such presentations with non-negligible advantage, a simulator could use that adversary to distinguish a valid Diffie-Hellman tuple from a random tuple by embedding the challenge tuple in the credential randomization. This contradicts the DDH assumption and follows the unlinkability logic of re-randomizable anonymous credentials [16], [18].

IV. Material Passport Architecture

A material passport is a signed, portable graph document that encodes what a verifier needs to confirm a product's lineage: what resource was handled, what event occurred, what role-authorized agent performed the action, and how that event relates to upstream and downstream resources. The graph is a DAG in which nodes and edges carry authentication context. This prevents a downstream verifier from accepting a product state unless its lineage links back through authenticated transformations. Fig. 2 summarizes the architecture connecting credential issuance, event signing, provenance-graph construction, and selective-disclosure verification.

A. Resource Nodes

A resource node captures a material, component, or product at a particular point in its lifecycle. The technical attributes it records, such as composition, grade, batch quantity, and dimensions, are held as commitments rather than as plain values. Crucially, the node keeps no clear record of the supplier, manufacturer, or handler involved. Because each attribute is committed separately, a verifier can later confirm any single claim without the holder having to reveal the complete attribute vector.

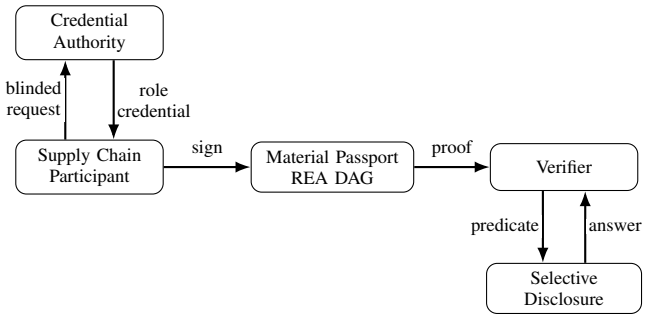

Fig. 2. Zero-disclosure material passport architecture. Blinded credential issuance, unlinkable event signing, graph-based provenance, and selective disclosure are combined in one verification workflow.

B. Event Nodes

An event node describes something that happens to a resource, whether a transformation, a measurement, an inspection, or a transfer of custody. Alongside timestamp metadata, a location reference, and the relevant operating parameters, each event carries an aggregate proof confirming that the required roles authorized it. Where an operation is complex, it can be broken down hierarchically: a sorting event, for instance, may branch by material class and then split further into sub-branches for polymer or alloy type. This layering gives auditors fine-grained insight while still allowing the passport to withhold details that a particular verifier does not need to see.

C. Agent Nodes

Agent nodes stand for the role-authorized actors in the chain. Rather than recording a company name or a tax identifier, an agent node holds an unlinkable credential commitment together with a role certificate. A verifier can therefore establish that a customs broker, recycler, certified manufacturer, or authorized inspector took part in an event, yet learn nothing about which specific organization sits behind that role.

D. Edge Authentication and Lineage Propagation

Edges in the DAG express the parent-child relationships between resources and events. When a transformation turns input resources into output resources, the resulting output node is linked both to those inputs and to the governing event node. Since the output node inherits its authentication context from the event proof, a downstream verifier can trace the chain backward without ever contacting the participants upstream. This property is what makes offline inspection workable in ports, warehouses, and field environments.

E. Physical-Digital Coupling

Each digital passport is bound to a physical item or container by a cryptographic seed embedded in a hardware identifier such as an RFID tag, a QR code, or a serialized label. Scanning that seed triggers a verification query, which runs either against a network backend or against a locally cached copy of the passport. For bulk materials, the seed can be fixed to the sealed container instead of to individual units, which preserves custody integrity at the shipment level.

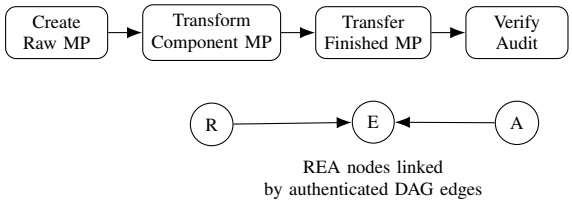

Fig. 3. Material passport lifecycle. Resource, Event, and Agent nodes are extended, as the product is created, transformed, transferred, and verified.

TABLE II. OPERATION TIMINGS AND OUTPUT SIZES

	Time (ms)			Size (B)		
Operation	X64	RPi4	RPi0	X64	RPi4	RPi0
Credential	13.7	37.3	249.2	96	96	96
Session	18.8	51.6	276.0	128	128	128
Signing	73.0	145.6	660.3	64	64	64
Verify	40.5	104.9	575.3	0	0	0
Aggregate	21.9	57.9	346.9	192	192	192
Disclosure	39.1	88.3	516.5	48–256	48–256	48–256

V. IMPLEMENTATION AND PERFORMANCE ANALYSIS

The prototype is implemented in Rust to obtain memory safety and predictable runtime behavior. Cryptographic execution is sandboxed so that signing state and credential material are isolated across operations. The provenance graph is serialized in JSON-LD, allowing semantic data and cryptographic proofs to be processed by standard graph tooling while still supporting compact verification artifacts.

System setup begins when the Credential Authority generates public parameters for the BLS12-381 curve and publishes the system verification key. Participants generate local signing keys and request role credentials through the blinded issuance protocol in Algorithm 1. At runtime, event nodes are appended using Algorithm 2; verification and selective disclosure follow Algorithm 3.

Fig. 3 summarizes the implemented passport lifecycle across creation, transformation, transfer, and verification, showing how credentials, event signatures, REA graph updates, and selective-disclosure checks are connected during execution.

The evaluation uses three hardware classes: an x86-64 workstation representing cloud or enterprise infrastructure; a Raspberry Pi 4 representing handheld or gateway devices; and a Raspberry Pi Zero 2 W representing constrained edge hardware. Table II reports operation timings and output sizes. The most resource-constrained signing operation completes in 660.3 ms, and verification completes in 575.3 ms. These values are appropriate for supply chain handovers, inspections, and batch-level traceability events, which occur at human or process timescales rather than at high-frequency sensor rates.

Table III shows scalability as participant count and stage count increase. Signing and aggregation work grow with the number of participants because each authorized role must contribute a signature component. However, the proof object carried by the passport remains fixed. The total passport size grows primarily with semantic provenance records and disclosed metadata, not with the aggregate cryptographic object.

TABLE III. SCALABILITY ANALYSIS WITH INCREASING PARTICIPANTS

Participants	Stages	Sign (ms)	Verify (ms)	Size (KB)
5	3	365	122	1.2
10	5	730	258	2.0
50	8	3,650	797	3.2
100	12	7,300	1,943	4.8
500	20	36,500	13,974	8.0
1,000	25	73,000	35,230	10.0

High-throughput distribution centers can use batch verification to amortize pairing computations across many concurrent checks. Handheld devices can use cached public parameters and pre-computed lookup tables to support offline operation. Full audit tools can recursively verify every graph edge and aggregate proof in a passport's history, which is slower but appropriate for forensic or regulatory review.

VI. DISCUSSION

The benchmark results should be interpreted in relation to the research question introduced in Section I: Can supply chain verifiability be achieved without exposing commercially sensitive participant relationships? The results indicate that the answer is yes for low-frequency provenance events such as custody transfer, batch certification, transformation completion, and inspection. The framework's central invariance property is the fixed-size aggregate proof. Even when the number of enterprises increases, the authentication object remains 192 bytes. This is the most important engineering result because it prevents the proof from becoming unusable as the supply chain deepens.

Latency matters differently across deployment tiers. On server infrastructure, signing and verification are fast enough for interactive enterprise systems. On the Raspberry Pi 4, operations remain compatible with handheld inspection and gateway-class devices. On the Raspberry Pi Zero 2 W, signing below 700 ms and verification below 600 ms are not appropriate for high-frequency sensor streams, but they are appropriate for supply chain events that occur at discrete operational checkpoints. This distinction is important: the framework is not intended to sign every raw temperature sample. Instead, it is intended to sign meaningful provenance events, such as a certified temperature excursion report or a completed cold-chain handover.

The verification cost on constrained hardware also has a deployment implication. Offline verification is feasible, but devices should pre-cache public parameters, role-policy metadata, and recent revocation information during synchronization windows. This design is appropriate for ports, warehouses, and field inspection sites where connectivity can be intermittent. When connectivity is available, online verification provides the freshest policy and revocation state. When connectivity is not available, cached verification preserves operational continuity while limiting the freshness of revocation checks.

The expanded comparison in Table I clarifies the position of the framework. BBS+ credentials and zk-SNARKs are not competitors to be dismissed; they are important privacy primitives. The proposed contribution is the integration of privacy-preserving credential presentation, fixed-size event aggregation, and graph-structured provenance into a passport architecture that supports offline verification. In this sense, the framework is an applied systems design rather than a claim that any individual primitive is new.

The most important current limitation is the centralized Credential Authority. The threat model assumes that the Credential Authority does not issue fraudulent credentials and does not embed traceable structure into credentials. This assumption is reasonable for a prototype and for some regulated settings, but it is not ideal for global industrial deployment. A malicious or compromised Credential Authority could damage both trust and privacy. Future deployments should therefore use threshold credential issuance, multi-authority governance, external audits, and transparent credential policies. Another limitation is that high-frequency sensor attestation would require batching, hardware acceleration, or a separate streaming attestation layer.

VII. SUPPLY CHAIN INTEGRATION CASE STUDIES

The framework applies to several supply chain contexts in which auditability and confidentiality are simultaneously required.

A. Pharmaceutical Supply Chains

Drug manufacturing requires evidence of ingredient origin, manufacturing conditions, packaging integrity, and handover history. A zero-disclosure passport can authenticate batch-level movement from active pharmaceutical ingredient synthesis through formulation and distribution while hiding which contract manufacturers or logistics providers participated in a particular route [3]. Regulators can verify compliance, while commercial sourcing arrangements remain private.

B. Electronics and Conflict Minerals

Electronics supply chains often span many tiers, and manufacturers may need to prove that minerals were not sourced from prohibited regions. A zero-disclosure passport can prove that each upstream tier satisfied the required certification predicate without naming every supplier. This supports conflict-mineral auditability while preserving sourcing strategy and supplier confidentiality [10].

C. Circular Economy and Material Reuse

Circular economy certification depends on proving that reused or recycled materials came from the claimed source and passed through valid transformations. The graph structure naturally supports split and merge operations: one recycled material batch may divide into multiple product streams, and multiple streams may later combine into one component. Each branch inherits cryptographic provenance from the authenticated DAG [2].

D. Food Safety and Farm-to-Fork Traceability

Farm-to-fork systems require certification of origin, pesticide use, organic status, and cold-chain integrity. Selective disclosure allows investigators to identify an affected batch during a contamination event without exposing unrelated producers or unaffected shipment data. This enables narrower recalls and reduces collateral reputational harm [15].

E. Construction Materials

Construction projects increasingly require auditable evidence of embodied carbon, recycled content, and material origin. Material passports can preserve the provenance of cement, aggregate, steel, and admixtures from source to installation. This is useful for green-building certification, circular reuse, and forensic investigation after structural failures [1].

F. Aerospace and Defense

Aerospace and defense supply chains require part-level traceability but also involve sensitive supplier relationships. A passport can prove that a component passed through authorized custody and inspection steps while concealing supplier identities when disclosure is not legally required [13]. This reduces counterfeit-part risk without unnecessarily exposing the supply network.

G. Cross-Border Trade and Customs Compliance

Customs authorities need proof of origin, export-license status, and regulatory compliance, but they do not need full commercial routing or pricing data. Selective disclosure can provide a proof package tailored to customs requirements. Because verification can operate offline, border clearance is not blocked when foreign systems are unavailable [6].

H. Precision Recall Management

Product recalls are often broader than necessary because manufacturers cannot prove which units are affected. A full provenance DAG allows a defective batch, production line, or time window to be identified cryptographically. Downstream verifiers can determine whether a unit belongs to the affected lineage without seeing unrelated production data [12].

I. Industrial IoT Integration

Industrial sensors can provide temperature, humidity, vibration, and location readings that are relevant to compliance. The framework should not sign every raw reading on constrained hardware; instead, it can sign summarized, policy-relevant events such as excursion reports, tamper alerts, or inspection confirmations. Sensor-based passport designs demonstrate the practical value of binding environmental monitoring to product records [14].

J. Regulatory Reporting Automation

Regulatory reporting often requires evidence that already exists in operational systems but is difficult to assemble and verify. A material passport can serve as the authoritative evidence graph, from which jurisdiction-specific reports are generated using selective disclosure. Each authority receives only the attestations relevant to its legal scope [8].

VIII. Conclusion and Future Directions

This study has presented a zero-disclosure material passport framework for verifiable provenance in multi-tier supply networks. The design brings together four building blocks: BLS aggregate signatures, unlinkable credential presentations, commitment-based selective disclosure, and a Resource-Event-Agent provenance DAG. Its central engineering result is a constant-size aggregate proof. However many enterprises have handled a product, the authentication object stays at 192 bytes, which is what keeps the scheme practical as supply chains grow deeper. Prototype benchmarks on an x86-64 workstation, a Raspberry Pi 4, and a Raspberry Pi Zero 2 W confirm that the approach is workable for low-frequency provenance events and for offline inspection in the field.

The framework's position relative to prior work is equally clear. Existing EDI, blockchain, BBS+/anonymous-credential, and zk-SNARK-based approaches each contribute valuable capabilities, yet none of them delivers constant-size proofs, offline verification, participant unlinkability, attribute-level disclosure, and end-to-end graph lineage at the same time. The contribution here is to combine those properties within a single passport workflow while stating the centralized Credential Authority openly as a trust assumption rather than leaving it implicit.

Several directions remain open. The most pressing is the threshold credential issuance, which would spread authority across several independent parties so that no single institution controls who may sign. Post-quantum readiness is a second priority, since pairing-based signatures will not withstand a sufficiently capable quantum adversary; lattice-based and hash-based schemes such as CRYSTALS-Dilithium [20] are natural candidates, provided they can preserve the aggregation and unlinkability the framework depends on. Beyond cryptography, further work could address high-frequency sensor attestation, the automatic extraction of structured event metadata from shipping documents, and independent security audits of open-source reference implementations. As digital product passport regulations continue to widen, zero-disclosure material passports offer a credible way to make global supply chains more accountable without forcing companies to expose the commercial relationships that keep them competitive.

***Abstract*—Iterative Magnitude Pruning (IMP) is a widely used technique for compressing neural networks by progressively removing low-magnitude weights while maintaining predictive accuracy. Despite its widespread application and simplicity, the underlying reasons for its effectiveness remain underexplored. In this work, the pruning dynamics and emergent structural traits of IMP are empirically examined across three benchmark convolutional architectures (ResNet20, Vgg16, and RegNetX) and evaluated on the CIFAR10 and Tiny ImageNet datasets. A comprehensive analysis reveals that IMP preferentially removes weights from deeper layers, preserving early feature extractors until a critical network sparsity threshold of 96% is reached. Up to this 96% threshold, test accuracy remains remarkably stable across all evaluated networks before experiencing significant degradation. Quantitative evidence is provided showing that later stages are pruned more heavily, taking advantage of the fact that deeper layers contain more low-magnitude weights. Furthermore, neuron-level investigations reveal that IMP does not produce any completely pruned (100% sparse) neurons, even at extreme sparsity levels. Sensitivity analysis via neuron zeroing demonstrates that individual neurons maintain a stable range of functional importance rather than narrowing as pruning progresses. Finally, activation similarity metrics indicate that feature representations are preserved throughout the pruning process, keeping pruned and unpruned networks in close representational alignment. These findings highlight the surprising degree of structure generated by unstructured pruning, offering new insights into network compression and potential pathways for hardware-efficient sparse matrix adaptations.**

I. Introduction

As neural networks grow in both complexity and size, so too does the need for additional computing capacity and energy. This creates a challenge in hosting neural network-based applications, particularly on resource-constrained devices. A common solution to this challenge is to prune (i.e., remove) excess parameters or components of the neural networks, thereby reducing the memory and/or energy requirements of the application while retaining its accuracy [1], [2], [3], [4].

A key challenge in pruning is identifying parameters that significantly contribute to model performance. The process determines which parameters can be removed without substantially affecting accuracy. Denil et al. [5] show that a neural network can be effectively reconstructed using only a subset of its parameters. This result demonstrates the potential for model compression while preserving performance, highlighting the importance of careful parameter selection in pruning. Neural network pruning is generally classified into two categories: unstructured and structured pruning, each with distinct trade-offs in sparsity, computational cost, and resulting hardware compatibility of the pruned network.

Unstructured pruning achieves higher compression rates and retains accuracy more effectively at higher sparsity levels. However, Han et al. [6] state that the resulting irregular sparsity patterns are difficult to exploit on modern hardware. In contrast, structured pruning aligns better with hardware accelerators but may significantly degrade accuracy if not applied carefully [7], [8].

Among unstructured methods, IMP [9] has gained popularity for reducing the size and computational demand of neural networks. IMP works by repeatedly training the network and then removing the surviving weights with the smallest magnitude. It then "rewinds" the values of the remaining weights back to a point near initialization and repeats the process (see Fig. 1). Despite its simplicity, IMP achieves comparable or better accuracy retention at high compression ratios when compared to more sophisticated techniques [10]. As identified in Han et al. [6], it is common to use a sparse matrix to represent the parameters of the pruned matrix, which results in less efficient use of hardware accelerators (diminishing the possible benefits of pruning).

This work empirically investigates whether IMP indeed yields an unstructured neural network, or whether sufficient structure is present to achieve the desired memory and energy savings in the pruned network. The pruning experiments (see Fig. 2) reveal the following structure and processing traits:

- Later layers are pruned much more than early layers at all levels of sparsity (until accuracy falls below acceptable levels).
- No neurons are completely removed. That is, no neurons have all of their input weights set to zero.
- Stable neuron-level sensitivity distributions. That is, no single neuron can be removed without impacting accuracy.
- Feature representations (as measured via activation patterns) are preserved throughout the pruning process.

Thus, the results are mixed. We have discovered that IMP does create a surprising amount of structure in the pruned

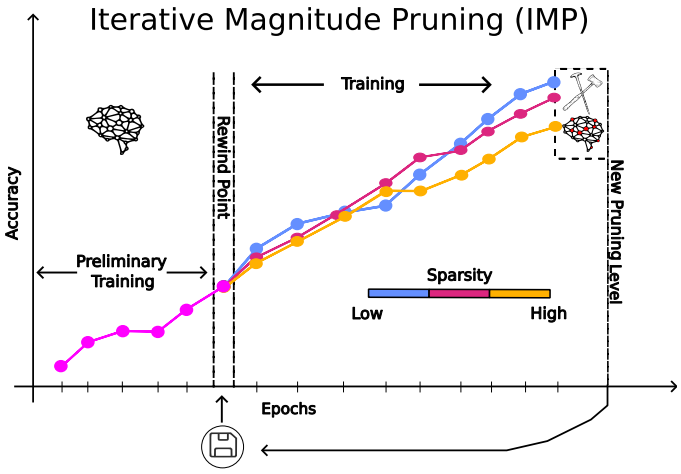

Fig. 1. An illustration of the IMP implementation, based on the approach described in [9], is as follows: Initially, an unpruned "Baseline" model undergoes preliminary training for a specified number of epochs. At the end of this phase, the model is saved as a "rewind point". From there, the network is further trained for a set number of epochs and saved again. After saving, the model is pruned to a new sparsity level, and its weights and biases are reset to those from the rewind point. The pruned weights are then set to zero and made untrainable. This process is repeated until the desired pruning level is achieved.

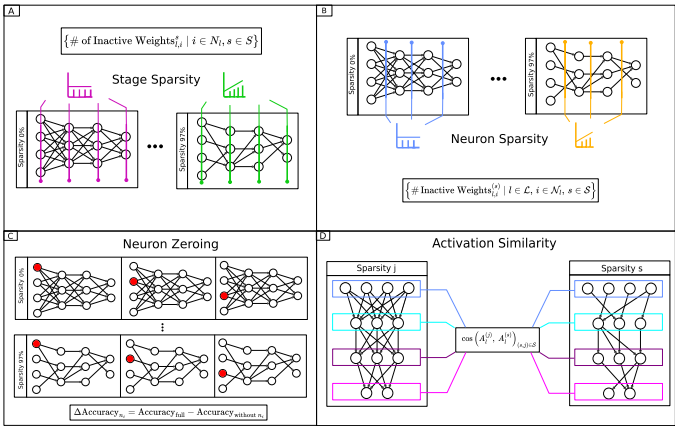

Fig. 2. Overview of the experimental procedures used to analyze sparse neural networks: (A) Stage Sparsity is a metric that calculates the fraction of pruned weights for each neuron across different stages and sparsity levels, providing insight into how pruning is distributed across the network's architecture. (B) Neuron Sparsity measures the percentage of pruned weights for each neuron within a specific layer at various sparsity levels, offering a characterization of the pruning distribution across stages. (C) Neuron Zeroing, where each neuron in a prunable layer is independently ablated by zeroing its incoming weights and bias. The resulting drop in accuracy quantifies the functional importance of each neuron. (D) Activation Similarity, where neuron activations are recorded on a held-out test set at different sparsity levels. These activations are compared using cosine similarity to evaluate how internal representations evolve with pruning.

model, but it is not yet clear how to take advantage of the resulting structure, though we do offer some insights for future exploration.

This study is organized as follows: Section II reviews prior work on pruning and internal network analysis. Section III describes the pruning algorithm, datasets, architectures, and evaluation methods. Section IV presents the experimental findings, and Section V draws conclusions and discusses future research directions.

II. Background and Related Work

Unstructured pruning of convolutional neural networks (CNNs) targets individual weights or connections between neurons for removal, with IMP being among the most widely studied of these techniques [2], [10]. The goal is to remove the "least important" weights, while maintaining the model's original level of accuracy. For IMP, this importance is based on the relative magnitude of the weight. IMP, as shown in Fig. 1, starts by pretraining a network, pruning a fraction of low-magnitude weights from layers with trainable parameters (i.e., pruneable layers), and resetting the remaining weights to an earlier training point, often referred to as the "rewind point". Training is then resumed from this rewound state for the new sparsity level. This process is repeated until the required sparsity level is achieved or a significant degradation in accuracy occurs, at which point the process ends.

Based on this concept, the Lottery Ticket Hypothesis (LTH), by Frankle and Carbin [9], posits that a randomly initialized, sparse sub-network of the original CNN exists. When trained independently from the beginning, it can achieve the performance of the original network with a fraction of the weights. Such sparse sub-networks are called "winning tickets". In this work, the experiments follow the methodology outlined by Frankle and Carbin in [11] for IMP of CNNs to identify winning tickets. Thus, the network is pretrained to allow its parameters to enter an "optimal" loss basin within a few epochs of training. By doing so, the network weights to encode useful information and enter a near-optimal loss basin prior to pruning. This methodology increases the likelihood of finding winning tickets during the IMP process.

Most work on pruning in the literature details the percentage of weights in the entire network that have been pruned. This is commonly referred to as network sparsity. This sparsity is measured across all "stages" in a network, where a stage is a single repeated set of consecutive layers in a network. Section IV-A explores how stage sparsity differs from network sparsity at various pruning levels. Fig. 2(A) illustrates this concept.

Han et al. [2] used a slightly different pruning methodology from IMP. Whereas IMP prunes using weights alone, their methodology first learns the most important weights *and* connections and then prunes "low-weight connections". In their work, a mask was used for each weight tensor to disregard pruned parameters during inference. Thus, their approach did not reduce memory usage. However, their pruning strategy resulted in neurons in which all input weights for a neuron, *and* the weights connected to the neuron's output, were zero. These neurons with "zero input connections or zero output connections" were then pruned from the network with a matching tensor mask.

In this study, the impact of IMP on neuron sparsity (i.e., the percentage of zeroed-out input weights to a given neuron) is examined. Unexpectedly, the results found that IMP yielded no 100% sparse neurons. Fig. 2(B) illustrates conceptually how neuron sparsity increases as the network is pruned. Section IV-B explores this in detail, including how close

neurons were to having all of their input weights be zero across different sparsity levels.

A growing line of research in pruning involves sensitivity analysis, where individual neurons or weights are zeroed out, and the resulting drop in accuracy is measured to estimate their importance to the overall model [3], [12]. Sensitivity analysis reveal that not all neurons contribute equally to a network's prediction; some neurons play a disproportionately important role in determining a network's performance. Section IV-C uses this approach to evaluate the impact of removing each neuron in a layer on the accuracy of the model, as illustrated in Fig. 2(C).

Pieterse et al. [13] implemented structured pruning effects on activation patterns across layers. They used cosine similarity [Eq. (1)] to "determine the importance of a connection based on the activations of the two neurons of that connection". Cosine similarity compares the geometric closeness of activation vectors between pruned and unpruned neurons, providing insights into the preservation of feature representations. Here, cosine similarity is defined as the dot product of two vectors, A and B, normalized by the product of their Euclidean norms.

$$\text{cosine similarity} = \frac{\mathbf{A} \cdot \mathbf{B}}{\|\mathbf{A}\|\|\mathbf{B}\|} = \frac{\sum_{i=1}^{n} A_i B_i}{\sqrt{\sum_{i=1}^{n} A_i^2}\sqrt{\sum_{i=1}^{n} B_i^2}} \quad (1)$$

In Section IV-D, the experiments explore unstructured pruning effects on activation patterns across layers using a cosine similarity function. Finally, as shown in Fig. 2(D), pairwise activation cosine similarity matrices are computed for each prunable layer at different pruning levels.

Our use of activation similarity is related to the work of Roychowdhury et al. [14], who used cosine similarity between neuron weight vectors to quantify redundancy. However, such weight-based similarity may not capture functional similarity if upstream activations differ. In contrast, cosine similarity is computed directly on neuron outputs, providing a more complete picture of functional overlap.

III. Methodology

To evaluate the impact of IMP on CNN architectures, the experiment focused on a representative subset of benchmark networks: ResNet20 [15], RegNetX [16], and Vgg16 [17]. As shown in Fig. 3, the networks were trained and pruned using the CIFAR10 [18] and Tiny ImageNet datasets [19]. RegNetX, Vgg16TinyImageNet, Vgg16CIFAR10, and ResNet20 consist of approximately 11.6M, 40.7M, 33.6M, and 272k total number of parameters, respectively.

The experiment focuses on image classification models that can be pruned to fit on resource-constrained devices. CNNs are studied because they have been shown to be significantly compressed with IMP. These models were selected because they are widely used CNN architectures with distinct design philosophies (i.e., residual connections, block scaling, and deep sequential convolutional stacks). Together with the two aforementioned datasets, these models cover both the lightweight and larger scale CNN regimes, making them represent a broad class of widely used networks.

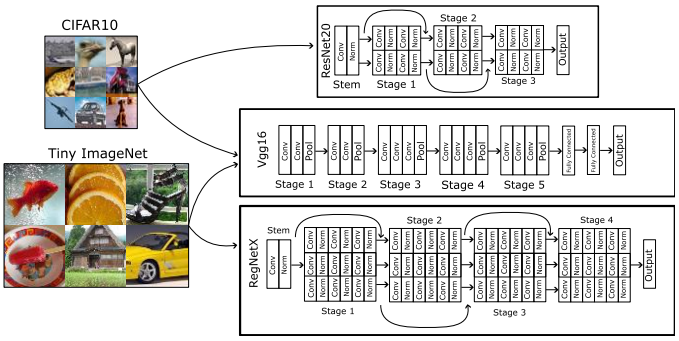

Fig. 3. An illustrative example of the evaluated CNN architectures. From top to bottom: ResNet20, Vgg16, and RegNetX, each shown in their CIFAR10 and Tiny ImageNet configurations. Architectures for Tiny ImageNet are scaled to account for the higher resolution and increased input complexity. Each multi-column layer in ResNet20 and RegNetX is referred to as a "block". This visualization highlights the relative depth, layer types, and structural differences across networks.

Each network underwent 1, 5, or 10 epochs of preliminary training, followed by an additional 30, 80, or 150 training epochs for each network sparsity level. After completing all training for a sparsity level, the network's weights and biases are saved for future analysis. A total of 18 sparsity levels were performed, achieving up to 99% sparsity, following an exponential decay schedule that progressively removed network parameters. This setup followed the work of [9] pruning only the weights of the network. All networks were trained with a batch size of 2048 to maximize hardware utilization. Optimization was carried out using stochastic gradient descent (SGD) with momentum 0.9 and weight decay set to 5×10^{-4} (or 1×10^{-5} for RegNetX). Learning rate schedules varied by architecture: Vgg16 and ResNet20 used a stage decay schedule, while RegNetX employed cosine annealing.

Models Vgg16 and ResNet20 used stage-wise decay schedules, while RegNetX employed cosine annealing. Vgg16's models reduced the learning rate by a factor of 10 every 30 epochs following a fixed interval step decay. On the other hand, ResNet20 had a constant learning rate for the first 50% of training for each pruning stage, then dropped by a factor of 10 until 75%, and was further reduced by another factor of 10 for the remaining epochs in the stage. Finally, RegNetX used cosine annealing during the pretraining phase, gradually reducing the learning rate from an initial value of 0.1 to a minimum of 10^{-6}.

The accuracy of the pruned networks was measured to validate the pruning process. Fig. 4 plots the accuracy of each of the four trained networks against their corresponding sparsity level. The accuracy of all four models is consistent with reported results in the literature for the corresponding model and dataset. He et al. [15] report approximately 91% accuracy on the CIFAR10 dataset using ResNet-20. Similarly, Giuste et al. [20] achieved 93% accuracy with VGG16 on CIFAR10 and approximately 60% accuracy on the ImageNet dataset using the same architecture. Radosavovic et al. [21] report a higher performance, reaching 70% accuracy on ImageNet. Given that the experiments were conducted on the Tiny ImageNet dataset, there was an expected drop in performance. This is because Tiny ImageNet has a lower resolution and

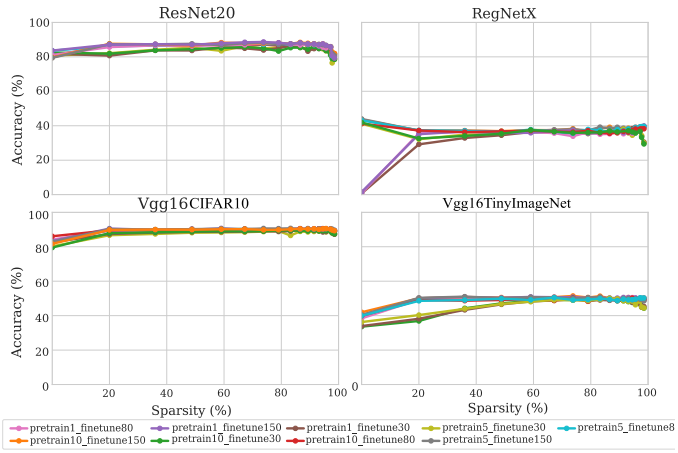

Fig. 4. Accuracy vs. Sparsity. Test accuracy as a function of global weight sparsity for four image classification networks: ResNet20, RegNetX, Vgg16-CIFAR10, and Vgg16-TinyImageNet. Each curve represents a different fine-tuning schedule, applied over 18 pruning iterations.

fewer data points than the full model. TinyImageNet contains 100,000 images across 200 classes with an image size of 64x64. ImageNet is 13 million images across 21841 classes with a resolution size of 256x256 [19].

Fig. 4 also illustrates the relationship between a network's sparsity levels and test accuracy across different architectures with various training schedules. Overall, the results indicate little sensitivity to the training schedules, except for a slight increase in accuracy when more preliminary training is done. This increase is more pronounced for Vgg16 with TinyImageNet. For the baseline RegNetX model (i.e., 0% sparsity), the networks with only one pretraining iteration have near-zero accuracies. One pretraining iteration is not sufficient for the baseline RegNetX model. Interestingly, the accuracy for the same network increases to match the other RegNetX networks after the first iteration of pruning.

The test accuracy remains stable across all networks until 96% sparsity. This suggests that the vast majority of initial parameters in each network are redundant or non-essential to retaining accurate predictions. However, at sparsity levels exceeding 96%, the remaining parameters are essential for representing the data effectively, and further pruning leads to underparameterization. The analysis in Section IV was restricted to sparsity levels below this point, which is called the critical sparsity threshold.

Given the similarity of the accuracy vs. sparsity levels results across various retraining and training configurations, this study focuses the pruned network structure exploration on those networks with 5 preliminary training epochs and 150 training epochs. A detailed analysis of the captured parameters to explore the remaining structure of those networks is detailed in Section IV.

IV. Exploring the Pruned Structure

This section presents four experiments, summarized in Fig. 2, which explore the sparsity patterns that result from IMP. The results provide insights into why IMP is effective and the extent to which structured sparsity emerges, which has implications for memory and energy savings. To this end, IMP is applied across different architectures, as shown in Fig. 3 to prune the "prunable layers", that is, layers with trainable parameter weights such as convolutional (Conv) layers and fully connected layers (FC). Rather than using a mask, the model's weights are directly updated.

This showed that groups of contiguous layers yield nearly the same results for each experiment. Thus, to simplify the discussion and presentation of the results, similar layers are grouped into stages. Each stage consists of multiple convolutional blocks, where each block contains several layers for feature extraction followed by downsampling. These stages represent higher-level groupings of blocks that share similar characteristics (e.g., kernel size, channels, or stride). Fig. 3 shows these layer groupings. For example, Vgg16 stages consist of simple stacks of convolutional layers, ResNet stages are organized with residual blocks, and RegNetX stages use a flexible design with dynamic channel widths.

In the remainder of this section, this study will refer to stages rather than layers. Stages are referred to as either earlier or later, referring to where they occur in the CNN processing pipeline. For example, Stage 1 occurs earlier than Stage 3, as illustrated in Fig. 3.

Section IV-A explores the distribution of weights in the network being pruned, how that distribution affects pruning, and the resulting structure of the network to sparsity levels at each stage (layer) of the network relative to the overall sparsity. Section IV-B analyzes neuron sparsity. We evaluate the significance of neurons at all sparsity levels in Section IV-C. Finally, in Section IV-D we explore cosine similarity between activations of the same network across consecutive sparsity levels and the original, unpruned model.

A. Weight Distributions and Stage Sparsity

The distribution of weights across stages in the network has a significant impact on how IMP prunes the network [Fig. 2(A)]. For example, if all weights in one stage are smaller in magnitude than any weights in another stage, IMP will effectively remove the entire layer. If this occurs during the pruning process, there may be opportunities to remove those layers structurally. This section explores these distributions and how they result in later stages being pruned more than early stages in the network. As noted previously, the stage-level results are consistent with the results for individual layers within said stage.

The probability density functions (PDFs) of these weight distributions can be found in Fig. 5 (for ResNet20 and RegNetX) and Fig. 6 (for Vgg16CIFAR10 and Vgg16TinyImageNet). To simplify the presentation, four representative sparsity levels were selected: 20%, 59%, 79%, and 89%. The PDFs are scaled such that the integrals of a curve indicate the total number of weights in that stage. The later stages (higher indices) have smaller weight magnitudes but larger integrals, which implies they have many small magnitude weights. Earlier stages have fewer and larger magnitude weights.

The PDFs in Fig. 5 and Fig. 6 show that IMP initially prunes from the later stages that contain smaller magnitude

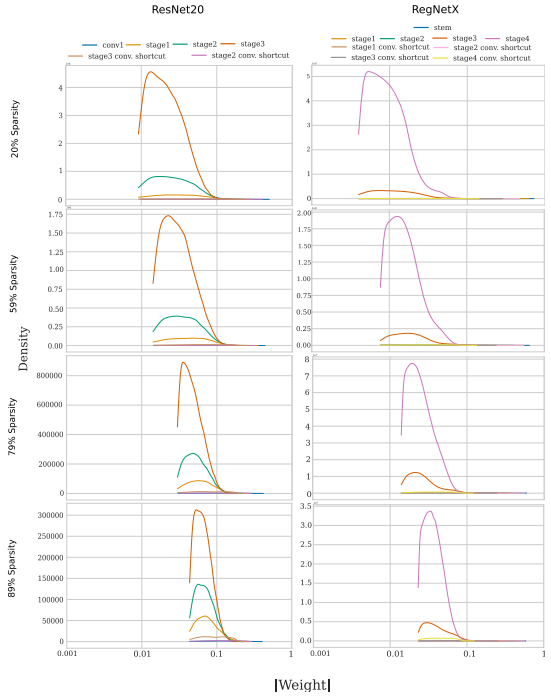

Fig. 5. The absolute value of the weight magnitude distribution across stages for varying sparsity levels for ResNet20 (Left) and RegNetX (Right).

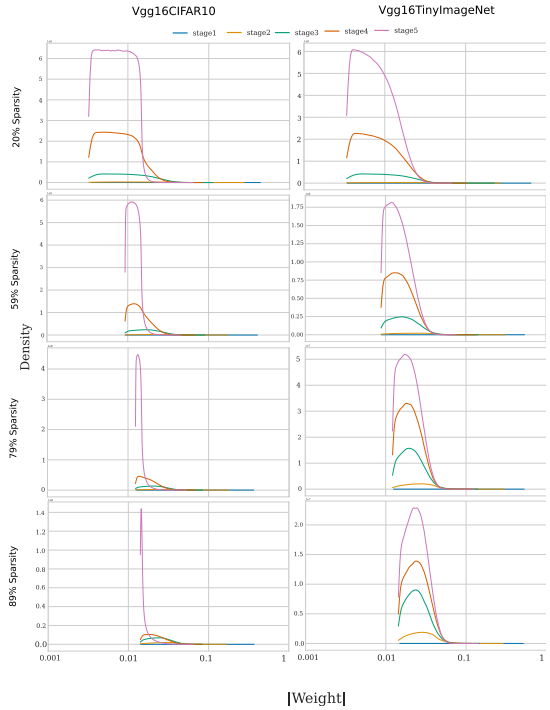

Fig. 6. The absolute value of the weight magnitude distribution across stages for varying sparsity levels for Vgg16CIFAR10 (Left) and Vgg16TinyImageNet (Right).

weights. While weights in earlier stages are still pruned, they experience less aggressive pruning, as illustrated in Fig. 7. Stage sparsity is defined as the percentage of weights pruned within a particular stage, and network sparsity as the overall percentage of pruned weights across the entire network.

We define stage sparsity as the percentage of weights in a stage that have been pruned. In contrast, the network sparsity is the percentage of weights in the *entire* network that have been pruned. In Fig. 7, the stage sparsity for each stage is plotted versus the total network sparsity. Data above or below the unit diagonal indicates that the sparsity of that stage is above or below the network average, respectively. At all network sparsities, the later stages have higher percentages of their weights pruned compared to earlier stages. This is consistent with the observations of the PDFs plotted in Fig. 5 and Fig. 6 that later stages have smaller values relative to earlier stages, resulting in later stages being more aggressively pruned. The figure illustrates these progressive sparsity dynamics up to the critical threshold, prior to the onset of accuracy degradation.

Although not plotted here, the differences in stage sparsity grow with rising network sparsity until the critical network sparsity, about 96% as mentioned previously. At that point, the sparsity of earlier stages increases rapidly. This is consistent with the degrading accuracy observed at this point in Fig. 4.

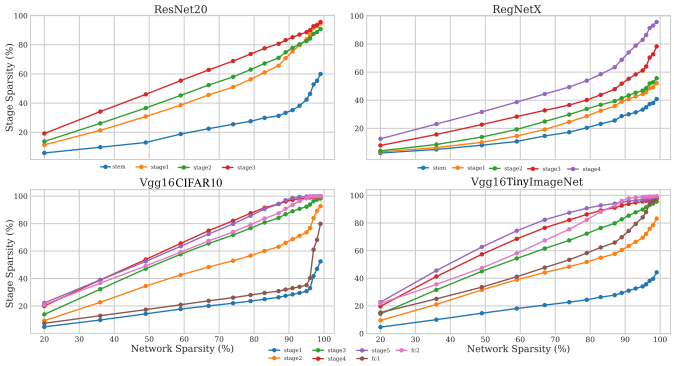

Fig. 7. **Stage-wise sparsity patterns.** Fraction of non-zero weights retained per stage and Fully Connected (FC) layers after the final sparsity level. Early stages are consistently more preserved across networks, while later stages are pruned more aggressively.

B. Neuron Sparsity

Building on insights into stage-wise pruning patterns, this study investigates the sparsity characteristics at the neuron level within these networks [Fig. 2(B)]. Given a highly sparse CNN, it is reasonable to expect that several neurons will exhibit a neuron sparsity of 100%, meaning all weights within the neuron are zeroed out. However, the experiments revealed that this was never observed. There are several reasons why this occurs. Given a constant-width layer, the probability that all the weights on an individual neuron are below the 99th percentile is given by (0.99^x), where x is the layer width. The probability that every neuron in the layer keeps at least one neuron is $(1 - 0.99^x)^x$, which tends towards 1 in an infinitely wide layer, meaning that it should not be expected to see any full neurons removed if pruning at initialization. Furthermore, it is reasonable to assume that after some weights are pruned the remaining weights in a neuron would undergo large gradient updates, further decreasing the likelihood of their removal after training. This is confirmed in Fig. 5 and Fig. 6.

This observation led to an exploration of neuron sparsity patterns within the network throughout the pruning process. The individual neuron sparsities were then grouped by layer to create layer-level neuron sparsity distributions. Tracking these distributions at each sparsity level attempts to uncover patterns in how neuron connectivity evolves. The procedure for doing this is outlined in Algorithm 1.

Algorithm 1 Layer-wise Neuron Sparsity Analysis

Require: Pruned model for all sparsity levels $\{M_s\}_{s=1}^{S}$, list of prunable layers $\mathcal{L}$

for each pruning level $s \in \{1, \ldots, S\}$ **do**
  Load network weights from checkpoint M_s
  for each layer $l \in \mathcal{L}$ **do**
    Extract weight tensor W_l of shape $[n_{\text{out}}, n_{\text{in}}]$
    Compute total weight count $T_l = n_{\text{out}} \times n_{\text{in}}$
    Compute zero weight count $Z_l = \text{count}(W_l == 0)$
    Compute layer sparsity $S_l = Z_l / T_l$
    for each output neuron $i \in \{1, \ldots, n_{\text{out}}\}$ **do**
      Compute neuron-level sparsity $s_{l,i} = \text{count}(W_l[i, :] == 0)/n_{\text{in}}$
    end for
    Store $\{S_l, \{s_{l,i}\}_{i=1}^{n_{\text{out}}}\}$
  end for
end for

Ensure: Per-layer and per-neuron sparsity statistics for all pruning sparsity levels

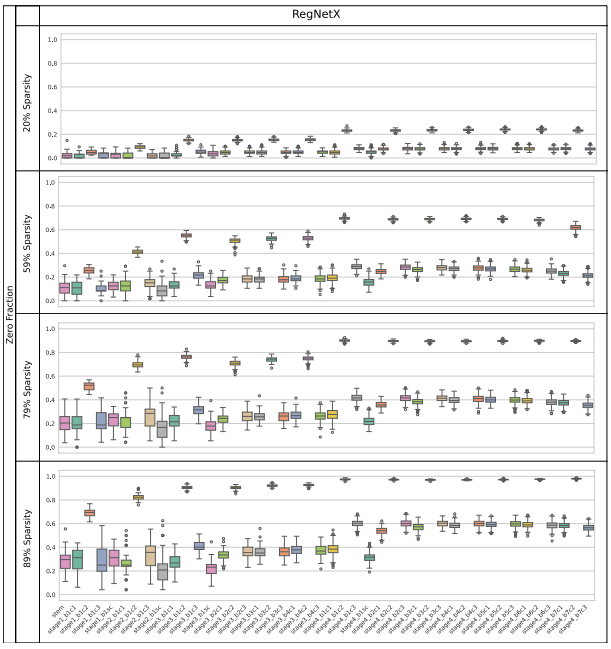

Fig. 8. Neuron sparsity distribution for each layer in RegNetX across different sparsity levels. Later layers show increased sparsity and clustering of inactive neurons, highlighting emergent structural sparsity.

Fig. 8, Fig. 9, and Fig. 10 present box-and-whisker plots of neuron sparsity across layers for each network at multiple sparsity levels. When the median neuron sparsity in a layer differs from the global network sparsity, it indicates that most neurons in that layer have been pruned more or less aggressively than average. This implies that these median values tend to increase with network depth, suggesting that neurons in later layers retain a smaller proportion of their incoming connections. This trend aligns with the stage-wise sparsity patterns shown in Fig. 7, where later layers consistently undergo heavier pruning.

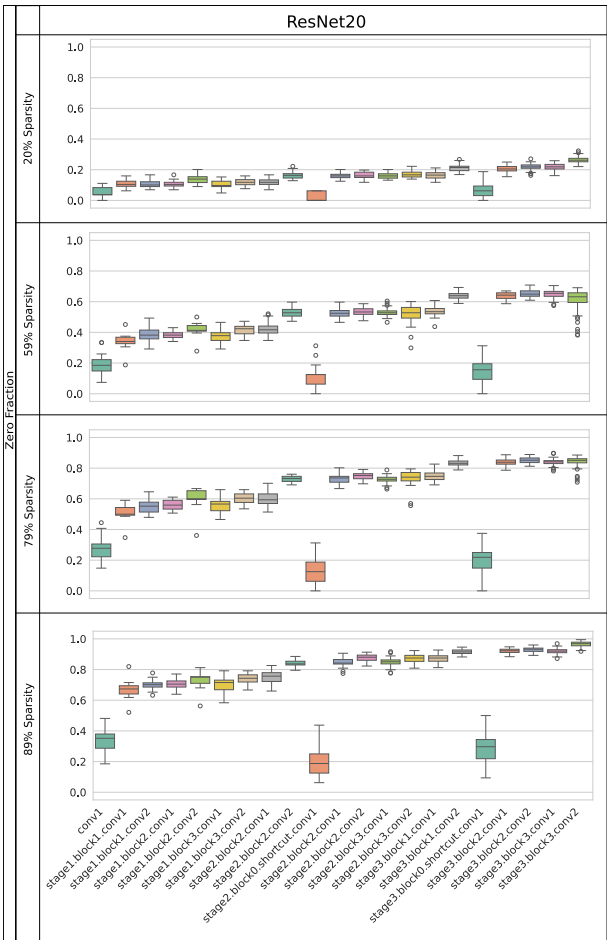

Fig. 9. Neuron sparsity distribution for each layer in ResNet20 across different sparsity levels. Later layers show increased sparsity and clustering of inactive neurons, highlighting emergent structural sparsity.

Layers that belong to the same stage, as indicated by their layer names, typically have similar neuron sparsity distributions. A notable exception to this pattern is the second convolutional layers in RegNetX, which have relatively high sparsities indicating that IMP preferentially prunes these layers. The vertical extent of the plots indicates the width of the distributions. The vertical extents are generally small compared to the variation between stages, especially for layers with high neuron sparsities. This suggests that, generally, in heavily pruned layers, all neurons are similarly sparse. However, even for the latest layers, at the highest network sparsities, no neurons exhibit exactly zero neuron sparsity.

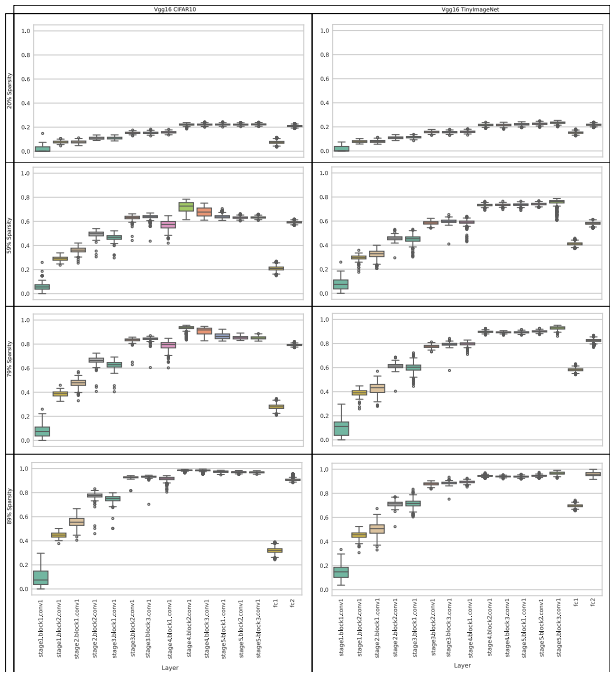

Fig. 10. Neuron sparsity distribution for each layer in Vgg16CIFAR10 and Vgg16TinyImageNet, respectively. Later layers exhibit increased sparsity and grouping of inactive neurons, indicating the presence of emergent structural sparsity.

Our neuron zeroing experiments (discussed in Section IV-C) show that removing neurons from these later layers typically results in a substantial decrease in prediction accuracy. This suggests that naive structured pruning, which removes neurons with the highest sparsity from the pruned network, would not be effective. However, this conclusion overlooks the fact that the neuron zeroing experiments do not involve retraining the networks after zeroing. Retraining following neuron removal could significantly reduce accuracy losses, potentially providing a pathway for structured pruning after IMP, but such an approach is prohibitively expensive for this investigation.

C. Neuron Zeroing

To further understand the contribution of individual neurons, a sensitivity analysis that measures the impact of neuron zeroing on prediction accuracy is conducted [Fig. 2(C)]. Neuron zeroing refers to the process of setting all weights for a specific neuron to zero. Algorithm 2 was applied to each sparsity level, with the results shown in Fig. 11 and Fig. 12.

In this work, accuracy and loss provided similar insights; since accuracy is more commonly plotted, only accuracy is reported.

Fig. 11 and Fig. 12 use box and whisker plots to show the change in accuracy distributions across all neurons. Although only the results for the first layer, two intermediate layers, and the final layer of each network are shown, all other layers show similar results.

These results show that neuron zeroing has a negligible impact on accuracy, with the highest variation being at 1.1% increase in accuracy for the unpruned Vgg16CIFAR10. For the other three cases, the sensitivity to neuron zeroing increases initially with pruning, which may indicate that as unnecessary weights are removed, each neuron is more likely to contribute favorably to the network's accuracy. This is in line with Fig. 5 and Fig. 6, where the weight magnitudes increase with each sparsity level. Then, with further pruning, rather than continuing to increase, the sensitivities remain fairly stable up to the critical sparsity.

Algorithm 2 Neuron Zeroing Experiment

Require: Trained network M, test Dataset TD, prunable layer list $\mathcal{L}$, baseline accuracy $(\text{Acc}_{\text{base}})$

```
for each layer l ∈ L do
    for each neuron i in layer l do
        Save the original weights and biases of neuron i
        Zero out weights and biases of neuron i
        Evaluate the network on TD to obtain Acc_i
        Compute ΔAcc_i = Acc_i − Acc_base
        Restore the original parameters of neuron i
    end for
end for
```

Ensure: Per-neuron sensitivity metrics for all layers

The observation that Vgg16CIFAR10 does not follow this trend may be related to the network's substantial overparameterization for the CIFAR10 dataset. This network contains 33.6 million parameters applied to a relatively low resolution dataset (32×32 image resolution). From the experimental setup, as described in Section III, the network struggles with generalization, as seen in the lower test accuracy of the unpruned network. Generalization refers to the model's ability to extract patterns from the training data and apply these patterns to unseen data, rather than memorizing specific examples. After the initial pruning step, the network shows very low sensitivity to the removal of neurons, suggesting a high degree of neuron redundancy. This behavior persists until 97% sparsity level, at which point, the model exhibits a sharp increase in neuron sensitivity. This occurs when the pruned network retains approximately 1 million parameters, which is comparable to the total parameter count of the unpruned ResNet20 (0.27 million parameters), which shows higher sensitivity from the outset of pruning. The trend is consistent with the hypothesis that, in the experiments, moderate pruning acts as a form of regularization by reducing excess capacity, thereby improving test performance before extreme pruning levels began to degrade accuracy (Fig. 4).

While retraining the network after a neuron removal could reduce accuracy loss, such an approach is computationally intractable for this scale of investigation. Furthermore, the one-shot zeroing experiments isolates the impact of each parameter, providing a strict lower-bound measure of the neuron's contribution to the network's overall accuracy.

D. Activation Similarity Across Sparsity Levels

To understand how a network's activations evolve across different levels of network sparsity using IMP, activation similarity, a measure of layer-wise activation on the same data, was analyzed across sparsity levels [Fig. 2(D)]. Specifically,

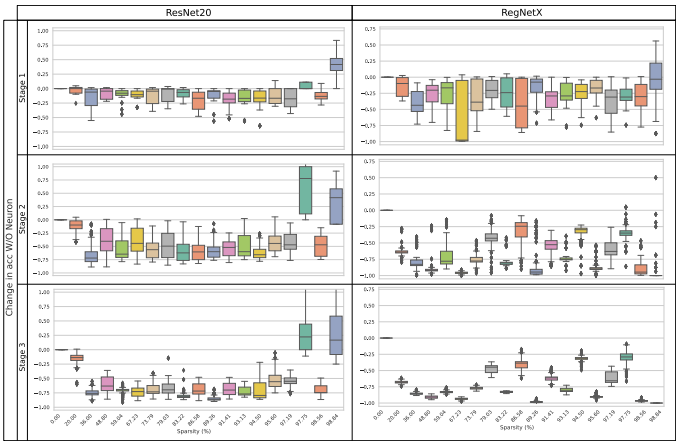

Fig. 11. The average accuracy change per stage (y-axis) from ablating individual neurons in (a) ResNet20 and (b) RegNetX networks, plotted as a function of sparsity levels (x-axis). These plots show the distribution of accuracy changes. As pruning increases, the variance and magnitude of neuron influence grow, indicating increasing functional specialization and reduced redundancy.

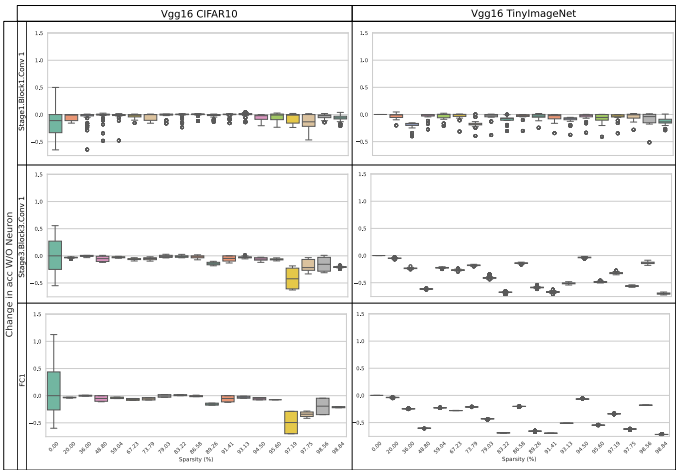

Fig. 12. Neuron zeroing impact across sparsity levels. Accuracy change (y-axis) from ablating individual neurons in (a) Vgg16CIFAR10 and (b) Vgg16TinyImageNet networks, plotted as a function of sparsity levels (x-axis). These plots show the distribution of accuracy changes. As pruning increases, the variance and magnitude of neuron influence grow, indicating increasing functional specialization and reduced redundancy.

the activation outputs of every neuron are recorded on the test set during inference at each sparsity level (after retraining the pruned network). Pairwise activation similarity matrices are then computed for the same layer across different sparsity levels using cosine similarity [Eq. (1)] to quantify changes in representation.

To compute the similarity matrices for each layer, neuron outputs are reshaped into two-dimensional matrices of shape $[\text{samples}, \text{neurons}]$. In convolutional layers, where each "neuron" corresponds to a filter, activations are first flattened to $[\text{samples} \times \text{width} \times \text{height}, \text{filters}]$ before computing cosine similarity. Algorithm 3 details this process.

The computed cosine similarity of layer-wise activation from a given sparsity level to the baseline network is shown

Algorithm 3 Activation Similarity Calculation

Require: Trained network M, test Dataset TD, prunable layer list $\mathcal{L}$, sparsity level s

1: Load network weights at sparsity level s
2: Run inference of M_s on TD, collecting activations A_l for each layer
3: Run inference of M_{s-1} or M_0 on TD, collecting activations B_l for each layer.
4: **for** each layer l **do**
5: Reshape A_l and B_l to $[\text{samples}, \text{neurons}]$
6: Compute similarity score S_l using Eq. (1).
7: **end for**

Ensure: $\{S_l\}_{l \in \mathcal{L}}$

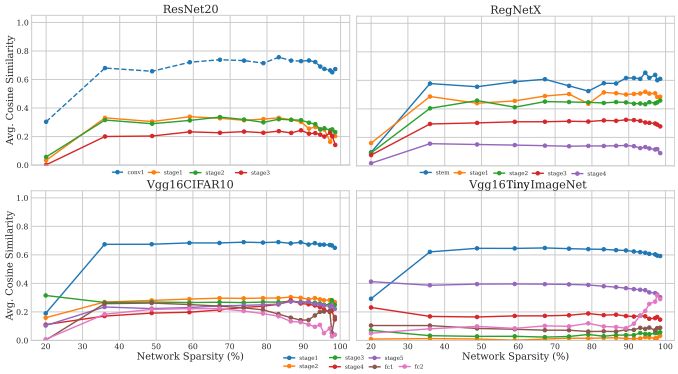

Fig. 13. Activation similarity to baseline network. The cosine similarity between layer-wise activations in the pruned network and the baseline network. This figure shows that early layers retain high similarity even at high sparsity levels, while later layers share little similarity.

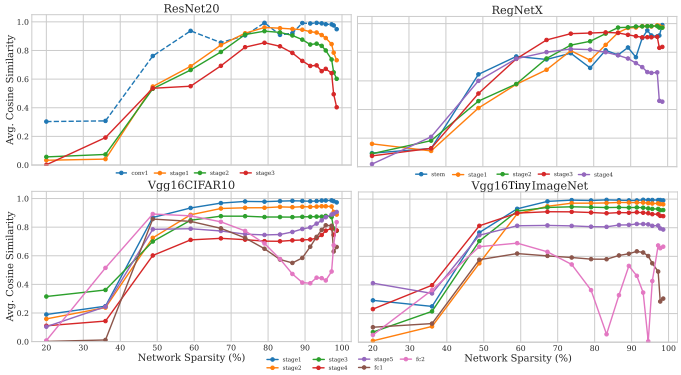

Fig. 14. Step-wise activation similarity across pruning iterations. The cosine similarity between activations of the same network across sparsity levels. The similarity declines gradually with pruning, but drops sharply near the critical sparsity level, signaling large degeneration in the network's representation.

in Fig. 13. It is observed that activation similarities between the sparsity level and the baseline decrease as the stage index increases. That is, later stages are less similar to the baseline than early stages. This is likely because the activations of later stages depend on those of earlier stages, thereby compounding the dissimilarity in subsequent stages.

This persistent similarity of activations to their values in the baseline network may imply that each pruned network consistently finds a similar basin of attraction in the loss landscape. In fact, pruning may increase the likelihood of finding the same basin of attraction by further constraining the solution as weights are set to zero.

The main exception to this activation similarity observation is at a network sparsity of 20%, where the similarities are substantially lower than at other points. This drop in similarity is observed (but not included in the manuscript) even with various pretraining and training epochs. As shown in Fig. 4, the accuracies at 20% network sparsity with 150 training epochs are not particularly low, so this suggests an alternate local minimum in the loss landscape has been identified. More investigation would be required to determine why such alternate minima are not identified at other network sparsities.

Next, similarities are considered between activations of the same network across sparsity levels, as shown in Fig. 14. The first two pruning iterations (20% and 36% sparsity) show that the activation function outputs change drastically between iterations. This is consistent with Fig. 13, where the first pruning iteration has low similarity to the baseline and the second has high similarity. Thus, the 20% sparsity level network is stage-wise dissimilar to the baseline, and then the next iteration is similarly dissimilar to the first iteration (and more similar to the baseline).

Subsequent stage-wise similarities are much higher, as they are similar to the second iteration (36% sparsity). Many of the similarities are even above 60% or even 80%, which is remarkable considering the high dimensionality of the vectors considered. This indicates that the neuron activations become highly similar between pruning iterations for all layers, with the highest similarities observed for the earliest convolutional layers. The stage-wise similarities of the convolutional layers remain high until the critical network sparsity. For the fully connected layers in Vgg, the stage-wise similarities begin to decrease well before the critical sparsity. This may be because these layers are the latest in the architecture and must adapt to changes in earlier layers.

V. Conclusion

This study explores the structure resulting from using IMP to prune a series of CNNs. A detailed analysis of IMP of both neurons and layers across three CNN architectures (ResNet20, RegNetX, and Vgg16) and two datasets (CIFAR10 and TinyImageNet) was conducted. We arrive at four key observations:

- Preferential pruning of deep layers Because CNNs concentrate more parameters in deeper layers and weight magnitudes typically scale inversely with layer width, IMP naturally removes more weights from late stages. This preserves early convolutions, critical for capturing fundamental image features, and explains why accuracy remains high up to extreme sparsities, only degrading as early layers are pruned substantially. The preferential pruning of deep layers suggests that inference performance may be improved by using differing data structures in various parts of the network (e.g., dense matrices in early stages and sparse matrices in later stages).
- Persistence of partially sparse neurons While many neurons retain high sparsity late into pruning, none reach full zeroing. The effect of these "last few weights" limits potential matrix-size reduction and, hence, hardware efficiency. The findings motivate IMP variants that explicitly target the removal of residual weights within neurons.
- Stable neuron-level sensitivity distributions Contrary to expectations, the variance of single-neuron importance does not narrow as pruning progresses: remaining neurons continue to exhibit a broad range of sensitivities. It is observed that one-shot zeroing experiments (without retraining) may overestimate individual neuron importance; future work could apply iterative zeroing with fine-tuning to refine these insights.
- Preservation of feature representations Cosine-similarity analysis show that IMP minimally perturbs activation patterns throughout pruning. This suggests pruned and unpruned networks occupy nearby regions of parameter space, maintaining the representational capacity that underlies accuracy preservation.

Overall, these observations clarify why IMP achieves very high unstructured sparsities without sacrificing accuracy, and they highlight why magnitude-based pruning alone is unlikely to yield structured sparsity patterns conducive to hardware acceleration. Future experiments hope to: 1) develop IMP extensions that incentivize fully zeroing neurons, 2) evaluate the runtime and energy impacts on real hardware, and 3) extend the analysis to other model families (e.g., transformers and graph networks).

***Abstract*—The increasing adoption of large language models (LLMs) and domain-adapted transformers in healthcare has created a new privacy challenge: fine-tuned models may memorize rare clinical strings and later reveal them through generation or scoring behavior. A controlled study of privacy leakage and memorization in clinical language models trained on narrative transcriptions is presented. A canary-based audit pipeline was instantiated on a 4,000-note subset of the Medical Transcriptions (MTSamples) corpus, with 40 synthetic secrets injected only into the training partition and evaluated using three complementary attack families: prompt extraction, exposure-style ranking, and reference-based membership inference. Two experiments are reported. Experiment I compares baseline fine-tuning, early stopping, and a conservative regularized training profile combining lower learning rate, higher weight decay, and partial layer freezing. Experiment II fixes the training protocol and compares DistilGPT2, GPT-2, and BioGPT. A clear privacy-utility tension was observed. In Experiment I, early stopping produced the best held-out language-model utility, whereas the combined regularized profile eliminated observed prompt leakage and reduced membership-inference strength, at the cost of worse perplexity. In Experiment II, stronger and more domain-specialized backbones achieved better clinical language modeling but also exhibited higher leakage and stronger membership-inference signals, with BioGPT yielding the strongest utility and the highest privacy risk under the evaluated attacks. These results indicate that privacy auditing should accompany utility evaluation in clinical LLM adaptation, and that backbone choice can materially affect memorization risk in this controlled setting.**

***Keywords*—Clinical language models; privacy leakage; memorization; membership inference; canary exposure; BioGPT; GPT-2; healthcare NLP; model auditing**

I. Introduction

Large language models are rapidly becoming part of healthcare AI pipelines, including clinical decision support, summarization of electronic health records (EHRs), documentation assistance, patient communication, and biomedical question answering [2], [3], [4], [5], [6]. Their appeal is clear: once adapted to clinical language, such models can absorb domain vocabulary, structure, and reasoning patterns that are costly to encode manually. At the same time, their deployment introduces an acute privacy question: *when a general or biomedical backbone is fine-tuned on clinical text, does it merely generalize, or does it also memorize rare sensitive sequences strongly enough to leak them later?*

This question is especially pressing in healthcare because patient narratives often contain sparse, low-frequency identifiers and clinically meaningful attributes. Even when direct identifiers are removed, combinations of age, disease code, specialty, procedural detail, and treatment narrative can become quasi-identifying. Responsible machine learning in medicine therefore requires more than utility evaluation alone; it requires explicit privacy auditing and leakage measurement [1], [7], [33], [8].

Privacy concerns in language models are not hypothetical. Work on unintended memorization, training-data extraction, and membership inference has shown that generative models can reveal exact or near-exact traces of the data seen during training [9], [10], [11], [12], [13], [14]. Recent findings further suggest that stronger or more domain-adapted models may become more data efficient but simultaneously more privacy sensitive [15], [16], [17], [19].

Clinical adaptation adds another layer of complexity. Biomedical and clinical language models such as BioBERT, PubMedBERT, GatorTron, Med-BERT, BEHRT, and BioGPT outperform general models on many healthcare tasks [26], [27], [29], [30], [31], [28]. However, stronger in-domain fit may also increase the probability of memorizing rare strings. The literature has discussed this possibility conceptually, but practical, reproducible demonstrations on clinical-style corpora are still limited, especially when both defenses and backbone choice are evaluated within the same study.

That gap is addressed here through a controlled dual-experiment study on clinical narrative transcriptions. The Medical Transcriptions (MTSamples) dataset is used as a multi-specialty corpus for clinical free text, and a canary-based audit protocol is designed in which synthetic secrets are inserted *only into the training split*. The resulting fine-tuned models are then tested for leakage through generation and for memorization through lower loss and higher ranking scores (Fig. 1).

Four contributions are made:

- A defense-oriented privacy audit. Baseline fine-tuning, early stopping, and a combined regularized training

profile are compared on the same controlled clinical fine-tuning task.

- A backbone-oriented privacy audit. DistilGPT2, GPT-2, and BioGPT are compared under the same dataset, split, canary set, and attack suite.
- A multi-attack evaluation protocol. Leakage is quantified with prompt-based extraction, candidate ranking with exposure-style scoring, and reference-based membership inference using ROC-AUC, PR-AUC, accuracy, precision, recall, F1, specificity, and balanced accuracy.
- A defensible privacy and utility analysis. The reported results indicate that stronger utility does not guarantee better privacy, and that backbone choice is itself a privacy-relevant design decision in clinical LLM fine-tuning.

II. Related Work

A. Healthcare Language Models and Clinical Adaptation

Clinical and biomedical transformer models have progressed rapidly, from early domain adaptation strategies to large-scale specialized pretraining. BioBERT improved biomedical text mining with domain-adapted contextual representations [26]. PubMedBERT showed that in-domain pretraining from scratch can outperform general-domain initialization in biomedical NLP [27]. Structured-clinical representation learning advanced through Med-BERT and BEHRT, which demonstrated that transformer-based pretraining on large EHR repositories benefits downstream prediction tasks [30], [31]. At larger scale, GatorTron and BioGPT extended this line to generative and clinical-free-text modeling [29], [28]. More recently, Med-PaLM-style systems and health system-scale language models have highlighted the emerging power of foundation models in healthcare [4], [5], [6], [41].

B. Privacy Risks in Machine Learning and Clinical AI

The healthcare literature has repeatedly emphasized that high utility alone is insufficient in medical AI. Responsible deployment requires privacy, governance, reproducibility, and harm-aware design [1], [2], [3]. In medical imaging and distributed healthcare learning, privacy-preserving federated methods and secure training protocols have become major themes [7], [32], [33], [34], [35], [8]. Yet privacy issues in generative clinical text models remain comparatively underexplored, especially under white-box or score-based audit settings.

C. Memorization, Training-Data Extraction, and Membership Inference

Membership inference emerged as a canonical privacy threat in machine learning through black-box attacks that infer whether a sample belonged to the training set [11]. In language models, memorization and extraction risks became especially visible with canary-based audits and direct generation attacks [9], [10]. Later work showed that deduplication, training dynamics, and neighborhood-based attacks strongly affect leakage behavior [15], [16], [12], [13], [17], [18], [19]. Recent work has extended the threat model to code models, context-aware membership inference, unlearning of personally identifiable information, and broad privacy-risk surveys for LLMs [20], [21], [22], [25], [23], [24].

D. Differential Privacy and Related Defenses

Differential privacy remains the most principled formal defense against memorization, beginning with DP-SGD [36]. Its use in language modeling and large-model fine-tuning is active but computationally expensive, and often introduces a non-trivial utility penalty [37], [38], [39]. Outside formal privacy, practical mitigations include data deduplication, regularization, early stopping, dropout, freezing submodules, prompt filtering, and unlearning [15], [16], [22]. However, these defenses are rarely compared side by side on clinical-style generative fine-tuning under the same controlled attack suite.

The study is positioned at this intersection: clinical-language fine-tuning, memorization-aware auditing, defense comparison, and backbone comparison, all grounded on the same clinical narrative corpus.

III. Materials and Methods

A. Dataset and Sampling Protocol

Both experiments were conducted on the Medical Transcriptions (MTSamples) dataset, available at https://www.kaggle.com/datasets/tboyle10/medicaltranscriptions. The corpus contains 4,999 clinical-style transcriptions spanning 40 specialty categories. After preprocessing, 4,000 notes were sampled. The resulting splits followed an 80/10/10 partition: 3,200 training notes, 400 validation notes, and 400 test notes. For both experiments, exact duplicates were removed before splitting.

The selected corpus is appropriate for privacy auditing because it contains long-form narrative prose, specialty-specific vocabulary, structured reporting habits, and heterogeneous note styles. These properties are important because memorization risk is driven not only by raw dataset size, but also by the presence of rare phrasings, repeated templates, and clinically meaningful identifiers embedded in free text.

TABLE I. Dataset and Core Protocol Settings Used in Both Experiments

Setting	Value
Base corpus	Medical Transcriptions (MTSamples)
Prepared note count	4,000 sampled notes
Train/validation/test split	3,200 / 400 / 400
Sequence length	128 tokens
Batch size	2
Gradient accumulation	4
Injected canaries	40
Control canaries	40
Canary repetitions in training	2
Prompt families	4
Candidate pool for ranking attack	64 condition codes

B. Synthetic Canary Design

To measure memorization under controlled conditions, synthetic canaries of the form below were injected:

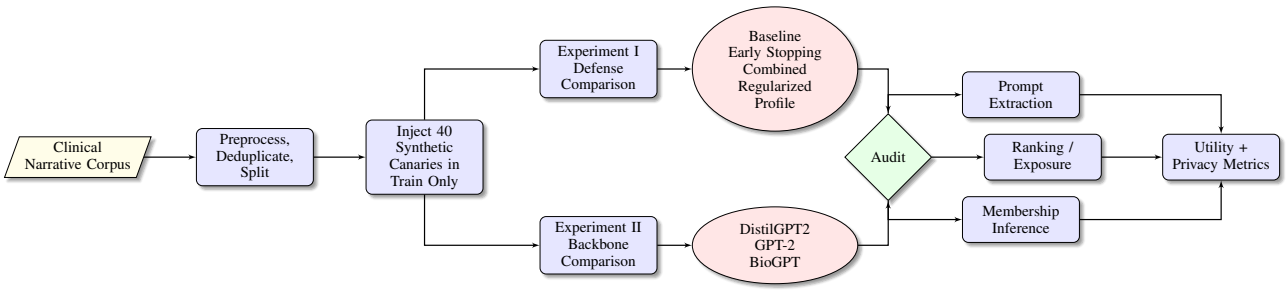

Fig. 1. Overall study design. A clinical narrative corpus is sampled, preprocessed, split, and augmented with train-only synthetic canaries. Experiment I compares defenses on one backbone, while Experiment II compares backbones under a fixed training protocol. All models are audited with prompt extraction, ranking and exposure analysis, and reference-based membership inference.

```
Patient identifier ZXQ-XXXX has condition
OMEGA-YY.
```

Each patient identifier and condition code was unique. The canaries were embedded in realistic clinical-note fragments and inserted *only into the training split*. An additional set of 40 control canaries was generated with the same syntactic structure but never injected into the model. This control set enabled membership inference and ranking-based discrimination between members and non-members.

C. Experiment I: Defense Comparison

Experiment I used DistilGPT2 as the backbone and compared three training settings:

- Baseline: 3 epochs, learning rate 5×10^{-5}, weight decay 0.01.
- Early stopping: up to 6 epochs with patience 2, same optimizer scale as baseline.
- Combined regularized profile: 4 epochs maximum, learning rate 2×10^{-5}, weight decay 0.05, warmup ratio 0.05, and freezing of the lower half of the transformer stack.

Because this third setting combines several interventions, the resulting privacy and utility changes should be interpreted at the profile level rather than attributed to any single component in isolation.

D. Experiment II: Backbone Comparison

Experiment II fixed the training protocol and compared three backbones:

- DistilGPT2 (81.9M parameters),
- GPT-2 (124.4M parameters),
- BioGPT (346.8M parameters).

All three models were trained for up to 4 epochs with learning rate 5×10^{-5}, weight decay 0.01, warmup ratio 0.03, and early stopping patience 2. This made the comparison as controlled as possible: only the backbone changed.

E. Experimental Architecture and Reproducibility Controls

Both notebooks implemented the same end-to-end experimental architecture. First, the corpus was downloaded, normalized, and partitioned into train, validation, and test splits with fixed seeds. Second, synthetic canaries were generated automatically and inserted only into the training split, while matched control canaries were retained as non-members. Third, a chosen causal-language-model backbone was fine-tuned under an explicitly declared profile. Fourth, the trained model was audited by three privacy-evaluation layers: prompt extraction, ranking-based memorization analysis, and reference-based membership inference. Finally, every run exported CSV summaries, plots, and serialized artifacts for downstream inspection and manuscript generation.

Several design choices strengthen scientific defensibility. The experiments used the same prompt templates across all runs, fixed train/validation/test boundaries, CPU-compatible batch sizes, explicit configuration blocks, persistent result files, and no post-hoc retuning of the privacy protocol after observing outcomes. In the backbone-comparison notebook, hyperparameters were held constant across backbones so that privacy differences could be interpreted with minimal optimization asymmetry. This improves comparability, although it does not eliminate configuration sensitivity. Reproducibility is further supported through fixed random seeds, persistent exported artifacts, and complete reporting of the principal training settings in Tables I, III, and IV. Software-version pinning, runtime-variance profiling across repeated executions, and memory-usage tracking were not analyzed in this study and should therefore be considered outside the present reproducibility envelope.

F. Attack-Suite Design

The attack suite was designed to cover multiple black-box interaction patterns rather than a single prompt template. Leakage can surface through chart-style lookups, incomplete clinical notes, routine continuation requests, or repeated model queries. For that reason, the notebooks tested several prompt families rather than one handcrafted query. Greedy decoding alone can underestimate risk, so beam-search and stochastic-sampling variants were also included. This mattered empirically: in Experiment I, some canaries only became exact leaks under sampled decoding, while greedy and beam decoding produced only partial continuations.

The ranking and membership attacks deepen the analysis beyond visible completions. Exposure-style ranking does not require a verbatim leak; it asks whether the true secret is scored unusually well relative to many plausible alternatives. Membership inference asks a related question: can an adversary infer whether a sensitive pattern was used during fine-tuning? In healthcare, even that signal can be consequential because it may reveal that a rare condition template, documentation style, or institution-specific phrase was present in the fine-tuning distribution. Taken together, the three attack families provide a stronger audit than prompt extraction alone.

G. Attack Suite

Three families of privacy attacks were used.

1) Prompt-based extraction: For each canary, four prompt families were evaluated:

- prefix completion,
- direct recall,
- partial note completion,
- chart lookup.

Each prompt was decoded with greedy decoding, beam search, and stochastic sampling. The prompt-based metrics were:

- exact-match recovery rate,
- condition recovery rate,
- patient-identifier recovery rate,
- partial-match rate,
- token recovery rate,
- average string similarity,
- leakage rate (fraction of canaries leaked at least once).

2) Ranking and exposure: Prompt attacks can underestimate memorization because a secret may be internally preferred without always appearing under one decoding strategy. Multiple candidate condition codes were therefore scored given a fixed patient identifier, and the true code was ranked among 64 candidates. Exposure-style memorization was computed as:

$$E = \log_2(N) - \log_2(r), \tag{1}$$

where, N is the candidate-pool size and r is the rank of the true secret. Higher exposure indicates stronger memorization.

3) Reference-based membership inference: For each fine-tuned model, a reference model with the same base weights before fine-tuning was retained. Each member and non-member canary note was scored by both the target model and the reference model. The primary membership score was the loss gap:

$$\Delta\mathcal{L} = \mathcal{L}_{\text{reference}} - \mathcal{L}_{\text{target}}. \tag{2}$$

ROC-AUC, PR-AUC, accuracy, precision, recall, F1, specificity, and balanced accuracy were then evaluated.

H. Utility Metrics

To assess language-model quality independently of privacy, validation loss, test loss, and perplexity were reported:

$$\text{Perplexity} = \exp(\mathcal{L}), \tag{3}$$

where, $\mathcal{L}$ is the mean next-token cross-entropy loss on the corresponding split.

I. Statistical Uncertainty

The model-comparison notebook additionally computed bootstrap confidence intervals for leakage rate, exposure, and ROC-AUC, as well as paired Wilcoxon signed-rank tests on per-canary exposure values. The bootstrap intervals are used descriptively to summarize uncertainty around the reported metrics, whereas the Wilcoxon tests are used only for cautious pairwise interpretation of exposure differences (Table II).

IV. Results: Experiment I: Defense Comparison

A. Training Dynamics and Utility

The three training settings converged cleanly, but their utility profiles diverged markedly. As shown in Fig. 2, early stopping achieved the strongest held-out language modeling with validation loss 1.770 and validation perplexity 5.87, outperforming the baseline (validation perplexity 7.10). The combined regularized profile substantially weakened language-model fit, yielding validation perplexity 10.46 and test perplexity 10.36.

Fig. 2 shows that the training curves do not simply indicate optimization success; they also frame the privacy interpretation. The early-stopping run descends below the baseline on validation loss and preserves stable generalization behavior, confirming that it is the strongest utility configuration in Experiment I. The combined regularized profile, by contrast, converges more conservatively and remains consistently higher on validation loss, which is consistent with stronger capacity control.

The privacy summary in the companion panel is equally important. It shows that the configuration with the best language-model fit is not the one with the best privacy behavior. This visual contrast is central to the study's argument because it demonstrates that utility metrics alone would have selected a more privacy-sensitive model.

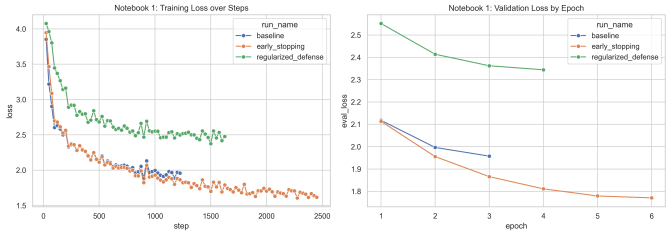
B. Prompt Leakage

The prompt-based results show that utility improvements did not translate into better privacy. Baseline and early stopping both leaked 7 canaries out of 40, corresponding to a leakage rate of 0.175. The combined regularized profile reduced the number of leaked canaries to zero. Exact-match recovery was also lowest for that profile (0.000), compared with 0.0075 for the baseline and 0.01375 for early stopping.

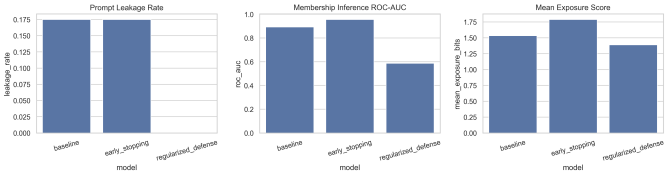
An important nuance is that the patient-identifier recovery rate saturated at 1.0 for all settings because the prompts explicitly included the patient identifier. Accordingly, the most meaningful prompt-level privacy indicators in this study are

TABLE II. ATTACK TAXONOMY AND EVALUATION METRICS USED THROUGHOUT THE STUDY

Attack family	Operational idea	Primary metrics
Prompt extraction	Generate continuations from clinically plausible prompts	Exact match, condition recovery, leakage rate
Ranking / exposure	Rank the true condition against 64 candidate codes	Mean rank, top-1 success, exposure bits
Membership inference	Distinguish seen from unseen canary notes using loss-gap scores	ROC-AUC, PR-AUC, F1, specificity, balanced accuracy



(a) Training loss and validation loss for Experiment I.



(b) Privacy summary for Experiment I.

Fig. 2. Experiment I results. Early stopping gave the best utility, whereas the combined regularized profile most strongly reduced the observed privacy risk metrics.

the condition recovery rate, exact-match recovery rate, and per-canary leakage rate. On those metrics, early stopping slightly worsened privacy relative to the baseline, while the combined regularized profile eliminated observed prompt leakage. Because the profile bundles lower learning rate, higher weight decay, and lower-layer freezing, these gains should be interpreted as the effect of the combined training configuration rather than as evidence for any single defense mechanism.

C. Ranking and Membership Inference

Ranking-based memorization and membership inference reinforce the same conclusion. Early stopping had the highest mean exposure score (1.79 bits) and the strongest membership-inference signal (ROC-AUC 0.956), whereas the combined regularized profile had the lowest mean exposure score (1.39 bits) and a much weaker membership signal (ROC-AUC 0.586). The baseline was intermediate, with ROC-AUC 0.893 and mean exposure 1.53 bits.

Experiment I therefore indicates that the strongest utility configuration was also the most privacy-sensitive, while the combined regularized profile reduced the observed leakage metrics at the cost of substantially worse clinical language modeling. In other words, in this setting, early stopping was not a privacy defense even though it remained a useful optimization strategy (Fig. 3).

The attack-type breakdown adds another layer of interpretation. Direct-recall prompts were the least effective across settings, whereas prefix completion and partial-note completion were more likely to reveal condition codes. This matters because it shows that privacy leakage is tied closely to continuation behavior in clinically shaped contexts. In practical terms, the attack surface is not limited to explicit question prompts; it extends to standard completion workflows that resemble documentation assistance or chart continuation.

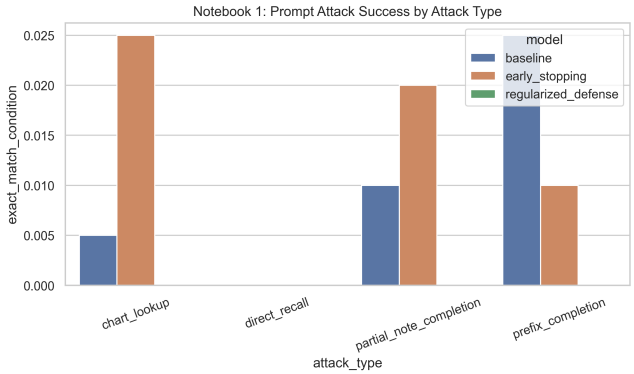


Fig. 3. Prompt attack success by attack type in Experiment I. Prefix-style and partial-note completions were more effective than direct recall prompts.

V. RESULTS: EXPERIMENT II: BACKBONE COMPARISON

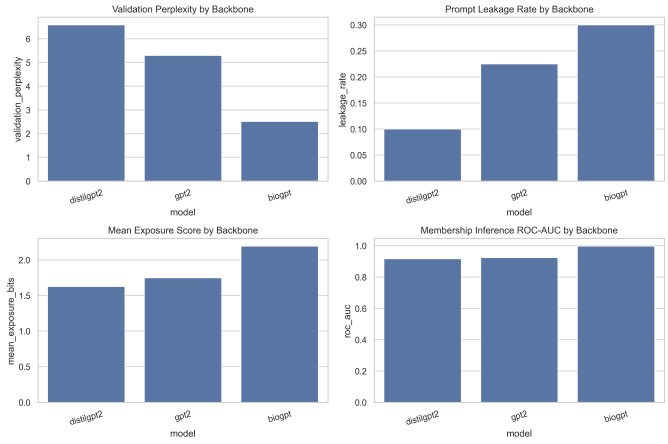
A. Utility Comparison Across Backbones

The model-comparison study yielded a clear performance ordering. DistilGPT2 achieved validation perplexity 6.59 and test perplexity 6.55. GPT-2 improved on this with validation perplexity 5.30 and test perplexity 5.33. BioGPT substantially outperformed both, reaching validation perplexity 2.52 and test perplexity 2.60. The training curves in Fig. 4 show faster and deeper optimization for BioGPT than for GPT-2 or DistilGPT2.

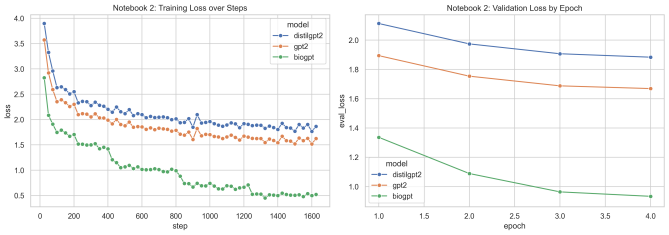
The two panels in Fig. 4 deserve joint interpretation. The utility panel shows a sharp improvement from DistilGPT2 to GPT-2 and then to BioGPT, especially in perplexity. The training-curve panel complements this by showing that BioGPT does not merely finish with a lower loss; it reaches a lower validation regime earlier and maintains that advantage across epochs. This pattern is consistent with a backbone that starts closer to the biomedical target distribution and adapts more efficiently to the corpus.

TABLE III. DEFENSE COMPARISON RESULTS (EXPERIMENT I)

Setting	Val. PPL	Test PPL	Leakage	Exact Match	Exposure	ROC-AUC	PR-AUC	F1
Baseline	7.10	7.05	0.175	0.0075	1.533	0.893	0.895	0.831
Early stopping	5.87	5.88	0.175	0.0138	1.788	0.956	0.953	0.907
Combined regularized profile	10.46	10.36	0.000	0.0000	1.388	0.586	0.537	0.692



(a) Utility and privacy summary across backbones.



(b) Training and validation curves across backbones.

Fig. 4. Experiment II results. BioGPT achieved the best utility, but also the highest leakage, exposure, and membership-inference risk.

B. Prompt Leakage and Memorization

The privacy ordering was the inverse of the "safest utility" interpretation. DistilGPT2 had the lowest leakage rate (0.10, i.e., 4 leaked canaries out of 40), GPT-2 leaked 9 canaries (0.225), and BioGPT leaked 12 canaries (0.30). Exact-match recovery rate rose from 0.00625 for DistilGPT2 to 0.02344 for GPT-2 and 0.03594 for BioGPT. Likewise, condition recovery rate increased monotonically across the same ordering.

Ranking-based exposure confirmed this pattern. Mean exposure rose from 1.63 bits for DistilGPT2 to 1.75 bits for GPT-2 and 2.19 bits for BioGPT. The average rank of the true secret improved (that is, privacy worsened) from 26.1 for DistilGPT2 to 25.1 for GPT-2 and 19.4 for BioGPT. The best-performing clinical backbone therefore also ranked the true secret highest among decoys.

C. Membership Inference

Membership inference produced the strongest privacy signal in Experiment II. DistilGPT2 and GPT-2 already had very high ROC-AUC values (0.918 and 0.925), but BioGPT approached perfect separation with ROC-AUC 0.998 and PR-AUC 0.998. The corresponding 95% bootstrap confidence interval for BioGPT was [0.991, 1.000], making it highly unlikely that the observed effect is a numerical artifact. This finding means that, under the evaluated loss-gap attack, the fine-tuned BioGPT almost perfectly distinguished seen canary notes from unseen controls.

D. Attack-Type Analysis

The backbone comparison also revealed prompt-family differences. Direct recall prompts were the weakest overall, whereas prefix completion, chart lookup, and partial-note completion were more successful. BioGPT dominated these attack families, suggesting that clinically plausible continuation contexts are especially effective at surfacing memorized strings from stronger biomedical backbones.

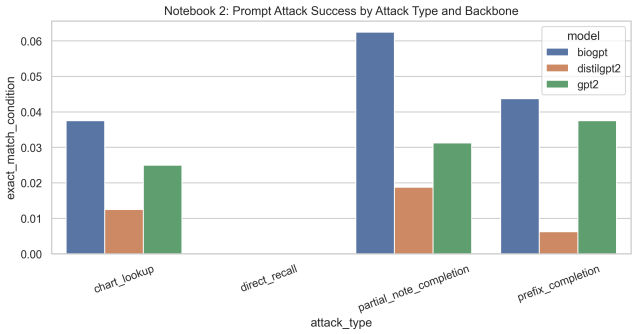


Fig. 5. Prompt attack success by attack type and backbone. Clinically natural completion prompts were more effective than direct recall prompts, especially against BioGPT.

This figure (Fig. 5) is useful not only because BioGPT is highest in aggregate, but also because the ordering is stable across attack families. That stability reduces the likelihood that the result is an artifact of one particular prompt wording. Instead, it suggests that the observed privacy ordering is not confined to a single prompt family.

E. Confidence Intervals and Paired Statistics

Bootstrap intervals preserved the same descriptive ordering. DistilGPT2 had a leakage-rate interval of [0.025, 0.200], GPT-2 had [0.075, 0.375], and BioGPT had [0.175, 0.450].

TABLE IV. BACKBONE COMPARISON RESULTS (EXPERIMENT II)

Backbone	Val. PPL	Test PPL	Leakage	Exact Match	Exposure	ROC-AUC	PR-AUC	F1	Train Time (s)	Params
DistilGPT2	6.59	6.55	0.100	0.0063	1.627	0.918	0.918	0.843	5226	81.9M
GPT-2	5.30	5.33	0.225	0.0234	1.748	0.925	0.922	0.822	7842	124.4M
BioGPT	2.52	2.60	0.300	0.0359	2.194	0.998	0.998	0.974	13588	346.8M

Membership ROC-AUC intervals also separated the models, with BioGPT concentrated near one. The paired Wilcoxon analysis on per-canary exposure values showed directionally higher exposure for BioGPT than for the other backbones, although at this sample size the pairwise p-values (0.086 to 0.100) remained above 0.05. DistilGPT2 and GPT-2 were not significantly different on exposure under the same test ($p = 0.615$).

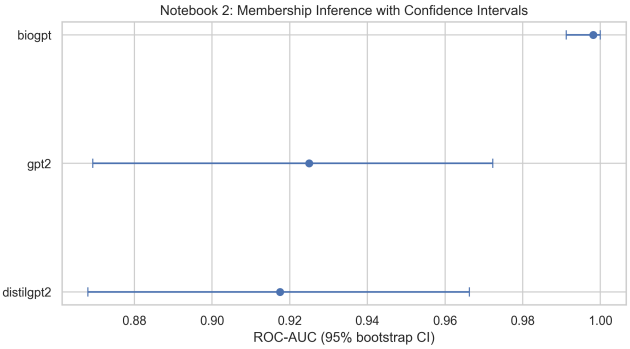

Fig. 6. Membership-inference ROC-AUC with 95% bootstrap confidence intervals in Experiment II. BioGPT exhibits near-perfect separability between member and non-member canary notes.

model_a	model_b	mean_exposure_a	mean_exposure_b	wilcoxon_statistic	p_value
biogpt	distilgpt2	2.1937	1.6275	287.5	0.0996
biogpt	gpt2	2.1937	1.7481	252.0	0.0857
distilgpt2	gpt2	1.6275	1.7481	354.0	0.6154

Fig. 7. Pairwise Wilcoxon exposure comparison among the three backbones. The direction of the effect consistently favors higher exposure for BioGPT, although the current sample size does not yield sub-0.05 p-values and the pairwise differences should therefore be interpreted cautiously.

The confidence-interval figure (Fig. 6) strengthens the interpretation by showing that the membership-inference advantage of BioGPT is not marginal. Its interval is compressed near one, while the smaller backbones remain clearly lower. The pairwise-exposure figure (Fig. 7) adds a useful nuance: although the direction of the effect consistently favors higher exposure for BioGPT, the present sample size limits formal pairwise significance. That nuance is important because it keeps the interpretation statistically disciplined while preserving the descriptive cross-metric ordering.

VI. DISCUSSION

The two experiments jointly support several main conclusions.

A. Better Utility Does Not Imply Better Privacy

Experiment I showed that early stopping improved utility substantially but did not reduce leakage. In fact, it produced the highest exposure and strongest membership-inference signal among the three training settings. This is an important practical lesson: interventions typically associated with better generalization in task performance should not automatically be described as privacy defenses. In a clinical LLM setting, the privacy and utility relationship is more nuanced.

At the same time, the combined regularized profile should be interpreted carefully. Because lower learning rate, higher weight decay, and lower-layer freezing were applied together, the present results support the privacy value of that conservative training profile as a whole, but they do not isolate the contribution of each component.

B. Backbone Choice Is a Privacy-Relevant Design Decision

Experiment II yielded a monotonic descriptive ordering across the evaluated backbones. DistilGPT2 had the weakest utility but the lowest privacy risk. GPT-2 improved utility and leaked more. BioGPT, the strongest and most domain-specialized model, achieved the best clinical language modeling but also the highest leakage, exposure, and membership-inference susceptibility. The exposure-based pairwise tests did not reach conventional significance thresholds at the current sample size, but the cross-metric pattern remained consistent across prompt leakage, exposure, and membership inference. Backbone selection in healthcare should therefore be treated not only as a performance decision but also as a privacy-governance decision.

C. Why Did BioGPT Leak More?

The most plausible explanation is not simply model size, but the combination of size and domain specialization. BioGPT began closer to the target distribution and therefore fit the clinical corpus more effectively. Better fit can improve generalization, but it can also increase the probability that the model assigns high confidence to rare, repeated strings such as synthetic canaries. The exposure and membership results support this interpretation. The model was not only better at generating clinically plausible text; it was also more sensitive to whether a canary note had been seen during training.

D. What the Prompt Results Mean

The prompt results suggest that privacy leakage is more easily elicited in clinically natural completion settings than in explicit question-answer forms. Direct recall prompts were generally weak, whereas partial-note completion and prefix-style prompts were more successful. This is important for real-world security because an attacker is not required to ask bluntly for the secret; instead, leakage may surface through

routine-looking note continuations, chart lookups, or audit-style prompts.

E. Interpreting the Saturated Identifier Metric

One metric deserves careful interpretation: patient-identifier recovery rate was 1.0 in several tables. This does not mean the models invented the identifier. The prompts themselves already contained the patient identifier. Accordingly, that metric is less informative than exact-match recovery, condition recovery, per-canary leakage rate, exposure, and membership ROC-AUC. These latter metrics should be emphasized in any formal presentation of the results.

F. Implications for Privacy-Aware Clinical NLP

Taken together, the findings imply that healthcare organizations adapting language models to internal notes should not rely on utility validation alone. A model with excellent perplexity may still leak or encode member-specific traces strongly enough to support membership inference. Conversely, stronger empirical mitigation profiles can reduce leakage, but may impose a non-trivial utility cost. This underscores the need for explicit privacy auditing, careful dataset governance, privacy-preserving representation design [40], and, where feasible, formal defenses such as differential privacy when the underlying data are truly sensitive [36], [37], [39]. The present study is empirical rather than formally private: no differentially private optimization arm was included, and the reported mitigations should not be interpreted as providing a formal privacy guarantee.

G. Practical Recommendations for Deployment

The results support several concrete recommendations. First, privacy auditing should be integrated into model-selection workflows before deployment approval rather than treated as a retrospective security test. Second, backbone choice should be documented in governance reviews as a privacy-sensitive design decision, especially when moving from a smaller general-purpose backbone to a larger or biomedical-specialized one. Third, when private optimization is not yet deployed, conservative regularization profiles and dataset deduplication should be treated as default baselines rather than optional extras. Fourth, prompt-space stress testing should emphasize clinically natural completions and multiple decoding modes, because these were more effective than direct recall prompts in both notebooks. Fifth, deployment review should weigh computational cost together with utility and privacy: in Experiment II, the highest-risk backbone was also the most computationally expensive, so more computation did not buy greater privacy. Finally, institutions fine-tuning on sensitive records should view the present protocol as a minimum empirical audit layer that complements, but does not replace, stronger controls such as secure infrastructure, access governance, red-team testing, data-minimization practice, documented approval workflows, and broader privacy-preserving machine-learning governance frameworks [42].

VII. Scope and Generalization Considerations

The present study is intentionally focused and controlled, which supports clear interpretation of the observed effects. Several points nevertheless help frame the scope of the findings.

1) Corpus scope: The experiments target a multi-specialty clinical transcription corpus with long-form narrative structure. This is a strong setting for comparative privacy analysis, although MTSamples is not a modern production EHR repository and does not fully reflect current documentation workflows, institution-specific templates, longitudinal note chains, or heterogeneous authoring practices. Exact leakage magnitudes may therefore vary for other note distributions, longer contexts, or operational EHR settings.

2) Configuration sensitivity: The reported rankings were obtained under one controlled configuration per experiment, including fixed sequence length, batch size, warmup, optimizer settings, and training duration. The controlled setup supports cleaner comparison, but it does not establish invariance of the results under all plausible hyperparameter changes.

3) Run-to-run uncertainty: The principal comparisons were executed with fixed seeds to preserve strict comparability, and bootstrap confidence intervals were reported for key privacy metrics. Additional repeated-seed experiments would refine uncertainty estimates and runtime-variance analysis without changing the central comparative design.

4) Threat-model coverage: Canary insertion, exposure scoring, and membership inference provide complementary views of memorization. They do not exhaust all possible privacy risks, such as attribute inference, model inversion, gradient leakage, embedding reconstruction, adaptive adversarial prompting, or linkage-based attacks, but they capture three established and measurable leakage pathways in generative-model auditing.

5) Defense scope: The study emphasizes controlled comparison among practical fine-tuning profiles and backbone choices. Formal privacy mechanisms, including end-to-end differentially private optimization, remain an important extension for settings in which auditable privacy guarantees are required.

VIII. Conclusion

A controlled study of privacy leakage and memorization in fine-tuned clinical language models was presented using clinical narrative transcriptions, train-only synthetic canaries, and three complementary attack families. Two experiments were performed. The first compared training settings and showed that early stopping improved utility but did not mitigate privacy risk, whereas a combined regularized training profile eliminated observed prompt leakage and sharply reduced membership-inference susceptibility at the cost of degraded utility. The second compared backbones and showed a clear privacy and utility trade-off: DistilGPT2 was the safest but weakest model, GPT-2 was intermediate, and BioGPT achieved the best utility but also the highest prompt leakage, exposure, and membership-inference risk under the evaluated attacks.

The results support a practical but important conclusion for healthcare AI: *better clinical language modeling can coincide with worse privacy behavior, and backbone choice itself is a privacy-relevant design decision*. For deployable clinical LLMs, privacy auditing should therefore be treated as a first-class evaluation axis alongside utility, latency, and resource

cost. The exposure-based pairwise statistics in Experiment II remained underpowered for conventional significance claims, but the overall descriptive pattern across multiple privacy metrics remained consistent.

Future work should extend the same protocol to credentialed EHR corpora, repeated seeds, formally private optimization, and more adaptive extraction attacks. Nonetheless, the present study already offers a reproducible, defensible, and methodologically strong baseline for auditing privacy leakage in clinical language-model fine-tuning.

ACKNOWLEDGMENT

This research received no external funding. Appreciation is extended to Mohammed First University for providing the computational environment used to conduct the experiments.

AUTHORS' PROFILE

Yassine Chahid received the M.Sc. degree in science and technology from the Faculty of Science and Technology, Settat, Morocco, in 2014, and the Ph.D. degree in mathematics and computer science from the Faculty of Sciences, Mohammed First University, Oujda, Morocco, in 2022. Since 2014, he has worked with several private-sector companies, where he has held technical and research-oriented positions. He is currently a Technical Lead specializing in artificial intelligence and cybersecurity solutions. His research interests include federated learning, information security, cryptography, and distributed systems.

Anas Chahid received the Engineering degree in computer science from the National School of Applied Sciences (ENSA), Oujda, Morocco. He is currently a Software Engineer and a Ph.D. student in medical artificial intelligence. His work focuses on the design of intelligent and customized software systems. His professional interests include artificial intelligence, data analytics, software engineering, and healthcare applications.

Ismail Chahid received the DUT degree in information technology from the École Supérieure de Technologie, Oujda, Morocco, in 2008, the B.Sc. degree in IT management from the Faculty of Polydisciplinary Studies, Tétouan, Morocco, in 2009, and the M.Sc. degree in business intelligence from the Faculty of Science and Technology, Béni Mellal, Morocco, in 2012. He is currently the Head of the IT Department at the Faculty of Medicine and Pharmacy of Oujda, where he has been working since 2019. His professional interests include business intelligence, data warehousing, information systems management, and software engineering.

Aissa Kerkour El Miad received the M.Sc. degree in operational research and informatics and the Ph.D. degree in computer science from Mohammed First University, Oujda, Morocco. He is currently a Professor with the Department of Computer Science, Faculty of Sciences, Mohammed First University, Oujda. His research interests include image processing, artificial intelligence, high-performance computing, and data mining.

Deployer-Side XAI Instrumentation for Regulated AI: A Clinical Case Study in ICL Sizing

***Abstract*—Regulated AI creates a monitoring problem for deployers who must organise human oversight, log-retention and post-market surveillance while often having access only to the prediction interface. This study specifies a deployer-side XAI instrumentation protocol for the output→action boundary, where a model output becomes a reason for action. The protocol reorganises KernelSHAP, nearest-neighbour envelope checks, bounded perturbation, and rank-order stability into a per-decision evidence record computed from `predict()` calls. We instantiate the protocol in a clinical case of phakic Implantable Collamer Lens sizing, using a 55-eye held-out cohort and an Extra Trees regressor for post-operative vault prediction. The record contains five signals: `score_margin`, `constraint_enforcement`, `envelope_validity`, `decision_robustness`, and `record_integrity`, plus two cohort-level oversight aggregates. The case study shows how the same record can support decision-time human oversight, later audit and post-market surveillance under the EU AI Act and the Medical Devices Regulation.**

***Keywords*—Explainable AI; XAI instrumentation; human oversight; Medical Device Software; EU AI Act; ICL sizing**

I. Introduction

Regulated AI creates a practical problem for deployers. They must monitor systems they often cannot inspect. Source code, gradients, training data, weights, tree structures and provider-side documentation may remain unavailable because of proprietary, contractual or organisational restrictions. In many deployments, the deployer can only call the prediction interface. This limited-access setting has to be reconciled with legal duties of human oversight, monitoring, log retention and post-market surveillance under the EU AI Act [1] and the Medical Devices Regulation (MDR) [2]. Explainable AI (XAI) methods can operate from this interface: KernelSHAP [3] against a fixed background sample, distance-based envelope checks and bounded perturbation tests. What is still missing is a specification of which method should produce which evidence, for which deployer-side function, and in what computable form when a prediction is used as a reason for action.

This study specifies that mapping. Its objective is to make a single prediction usable as defensible evidence for action under regulation, using only the prediction interface. The study defines the output→action boundary—the point at which a prediction becomes a reason for action—as its unit of analysis, maps four documented failure modes at that boundary to measurement requirements, and specifies a decision-boundary instrumentation protocol that computes the required evidence from `predict()` calls alone.

This study tests that protocol in a clinical case. Phakic Implantable Collamer Lens (ICL) sizing is a pre-operative decision in which the surgeon chooses one of four available lens sizes. The main safety variable is the post-operative vault, which should remain within a clinically acceptable band to avoid contact- and pressure-related complications [4]. The band used in this study is defined in Section IV-A. A model that predicts post-operative vault from pre-operative biometry and anterior-segment OCT can therefore influence a high-stakes clinical decision. In the regulatory setting used here, the tool is treated as Medical Device Software under the MDR and as high-risk Medical Device Artificial Intelligence under Annex III of the AI Act. The clinical deployer is then responsible for organising oversight in use.

The protocol emits a per-decision telemetry record whose five core signals are `score_margin`, `constraint_enforcement`, `envelope_validity`, `decision_robustness` and `record_integrity`, complemented by two cohort-level oversight fields, `sustainability_impact` and `human_ai_teaming`. It is instantiated end-to-end on a 55-eye held-out cohort of an ICL vault prediction regressor (Extra Trees, held-out mean absolute error 160.37 µm), producing per-decision JSON records and a 4×55 counterfactual matrix over the lens-size decision space, and the resulting record is mapped to EU AI Act Article 14 and MDR Articles 83 and 88. Model performance and lens-size superiority are outside the study's claim.

The study is organised as follows: Section II reviews XAI methods, the deployer's position under regulation, the standards frame and the clinical context of ICL sizing. Section III defines the methodological framework and the output→action boundary as the unit of analysis. Section IV introduces the case study, dataset, deployment context and deployed regressor. Section V develops the signal architecture under limited-inspection deployment. Section VI applies the protocol to the held-out cohort, reports the per-decision records, estimates cohort-level review workload and analyse the counterfactual sweep over the four lens sizes. Section VII and Section VIII discuss the findings and conclude.

II. Background and Related Work

A. XAI Methods and their Classical Destination

Post-hoc XAI is usually grouped into four method families. Feature-attribution methods, including KernelSHAP [3] and LIME [5], assign a per-feature contribution to a single prediction. Counterfactual-explanation methods [6], including DiCE-style procedures, search the input neighbourhood for changes

that would alter the model output. Prototype- and influence-based methods locate a prediction in relation to training examples. Surrogate-tree methods approximate an opaque model with a globally interpretable structure. Arrieta et al. [7] provide the taxonomy used here as background.

Recent work has made the model-centred use of post-hoc XAI harder to defend without qualification. Adebayo et al. [8] showed that several saliency methods can produce visually similar attributions even after model randomisation. Slack et al. [9] showed that LIME and SHAP can be manipulated by an adversary controlling the prediction interface, leaving the explanation blind to fairness-relevant features. Rudin [10] argued that high-stakes decisions should use interpretable models where possible instead of post-hoc explanations for opaque models.

A second critique matters more for deployment: who is meant to use the explanation, and for what. Bhatt et al. [11] document that XAI outputs in many organisations are still mainly consumed by model developers, rather than by the operators who must act on model outputs. Liao and Varshney [12] argue that XAI remains incomplete when the user question is not specified. Doshi-Velez and Kim [13] anticipated this separation by distinguishing functionally grounded proxies from human-grounded and application-grounded evaluations.

The literature, therefore, separates two uses of post-hoc XAI. One use serves development: model construction, debugging and selection. It works close to the model and characterises model-level behaviour. The other use serves deployment: a specific output is about to be used as a reason for action. It works from the prediction interface and must characterise one decision in context.

Table I summarises this distinction. Fig. 1 locates the point where the two uses meet: the output→action boundary. Most XAI methods, including the methods used in this study, were designed for model-centred work. The question here is how to reorganise them into deployer-side evidence records.

For the deployer, the useful destination of XAI is the decision record. A SHAP attribution, a counterfactual explanation or a surrogate model is useful in regulated deployment only if it helps document why a specific output could be used, disregarded, overridden or reviewed at that point in the workflow. This study, therefore, treats XAI as instrumentation for functional characterisation, observable behaviour analysis, validation and technical trust evidence at decision time.

B. The Deployer's Predicament Under Regulation

The EU AI Act distinguishes the provider that develops or places an AI system on the market from the deployer that uses the system under its authority. Article 26 assigns deployers of high-risk AI systems duties around use according to instructions, assignment of human oversight, monitoring of operation, reporting of risks or serious incidents, and retention of automatically generated logs when those logs are under their control [1]. Article 14 defines the human-oversight capabilities that high-risk systems must enable: understanding capacities and limitations, remaining aware of automation bias, interpreting outputs and deciding when to disregard, override or reverse an output [1].

The MDR adds clinical evaluation, post-market surveillance and vigilance [2]. For AI-enabled medical devices, the MDCG–AIB guidance [14] clarifies that the AI Act and the MDR/IVDR apply together, while separating the AI Act deployer from the MDR manufacturer. In many clinical uses, the surgeon, hospital or clinic operating the tool is the deployer.

This creates a gap between responsibility and access. The deployer must monitor a system in use, while model internals, training data, source code and provider-side validation material may remain unavailable for technical, legal, organisational or commercial reasons [15], [16], [17]. This study addresses that access regime: the deployer has the case input, a fixed background sample and the ability to call `predict()`.

C. Regulatory and Standards Frame

The operational frame combines the binding regulation of Section II-B with voluntary management standards.

Voluntary frameworks give organisations procedures for organising AI risk and evidence. The NIST AI Risk Management Framework 1.0 [18] organises that work through four functions: *Govern*, *Map*, *Measure* and *Manage*. ISO/IEC 42001:2023 [19] specifies an AI management system based on a plan-do-check-act cycle and auditable operational records.

These frameworks define the organisational need: risks must be governed, mapped, measured, managed and recorded. The protocol developed here supplies an operational mechanism for producing such records at the point where an AI output may become a reason for action.

D. Clinical Context: ICL Sizing as a Regulated AI Decision

The case study uses phakic ICL sizing for refractive correction. The ICL outcomes literature commonly treats the band $[250, 750]$ µm as the range of clinical sufficiency for post-operative vault [4]. This study adopts that band as the operational decision boundary for the case study (Section IV-A).

An ICL sizing tool can influence a high-stakes clinical decision. The model output can shape the lens size selected before surgery. If the predicted vault lies outside the clinically acceptable band, the output becomes part of the reasoning behind a surgical decision with safety implications. Under the medical-device regime, that use needs evidence for oversight, validation and post-market monitoring.

Clinical XAI literature raises the same concern from the healthcare side. Babic et al. [20] warn that explanations in healthcare can overstate what they show, especially when post-hoc rationalisations do not reflect the basis of the prediction. Tonekaboni et al. [21] show that clinicians ask for explanations tied to the clinical situation, timing and decision context, while many XAI methods provide outputs that do not match those needs. Amann et al. [22] frame explainability in healthcare as a multidisciplinary requirement linked to ethical values, safe use and accountability. These contributions support the move from model-centred explanation to decision-time evidence.

The dataset used here comes from clinical operations at three centres of a multi-site ophthalmology network. It was first organised for predictive modelling in earlier clinically

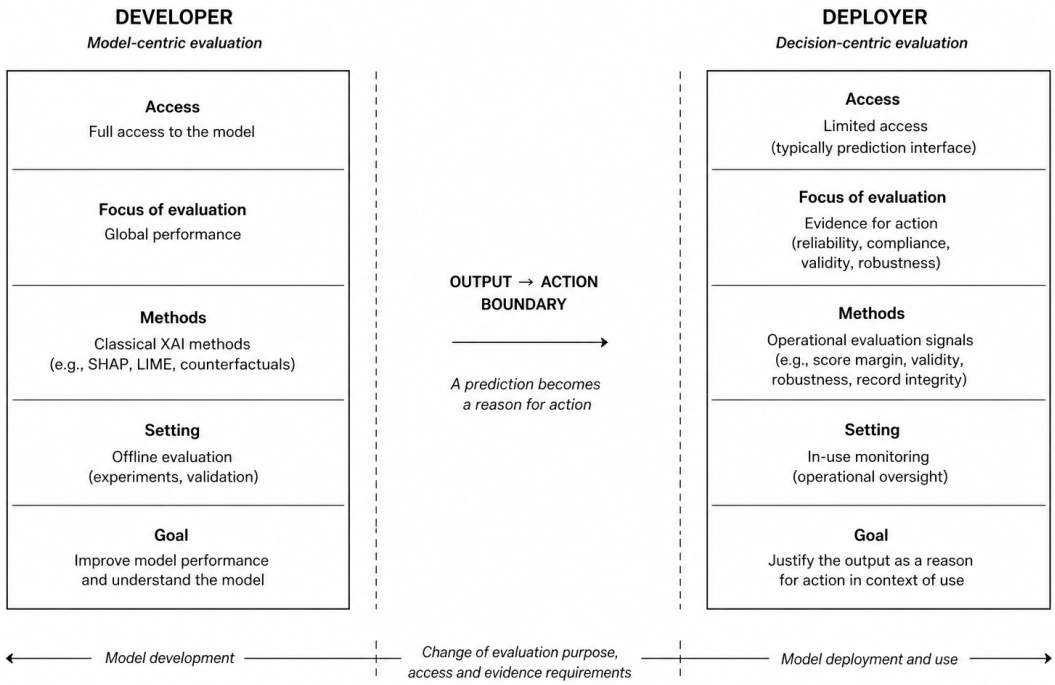

Fig. 1. Developer-side and deployer-side destinations for post-hoc XAI under regulated deployment. The developer-side destination is model-centred: it assumes broad access to the model and supports development, debugging and model selection. The deployer-side destination is decision-centred: it usually works from the prediction interface and supports evidence for action, in-use monitoring and audit. The two destinations meet at the output→action boundary, where a prediction becomes a reason for action.

TABLE I. DEVELOPER-SIDE XAI VS. DEPLOYER-SIDE INSTRUMENTATION: TWO DESTINATIONS FOR POST-HOC EXPLANATION UNDER REGULATED DEPLOYMENT.

Aspect	Developer-side XAI	Deployer-side instrumentation
Access to the model	weights, gradients, training data, architecture, internals	prediction interface only (`predict()` calls)
Unit of analysis	the model	the individual decision
Phase of the lifecycle	development, debugging, model selection	deployment, decision time, post-market surveillance
Primary consumer	model developer, ML researcher	deployer: operator, clinician, audit team
Output form	global explanations, fidelity diagnostics, debugging outputs	per-decision evidence record + cohort aggregates
Regulatory anchor	usually indirect	EU AI Act Art. 14 and Art. 26; MDR Art. 83 and Art. 88
Question answered	does this model behave as expected in general?	is this specific output defensible as a reason for action now?

supervised work. This study inherits the clinical motivation, feature inventory and filtering criteria from that work.

The dataset and the regression model are used to expose the AI-decision structure on which the instrumentation protocol is tested.

E. Accountability Artefacts and Decision Logging

A parallel line of work proposes documentation and logging artefacts for accountable AI. Model Cards [23], FactSheets [24] and Datasheets for Datasets [25] standardise what a provider should disclose about a model, a service or a dataset, while internal audit frameworks such as the one of Raji et al. [26] organise accountability as an organisational process. Decision provenance [27] extends this from static documentation towards logging the data flow behind individual decisions. These artefacts are mostly produced at model or dataset release, on the provider or developer side, and they characterise the system rather than a single output. The protocol developed here is complementary and sits at a different point: it is a per-decision, deployer-side evidence record computed at prediction time from `predict()` calls, so that the actor who acts on an output can attach defensible, auditable evidence to that specific decision under limited inspection.

F. Position of this Work

The architecture maps the deployer's monitoring problem to four failure modes at the output→action boundary, each turned into a measurement computable from `predict()` calls alone (Section III). This study adapts it to a clinical regression case and applies it end to end to a real ophthalmology cohort.

The ICL case has three useful properties for the protocol.

First, the predictive task is regression on a continuous safety variable, so the relevant boundary is a clinical band rather than a probability threshold. Second, the dataset comes from a real multi-centre clinical cohort operating under the medical-device regime. Third, the decision space is small and discrete: the surgeon chooses one of four lens sizes. That discreteness allows the counterfactual component to enumerate all decision alternatives. For each held-out eye, the protocol queries the model under each candidate lens size while holding anatomy and biometry fixed, and then recomputes the boundary-relevant signals for each alternative. The premise is narrow. XAI outputs used in regulated deployment must be structured well enough to count as evidence. The question is whether each decision record supports functional characterisation, observable behaviour analysis, validation and technical trust evidence at the moment when a prediction is used as a reason for action.

III. Methods

This section defines the framework applied in the clinical case. The framework was introduced in the companion manuscript [28]. Here it is adapted to a regression task on a continuous safety variable and later implemented for the ICL vault prediction model.

A. Unit of Analysis: The Output→Action Boundary

The framework takes the output→action boundary as its unit of analysis. This is the point at which a single prediction becomes a reason for action in a clinical, financial or industrial workflow.

At that point, the question is evidential. The deployer responsible for monitoring the system in use must be able to attach evidence to the prediction before the decision is taken. Under the access conditions described in Section II-B, that evidence must be computable from the prediction interface. The framework therefore specifies what evidence is needed, how it is structured and which part of the output→action relation it characterises.

B. From Failure Modes to Measurement Requirements

Four safety and human-factors perspectives identify failure modes at the output→action boundary.

Leveson [29] identifies constraint-enforcement failure: the action proceeds on grounds that the institution would not recognise as legitimate. Rasmussen [30] identifies envelope migration: the case has moved beyond the population on which the model was validated. Parasuraman [31] identifies automation bias: a fragile output is treated as robust because the operator has no evidence of fragility. A fourth failure is procedural: accountability failure, where no reproducible record links the output, the decision context and the evidence used at the time of action.

Each failure mode defines a measurement requirement. Constraint-enforcement failure requires evidence about whether the local prediction is supported by legitimate variables or by decision-linked variables. Envelope migration requires evidence about the distance between the case and the validated population. Automation bias requires evidence about whether decision-band membership is stable under bounded perturbation. Accountability failure requires evidence about whether the explanation is stable enough to be used as a record.

The framework also includes a domain-derived signal. In the ICL case, the predicted vault must be located relative to the operational clinical band. This signal indicates whether the predicted vault is safely inside the band, close to a threshold or outside the clinically acceptable range.

C. From Measurement Requirements to Prediction-Interface Methods

The deployer's access condition restricts the available methods. The framework therefore selects XAI and validation methods that can operate from the prediction interface.

KernelSHAP [3] computes feature attributions from `predict()` calls against a fixed background sample. It can therefore measure attribution mass on legitimate and decision-linked variables. *k*-nearest-neighbour distance operates on the input feature space and measures envelope validity. Bounded perturbation repeatedly calls `predict()` on perturbed versions of the same input and estimates the flip rate used for `decision_robustness`. Rank-order stability under micro-noise recomputes the attribution procedure on small perturbations of the input and produces `record_integrity`.

The methodological step is the binding between failure mode, measurement requirement, computable signal and prediction-interface method. Each XAI or validation method receives a specific evidential function at the output→action boundary.

D. Properties of the Resulting Protocol

The protocol has three methodological properties.

First, the protocol is compatible with prediction-interface-only access. It requires the case input, a fixed background sample and the ability to call `predict()`. It does not require model weights, gradients, trees, source code, training data or provider-side documentation.

Second, the protocol is non-compensatory. Each signal addresses a different failure mode. A high value on one signal does not offset a failure on another. A stable attribution does not compensate for a prediction outside the clinical band. Robust band membership does not compensate for reliance on decision-linked variables.

Third, the protocol is decision-boundary local. Each signal is computed for the specific case on which the deployer is acting. The protocol produces a per-decision evidence record attached to one prediction at the moment that prediction may support action. Model-level validation remains necessary, but it answers a different question.

IV. Case Study

A. Clinical Target and Decision Space

The clinical target of an ICL sizing model is the post-operative vault: the distance between the implanted lens and the natural crystalline lens. A vault below the clinically acceptable range may increase the risk of contact-related

complications. A vault above that range may increase intraocular pressure and the risk of secondary glaucoma. The ICL outcomes literature commonly uses $[250, 750]$ µm as the range of clinical sufficiency [4].

The decision supported by the tool is the pre-operative choice of lens size. In this case, the available sizes are the four standard options used at the contributing sites: {12.1, 12.6, 13.2, 13.7} mm. The decision uses anterior-segment optical coherence tomography (OCT), biometric measurements and the clinician's selected refractive correction.

The regression model analysed here evaluates candidate decisions. For each candidate lens size and selected refractive correction, the model uses the available anatomical and biometric measurements to predict the post-operative vault expected from that combination. The model supports sizing by estimating the safety variable associated with each candidate decision.

B. Dataset

The dataset comes from clinical ophthalmology operations at three centres of a multi-site ophthalmology network. The data were first organised for predictive modelling in earlier clinically supervised work. This study inherits three elements from that work: clinical motivation, feature inventory and cohort filtering criteria.

The clinical motivation is vault prediction, as the principal safety variable in ICL sizing. The feature inventory contains 25 pre-operative variables combining anterior-segment OCT indices, biometric and refractive measurements, and categorical descriptors of the implant decision. The filtering criteria retain eyes with complete pre-operative OCT, biometry and post-operative vault measurement. After filtering, the cohort contains 545 eyes.

The dataset is reused to evaluate whether the instrumentation protocol can produce decision-level evidence from a deployed regressor.

The feature set contains 25 pre-operative variables grouped into three sets.

The OCT set includes anterior-segment indices: lens rise, anterior depth, limbus diameter and centre, pupil diameter and centre, and the temporal/nasal AOD/TISA pairs at the 750 µm reference.

The biometric and refractive set includes k1 keratometry, patient age at operation, pre-operative spherical equivalent and selected refractive correction.

The decision-descriptor set includes categorical variables encoded as one-hot indicators: lens family (`ICL`, `TICL`), refractive type (`Myopic`, `Toric Myopic`) and lens-size dummies (`lens_12.1`, `_12.6`, `_13.2`, `_13.7`).

The lens-size variables are encoded as four independent indicators, not as one numerical variable. This avoids treating lens size as a continuous ordered scale. It also aligns the feature representation with the discrete decision space defined in Section IV-A. The same encoding supports the counterfactual sweep in Section VI-C, where each eye is evaluated under the four candidate lens sizes.

All 25 features are available at the moment of the sizing decision. This matters for the deployment-time evaluation in Section VI: the model is evaluated using only information available before the clinical decision. Continuous features are imputed with the median of the training partition and the same imputers are applied to the held-out partition, avoiding held-out information in the imputation step.

Case identifiers used in the body of the study are anonymised as `case1`, `case2`, ..., `case5`. These labels do not correspond to clinical-record database entries.

C. Deployment Context

ICL sizing models are no longer only isolated research prototypes. Since 2021, several machine-learning pipelines have been published for vault prediction and lens-size selection on cohorts ranging from hundreds to thousands of eyes. These include Random Forest and gradient-boosted regressors trained on large EVO-ICL records [32], regression-tree ensembles trained on multicentre OCT–MS39 data [33], and deep-learning models trained on raw SS-OCT images and made publicly available through the `safevaulticl.com` interface [34].

The model studied here belongs to that emerging class of clinical decision-support software. Its relevance for this study is the operational structure of the decision: a model output can become part of the reasoning behind a surgical choice.

Section II set out the regulatory frame. In this case, the relevant actor is the clinical user of the system. In a clinical setting, the operator of the sizing AI is typically the refractive surgeon or the clinic's data team, not the model developer. This actor is the deployer under Article 26 of the EU AI Act and must organise system use, monitoring and human oversight in practice [1].

Article 14 defines the human-oversight capacities that the system must enable. Article 26 places the deployer in the operational position where those capacities must be used. MDR Articles 83 and 88 add the post-market surveillance and trend-reporting frame for the medical-device setting [2].

The problem is operational. The deployer is expected to monitor the system in use, while access to the model's internal design, training process and provider-side documentation may be limited [15], [16], [17]. The case study asks what evidence the deployer can document when an ICL vault prediction is used as a reason for a sizing decision.

D. The Deployed Regressor

From the 545-eye dataset described in Section IV-B, 490 eyes are used for training and 55 for held-out evaluation. The split is reproducible, with `test_size = 0.10` and `seed = 42`.

Five standard scikit-learn regressors are evaluated on the training partition using 10-fold cross-validation and mean absolute error (MAE) as the scoring metric: Extra Trees [35], Random Forest [36], Ridge regression, histogram-based gradient boosting and standard gradient boosting [37]. Table II reports the cross-validated MAE for each candidate.

TABLE II. CROSS-VALIDATED COMPARISON OF CANDIDATE REGRESSORS ON THE TRAINING PARTITION (490 EYES, 10-FOLD CV).

Rank	Model	MAE_cv (μm)
1	**Extra Trees** *(selected)*	**167.24**
2	Ridge	175.73
3	Random Forest	176.86
4	HistGradientBoosting	180.50
5	Gradient Boosting	182.99

The Extra Trees regressor is selected for the lowest cross-validated MAE; on the held-out partition its MAE is 160.37 μm, close to the cross-validated training value, which we read as evidence of no obvious train/held-out drift rather than a precision claim.

The model is serialised with its column order, per-feature imputation medians and lens-size column name; this object is the only model input consumed by the protocol in Section V. The regressor is not meant to outperform the clinical state-of-the-art: it is the test bed for the instrumentation protocol.

V. SIGNAL ARCHITECTURE UNDER LIMITED-INSPECTION DEPLOYMENT

A. Failure Modes at the Output→Action Boundary and the Measurements they Require

Sections II-B and Section II-C define the deployer-side access condition. Section III defines the failure-mode/measurement-requirement chain. This section turns that chain into operational signals and prediction-interface methods. The clinical case adds one domain signal: the distance between the predicted vault and the centre of the operational clinical band. That domain signal orients the four failure-mode signals. The methodological contribution is the binding itself: existing XAI and validation methods are assigned, one by one, to specific failure modes at the output→action boundary under prediction-interface-only access. Table III summarises the chain.

Each signal follows from a failure mode and from the access conditions of deployment. The chain is: failure mode, required measurement, computable signal, prediction-interface method.

B. Cohort-Level Aggregates: From Per-Decision Telemetry to Oversight Workload

The five signals in Section V-A, together with case identifier, timestamp, model version and lens-size selection, form the telemetry record emitted at the output→action boundary. The operator can use this record at decision time and persist it afterwards as the audit unit.

The record also contains two oversight fields: `sustainability_impact` and `human_ai_teaming`. Their cohort-level aggregates estimate how many outputs remain inside the operational band and how many can proceed under the AI-supported workflow before human review. This matters because Article 14 requires oversight measures that allow assigned persons to understand system capacities and limits, remain aware of automation bias, interpret outputs and decide when to disregard, override or reverse them [1].

`human_ai_teaming_cohort` measures the proportion of decisions that satisfy the joint sufficiency criterion envelope_validity $\geq \tau_{\text{env}}$ and score_margin $\geq \tau_{\text{margin}}$. Its complement is the expected human-review workload under Article 14. Both aggregates are computed from the same per-decision telemetry and require no additional measurements. The thresholds $(\tau_{\text{env}}, \tau_{\text{margin}})$ are set by the deployment context, balancing unnecessary routing against missed review.

C. Pipeline and Per-Decision Evidence Record

The three methodological properties in Section III-D instantiate, as shown in Fig. 2. The Listing given below gives one telemetry record from the held-out cohort. The same record is the decision-time view for the clinician and the later audit unit used by post-market surveillance.

Section VI reports what the protocol produces on every held-out eye.

VI. APPLICATION TO THE ICL VAULT PREDICTION MODEL

This section applies the protocol of [28] to the deployed ICL vault regressor, showing the evidence it produces from `predict()` calls only, for one sizing decision and for cohort-level oversight. Box 1 presents the glossary signals and parameters used in Section VI.

Section VI-A defines the calibration choices; Section VI-B reports the output on the 55-eye held-out cohort; Section VI-C evaluates the four lens sizes and the counterfactual matrix for oversight and post-market surveillance; Section VI-D states reproducibility.

A. Operational Calibration

Applying the architecture (Section V) to the deployed regressor (Section IV-D) requires four calibration choices: the clinical band (`score_margin`), the feature taxonomy (`constraint_enforcement`), the perturbation parameters (`decision_robustness`, `record_integrity`), and the operating point for cohort-level oversight. The clinical band $[250, 750]$ μm is taken from Section IV-A unchanged; Table IV summarises the calibration.

Clinical band. The `score_margin` signal reports the distance of the predicted vault from the centre of the clinical band, normalised by the band half-width. With centre $c = 500$ μm and half-width $h = 250$ μm, the signal is:

$$\text{score_margin}(\hat{y}) = 1 - \frac{|\hat{y} - c|}{h} \tag{1}$$

A prediction at the band centre yields 1.0, at either edge 0.0, and outside the band a negative value whose magnitude indicates how far outside the case lies.

Feature taxonomy. The legitimate/decision-linked split defines the clinical meaning of `constraint_enforcement`. In this case, the split separates variables that describe the eye from variables that encode, or partly encode, the clinical decision. The deployer needs to know whether the local prediction is mainly supported by anatomical and biometric

TABLE III. FAILURE MODES AT THE OUTPUT→ACTION BOUNDARY, THE MEASUREMENT THEY REQUIRE, THE SIGNAL THAT DELIVERS IT, AND THE PREDICTION-INTERFACE-COMPUTABLE METHOD.

Perspective	Failure	Measure	Signal	Method
Domain (clinical band)	Case far from operational threshold	Distance from band centre	`score_margin`	scalar of the prediction
Leveson (STAMP) [29]	Action proceeds on non-legitimate or decision-linked features	Share of attribution mass on legitimate features	`constraint_enforcement`	KernelSHAP [3] vs fixed background
Rasmussen [30]	Case outside validated envelope	Distance to validated population	`envelope_validity`	k-NN distance in feature space
Parasuraman [31]	Brittle output read as robust	Flip-rate under bounded perturbation	`decision_robustness`	repeated `predict()` over perturbations
Cross-cutting accountability	No reproducible record of evidential basis	Rank-order stability of the attribution	`record_integrity`	KernelSHAP recomputed under micro-noise

Listing. Example structure of one per-decision telemetry record.

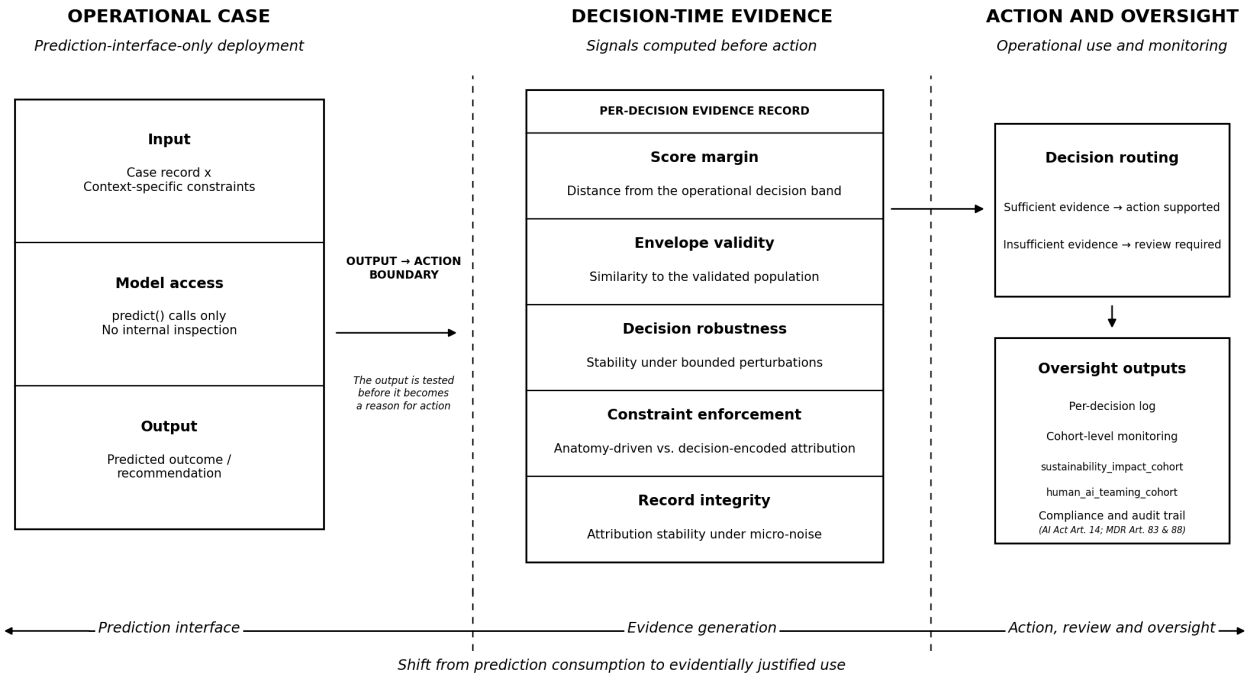

Fig. 2. Pipeline of the protocol on a single decision. The deployer queries the model through `predict()` only. The five core signals and two per-decision oversight fields are emitted as a JSON evidence record. Cohort-level aggregates are computed later by aggregating persisted records across cases.

Box 1 — Glossary of signals and parameters used in Section VI. The five core signals, the two cohort-level oversight aggregates and the calibration parameters used throughout this section are summarised below. Operational definitions and formulas are given in Section VI-A. Cohort-level results are reported in Section VI-B to Section VI-C. Dataset feature names with their legitimate/decision-linked classification appear in Table V.

Symbol / field	Description	Range / value
`score_margin`	distance to clinical-band centre, normalised by half-width	$(-\infty, 1]$
`constraint_enforcement`	KernelSHAP attribution mass on legitimate features	$[0, 1]$
`envelope_validity`	k-NN distance beyond validated population, clipped	$[0, 1]$
`decision_robustness`	fraction of perturbations preserving band membership	$[0, 1]$
`record_integrity`	mean Spearman rank-order stability under micro-noise	$[-1, 1]$
`sustainability_impact_cohort`	cohort fraction with prediction inside [250, 750] µm	$[0, 1]$
`human_ai_teaming_cohort`	cohort fraction satisfying joint sufficiency	$[0, 1]$
τ_{env}	sufficiency threshold for `envelope_validity`	0.5
τ_{margin}	sufficiency threshold for `score_margin`	0.3
σ	bounded-perturbation magnitude for `decision_robustness`	$0.10 \times$ std
ε	micro-noise magnitude for `record_integrity`	$0.01 \times$ std
N	bounded-perturbation samples per case	100
M	micro-noise replicates per case	50
k	k-NN neighbourhood size	5
$d_{\max}$	envelope distance threshold	90th percentile of train 5-NN mean
X_{bg}	KernelSHAP background sample size	50
$\mathcal{L}, \mathcal{D}$	legitimate / decision-linked feature partition (Table V)	14 / 11

Box 2 — Justification of calibration parameters. Each non-domain parameter used in Section VI-A is summarised here with its operational rationale and references.

Parameter	Value	Rationale	Reference / source
Clinical band $[v_{\text{lo}}, v_{\text{hi}}]$	$[250, 750]$ µm	domain-derived; clinical literature on ICL vault outcomes	[4]
X_{bg}	50	background sample size for KernelSHAP; in the recommended 50–1000 range, with empirical stability of SHAP explanations documented for sample sizes of this order	SHAP documentation; [38]
k	5	small neighbourhood size for k-NN-based out-of-distribution detection on a 490-eye reference set; consistent with deep k-NN OOD-detection literature	[39]
$d_{\max}$ rule	90th percentile of train 5-NN mean	percentile-based threshold for out-of-distribution detection; less sensitive to training-set outliers than a maximum-distance rule	[39]
σ	$0.10\times$ std	bounded-perturbation magnitude; of the order of inter-operator anterior-segment OCT measurement variability reported in the imaging literature	domain-derived; calibrated against OCT inter-operator variability
ε	$0.01\times$ std	micro-noise magnitude one order of magnitude below σ; tests rank-order stability of the explanation under noise that should leave clinical interpretation unchanged	derived; clinical-interpretation invariance
N	100	bounded-perturbation samples per case; standard Monte Carlo budget for flip-rate estimates at the precision used by `decision_robustness`	empirical; pilot stability test
M	50	micro-noise replicates per case; sufficient sample for the Spearman rank-order correlation estimate used by `record_integrity`	empirical; pilot stability test
$(\tau_{\text{env}}, \tau_{\text{margin}})$	$(0.5, 0.3)$	deployer-side operating point; conservative defaults used throughout this study. Sensitivity at three alternative values is reported in Table VI	deployer-side domain choice

TABLE IV. OPERATIONAL MAPPING OF THE 5 + 2 SIGNALS ON THE ICL VAULT PREDICTION MODEL

Signal	Domain choice	Parameters
`score_margin`	clinical band [250, 750] µm	half-width $h = 250$, centre $c = 500$
`constraint_enforcement`	L = 14, D = 11 (Table V)	$X_{\text{bg}} = 50$, `seed = 42`
`envelope_validity`	25-D feature space, post-imputation	$k = 5$, $d_{\max} =$ max train 5-NN mean
`decision_robustness`	bounded Gaussian perturbation on continuous features	$N = 100$, $\sigma = 0.10$ std
`record_integrity`	rank-order stability under micro-noise on continuous features	$M = 50$, $\varepsilon = 0.01$ std
`sustainability_impact_cohort`	inside clinical band	population fraction
`human_ai_teaming_cohort`	sufficiency thresholds	$\tau_{\text{env}} = 0.5,\ \tau_{\text{margin}} = 0.3$

measurements, or whether it is reproducing variables derived from the clinician's prospective choice.

The 25 pre-operative features are divided into a legitimate set $\mathcal{L}$ of fourteen anatomical, biometric, age and laterality variables, and a decision-linked/report-dependent set $\mathcal{D}$ of eleven variables. The full taxonomy is shown in Table V.

The legitimate set contains pre-operative anatomical and biometric measurements that exist independently of the sizing decision. The decision-linked/report-dependent set contains features whose values encode the clinician's prospective lens-size selection (`lens_*`, `selected_lens_size`, `selected_sph`), lens-family and refractive-type dummies linked to the clinical decision (`ICL`, `TICL`, `Myopic`, `Toric Myopic`), and patient-reported refraction, which is subject to instrument-of-reporting variability (`preop_sph`).

The *legitimate/decision-linked* partition is informational, not a judgement of clinical validity: lens size physically influences vault, so decision-linked variables are clinically relevant inputs. `constraint_enforcement` asks whether the prediction differentiates cases mainly through anatomical evidence (a high value: anatomy and biometry carry most of the attribution mass) or by tracking the lens choice already encoded in the input (a low value: dominated by decision-linked or report-dependent variables). Both modes can be clinically plausible and provide different evidence at the output→action boundary.

In the counterfactual sweep of Section VI-C, the lens-size variables are queried under each of the four candidate values as intervention variables. By contrast, `constraint_enforcement` is computed at the originally observed prediction, with all input features held at their recorded values.

Two caveats about the KernelSHAP background sample X_{bg}: it is drawn from the training partition here for reproducibility, but in deployment without training-data access the provider should supply an anonymised representative sample, since KernelSHAP needs a reference distribution for per-feature contributions [3]; and because KernelSHAP interpretations depend on that sample [38], the protocol relies on a provider-supplied or training-derived sample the deployer cannot fully verify from the prediction interface alone.

The `constraint_enforcement` signal is computed as:

$$\text{constraint_enforcement} = \frac{\sum_{i\in\mathcal{L}} |\phi_i|}{\sum_{i\in\mathcal{L}} |\phi_i| + \sum_{i\in\mathcal{D}} |\phi_i|}. \quad (2)$$

Here, ϕ_i is the per-feature KernelSHAP attribution computed by the protocol's regression-aware KernelSHAP variant. The cohort-level aggregates reported in Sections VI-B–VI-C are computed from these per-decision records.

1) Validation envelope: The `envelope_validity` signal reports whether the case remains inside the feature-space envelope of the training partition. The signal uses a *k*-nearest-neighbour distance estimator on the 25-D post-imputation feature space, with $k = 5$. Features are standardised with the training-partition mean and standard deviation before distance computation, so each variable contributes comparably to the Euclidean distance.

The threshold $d_{\max}$ is the 90th percentile of the per-training-point 5-NN mean distance over the 490-eye training partition, a choice consistent with out-of-distribution detection practice [39]. The signal is:

$$\text{envelope_validity}(x) = 1 - \max\left(0,\ \frac{d_{k\text{NN}}(x)}{d_{\max}} - 1\right), \quad (3)$$

clipped to $[0, 1]$: a value of 1.0 means the case remains within the calibrated training envelope, and lower values indicate greater distance beyond the threshold.

2) Perturbation parameters: The bounded-perturbation magnitude used by `decision_robustness` is set to $\sigma = 0.10$ of each continuous feature's training-partition standard deviation. Perturbations are applied only to continuous anatomical, biometric and refractive variables. One-hot categorical indicators and the candidate lens-size encoding are held fixed during bounded-perturbation and micro-noise tests.

This magnitude is of the same order as inter-operator OCT measurement variability, so a band-membership flip under it means the decision can change under deployment-level measurement noise.

Let s_j denote the training-partition standard deviation of continuous feature j. With $N = 100$ perturbations $\epsilon_n \sim \mathcal{N}(0, \text{diag}((\sigma s_j)^2))$ and band-membership indicator $b(\hat{y}) = \mathbf{1}[250 \le \hat{y} \le 750]$, the signal is:

$$\text{decision_robustness}(x) = \frac{1}{N}\sum_{n=1}^{N} \mathbf{1}\Big[b(\hat{f}(x+\epsilon_n)) = b(\hat{f}(x))\Big]. \quad (4)$$

A value of 1.0 indicates that no perturbation flips the case's band membership; lower values report the share that do.

The micro-noise magnitude used by `record_integrity` is set to $\varepsilon = 0.01$ of each continuous feature's training-partition standard deviation. This tighter regime tests whether the attribution ranking stays stable under noise that should leave the clinical interpretation unchanged.

With $M = 50$ micro-perturbed copies $\delta_m \sim \mathcal{N}(0, \text{diag}((\varepsilon s_j)^2))$ and Spearman rank-order correlation ρ_S, the signal is the mean correlation between the original attribution vector and each perturbed replicate:

$$\text{record_integrity}(x) = \frac{1}{M}\sum_{m=1}^{M} \rho_S(\phi(x),\ \phi(x+\delta_m)) \quad (5)$$

A value of 1.0 indicates a perfectly stable explanation under micro-noise; lower values flag an attribution whose ranking should be cited only with its noise envelope.

TABLE V. FEATURE TAXONOMY USED BY CONSTRAINT_ENFORCEMENT (25 FEATURES PARTITIONED INTO 14 LEGITIMATE + 11 DECISION-LINKED/REPORT-DEPENDENT VARIABLES).

#	Feature	Class	Domain group
1	lens_rise	L	anatomical OCT
2	anterior_depth	L	anatomical OCT
3	aod_nasal	L	anatomical OCT
4	aod_temporal	L	anatomical OCT
5	tisa_nasal	L	anatomical OCT
6	corneal_volume	L	anatomical OCT
7	pupil_x	L	anatomical OCT
8	pupil_y	L	anatomical OCT
9	pupil_diameter	L	anatomical OCT
10	limbus_y	L	anatomical OCT
11	limbus_diameter	L	anatomical OCT
12	age	L	biometric / age
13	k1	L	biometric
14	laterality	L	laterality
15	preop_sph	D	reported refraction
16	selected_sph	D	clinician's selection
17	selected_lens_size	D	clinician's selection (numeric)
18–21	lens_12.1, lens_12.6, lens_13.2, lens_13.7	D	one-hot encoding of the four candidate lens sizes
22–23	ICL, TICL	D	lens-family one-hot
24–25	Myopic, Toric Myopic	D	refractive-type one-hot

3) Operating point: The two sufficiency thresholds are set to $(\tau_{\text{env}}, \tau_{\text{margin}}) = (0.5, 0.3)$. This is the conservative operating point used throughout the study.

The routed-workload aggregate in Section VI-B is also reported at two alternative values of τ_{margin} (Table VI). Routed workload depends on the selected operating point. The architecture defines the aggregate. The deployer chooses the operating point. Among the three operating points reported in Table VI, $\tau_{\text{margin}} = 0.30$ was selected because it routes the fragile mid-band cases that $\tau_{\text{margin}} = 0.20$ leaves unrouted, while holding the human-review workload at 20% (11 of 55), below the 23.6% implied by $\tau_{\text{margin}} = 0.40$; this balances oversight coverage against the review capacity a single clinic can absorb.

B. Output of the Protocol on the Held-Out Cohort

The protocol is run on the 55-eye held-out cohort. Each prediction produces one JSON record with the five core signals, two per-decision oversight fields and case metadata.

The results are read at three levels: the individual decision record, the cohort aggregate used to estimate human-review workload, and the protocol-calibration level where signal distributions are checked on real data. The protocol output is produced at prediction time; if the record is persisted, the same record can later be audited.

Fig. 4 and Fig. 3 reproduce two records as they would appear at decision time, with retrospective outcome information shown separately. Case case4 shows counterfactual evidence supporting deviation from the evaluated lens option. Case case1 shows operational sufficiency despite a later large prediction error, separating decision-time evidence from model-quality assessment.

1) Per-decision evidence: The individual JSON record is the unit at which the deployer documents the output→action relation. Table VII reports five records from the held-out cohort. They were selected because each one shows a different behaviour that the protocol is designed to separate: clean, borderline, flip-prone, out-of-band and attribution-unstable.

Each column of Table VII is one JSON record produced at decision time and persisted for later audit. Two records are reproduced in full in Fig. 3 and Fig. 4. Retrospective measured vault is included only for the discussion of predictive accuracy in Section VII-A.

The five columns show different operational behaviours. The Clean column has every signal above threshold, although its later absolute prediction error is 308 µm. The Borderline and Flip-prone columns show fragile band membership under OCT-grade perturbation, with robustness values of 0.79 and 0.38. The Out-of-band column has stable attribution and band membership, but a negative score margin (-0.38). The Unstable column has the lowest record integrity in the cohort, so its SHAP ranking should be cited only with its noise envelope. A high value on one signal is not used to compensate for failure on another; the axes remain separate.

2) Per-cohort workload: The two cohort-level oversight aggregates in Table VIII convert the 55 decision records into an estimate of human-review workload. This is the cohort-level view relevant to Article 14 oversight. The aggregates are defined as

Definitions. For $N = 55$, the sustainability aggregate is the share of cases with $250 \leq \hat{y}_i \leq 750$. The teaming aggregate is the share of cases satisfying $\text{env}_i \geq \tau_{\text{env}}$ and $\text{margin}_i \geq \tau_{\text{margin}}$. Review required is the complement of the teaming aggregate.

The sustainability aggregate shows that 52 of 55 eyes receive a prediction inside the clinically plausible band. The human-AI-teaming aggregate shows that 44 eyes meet the joint sufficiency criterion and 11 do not. Under the operating point $(\tau_{\text{env}}, \tau_{\text{margin}}) = (0.5, 0.3)$, those 11 eyes represent 20% of the cohort flow. This is the workload routed to human review.

TABLE VI. COHORT ROUTING AGGREGATE UNDER THREE OPERATING POINTS OF THE SCORE-MARGIN SUFFICIENCY THRESHOLD ($\tau_{\text{ENV}} = 0.5$ FIXED).

τ_{margin}	Sufficient (AI-supported workflow)	Routed to review	Rationale
0.20	46 / 55 (0.836)	9 / 55 (0.164)	permissive: only clearly out-of-band cases routed
0.30	**44 / 55 (0.800)**	**11 / 55 (0.200)**	**operating point used in this study**
0.40	42 / 55 (0.764)	13 / 55 (0.236)	conservative: routes mid-band cases for review

TABLE VIII. COHORT-LEVEL OVERSIGHT AGGREGATES AND IMPLIED HUMAN-REVIEW WORKLOAD

Metric	Value	Reading
`sustainability_impact_cohort`	0.945	52 / 55 eyes inside [250, 750] µm
`human_ai_teaming_cohort`	0.800	44 / 55 eyes sufficient under AI-supported workflow
`review_required` (= 1 - teaming)	0.200	11 / 55 eyes routed to human review

Table IX maps each part of the protocol output to a human-oversight or post-market-surveillance function. The table is a traceability map between protocol outputs and the evidence that the deployer must organise and retain.

The clinician uses the record at decision time; persisted records can later be audited and aggregated for post-market surveillance. Both uses rely on `predict()` calls only.

The 11/55 routing result in Table VIII depends on the selected operating point. The deployer calibrates τ_{margin} against two costs: unnecessary routing and unrouted error.

Table VI reports the routed workload at three values of τ_{margin} while keeping τ_{env} fixed at 0.5. The routed workload increases monotonically from 9/55 at the permissive setting to 13/55 at the conservative setting.

3) Signal calibration over the cohort: Table X reports the empirical distribution of the core signals across the held-out cohort. This table gives protocol-level evidence. The clinician and the later auditor use the individual record, as shown in Table VII and Fig. 4 and Fig. 3.

The distribution addresses a methodological objection: the signals could collapse to constants on real data. Here they do not. `score_margin` ranges from -0.38 to 0.99, `constraint_enforcement` from 0.45 to 0.91, `record_integrity` from 0.77 to 0.95, and `decision_robustness` identifies six eyes with flip rates below unity.

4) Envelope-validity calibration: Under the percentile-based threshold, $d_{\max}$ is the 90th percentile of the per-training-point 5-NN mean distance ($d_{\max} = 5.06$). The held-out 5-NN mean distance ranges from 2.20 to 5.97. Fifty eyes remain saturated at `envelope_validity` $= 1.00$; five return values between 0.60 and 1.00. None falls below $\tau_{\text{env}} = 0.5$, so the 11 routed cases are still driven by the score-margin threshold in this cohort. The signal would become more decisive under genuine deployment shift, for example after changes in OCT device, surgeon protocol or patient population.

The cohort mean of `constraint_enforcement` is 0.676. The aggregate attribution share of the legitimate set is 0.681, agreeing to two decimals. Six of the ten highest-ranked features are legitimate, and the largest contributor is the anatomical feature `lens_rise` (Fig. 5). This independent agreement supports the claim that `constraint_enforcement` measures the attribution split it was defined to measure.

C. Counterfactual Over the Discrete Decision Space

Bounded perturbation tests local fragility. It does not compare the four surgical alternatives. The sizing decision is discrete: the surgeon chooses one lens size from four available options. The protocol can therefore query the model under each candidate lens size while holding all other features fixed.

For each held-out eye, the model is queried four times, once per available size. For each query, the protocol recomputes the three sweep-relevant signals: `score_margin`, `envelope_validity` and `decision_robustness`. The result is a 4×55 matrix. Each cell records the predicted vault for one eye under one candidate lens size, together with the three boundary-relevant signals recomputed for that hypothetical decision while all anatomical and biometric inputs remain fixed.

The body of the study reports two slices of the complete 220-row long-format matrix: one decision-level slice and one cohort-level slice.

The decision-level slice gives the operator evidence for disregarding, overriding or intervening under Article 14(4)(d–e). Fig. 4 shows this for case `case4`. The cohort-level slice aggregates across all 55 eyes by lens size and supports post-market surveillance under MDR Article 88. Table XI reports this aggregate.

1) Per-decision counterfactual evidence: Consider eye `case4` at the moment when the surgeon must commit to a lens

TABLE IX. MAPPING OF PROTOCOL OUTPUTS TO HUMAN-OVERSIGHT AND POST-MARKET-SURVEILLANCE FUNCTIONS

Protocol output	Evidence function supported
Per-decision JSON record (Figs. 3, 4)	`Art 14(4)(b)` capacities and limits of the system
`decision_robustness` flag	`Art 14(4)(c)` awareness of automation bias
`constraint_enforcement` taxonomy (legitimate / decision-linked)	`Art 14(4)(d)` basis for disregard, override or reversal
Counterfactual-by-lens matrix (Section VI-C)	`Art 14(4)(e)` basis for meaningful intervention
Cohort routing aggregate (Table VIII)	`Art 14(3)` oversight measures proportionate to risk
Cohort signal distribution (Table X)	`MDR Art 83 & 88` post-market surveillance and trend reporting

TABLE X. DISTRIBUTION OF THE FOUR INFORMATIVE CORE SIGNALS ACROSS THE 55 RECORDS (SIGNAL-CALIBRATION EVIDENCE; NOT PART OF THE PER-DECISION AUDIT UNIT). ENVELOPE_VALIDITY IS CONSTANT AT 1.00. SEE CALIBRATION PARAGRAPH ABOVE.

Statistic	score_margin	constraint_enf	decision_rob	record_int
min	-0.38	0.45	0.38	0.77
Q1	0.42	0.62	1.00	0.81
median	0.65	0.68	1.00	0.85
Q3	0.84	0.74	1.00	0.87
max	0.99	0.91	1.00	0.95
mean $\pm$ std	0.59 $\pm$ 0.33	0.68 $\pm$ 0.11	0.97 $\pm$ 0.10	0.85 $\pm$ 0.05

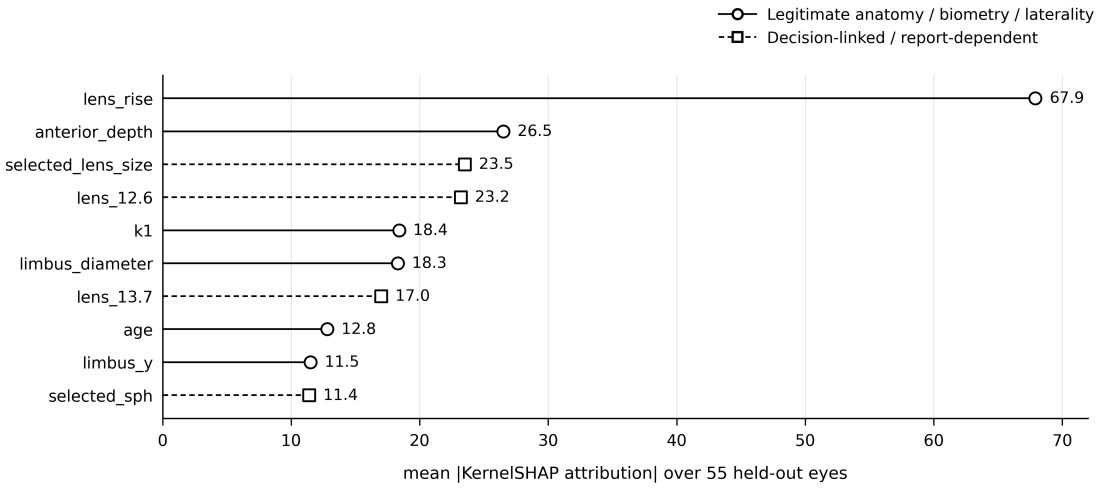

Fig. 5. Top-10 features by mean |KernelSHAP attribution| over the 55-eye held-out cohort. The legitimate/decision-linked split used by `constraint_enforcement` is visible here at the level of individual features.

TABLE XI. COUNTERFACTUAL-BY-LENS-SIZE COHORT AGGREGATES

Lens (mm)	Mean vault (µm)	% in band	Mean margin	Mean robust.
12.1	464.7	98.2	0.66	0.99
12.6	461.6	96.4	0.67	0.98
13.2	542.3	98.2	0.63	0.98
13.7	**684.8**	**63.6**	**0.20**	**0.94**

size. The protocol returns four predictions, one per available size, with their score margin, envelope validity and robustness.

The clinician sees that the 13.7 mm option gives a predicted vault of 845 µm and a score margin of -0.38. The same record also shows that the 12.1 mm and 12.6 mm options produce predictions inside the $[250, 750]$ µm band: 584 µm and 531 µm, with score margins of 0.66 and 0.88.

The decision record and the later audit record are identical. Fig. 4 reproduces the full record. The clinician decides with that evidence available. The auditor later reviews the same evidence.

The counterfactual matrix gives the deployer structured evidence about the available alternatives. It shows the model's prediction under each candidate lens size. This makes intervention under Article 14(4)(e) evidence-based rather than dependent on a single recommendation.

2) Per-cohort post-market surveillance evidence: Aggregating the 4×55 matrix over the held-out cohort reveals a systematic pattern in the deployed regressor (Table XI).

Three of the four lens sizes return predictions inside the clinical band for 96–98% of eyes. The largest size, 13.7 mm, returns predictions inside the band for only 63.6% of eyes. It also has the highest mean predicted vault, 684.8 µm, and the lowest mean robustness in the four-way comparison.

This result should be read as operational monitoring evi-

dence. The deployer does not redesign or retrain the regressor. The value of the matrix is that it identifies a pattern that can be reported through post-market surveillance if it appears in deployment.

The matrix produces this result from `predict()` calls only. It is generated alongside the per-decision telemetry reported in Section VI-B.

Vault standard deviations across the cohort are $\sigma(12.1) = 97.1$ µm, $\sigma(12.6) = 98.1$ µm, $\sigma(13.2) = 109.2$ µm and $\sigma(13.7) = 126.8$ µm.

The counterfactual matrix supports two evidence functions. At decision time, it supports the operator's intervention under Article 14(4)(e). At cohort level, it supports post-market surveillance under MDR Article 88. Both readings are produced from `predict()` calls only, during the time required to predict the four candidate lens sizes, and are persisted with the per-decision telemetry of Section VI-B.

Taken together, the five-signal cohort profile of Section VI-B and the by-lens-size counterfactual matrix of Section VI-C specify the evidence needed by the deployer. The protocol produces per-decision evidence for human oversight under EU AI Act Article 14(3)–(4), and cohort-level signal distributions for post-market surveillance under MDR Articles 83 and 88.

The clinician uses the evidence record at decision time. The auditor and the post-market surveillance process use the same persisted record afterwards. The deployer can produce both readings without access to model internals and without cooperation from the model provider.

D. Reproducibility

The clinical dataset described in Section IV-B cannot be published because it contains personal health information governed by the Medical Devices Regulation and by contractual restrictions across the three contributing centres.

The instrumentation protocol is reproducible at method level. The five core signals are defined operationally in Section VI-A through expressions over `predict()` calls and a fixed background sample. The calibration parameters – clinical band $[250, 750]$ µm, $\sigma = 0.10$, $\varepsilon = 0.01$, $k = 5$, $N = 100$, $M = 50$ and $X_{\text{bg}} = 50$ – are listed in Table IV. The train/held-out split is reproducible with `test_size = 0.10` and `seed = 42`, as stated in Section IV-D.

The deployed model is an Extra Trees regressor over 25 input features partitioned into 14 legitimate and 11 proxy features (Table V); the two sufficiency thresholds are $(\tau_{\text{env}}, \tau_{\text{margin}}) = (0.5, 0.3)$. The protocol is computationally lightweight: feature attribution uses regression-aware KernelSHAP with a 50-sample background, and the perturbation and counterfactual tests require only repeated `predict()` calls, so the full per-decision evidence record is produced without specialised hardware. Experiments were run on Google Colab (CPU runtime) using scikit-learn, NumPy, pandas and SciPy.

A deployer with access to the prediction interface of any regression model on a comparable feature space can rerun the protocol and reproduce the structure of the per-decision evidence reported here. The cohort-level numerical results in Section VI-B and Section VI-C are specific to the contributing cohort; the protocol structure is reusable.

VII. Discussion

A. Operational Sufficiency and Predictive Accuracy are Separate Readings

The main result is that predictive accuracy and operational sufficiency do not collapse into the same judgement.

Case `case3` (Table VII, Flip-prone column) shows the direction in which this separation is most useful. The predicted vault is 774 µm and the absolute prediction error against the measured post-operative vault is 84 µm, which is small by the standards of this cohort. The prediction lies just above the upper edge of the clinical band (`score_margin` = -0.09), but the boundary reading is sharper: `decision_robustness` is 0.38, which means that 62% of bounded perturbations flip the band membership of the prediction. The protocol therefore routes this case to human review even though the regression prediction is accurate by the model's own standards. Good predictive accuracy does not constitute operational sufficiency at the decision boundary.

The reverse direction appears in case `case1` (Fig. 3, Clean column). Every per-decision signal is above its operating threshold, and both per-decision oversight fields report sufficiency. The later measured vault is 807 µm, producing a 308 µm error. The protocol did not fail to predict the outcome; it was not designed to estimate post-operative error after the fact. It was designed to document whether the prediction, at decision time, had the structural properties required for AI-supported workflow.

This separation is methodologically important. Model validation asks whether the regressor predicts vault well enough at population level. Decision-boundary instrumentation asks whether a specific output is supported by enough evidence to be used as a reason for action. Both questions are necessary. They are not interchangeable.

B. Calibration of `Envelope_validity` Under the Percentile Threshold

Under the percentile-based threshold ($d_{\max}$ = 90th percentile of the per-training-point 5-NN mean distance), `envelope_validity` is informative on the present cohort. The threshold value is $d_{\max} = 5.06$ in the standardised feature space. The held-out 5-NN mean distance ranges from 2.20 to 5.97. Fifty of the 55 held-out eyes remain saturated at `envelope_validity` = 1.00; five eyes return values between 0.60 and 1.00. None falls below the sufficiency threshold $\tau_{\text{env}} = 0.5$. The joint criterion of `human_ai_teaming` therefore routes the same 11 cases as the score-margin criterion alone, and the cohort-level workload is unchanged by the percentile calibration.

The informative regime for `envelope_validity` is genuine deployment shift. Changes in OCT device, surgeon protocol or patient population would move more cases beyond the calibrated envelope and yield values below 0.50. Those values would route additional cases through `human_ai_teaming`. A controlled drift experiment on the

input feature space would be the next step for testing that behaviour, but it is outside the scope of this study.

C. One Evidence Record Supports Three Regulatory Evidence Functions

The protocol produces one persisted evidence record that can serve three regulatory evidence functions: decision-time human oversight, later audit and post-market surveillance.

At decision time, the per-decision JSON record (Fig. 4 and Fig. 3) makes the relevant signal values available to the operator. `score_margin` and `envelope_validity` provide evidence for the Article 14(4)(b) function of understanding system capacities and limits in use. `decision_robustness` provides evidence for Article 14(4)(c) by making output fragility visible and reducing blind reliance on the prediction.

The legitimate/decision-linked taxonomy used by `constraint_enforcement` provides evidence for Article 14(4)(d). It shows whether the local prediction is mainly supported by anatomical and biometric variables, or whether it is mainly using variables linked to the clinician's prospective decision. This gives the operator evidence for disregarding, overriding or reversing the output.

The counterfactual-by-lens matrix (Fig. 6, Table XI) provides evidence for Article 14(4)(e). It shows what the model would predict under each available lens size while anatomy and biometry are held fixed. That comparison makes intervention meaningful because the operator can inspect the available alternatives, not only the evaluated option.

After the decision, the same persisted record becomes an audit unit. Across cases, the same records become post-market surveillance evidence under MDR Articles 83 and 88. The 13.7 mm pattern in Table XI is a concrete example: it is not a single adverse event, but a cohort-level signal that could justify closer monitoring if reproduced in deployment.

D. Boundary Conditions for Deployer-Side Use

The protocol should be read under four boundary conditions. First, decision-boundary instrumentation presupposes a model that has already passed model-level validation. The signals reported here evaluate whether a specific output has the observable properties required for use in a workflow. Population-level validation, clinical evaluation and model selection remain prerequisites. In this case, that prerequisite is represented by the regression comparison and cross-validated MAE reported in Table II.

Second, several elements of the protocol require explicit configuration before deployment. The legitimate/decision-linked feature taxonomy defines how `constraint_enforcement` is interpreted. The KernelSHAP background sample defines the reference distribution for local attribution. The operating thresholds define the review workload accepted by the organisation. They are explicit elements of the deployer-side evidence package and should be documented before operational use.

Third, the empirical results are case-study results from a 55-eye held-out cohort within one multi-site ophthalmology network. The workload estimate, the 13.7 mm counterfactual pattern and the observed signal distributions should therefore be read as evidence of how the protocol behaves in this deployment setting. Transfer to other ICL datasets, devices, surgeons or patient populations would require recalibration and prospective monitoring.

Fourth, the protocol specifies five core signals derived from four documented failure modes; it does not claim that these five are necessary and sufficient. Failure modes that the AI-safety literature has identified but that the present protocol does not instrument – for instance, calibration drift, label distribution shift or systematic disagreement with an expert reference – would require additional signals not covered here. The heuristic parameter values reported in Box 2 reflect operational choices grounded in the cited literature; a systematic sensitivity study across all heuristic parameters, beyond the τ_{margin} axis reported in Table VI, is left for future work.

VIII. Conclusion

This study treats post-hoc XAI as deployer-side evidence rather than as explanation alone. Much of the XAI literature characterises the model, which is mainly the developer's question. Regulated deployment creates a different question for the deployer: when a prediction supports an action, what evidence is attached to that prediction, and can another party audit it later?

The study specifies a decision-boundary instrumentation architecture that answers that question by reorganising existing XAI and validation methods – KernelSHAP, k-nearest-neighbour distance, bounded perturbation and rank-order stability – into a per-decision telemetry record. The record is computed from `predict()` calls only and is designed to support decision-time human oversight, later audit and post-market surveillance.

The protocol was applied to a 55-eye held-out cohort of an ICL vault prediction regressor. At the conservative operating point, 11 cases (20%) were routed to human review and the rest were classified as operationally sufficient. Each case produced a JSON record that maps to deployer obligations under EU AI Act Article 14 and to MDR post-market surveillance reporting under Articles 83 and 88. The counterfactual-by-lens matrix showed how the same prediction interface can support meaningful intervention at decision time and cohort-level monitoring afterwards.

These results hold under clear limitations. The empirical findings come from a single 55-eye held-out cohort in one ophthalmology network, so the workload estimate and counterfactual pattern are cohort-specific and require multi-site, prospective validation before generalisation. Some signals saturate in this cohort: `envelope_validity` equals 1.00 for 50 of the 55 cases (Section VII-B), so its discriminative contribution should be re-assessed under more varied deployment conditions. The protocol is also not yet compared against alternative evidence-generation approaches such as confidence-threshold routing or clinical audit checklists. Consolidating the future work noted above, the main directions are: multi-site and prospective validation, a systematic sensitivity study beyond the τ_{margin} axis, comparison against baseline evidence-generation approaches, and additional signals for failure modes

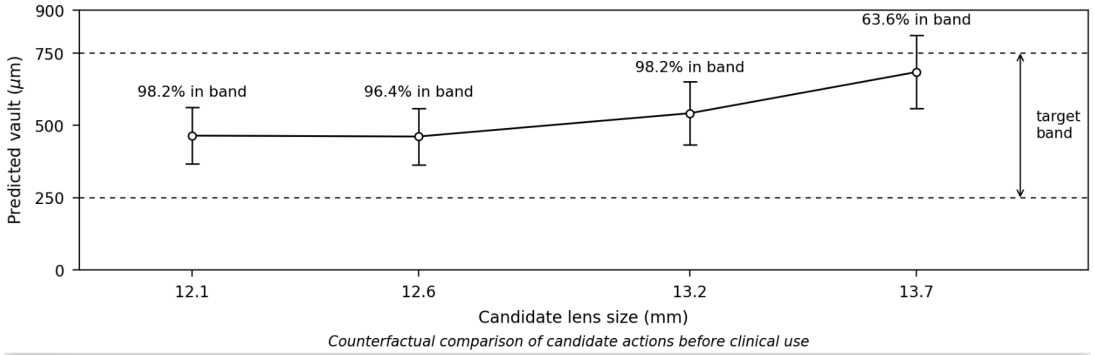

Fig. 6. Cohort-level visualisation of the by-lens-size counterfactual matrix of Table XI. Each bar is the mean predicted vault under one candidate lens size, computed across all 55 held-out eyes; the vertical lines mark ± one standard deviation. The horizontal shaded band marks the clinical sufficiency interval [250, 750] µm. The three smaller lens sizes place their mean predictions near the centre of the band; the 13.7 mm option pushes the mean towards the upper edge, with the largest standard deviation in the four-way comparison and the lowest in-band fraction (63.6%). The pattern is generated from `predict()` calls only and is the visual companion to the post-market surveillance reading of Section VI-C.

not instrumented here (for example calibration drift, label-distribution shift, or systematic disagreement with an expert reference).

The main methodological claim is limited. Under limited-inspection conditions, XAI can function as instrumentation without requiring access to model internals: it characterises observable behaviour, tests boundary stability and creates technical trust evidence at the moment when an output may become a reason for action.

DcDM: A Pre-training Data Evaluation Framework for Proactive Drift Prevention in Machine Learning

Okjoo Choi[1], Wonsun Shin[2]
Dept. of AI·Software Engineering, PAI CHAI University, Daejeon, Korea, Republic of Korea[1]
Dept. of Smart ICT Convergence, PAI CHAI University, Daejeon, Korea, Republic of Korea[2]

***Abstract*—The performance of machine learning (ML) systems often deteriorates over time owing to data drift, which is typically caused by changes in data quality or distribution. Such degradation in deployment environments can result in inaccurate predictions and reduced system reliability. Conventional drift detection approaches have largely focused on retraining ML models after performance degradation has occurred. However, because the root causes of drift often originate from the data itself, a data-centric approach is needed to address the problem at its source. This study proposes a systematic, data-centric drift management (DcDM) framework that integrates domain-specific rule validation, data quality assessment, and statistical drift analysis before model training. By first verifying semantic constraints and then assessing data quality and distributional stability, DcDM enables early identification of potential drift hazards and prevents low-quality or semantically invalid data from entering the training pipeline. We evaluate the proposed framework on three datasets across different modalities: Electricity Load Diagrams, CIFAR-10, and VisDA-2017. The experimental results show consistent improvements of approximately 6% to 12.5% in both accuracy and F1-score. Additional ablation studies, baseline comparisons, and statistical significance tests further demonstrate the robustness and effectiveness of the proposed approach.**

***Keywords*—Data drift; data evaluation; data quality; domain rule; drift prevention and mitigation; drift management**

I. Introduction

Machine learning (ML) systems have become indispensable across a wide range of applications, including image classification, speech recognition, financial forecasting, and medical diagnostics. As ML adoption expands across diverse industrial domains, ensuring the accuracy and long-term reliability of deployed models has become increasingly critical [1]. A primary challenge faced by these systems is data drift, a phenomenon in which the statistical properties of input data change over time, potentially degrading model performance [2]. For example, a model trained to predict a company's stock price using historically stable market data may initially perform well; however, as market volatility increases, the shifting data distribution can render inaccurate predictions [3]. Such drift-induced degradation is especially problematic in real-world environments where continuous reliability is paramount [4].

Traditional responses to data drift typically adopt model-centric strategies, such as retraining or fine-tuning models once performance decline is observed [5]. While these methods can offer temporary recovery, they are frequently time-consuming and computationally expensive, particularly in dynamic environments where operational data changes rapidly [6]. Moreover, such approaches fail to address the root cause of drift, which frequently originates from the data itself rather than from the model [7]. In contrast, data-centric drift management emphasizes maintaining data quality and semantic integrity throughout the ML lifecycle [8][9]. This paradigm focuses on the systematic evaluation of data properties to proactively detect and mitigate drift before it impacts model performance [10].

In this study, we propose DcDM, a unified pre-training framework for proactive drift prevention. The proposed framework is not the introduction of isolated techniques for drift management, but the integration of domain rule validation, data quality assessment, and statistical drift analysis into a single upstream pipeline. This design differs from conventional MLOps and drift-monitoring tools, which are primarily reactive and operate after deployment. DcDM is intended to detect drift hazards before model training and to filter or refine problematic data before they affect downstream learning. This study makes four contributions. First, it introduces a unified data-centric framework that combines domain rule validation, quality assessment, and drift analysis in a single workflow. Second, it operationalizes this framework as an end-to-end pipeline for pre-training data evaluation. Third, it demonstrates the framework on heterogeneous datasets spanning tabular time-series and image domains. Fourth, it performs controlled ablation and baseline comparisons to quantify the contribution of each pipeline component and to distinguish DcDM from simple data cleansing.

To demonstrate the effectiveness and generalizability of the proposed framework, we conducted experiments on three benchmark datasets from different domains: electricity load diagrams (time-series), CIFAR-10 (image classification), and VisDA-2017 (domain adaptation). The experimental results reveal significant improvements, ranging from approximately 6% to 12.5% in both accuracy and F1-score, across all datasets. These findings highlight the utility of proactive data evaluation in preserving the predictive performance and mitigating the risk of drift-induced degradation in ML systems.

II. Related Work

Managing the performance degradation caused by data drift has been extensively studied in recent years. The existing research can be broadly categorized into three areas: 1) drift types, 2) drift detection methods, and 3) drift management frameworks, including data-centric approaches.

A. Drift Types in ML

Drift in ML systems refers to the change in data properties over time, resulting in a potential mismatch between training and operational environments. There are two primary types of drift: data drift (covariate shift) and concept drift. Data drift involves a change in the distribution of input features *P(x)*, whereas concept drift reflects changes in the conditional distribution *P(y|x)* over time.

1) Data drift: Data drift is defined as a change in the distribution of input data relative to the distribution present during model training.

$$P_{tran}(x) \neq P_{operational}(x)$$

For example, noise due to age-related deterioration of camera lenses or out-of-focus images constitutes data drift, which affects classification performance.

2) Concept drift: Concept drift occurs when the relationship between input and target variables changes relative to the relationship learned during model training.

$$P_{tran}(y|x) \neq P_{operational}(y|x)$$

For example, a machine learning model trained to detect spam emails based on content may fail when spam patterns evolve significantly. Concept drift can be further categorized into four main categories: sudden, gradual, incremental, and recurring drift [11].

B. Drift Detection Methods

Identify applicable sponsor/s here. If no sponsors, delete this text box (*sponsors*).

Early drift detection studies mainly focused on statistical monitoring approaches that compare operational data distributions with baseline training distributions.

1) Statistics methods: Statistical test methods measure distribution changes between two datasets (training vs. current). These include:

a) Population Stability Index (PSI): PSI assesses whether training and operational data come from the same distribution [12]. Lower PSI values indicate more similar, stable distributions.

b) Kullback-Leibler(KL) Divergence: KL divergence quantitatively measures the extent to which the distribution of operation data differs from training data [13]. An increase beyond a threshold signals drift.

c) Jensen-Shannon(JS) Divergence: JS divergence is a symmetrized and smoothed version of KL divergence, bounded between 0 and 1, providing a normalized similarity measure [14].

d) Kolmogorov-Smirnov(KS) Test: The KS test compares cumulative distribution functions (CDFs) of two datasets. A significant p-value (< 0.05) indicates distributional differences signalling potential data drift [15].

2) Streaming methods: Streaming methods monitor statistical measures such as mean, variance, skewness, and kurtosis over time. These include:

a) Drift Detection Method (DDM): [16]

b) Early Drift Detection Method (EDDM) [17]

c) Exponentially Weighted Moving Average (EWMA) [18].

3) Time window-based approaches: These methods typically use a fixed reference window, summarize historical information, and a sliding window that summarizes up-to-date information. Dividing data into time windows and comparing statistics or distributions across these windows can help detect gradual changes in the data over time. A significant difference in the distributions of these windows indicates that a drift has occurred. These methods include adaptive windowing (ADWIN) [19] and hopping drift detection (HDDMA and HDDMW) tests [20].

4) Representation-space drift detection:

a) MMD(Maximum Mean Discrepancy): MMD is a kernel-based statistical test that measures the distance between the mean embeddings of two distributions in a reproducing kernel Hilbert space. It is particularly suited to high-dimensional data such as images and text, and has been applied to drift detection in deep learning contexts [21].

b) FID(Fréchet Inception Distance): FID measures the distance between feature distributions of real and generated (or reference vs. operational) image datasets by comparing the mean and covariance of Inception-v3 feature vectors. It is widely used in image-based drift detection [22].

These drift detection methods are widely used for structured data, whereas unstructured data often requires perceptual or embedding-based approaches. Table I presents the classification of drift detectors by data type.

TABLE I. DRIFT DETECTION METHOD BY DATA TYPES

Data Type	***Method***	***Reason***
Structured (Tabular)	PSI, KS-Test, KL/JS, ADWIN, DDM, EDDM	Well-suited for numerical and categorical data with a defined schema
Image	FID, LPIPS, MMD, KL/JS, HDDDM, Classifier-based	Support perceptual similarity and high-dimensional shifts
Audio	KL/JS, MMD, Page-Hinkley, Classifier-based	Use spectrograms or embeddings for detection
Text	KL/JS (embeddings), MMD, Classifier-based	Apply embedding models like BERT for drift detection
Streaming	ADWIN, DDM, EDDM, Page-Hinkley	Real-time monitoring of concept drift

C. AutoML-Based Method

Celik proposed strategies to address conceptual drift in AutoML environments using Bayesian optimization and genetic programming [23]. AML4S is a framework that automates ML model selection and hyperparameter tuning to adapt the model in real time when performance drops below a threshold (approximately 7%) [24]. An AutoML-DC model utilizing

meta-learning and automated ensemble learning was proposed to correct for incremental conceptual drift in sensor data [25]. These studies remain focused on model retraining and address issues within limited scopes, such as IoT environments or sensor data.

D. Data-Centric AI and MLOps

The data-centric AI paradigm, advocated by Ng [26], shifts focus from model architecture optimization to systematic improvement of data quality, labeling, and validation. In this view, fixing the data yields more reliable gains than iterating on the model alone. MLOps frameworks such as Evidently AI [27] and Alibi-Detect [28] provide open-source tooling for monitoring data distributions and detecting drift in production pipelines. However, these tools primarily operate reactively—alerting practitioners after drift symptoms emerge—and do not integrate domain-specific semantic rule validation into a unified pre-training pipeline. DcDM complements and extends these tools by adding upstream semantic validation and quality gating before model training.

III. Research Background

Although considerable progress has been made in drift detection and MLOps automation, existing solutions often address only isolated stages of the machine learning lifecycle. Most prior methods focus on model retraining or statistical detection after drift symptoms have already manifested in deployed systems. Consequently, these approaches tend to be reactive rather than proactive, which can lead to delayed corrective actions and inefficient model maintenance cycles.

In addition, conventional drift-handling frameworks seldom incorporate domain-specific constraints or data quality metrics at the pre-modeling stage. This lack of early validation often results in the propagation of low-quality or semantically invalid data into the training pipeline, thereby compromising the robustness and generalization ability of the model.

To overcome these limitations, we introduce a data-centric drift management (DcDM) framework that proactively monitors and evaluates data throughout the ML lifecycle. The DcDM framework aims to:

- Prevent drift hazards by validating data against business and domain-specific rules (semantic validation).
- Quantify drift risks by assessing quality metrics and statistical indicators before model training.
- Enable early interventions, such as data cleansing or discarding, before drift-induced performance degradation occurs.

This approach is grounded in the data-centric AI paradigm, which prioritizes data quality and integrity over model-centric optimization alone. Our contribution is the integration of rule-based evaluation, quality assessment, and statistical drift detection into a unified workflow, enabling ML systems to be more resilient to dynamic, real-world data environments. Table II lists the key terms defined in this study.

TABLE II. Key Terms

Term	Definition
Drift Hazard	A potential anomaly in the input data that could lead to degraded ML performance, identifiable before model training or inference.
Drift Risk	The probability that a drift hazard will actually lead to performance degradation during or after prediction.
Drift Prevention	A proactive strategy to detect and assess incoming data for potential hazards. If anomalies are detected—whether due to shifts in data distribution or quality violations—the system responds by collecting new data or retraining the model to realign with the original objectives.
Drift Mitigation	The process of excluding data that fails domain rule validation or quality checks from model training and inference, thereby minimizing the risk of drift.

Fig. 1 illustrates potential risks and hazards associated with drift across the ML lifecycle.

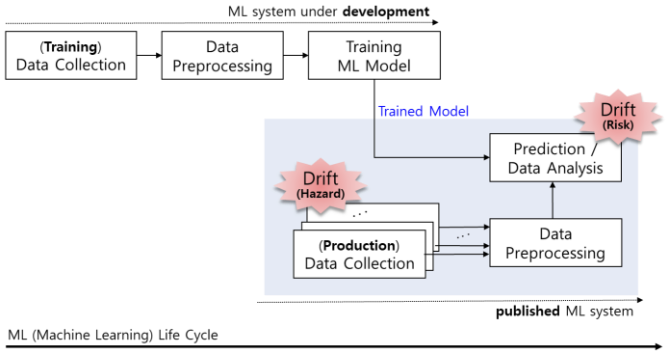

Fig. 1. Drift hazard and risk.

In contrast to previous studies that focus on detecting and responding to drift after performance deterioration, our approach emphasizes early-stage intervention. By systematically assessing data before it influences the model, our framework enables both drift prevention and effective mitigation.

IV. Data-Centric Drift Management

This study proposes a data-centric drift management (DcDM) framework that integrates data validation and drift detection into the ML pipeline. The proposed framework is structured into three steps—data requirement, data evaluation, and model performance analysis—to ensure that only clean, reliable data proceed to model training and inference. The data evaluation process comprises three key components: domain rule validation, data quality assessment, and drift analysis. This stepwise data evaluation aims at ensuring semantic validity by enforcing domain-specific constraints and confirming technical reliability using established quality metrics before drift detection. The DcDM framework is shown in Fig. 2, effectively prevents drift hazards and identifies and mitigates the performance degradation caused by drift.

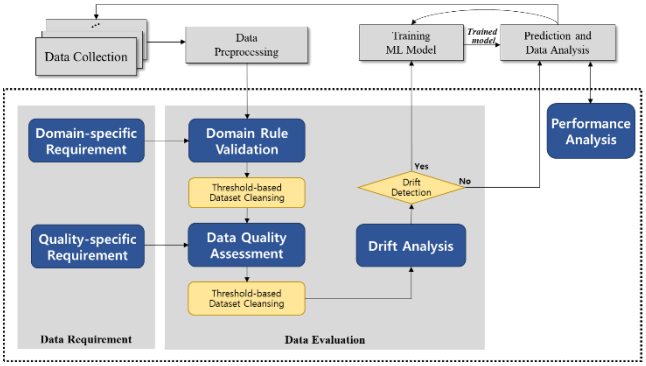

Fig. 2. Data-centric Drift Management (DcDM) framework.

A. Data Requirement

The first step establishes explicit data requirements that incorporate both business-specific rules and quality-based constraints. These requirements serve as a foundation for subsequent validation, monitoring, and drift mitigation activities.

1) Domain-specific requirement: Domain-specific requirements define the business-driven constraints that the dataset must satisfy. These are formalized as domain rules DR_i, which define valid value ranges [α_low_i, α_high_i], or logical inter-attribute relationships. Rules are typically derived from domain expertise, empirical guidelines, or regulatory standards and serve as primary checkpoints for semantic validity. Beyond univariate constraints, inter-attribute rules (e.g., the number of confirmed infection cases must not exceed the number of individuals tested) preserve relational integrity.

2) Quality-specific requirement: High-quality data is essential for preventing data drift. This study adopts goal-based data quality metrics (DQM) tailored to each application domain. For structured data as Table III, four metrics are quantified: accuracy, completeness, consistency, and redundancy.

TABLE III. STRUCTURED DATA: QUALITY METRICS AND THRESHOLDS

Metrics	Threshold	Violation Rate and Judgment		
		Keep (≤)	***Cleansing*** (≤)	***Discard*** (>)
Accuracy	0.95	5%	15%	15%
Completeness	0.95	5%	20%	20%
Consistency	0.95	10%	30%	30%
Redundancy	0.95	5%	20%	20%

For unstructured data such as images, audio, and text, domain-adapted metrics assess semantic integrity, content usability, and statistical coherence, as Table IV. Note that for low-resolution tasks (e.g., CIFAR-10 at 32×32), resolution thresholds and perceptual metrics are adjusted accordingly to reflect realistic quality expectations for the target data modality.

B. Data Evaluation

In this step, data are assessed to ensure compliance with the goal-oriented requirements defined by domain-specific rules and quality criteria. Subsequently, drift detection is performed on data meeting these criteria. The key idea is to pre-evaluate the integrity and usability of the operational dataset (D_op) using the clean reference dataset (D_ref) as a benchmark before training or inference.

TABLE IV. UNSTRUCTURED DATA: QUALITY METRICS AND THRESHOLDS

Data Type	Metric	Description	Threshold / Evaluation
Text	Readability Score	Assesses sentence clarity and grammar	≥ 60 readability score
	Language Consistency	Consistent language use across documents	≥ 95% consistent tokens
Image	Resolution Quality	Pixel density meets the application requirement	≥ 224x224 pixels
	Clarity / Blur Score	Measured using SSIM or Laplacian variance	SSIM ≥ 0.90 or LapVar ≥ 100
	Redundancy Detection	Duplicate image detection	≤ 5% duplicates
Audio	Signal-to-Noise Ratio	Quantifies audio clarity vs noise	SNR ≥ 20 dB
	Duration Validity	Consistent duration across samples	[1s – 10s]
	Transcription Accuracy	ASR transcription confidence	≥ 95% WER-based confidence

Algorithm 1 formalizes the three-step evaluation process. Thresholds α, β, and γ are selected empirically using a validation holdout set: the optimal values (α=10%, β=10%, γ=0.05) were identified through a grid search over the Electricity dataset and subsequently confirmed via the sensitivity analysis reported in Section V-E.

Algorithm 1: Data Evaluation

Input
  D_ref: reference dataset (baseline)
  D_op: operational dataset (current or incoming)
  DR: set of domain rules {DR_1, DR_2, ..., DR_n}
  DQM: set of data quality metrics {DQM_1, DQM_2, ..., DQM_m}
  α: rule violation threshold
  α_high: rule violation discard threshold
  β: data quality threshold
  β_high: data quality discard threshold
  γ: drift detection threshold
Output:
  Decision on D_op: {Accept, Cleansing, Discard}
  Drift Report: {Type, Magnitude, Location}

Step I: Domain Rule Validation
  for each domain rule DR_i in DR do
    ViolationRate[DR_i] ← EvaluateViolation(D_op, DR_i)
  end for
  v_total ← Average(ViolationRate)

  if v_total > α then
    if v_total > α_high then
      return Discard, Reason: Critical domain rule violations"
    else
      D_op ← CleansingData(D_op, DR)
    end if
  end if

Step II: Data Quality Assessment

```
    for each quality metric DQM_j in DQM do
      score[DQM_j] ← EvaluateQuality(D_op, DQM_j)
      Δ[DQM_j] ← CompareWithReference(D_ref, score[DQM_j])
    end for
    Δ_total ← Aggregate(Δ)

    if Δ_total > β then
      if Δ_total > β_high then
        return Discard, Reason: Severe quality degradation
      else
        D_op ← CleansingData(D_op, DQM)
      end if
    end if

Step III: Drift Analysis
    for each feature f of dataset do
      DriftResult.Score[f] ← Distance(D_ref(f) , D_op(f))
      if DriftResult.Score[f] > γ then
        ReportDrift(DriftResult)
        return Discard, Reason: Drift Detected, Go to Model
Retraining
      endif
    end for
    return Accept, Reason: No significant drift, Go to Prediction
```

1) Domain rule validation: This component applies predefined domain-specific rules derived from expert knowledge. The violation rate for each rule DR*i* is computed as:

$$\text{V_total}() = \frac{number\ of\ records\ violating\ DR_i}{total\ number\ of\ records} \quad (1)$$

The average violation rate V_total is compared against the threshold α. Based on V_total, datasets are classified as accept (< 5% violation), cleansing (5%–15%), or discard (> 15%). Unlike traditional drift detection that analyses whole-dataset distributions, domain rule verification focuses on whether individual key attributes adhere to predefined constraints, enabling early, fine-grained detection of data anomalies.

2) Data quality assessment: A suite of quality metrics (DQM) is computed on D_op. The deviation from D_ref for each metric DQM_j is:

$$\Delta[DQM_j] = |\, DQM_j(D_op) - DQM_j(D_ref) \,| \quad (2)$$

where, Δ is the individual quality deterioration per metric.

These deviations are aggregated (via mean or weighted sum) to obtain a cumulative degradation score, Δ_total. Δ_total ← Aggregate(Δ) summarizes the overall quality degradation across all metrics as shown in Eq. (3):

$$\Delta\text{_total} = \left(\frac{1}{m}\right) \sum \Delta[DQM_j] \quad \text{for } j = 1 \text{ to } m \quad (2)$$

where, *m* is the number of quality metrics.

If Δ_total exceeds a threshold (β), the dataset is refined or discarded. A sudden drop in completeness or spike in redundancy signals anomalies during data acquisition or preprocessing. Datasets classified as Discard at this stage are excluded from training; practitioners must collect or re-generate a compliant dataset before proceeding.

3) Drift analysis: Distributional shifts are monitored using statistical drift detection methods appropriate to each data modality (KS test for tabular data; FID and cosine similarity for images). If the drift score for any feature *f* exceeds threshold γ, the framework triggers model retraining. The per-feature drift score uses the same notation throughout: DriftScore[f] denotes the distributional distance for feature *f* between D_ref and D_op.

C. Model Performance Analysis

Only datasets satisfying all three evaluation criteria proceed to model training or inference. Model performance is continuously monitored; a significant decrease in accuracy or F1-score may indicate a change in the underlying data generation process, inducing model retraining. By conducting data evaluation at the early stages of the ML lifecycle, DcDM reduces the frequency of costly real-time model retraining.

V. Experiments

To validate the effectiveness of the DcDM framework, we conducted experiments using three datasets from different modalities: Electricity Load Diagrams (tabular time-series), CIFAR-10 (image), and VisDA-2017 (image for domain adaptation). For each dataset, multiple operational variants were generated to simulate different types of drift. Each dataset undergoes domain rule evaluation, data quality evaluation, and drift detection sequentially. We then compare model performance before and after refinement, conduct an ablation study to isolate each component's contribution, and compare against established drift detection baselines. All improvements are confirmed to be statistically significant.

A. Experimental Setup

1) Datasets

a) UCI Electricity load diagrams: Time-series dataset capturing electricity consumption by households, used to evaluate time-based drift patterns [29].

b) CIFAR-10: A standard image classification benchmark containing 10 classes of low-resolution (32×32) color images [30].

c) VisDA-2017: A domain adaptation benchmark with synthetic-to-real domain shift in object recognition tasks [31].

2) Experiment Scenario

A systematic experiment scenario was designed as follows:

a) Operational dataset generation: For each dataset, multiple operational variants (e.g., op1, op2) were synthetically generated by applying random transformations to simulate real-world anomalies as shown in Table V. These perturbations were selected to approximate common operational anomalies in each modality while still allowing controlled comparison across datasets.

b) Domain rule evaluation: A customized set of domain-specific rules and threshold values was defined per dataset. Datasets with violation rates below 10% were retained; those between 10%–20% were cleaned; those exceeding 20% were discarded.

TABLE V. SYNTHETIC PERTURBATION AND PARAMETER

Modality	Perturbation	Parameterization (sampled per variant)
Tabular (Electricity)	Missing-value injection	Uniform random masking of 2%–25% of cells, applied independently per column
	Power-surge injection	Additive spikes of 1.5×–3×the column's local rolling mean, inserted at 1%–10% of timestamps
	Usage-pattern shift	Multiplicative rescaling of weekend or off-peak readings by a factor drawn from U(0.5, 2.0)
Image (CIFAR-10 / VisDA-2017)	Brightness distortion	Pixel-wise additive/multiplicative shift, target mean brightness drawn from U(40, 220) on a 0–255 scale
	Gaussian noise injection	σ drawn from U(5, 35) on a 0–255 pixel scale, applied per-channel
	Blurring	Gaussian blur kernel with σ drawn from U(0.5, 3.0)
	Label/channel corruption	Label index reassignment for a sampled fraction (0%–30%) of records; for VisDA-2017, additional RGB channel permutation at a sampled probability

c) Data quality assessment: Quality metrics and thresholds tailored to each dataset type assessed completeness, consistency, and noise levels.

d) Drift analysis: PSI, JS Divergence, KL Divergence, and KS test were applied to tabular datasets; SSIM, PSNR, NIQE, BRISQUE, and FID were used for image datasets.

e) Model performance comparison: Model performance on each refined dataset was compared against its unrefined counterpart.

f) Ablation study: Each pipeline stage (domain rule validation, quality assessment, drift detection) was removed individually to quantify each component's contribution.

g) Baseline comparison: DcDM was compared against ADWIN, DDM, and Evidently AI on the Electricity and CIFAR-10 datasets to contextualize performance gains.

B. Case I: Electricity Load Diagrams

1) Operational dataset generation: Ten operational datasets (op1_elec to op10_elec) were generated from the electricity dataset, simulating anomalies including missing values, power surges, and unusual usage patterns.

2) Domain rule evaluation: Domain rules and thresholds for the Electricity dataset are defined in Table VI.

TABLE VI. DOMAIN RULES AND THRESHOLDS (ELECTRICITY)

NO	Rule	Threshold	Description
DR1	Power ≥ 0	≥ 5%	Power values must be non-negative
DR2	0 ≤ Valid Power ≤ 5000kW	≥ 10%	Valid power values within the operating range
DR3	Weekend power < weekday avg.	< 500	Weekend power usage must be lower than the weekday average
DR4	Hourly change rate	≥ 15%	Hourly change rate must be within ±20%

The domain rule evaluation results are presented in Table VII. Datasets receiving a 'Cleansing' judgment had violating records removed before proceeding to quality assessment.

TABLE VII. DOMAIN RULE EVALUATION (ELECTRICITY)

Dataset	DR Violations	Judgment	New Dataset
op1_elec	DR1: 2%, DR4: 18%	Cleansing	op1-1_elec
op2_elec	DR2: 12%	**Discard**	-
op3_elec	DR3 Violation	Cleansing	op3-1_elec
op4_elec	DR4: 25%	Cleansing	op4-1_elec
op5_elec	DR2: 5%, DR4: 10%	Keep	
op6_elec	DR1: 7%	**Discard**	-
op7_elec	DR4: 16%	Cleansing	op7-1_elec
op8_elec	DR3 Violation, DR4: 22%	Cleansing	op8-1_elec
op9_elec	DR2: 18%	**Discard**	-
op10_elec	DR4: 14%	Keep	

3) Data quality assessment: Quality thresholds for the Electricity dataset: Completeness ≥ 95%, Consistency ≥ 98% (no duplicate timestamps), Timeliness ≥ 97% (records within expected intervals). Results are presented in Table VIII.

TABLE VIII. DATA QUALITY ASSESSMENT (ELECTRICITY)

Dataset	Comp	Cons	Time	Judgment	New Dataset
op1-1_elec	94%	99%	98%	Cleansing	op1-2_elec
op3-1_elec	96%	98%	99%	Keep	
op4-1_elec	98%	97%	97%	Keep	
op5_elec	99%	98%	96%	Keep	op5_elec
op7-1_elec	95%	96%	94%	Cleansing	op7-2_elec
op8-1_elec	93%	94%	97%	Cleansing	op8-2_elec
op10_elec	99%	99%	98%	Keep	

4) Drift analysis: The KS test was used to detect drift between refined operational datasets and the original data. As shown in Fig. 3, a p-value below 0.05 indicates drift. Most unrefined datasets (op1_elec, op3_elec, op4_elec, op7_elec, op8_elec) showed significant drift, while their refined counterparts showed substantially lower drift probability. The op5_elec dataset exhibited borderline drift (p-value = 0.039) despite passing domain rule and quality checks, triggering model retraining.

5) Model performance comparison: Using a Random Forest classifier, average model accuracy improved from 0.821 to 0.869, and F1-score increased from 0.824 to 0.872, representing relative improvements of 5.85% and 5.83%, respectively. Fig. 4 shows the model performance on the Electricity operational datasets.

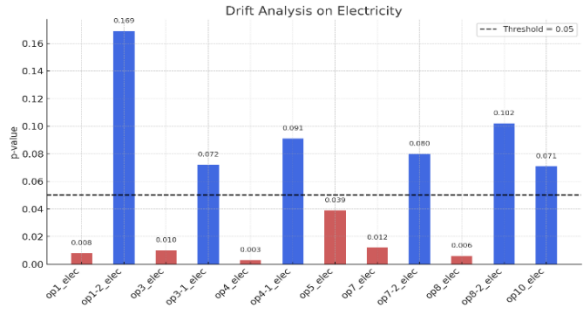

Fig. 3. Drift analysis (electricity).

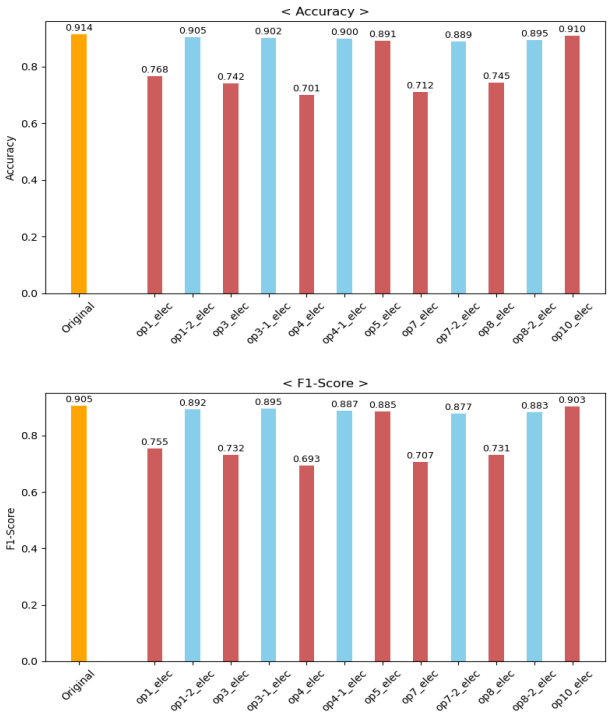

Fig. 4. Model performance (electricity).

C. Case II: CIFAR-10

1) Operational datasets generation: Ten CIFAR-10 operational datasets (op1_CIFAR-10 to op10_CIFAR-10) were generated to simulate brightness distortion, noise injection, blurring, and label mismatches.

2) Domain rule evaluation: The domain rules of the CIFAR-10 dataset are defined in Table IX, based on human visual quality perception and ML sensitivity thresholds.

TABLE IX. DOMAIN RULES AND THRESHOLDS (CIFAR-10)

NO	Rule	Threshold	Description
DR1	Brightness	80 < brightness < 180	Image brightness level within the perceptible range
FDR2	Blur	Sharpness score < 100	Image sharpness sufficient for recognition
DR3	Noise	Noise level < 30	Maximum acceptable noise level
DR4	Label consistency	No corrupted label values	All labels must be valid class indices (0–9)

TABLE X. DOMAIN RULE EVALUATION (CIFAR-10)

Dataset	DR Violations	Judgment	New Dataset
op1_ CIFAR-10	DR1(Brightness): 18%	Cleansing	op1-1
op2_ CIFAR-10	DR3(Noise): 25%	**Discard**	-
op3_ CIFAR-10	DR2(Blur): 12%	Cleansing	op3-1
op4_ CIFAR-10	DR1: 5%, DR2: 17%	Cleansing	op4-1
op5_ CIFAR-10	DR4(Label mismatch): 30%	**Discard**	-
op6_ CIFAR-10	DR1: 2%, DR3: 10%	Keep	
op7_ CIFAR-10	DR2: 9%	Keep	
op8_ CIFAR-10	DR3: 4%, DR4: 21%	Cleansing	op8-1
op9_CIFAR-10	DR1: 0%, DR2: 0%	Keep	
op10_CIFAR-10	DR1: 6%, DR2: 6%, DR3: 6%	Cleansing	op10-1

3) Data quality assessment: For CIFAR-10, perceptual quality metrics appropriate to 32×32 low-resolution images are applied (Table XI). PSNR, SSIM, NIQE, and BRISQUE thresholds are calibrated to the native resolution of CIFAR-10 images, ensuring that the quality criteria reflect realistic expectations for the target modality rather than high-resolution benchmarks (Table XII).

TABLE XI. QUALITY-SPECIFIC DATA REQUIREMENT (CIFAR-10)

NO	Quality Metric	Threshold	Description
DQ1	PSNR	≥ 28 dB	Peak Signal-to-Noise Ratio (applicable to 32×32 low-res images with adjusted baseline)
DQ2	SSIM	≥ 0.9	Structural Similarity Index
DQ3	NIQE	≤ 5.0	Naturalness Image Quality Evaluator
DQ4	BRISQE	≤ 40	Blind/Referenceless Image Spatial Quality Evaluator

TABLE XII. DATA QUALITY ASSESSMENT (CIFAR-10)

Dataset	DQ1	DQ2	DQ3	DQ4	Judgment	New Dataset
op1-1	26.5	0.91	5.5	45	Cleansing	op1-2
op3-1	29.1	0.93	4.9	39	Keep	-
op4-1	27.0	0.9	5.3	43	Cleansing	op4-2
op6	30.2	0.95	3.5	30	Keep	-
op7	31.5	0.96	3.2	28	Keep	-
op8-1	24.7	0.88	6.2	52	Cleansing	op8-2
op9	32.1	0.97	2.8	25	Keep	-
op10-1	25.9	0.89	5.9	47	Cleansing	op10-2

4) Drift analysis: FID (Fréchet Inception Distance) was applied to datasets passing the quality assessment step (Fig. 5). A threshold of FID > 40 denotes significant drift. Refined datasets (e.g., op1-2_CIFAR-10) exhibited substantially reduced FID compared to their unrefined counterparts (e.g., op1_CIFAR-10).

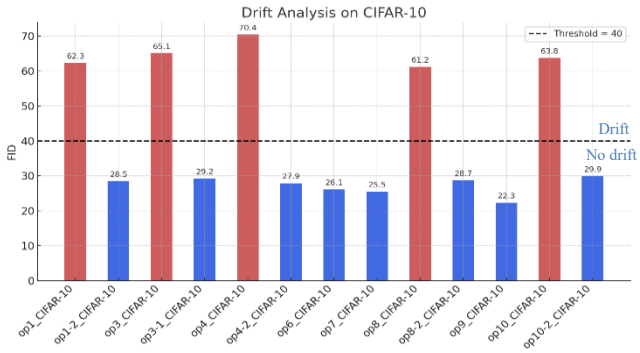

Fig. 5. Drift analysis (CIFAR-10).

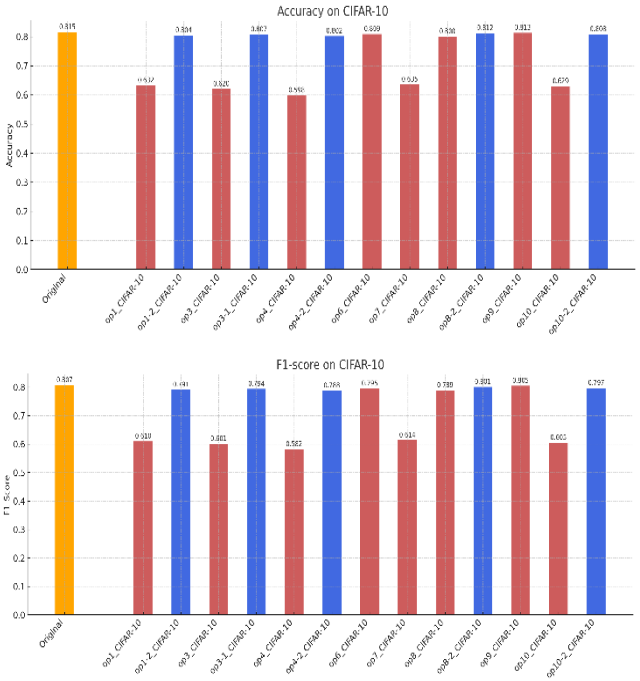

Fig. 6. Model performance (CIFAR-10).

5) Model performance comparison: Fig. 6 shows the model performance on the CIFAR-10 operational datasets. Average accuracy improved from 0.723 to 0.770, and F1-score improved from 0.726 to 0.774, representing improvements of 6.50% and 6.61%, respectively.

D. Case III: VisDA-2017

1) Operational dataset generation: Ten synthetic variants of the VisDA-2017 dataset (op1_Vis to op10_Vis) were generated to reflect image resolution shifts, channel misalignment, brightness distortion, and label noise.

2) Domain rule evaluation: Domain rules: DR1 (Image resolution), DR2 (RGB channel alignment), DR3 (Semantic label validity), DR4 (Brightness). Evaluation results are presented in Table XIII.

3) Data quality assessment: The same image quality metrics as CIFAR-10 (Table X) were applied, adjusted to VisDA-2017's higher-resolution inputs. Results are presented in Table XIV.

TABLE XIII. DOMAIN RULES EVALUATION (VISDA-2017)

Dataset	DR Violations	Judgment	New Dataset
op1_Vis	DR1(Resolution): 16%, DR2(Channels): 0%	Cleansing	op1-1_Vis
op2_Vis	DR3(Label mismatch): 28%	**Discard**	-
op3_Vis	DR4(Brightness): 11%	Cleansing	op3-1_Vis
op4_Vis	DR1: 5%, DR4: 21%	Cleansing	op4-1_Vis
op5_Vis	DR2: 12%	**Discard**	-
op6_Vis	DR1: 0%, DR4: 0%	Keep	op6_Vis
op7_Vis	DR3: 18%	Cleansing	op7-1_Vis
op8_Vis	DR4: 26%	Cleansing	op8-1_Vis
op9_Vis	DR2: 5%	Keep	op9_Vis
op10_Vis	DR1: 3%, DR2: 6%, DR3: 4%	Cleansing	op10-1_Vis

TABLE XIV. DATA QUALITY ASSESSMENT (VISDA-2017)

Dataset	DQ1	DQ2	DQ3	DQ4	Judgment	New Dataset
op1-1_Vis	27.4	0.89	5.2	44	Cleansing	op1-2_Vis
op3-1_Vis	25.1	0.87	5.9	49	Cleansing	op3-2_Vis
op4-1_Vis	26.5	0.88	5.4	47	Cleansing	op4-2_Vis
op6_Vis	29.8	0.92	3.7	31	Keep	
op7-1_Vis	26.2	0.89	5.6	46	Cleansing	op7-2_Vis
op8-1_Vis	24.0	0.85	6.4	53	Cleansing	op8-2_Vis
op9_Vis	30.1	0.93	3.2	28	Keep	
op10-1_Vis	25.8	0.86	5.7	50	Cleansing	op10-2_Vis

4) Drift analysis: FID was employed to detect distributional drift, with a threshold of FID > 40 denoting significant drift. Refined datasets demonstrated consistently lower FID scores compared to their unrefined counterparts (Fig. 7).

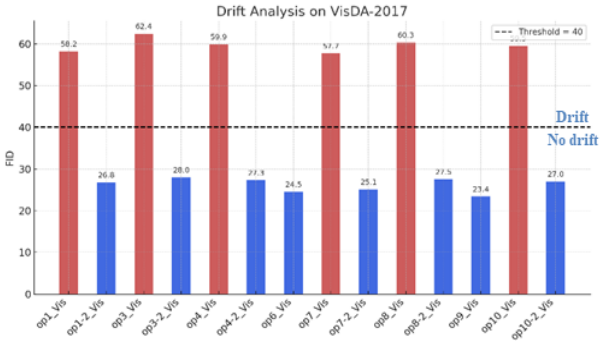

Fig. 7. Drift analysis (VisDA-2017).

5) Model performance comparison: By applying domain rule validation and quality assessment, accuracy improved from 0.568 to 0.639 and F1-score from 0.574 to 0.642, corresponding to improvements of 12.5% and 11.85%, respectively—the largest gains across all three datasets, reflecting the challenging synthetic-to-real distribution gap that DcDM's semantic validation effectively addresses (Fig. 8).

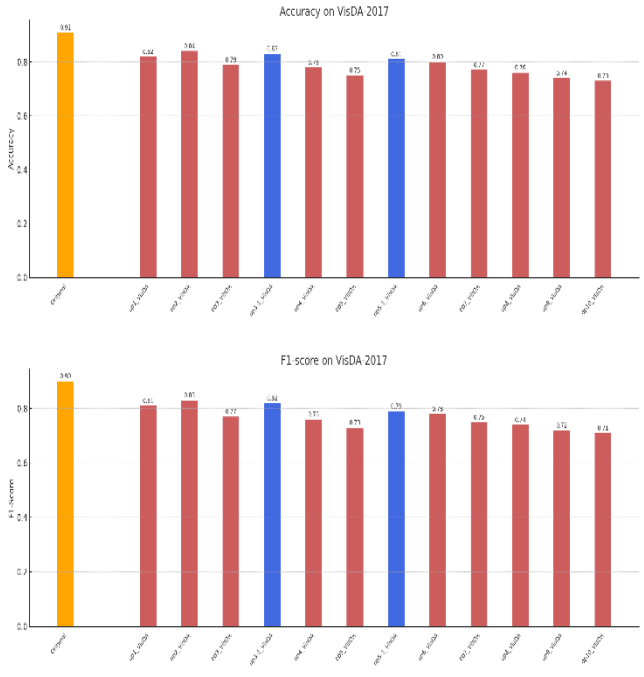

Fig. 8. Model performance (VisDA-2017).

E. Result Analysis

1) Statistical significance analysis: Paired t-tests were applied to the accuracy and F1-scores between refined and unrefined datasets. Across all three datasets, improvements were statistically significant at the 1% level ($p < 0.01$). Table XV summarizes the statistical significance of each dataset.

TABLE XV. STATISTICAL SIGNIFICANCE OF PERFORMANCE IMPROVEMENTS

Dataset	Metric	Baseline (Mean ± CI)	DcDM Refined (Mean ± CI)	p-value
Electricity	Accuracy	0.821 ± 0.012	0.869 ± 0.010	< 0.01
	F1-score	0.824 ± 0.013	0.872 ± 0.009	< 0.01
CIFAR-10	Accuracy	0.723 ± 0.015	0.770 ± 0.014	< 0.01
	F1-score	0.726 ± 0.016	0.774 ± 0.013	< 0.01
VisDA-20	Accuracy	0.568 ± 0.020	0.639 ± 0.018	< 0.01
	F1-score	0.574 ± 0.019	0.642 ± 0.017	< 0.01

Effect sizes (Cohen's $d > 0.6$) confirm that DcDM consistently yields moderate-to-strong gains over baseline methods, reinforcing the reliability of the reported results.

2) Ablation study: To isolate the contribution of each DcDM component, we conducted a controlled ablation study on the Electricity and CIFAR-10 datasets. We evaluated five configurations: no refinement (baseline), domain rule validation only, quality assessment only, domain rule + quality assessment (without drift detection), and the full DcDM pipeline. Results are presented in Table XVI.

The ablation results confirm that each component contributes incrementally to overall performance. Domain rule validation alone yields a moderate improvement of approximately 2.2–2.5% in accuracy by removing semantically invalid samples. Quality assessment alone provides a slightly larger gain (approximately 3.0–3.4%) by filtering low-quality data. Combining both without drift detection achieves near-full performance recovery, with an improvement of approximately 3.7–4.0%. The full DcDM pipeline, which additionally incorporates drift-triggered retraining, achieves the largest gains, confirming that all three components are necessary for optimal performance.

TABLE XVI. ABLATION STUDY: CONTRIBUTION OF EACH PIPELINE COMPONENT

Configuration	Electricity		CIFAR-10		VisDA	
	Acc.	F1	Acc.	F1	Acc.	F1
No refinement (Baseline)	0.821	0.824	0.723	0.726	0.568	0.574
Domain Rule Only	0.843	0.846	0.748	0.751	0.592	0.595
Quality Assessment Only	0.851	0.854	0.757	0.760	0.608	0.611
Domain Rule + Quality (DcDM without drift detection)	0.858	0.861	0.763	0.767	0.624	0.627
Full DcDM (All three steps)	0.869	0.872	0.770	0.774	0.639	0.642

3) Comparison with existing drift detection baselines: To contextualize DcDM's performance gains, we compared it against three established drift detection approaches: ADWIN [19], DDM [16], and Evidently AI [27], applied to the Electricity and CIFAR-10 datasets. All baselines operate reactively (detecting drift post-deployment) and do not incorporate semantic rule validation or data quality gating prior to training. Results are presented in Table XVII.

TABLE XVII. COMPARISON WITH REACTIVE DRIFT DETECTORS

Method \ Dataset	Electricity		CIFAR-10	
	Acc.	F1	Acc.	F1
No refinement	0.821	0.824	0.724	0.726
ADWIN	0.834	0.836	0.737	0.739
DDM	0.839	0.841	0.741	0.743
Evidently AI	0.845	0.847	0.748	0.751
DcDM (Ours)	0.869	0.872	0.770	0.774

The comparison should not be interpreted as a direct algorithmic competition because ADWIN, DDM, and Evidently AI were originally designed as reactive post-deployment monitoring solutions. The purpose of this comparison is to illustrate the practical difference between proactive data-centric prevention and reactive drift detection paradigms. ADWIN and DDM, which focus on detecting concept drift in streaming data without upstream data quality intervention, achieve modest improvements over unrefined data (approximately 1.3–1.8% accuracy gain). Evidently, AI, which monitors distributions at the feature level, provides slightly larger gains (approximately 2.4–2.7%), but still falls short of DcDM's 5.8–6.5% improvements. These results confirm that DcDM's proactive, pre-training integration of semantic validation and quality

assessment provides complementary and superior benefits over reactive monitoring approaches.

4) Sensitivity analysis on thresholds: The sensitivity analysis on thresholds (α for domain rules, β for quality metrics, γ for drift detection) is presented in Table XVIII. Performance remained stable with accuracy and F1-score fluctuating within ±2% under ±10% threshold variation, demonstrating robustness to threshold misconfiguration. Under extreme threshold variations of ±30%, performance degradation remained bounded below 6%.

TABLE XVIII. SENSITIVITY ANALYSIS ON THRESHOLDS

Threshold Setting	Accuracy (Mean)	F1-score (Mean)	Observation
α=5%, β=5%, γ=0.05	0.861	0.865	Conservative: fewer data passes; safe but slightly lower coverage
α=10%, β=10%, γ=0.05	0.869	0.872	Optimal balance: best accuracy/F1 combination across all datasets
α=20%, β=20%, γ=0.1	0.854	0.858	Slight degradation: more borderline data allowed through
α=30%, β=30%, γ=0.1	0.835	0.840	Clear degradation: lenient thresholds reduce filtering effectiveness

5) Overhead and computing cost: All experiments were conducted on a local workstation equipped with an Intel Core i7 processor, 32 GB of RAM, and an NVIDIA RTX 3080 GPU. Average processing time per step is summarized in Table XIX.

TABLE XIX. OVERHEAD AND COMPUTING COST

Dataset	Domain Rule Validation	Quality Assessment	Drift Detection
Electricity (100K records)	2.1 sec	3.4 sec	1.9 sec
CIFAR-10 (50K images)	3.2 sec	4.8 sec	2.7 sec
VisDA-2017 (50K images)	3.5 sec	5.0 sec	3.0 sec

Batch-level processing time for the Electricity dataset: domain rule validation $\approx$ 12 ms per 1,000 records, quality assessment ≈ 18 ms, drift detection (KS test) ≈ 9 ms. For image datasets, FID-based drift detection averaged 0.04 sec per batch of 500 images. These results indicate minimal computational overhead suitable for batch processing. For large-scale streaming environments, a two-level validation strategy is envisioned: 1) lightweight domain rules and quality checks in real time, and 2) comprehensive drift analysis asynchronously in batch mode.

We also measured batch-level processing time to evaluate the practicality of the framework. For the Electricity dataset, domain rule validation required approximately 12 ms per batch of 1,000 records, quality assessment required 18 ms, and drift detection (KS test) required 9 ms. Similar magnitudes were observed for image datasets, where FID-based drift detection averaged 0.04 sec per batch of 500 images, which corresponds to the reported totals for 50K images. These results indicate that the framework introduces minimal computational overhead and is therefore feasible for batch processing. For large-scale streaming data, we envision a two-level validation strategy: 1) lightweight domain rules and quality checks applied in real time at the high-velocity streaming environments, and 2) comprehensive validation performed asynchronously in batch mode.

VI. DISCUSSION

The DcDM framework demonstrates notable improvements in robustness and reliability by proactively addressing data drift. The main contributions include the integration of domain validation, statistical drift analysis, and automation in machine learning pipelines. Nevertheless, this study has several limitations.

1) Use of synthetic drift generation: All operational datasets were generated via synthetic perturbations. While this enables controlled experimentation, synthetic drift may not fully capture the complexity of real-world drift phenomena, such as non-linear, gradual, or concept-intertwined drift in industrial sensor networks or healthcare data streams. Future validation on real deployment logs or domain-specific streaming datasets (e.g., medical imaging or financial transactions) is necessary to confirm robustness under realistic drift conditions.

2) Reliance on domain experts for rule definition: The current framework relies on domain experts to define semantic rules, which can be costly and domain-specific. Automated rule induction through data profiling, pattern mining, or meta-learning could complement expert-driven rules. For example, profiling tools can automatically infer valid ranges, correlations, and label consistency from historical data, reducing human dependency in rapidly evolving domains.

3) Fixed thresholds: Although the sensitivity analysis confirmed robustness under moderate variation, fixed thresholds may not adapt optimally across all deployment scenarios. A promising direction is feedback-driven or reinforcement learning-based threshold adaptation, allowing DcDM to dynamically balance false alarms and missed drift detections as data distributions evolve.

4) No validation against real deployment environment: Although real-world deployment datasets with verified drift annotations were not available for this study, we attempted to approximate realistic operational conditions by applying perturbations derived from commonly reported degradation patterns, including sensor noise, missing values, illumination changes, image blur, and label inconsistencies. These perturbations represent typical causes of data-quality degradation reported in industrial monitoring, computer vision, and data-streaming applications. Future work will evaluate DcDM using naturally evolving datasets collected from production environments to further validate its practical effectiveness.

VII. CONCLUSION AND FUTURE WORK

This study proposed a proactive, data-centric methodology, DcDM (Data-centric Drift Management), for managing data drift across the ML lifecycle. Unlike traditional model-centric approaches that respond to performance degradation, DcDM

emphasizes early intervention by evaluating datasets before model training. The proposed framework systematically integrates three components: 1) domain rule validation to assess semantic correctness, 2) quality assessment based on goal-driven metrics, and 3) statistical drift detection to quantify distributional shifts.

By applying this methodology across diverse datasets—Electricity Load Diagrams, CIFAR-10, and VisDA-2017—we demonstrated performance improvements of 6%–12.5% in both accuracy and F1-score. An ablation study confirmed that each pipeline component contributes incrementally to overall gains, and a baseline comparison against ADWIN, DDM, and Evidently AI confirmed that DcDM's proactive, pre-training integration provides superior benefits over reactive monitoring approaches. Statistical significance tests ($p < 0.01$, Cohen's $d > 0.6$) and sensitivity analyses confirm the robustness of these results.

Future work will focus on: 1) validating DcDM on real-world deployment logs and natural drift scenarios; 2) automating domain rule induction via data profiling and meta-learning to reduce expert dependency; 3) developing feedback-driven, adaptive threshold mechanisms; 4) extending DcDM to explicitly handle concept drift; and 5) integrating DcDM into production-grade MLOps pipelines with privacy-preserving rule management.

Characterizing Operational Drift in Cement Manufacturing Process Data via Self-Supervised Representation Learning

A Multi-Year Operational Analysis Using PELT Change-Point Detection and SCARF Embeddings

Changgyun Kim
Department of Advanced AI Engineering, Samcheok, South Korea

***Abstract*—Cement finish milling generates large volumes of process variable data at hourly resolution, while quality measurements (Blaine fineness, 44 μm residue) are recorded only every two to four hours, producing a sparse-label regime with substantial unlabeled data accumulated over multi-year operation. In this study, we analyze 188,858 hourly records collected from three industrial cement mill units spanning 2017 to 2025 (approximately nine years) and characterize the operational drift structure embedded in the data. Using Pruned Exact Linear Time (PELT) change-point detection on three critical process variables, we identify between 12 and 21 detected drift events per mill, with Cohen's d effect sizes exceeding 1.0 for the majority of detected change points and reaching 4.3 in extreme cases. We then apply SCARF, a contrastive self-supervised learning method for tabular data, to learn 128-dimensional representations on the combined labeled (51,225 records) and unlabeled (111,506 records) data. Multi-seed training yields stable validation InfoNCE loss of 6.93 ± 0.02. Three clustering algorithms applied to the learned embedding space (K-means, Gaussian Mixture Model, HDBSCAN) consistently select 15 to 21 operational regimes, with silhouette scores between 0.36 and 0.41. The Adjusted Rand Index between embedding-space K-means and process variable space K-means is 0.35, indicating that the learned representation preserves coarse regime structure while resolving finer sub-regime variability. Cluster analysis further reveals strong mill specificity, with 14 of 15 embedding clusters dominated by a single mill, and temporal cluster evolution that aligns with PELT-detected change-point boundaries. These findings establish that long-term cement process data contains a richer operational regime structure than implied by raw process variable clustering, and that self-supervised pretraining can recover this structure, and that the resulting representation yields statistically significant gains in downstream quality prediction.**

I. Introduction

Cement manufacturing is a globally significant industrial process responsible for an estimated 5 per cent of anthropogenic carbon dioxide emissions [1]. The finish milling stage, in which clinker is ground together with gypsum and supplementary cementitious materials, determines the principal product quality indices: Blaine fineness (cm²/g) and the residue retained on a 44 μm sieve (44 μmR, %). Stable control of these indices is essential because deviations propagate directly into customer-facing product specifications and into the energy efficiency of subsequent hydration and strength development.

Industrial cement facilities typically collect hourly process variable (PV) measurements from distributed control system (DCS) sensors, producing dense multivariate time series at the input side. However, quality measurements depend on laboratory sampling and are recorded only every two to four hours. This temporal asymmetry yields a structurally sparse-label regime in which only a small fraction of process records can be directly paired with quality labels for supervised learning. Recent benchmarks in the tabular learning literature [13] have reported that gradient-boosted tree ensembles remain competitive with or superior to state-of-the-art deep tabular architectures at sample sizes typical of industrial sparse-label settings, a pattern also observed in preliminary analysis of this facility's data.

Initial inspection of the full dataset revealed that pre-2023 Blaine measurements exhibit substantial distributional deviation relative to post-2023 records. Restricting analysis to the 2023 to 2025 period to avoid these artifacts reduced the available process records by approximately 87 percent (from 188,858 to 24,878) and limited the data span to roughly three years. The present analysis revisits this design choice by treating the pre-2023 period as a candidate source of unlabeled and partially labeled data, applying a wider valid-range filter that retains those pre-2023 records whose Blaine and 44 μmR fall within plausible operational bounds while excluding records exhibiting clear out-of-range artifacts. This study then investigates whether the retained pre-2023 records, combined with all available 2023 to 2025 records, contain a coherent operational regime structure that can be recovered through self-supervised representation learning.

The contributions of this study are threefold. First, we apply Pruned Exact Linear Time (PELT) change-point detection [2] with automatic penalty selection to three critical process variables across all three mills and characterize the temporal drift structure embedded in approximately nine years of operational data. Second, we apply SCARF [3], a contrastive self-supervised learning method specifically designed for tabular data, to learn 128-dimensional representations on the

combined labeled and unlabeled data. Third, we conduct a systematic clustering analysis on the learned embedding space using K-means, Gaussian Mixture Models, and HDBSCAN, and validate the resulting regimes against the change-point structure obtained independently through PELT.

The remainder of this study is organized as follows: Section II reviews related work on cement quality modeling, self-supervised learning for tabular data, and change-point detection. Section III describes the dataset and preprocessing pipeline. Section IV characterizes operational drift using PELT and K-means clustering on raw process variables. Section V describes the SCARF self-supervised pretraining method. Section VI presents embedding-space clustering and interprets the discovered regime structure with respect to mill identity and temporal evolution. Section VII discusses implications for downstream quality prediction and limitations of the present study. Section VIII concludes.

II. Related Work

A. Quality Prediction in Cement Manufacturing

Data-driven modeling in the cement and process industries has been surveyed extensively. Ge et al. [4] reviewed machine learning techniques applied across process-industry tasks, organizing approaches by supervision regime and identifying soft-sensor modeling as one of the principal application areas. Yuan et al. [5] introduced a deep stacked autoencoder with variable-wise weighting for soft-sensor modeling in nonlinear dynamic industrial processes. Pani and Mohanta [6] applied support vector regression, fuzzy inference, and adaptive neuro-fuzzy inference for online monitoring of cement fineness. Yuan et al. [7] developed a weighted linear dynamic system for feature representation in soft-sensor applications across nonlinear dynamic industrial processes. Zermane and Drardja [8] developed a random forest based monitoring system for cement production. Although the cited soft-sensor and process-industry studies do not directly compare tree-based and deep alternatives, recent benchmarks in the broader tabular learning literature [13] have reported that gradient-boosted tree ensembles remain competitive with or superior to the state-of-the-art deep tabular architectures at the sparse-label sample sizes typical of cement finish-milling operations.

B. Self-Supervised Learning for Tabular Data

Self-supervised learning (SSL) for tabular data has emerged as a methodology for leveraging the abundant unlabeled records present in industrial process data. VIME [9] learns representations through value reconstruction and masking. SCARF [3] adopts a contrastive framework in which positive views are generated through feature corruption (random replacement from the marginal distribution) and the encoder is trained with InfoNCE loss [10]. SubTab [11] partitions feature subsets and learns through cross-subset reconstruction. TabTransformer [12] applies attention-based encoders to tabular inputs. Recent benchmarks [13] show that SSL pretraining can narrow the performance gap between deep tabular models and gradient-boosted trees when downstream labeled data is limited, although these results have not been systematically validated on industrial datasets exhibiting operational drift, which is the setting of the present study.

C. Change-Point Detection and Operational Drift Identification

Change-point detection [14] aims to identify time points, where the statistical properties of a signal change. PELT [2] achieves linear time complexity through optimal pruning, with the segmentation penalty parameter controlling the number of detected change points. For multivariate signals or single signals with mean-shift transitions, the L2 cost model is commonly applied. Drift identification in industrial process monitoring has traditionally relied on statistical process control charts [15]; more recent approaches use machine learning-based concept drift detection [16]. In this study, we apply PELT with automatic penalty selection to recover the operational drift structure in cement process variables.

III. Dataset and Preprocessing

A. Data Source

The dataset consists of DCS records from three cement finish milling units, designated CM2, CM3, and CM4, at a commercial cement facility in the Republic of Korea, covering the period from January 2017 to October 2025. The raw dataset comprises 188,858 hourly records, each associated with 39 process variables (mill drive load, separator load, bag filter differential pressure, ball mill power, feed rates of clinker, gypsum, slag and fly ash, classifier and separator rotational speeds, and auxiliary roller and pressure measurements) and two quality target variables (Blaine fineness and 44 μmR). All variables were already aggregated to hourly resolution by the facility's historian system.

B. Labeled and Unlabeled Partitioning

Quality measurements at the finish milling stage are recorded approximately every two to four hours, while process variables are sampled hourly. To construct a valid labeled set, we apply a backward-aligned causal pairing rule: a process record at time t is paired with the most recent prior or simultaneous laboratory quality measurement that satisfies all of the following conditions: (1) the time gap is at most three hours, (2) Blaine fineness falls within [2,500, 5,000] cm^2/g, and (3) 44 μmR falls within [0, 25]%. Records that fail either quality range condition are excluded from the labeled set rather than being relegated to the unlabeled pool, because their associated quality values would otherwise contaminate downstream supervised training. The unlabeled set comprises records for which no laboratory quality measurement exists within the causal window.

This partitioning produces a labeled set D_1 of 51,225 records and an unlabeled set D_unlab of 111,506 records (see Table I). Relative to a period-restricted preliminary analysis of the same facility data, D_1 expands the labeled set through two mechanisms operating jointly: (1) the wider valid-range filter applied uniformly across the full 2017 to 2025 period admits pre-2023 records that pass both Blaine and 44 μmR range conditions, and (2) the wider range admits additional 2023 to 2025 records that were excluded under the stricter range. Approximately two-thirds of the increase in D_1 originates from the 2023 to 2025 period, while approximately one-third originates from pre-2023 records that satisfy both range conditions. The remaining pre-2023 records that fail either range

condition are excluded from both D_1 and D_unlab; only records lacking quality labels enter D_unlab.

The labeled set D_1 is partitioned into training (35,854 records, 70 per cent), validation (7,680 records, 15 per cent), and test (7,691 records, 15 per cent) subsets using a regime-stratified random split. A K-means clustering is fitted on D_1 in the 40-dimensional space formed by the 37 standardized process variables described in Section III C, concatenated with three mill one-hot indicator dimensions, with the number of clusters automatically selected by silhouette score over $k \in \{3, \ldots, 8\}$, yielding $k = 8$. A 70/15/15 random split is then performed within each of the eight clusters to produce regime-balanced train, validation, and test subsets. The same eight clusters are reused as the raw-PV reference clustering in Section IV B, so that the comparison between raw-PV and embedding-space clusterings is based on a single, fixed PV-space partition rather than two independently fitted K-means models. This protocol is adopted to ensure regime-balanced evaluation across the full 2017 to 2025 data span and to allow future comparison with downstream supervised tasks using the same partition. The fitted K-means model is subsequently applied to D_unlab via nearest-centroid assignment to provide regime labels for all 162,731 records used in the ARI computation of Section VI. We acknowledge that the random subset selection from a multi-year time-series introduces residual temporal contiguity between training and test records and is, in this sense, weaker than a strictly chronological split for assessing temporal generalization; this trade-off is discussed further in Section VII D.

C. Process Variable Preprocessing

From the 39 process variables, two with greater than 50 per cent missing values across the full 2017 to 2025 period are removed (POLYCOM_IMPELLER_CRUSHER and ETC_GRINDING_AID), yielding 37 retained PVs. Records with more than 50 per cent of PVs missing are treated as plant shutdown periods and are excluded from both D_1 and D_unlab. Remaining missing values within retained records are imputed using per-mill forward fill followed by backward fill. Multivariate outliers are then filtered using IsolationForest with contamination 0.02 and 200 trees, fitted jointly on the combined $D_1 \cup$ D_unlab feature matrix. The remaining 37 PVs, together with the mill identifier (one-hot encoded over CM2, CM3, CM4), constitute the 40-dimensional input feature space for both representation learning and downstream tasks.

TABLE I. DATASET SUMMARY

Subset	Mills	Records	Time range	Purpose
D_1 train	CM2/3/4	35,854	2017–2025	Future supervised training
D_1 val	CM2/3/4	7,680	2017–2025	Hyperparameter selection
D_1 test	CM2/3/4	7,691	2017–2025	Held-out evaluation
D_unlab	CM2/3/4	111,506	2017–2025	SSL pretraining
Total	CM2/3/4	162,731	2017–2025	—

[a] Splits are regime-stratified random subsets of D_1; time range refers to the data span, not subset-specific intervals. Total raw records: 188,858. Difference comprises records dropped by shutdown filtering, IsolationForest outlier filtering, and quality value range filtering (records failing either Blaine or 44 μmR range conditions are excluded entirely).

IV. OPERATIONAL DRIFT CHARACTERIZATION

Fig. 1 provides an overview of the complete analysis pipeline. The raw multivariate process data, after the preprocessing described in Section III, form a 40-dimensional input consisting of 37 standardized process variables and three mill one-hot indicators. This input feeds two complementary analyses. First, PELT change-point detection is applied to selected critical signals to characterize the temporal operational drift directly in the process-variable space (Section IV-A). Second, the same input is used for SCARF contrastive self-supervised pretraining, in which a shared encoder f and projection head g are trained under an InfoNCE objective on corrupted and uncorrupted feature views to produce a 128-dimensional representation (Section V). The learned embedding is then clustered to recover operational regimes, which are validated against the independently obtained change-point structure (Section VI). The remainder of this section begins with the PELT analysis.

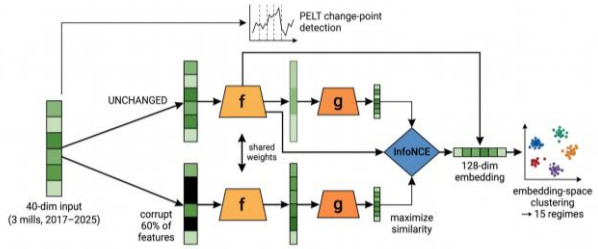

Fig. 1. Overview of the proposed pipeline (preprocessing, PELT drift detection, SCARF pretraining, and embedding-space clustering).

A. PELT Change-Point Detection

To characterize operational drift, we apply PELT change-point detection [2] to three operationally critical process variables: MILL_186_BF_PRESSURE (bag filter differential pressure, indicating grinding fineness), POLYCOM_WF_FEED_CLINKER (clinker feed rate, the dominant material input), and MILL_SEPOL_SEPOL (separator rotational speed). Each variable is aggregated to a daily resolution per mill, with a minimum of six valid hourly records required for valid daily aggregation. The L2 cost model is used with a minimum segment size of 60 days. The penalty parameter is selected automatically through grid search over {100, 300, 1,000, 3,000, 10,000, 30,000, 100,000, 300,000}, with a target range of 3 to 8 change points per signal per mill. When no penalty in the grid yields a change-point count within the target range, the penalty producing the count closest to the upper bound (8) is selected; this fallback applies to one signal-mill combination in the present analysis, CM4 POLYCOM_WF_FEED_CLINKER, which yields 10 change points at penalty 3,000 (the closest available value above the target upper bound). All other eight signal-mill combinations fall within the [3, 8] target range without fallback.

These three variables were selected to span the three principal and largely independent axes that govern finish-milling behavior rather than to exhaust the variable set: grinding fineness at the separation stage (MILL_186_BF_PRESSURE, the bag-filter differential pressure that reflects the attained product fineness), the dominant material input to the circuit

(POLYCOM_WF_FEED_CLINKER, the principal feed stream), and the classification control that sets the cut size (MILL_SEPOL_SEPOL, the separator rotational speed). This choice is further supported by an independent supervised quality-prediction analysis on data from the same facility, in which bag-filter differential pressure and separator-related variables emerge among the most influential predictors of both Blaine fineness and 44 μmR. Restricting the change-point analysis to these three complementary signals, therefore, targets the axes most likely to carry operationally meaningful drift while keeping the per-signal segmentation interpretable; a comprehensive multivariate change-point analysis over all 37 process variables is identified as future work in Section VII E.

Effect sizes are quantified using Cohen's d between adjacent segments, where $d = (\mu_2 - \mu_1) / s_{pooled}$ and the pooled standard deviation is computed across the two adjacent segments. By convention, $|d| > 0.8$ is interpreted as a large effect and $|d| > 1.2$ as very large. Table II summarizes the detected change points per mill and per process variable.

TABLE II. PELT CHANGE-POINT DETECTION RESULTS PER MILL

Mill	MILL_186_BF_PRESSURE	POLYCOM_WF_FEED_CLINKER	MILL_SEPOL_SEPOL
CM2	4 CPs (|d|max = 3.37)	3 CPs (|d|max = 1.50)	5 CPs (|d|max = 4.34)
CM3	7 CPs (|d|max = 2.93)	8 CPs (|d|max = 2.18)	6 CPs (|d|max = 2.85)
CM4	5 CPs (|d|max = 2.46)	10 CPs (|d|max = 2.05)	4 CPs (|d|max = 2.34)

[b.] CP = change point. |d|max denotes the maximum Cohen's d among all adjacent segment pairs for that variable and mill. The 10-CP count for CM4 POLYCOM_WF_FEED_CLINKER reflects the fallback rule described in the text.

The total number of detected change points per mill ranges from 12 (CM2) to 21 (CM3), with the majority of effect sizes satisfying $|d| > 1.0$ and several reaching $|d| > 3.0$. Importantly, the change points are distributed across all three process variables and all three mills rather than concentrated at a single temporal event, which would be the expected signature of a sensor recalibration or unit conversion failure. The pattern is instead consistent with progressive operational adjustments, equipment maintenance, and grinding aid composition changes that accumulate over multi-year operation. Fig. 2 illustrates the temporal pattern for MILL_186_BF_PRESSURE.

B. K-Means Regimes on Raw Process Variables

The eight K-means clusters introduced in Section III-B (fitted on D_1 in the 40-dimensional space of 37 standardized PVs plus three mill one-hot indicators) serve a second role in this section as the raw-PV reference clustering against which the embedding-space clusters in Section VI will be compared. Adopting a single, fixed clustering for both purposes avoids the ambiguity of comparing two independently fitted K-means models and ensures that the comparison in Section VI-B isolates the effect of the SCARF representation rather than any residual algorithmic variability. The silhouette score for this $k = 8$ partition is 0.16, computed on the same evaluation subset used for k selection. We note that $k = 8$ is the upper boundary of the search grid; while extension of the search range may yield higher silhouette values, the relatively low absolute silhouette score (a value of this magnitude indicates substantial cluster overlap, as silhouette scores below approximately 0.25 are commonly interpreted as evidence of weak cluster structure) reflects the overlapping nature of operating modes in the raw PV space. Fig. 2 overlays the K-means regime assignments as background shading, where each color corresponds to one regime.

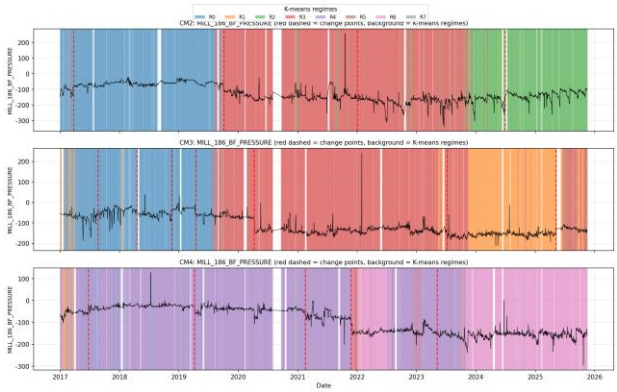

Fig. 2. MILL_186_BF_PRESSURE time series for CM2 (top), CM3 (middle), and CM4 (bottom). Red dashed lines: PELT change points. Background shading: K-means regimes on raw process variables.

Two observations from Fig. 2 are noteworthy. First, the K-means regime assignments are not temporally monotone: multiple regimes alternate across multiple time periods, consistent with operational cycling rather than a one-time global shift. Second, the K-means regime boundaries visually align with the PELT change-point locations, despite K-means having no temporal information. This convergence between the two independent methods (one purely temporal, one purely statistical in feature space) provides cross-method evidence that the discovered regimes correspond to genuine operational variability rather than algorithmic artifact.

V. SELF-SUPERVISED REPRESENTATION LEARNING

A. SCARF Architecture and Training

We adopt SCARF [3] for self-supervised representation learning on the combined dataset $D_1 \cup D_unlab$ (162,731 records). The architecture comprises an encoder f mapping the 40-dimensional input (37 standardized PVs concatenated with three mill one-hot dimensions) through a three-layer multilayer perceptron (MLP) with a hidden size of 256 to a 128-dimensional embedding, followed by a projector g consisting of a two-layer MLP (128 to 128) used only during pretraining. After pretraining, the projector is discarded, and only the encoder is used to produce embeddings.

SCARF training optimizes the InfoNCE contrastive loss [10], in which each sample's positive view is generated through feature corruption (random replacement of 60 per cent of features with values sampled from the empirical marginal distribution of each feature) and the embedding is trained to maximize similarity between corrupted positive pairs versus dissimilarity to other samples in the batch. The InfoNCE loss for sample i in a batch of size N is defined as in Eq. (1):

$$L_{NCE}(i) = -\log \left[\exp(\mathrm{sim}(z_i, z_i^+)/\tau) / \Sigma_{j \in B(i)} \exp(\mathrm{sim}(z_i, z_j)/\tau) \right] \quad (1)$$

where, $z = g(f(x))$ is the projected embedding, $\mathrm{sim}(\cdot, \cdot)$ is cosine similarity, $\tau = 0.5$ is the temperature parameter, and $B(i)$ denotes the set of all $2N - 1$ distinct in-batch views excluding

the anchor z_i itself (that is, the positive view z_i^+ and all other corrupted views from the same mini-batch of size N = 1,024). The implementation follows the standard SimCLR-style 2N-batch convention. Training uses AdamW optimizer with learning rate 1×10^{-3} and weight decay 1×10^{-5}, batch size 1,024, and maximum 100 epochs with early stopping (patience 15) on validation InfoNCE loss measured on a 10 percent random held-out split of $D_1 \cup D_unlab$. The model is initialized from three random seeds (42, 123, 456), and the embedding with the lowest validation loss is selected for downstream analysis.

B. Pretraining Convergence

Multi-seed pretraining yields stable convergence behavior. The best validation InfoNCE losses across the three seeds are 6.92, 6.92, and 6.96, with a mean of 6.93 and a standard deviation of 0.02. For the 2N-batch convention used here with N = 1,024, the random-baseline expected loss under uniform negative sampling is $\log(2N - 1) = \log(2{,}047) \approx 7.62$ nats; the observed losses are below this baseline by approximately 0.7 nats. We acknowledge that the absolute InfoNCE value is sensitive to the choice of negative sampling convention, and the downstream evidence for meaningful representation learning is provided by the clustering quality and external validity analyses in Section VI rather than by the raw InfoNCE value alone. Fig. 3 shows training and validation loss curves across the three random seeds.

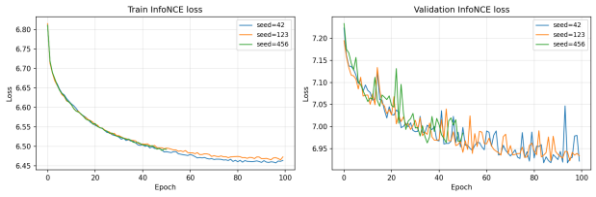

Fig. 3. SCARF training and validation InfoNCE loss curves across three random seeds.

VI. Embedding-Space Clustering

A. Clustering Algorithms and Selection

After pretraining, we apply L2 normalization to the 128-dimensional embeddings, projecting each sample onto the unit hypersphere. This is standard practice for contrastive embeddings, where cosine similarity (rather than Euclidean distance) was the training objective. Three clustering algorithms are then compared: K-means with silhouette-based k selection over {3, 5, 8, 10, 12, 15, 20}; Gaussian Mixture Model (GMM) with diagonal covariance and Bayesian Information Criterion (BIC) selection over {3, 5, 8, 10, 12, 15}; and Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) with minimum cluster size selection over {200, 500, 1,000, 2,000} and minimum samples 50.

TABLE III. Embedding-Space Clustering Comparison

Algorithm	k	Silhouette	Davies–Bouldin	Calinski–Harabasz	ARI vs PV	Noise %
K-means	15	0.366	1.132	5,338	0.354	0.0%
GMM	15	0.363	1.072	5,245	0.378	0.0%
HDBSCAN	21	0.407	0.948	4,959	0.234	16.5%

[c.] Silhouette and Davies–Bouldin computed on a 30,000-sample subset for tractability. ARI is computed on full data.

Table III reports the clustering quality metrics. K-means selects k = 15 with silhouette 0.366, GMM selects k = 15 by BIC with silhouette 0.363, and HDBSCAN identifies 21 components at minimum cluster size 2,000 with silhouette 0.407 on non-noise samples (16.5 per cent of samples designated as noise). The Adjusted Rand Index (ARI) between each embedding-space clustering and the PV-space K-means clustering (Section IV) is 0.354 for K-means, 0.378 for GMM, and 0.234 for HDBSCAN. These ARI values indicate weak-to-moderate agreement, meaning that the embedding-space clusters preserve coarse PV-regime structure while introducing finer subdivisions. Fig. 4 visualizes the relative performance of the three algorithms across all four metrics.

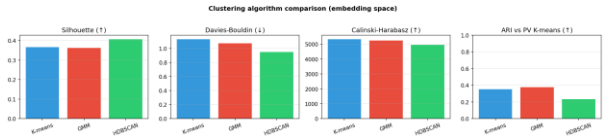

Fig. 4. Clustering algorithm comparison in the embedding space (silhouette, Davies–Bouldin, Calinski–Harabasz, and ARI versus PV K-means).

Three observations are worth emphasizing. First, the embedding-space silhouette score (0.37) substantially exceeds the raw PV-space K-means silhouette (0.16), indicating that the SCARF representation has produced a feature space where operating regimes are more cleanly separable; we acknowledge that the two silhouettes are computed in spaces of different dimensionality (128-dimensional L2-normalized embedding versus 40-dimensional standardized PV plus mill one-hot space) and that the contrastive objective directly optimizes for cluster-like compactness, so the quantitative ratio of the two silhouettes should be interpreted as a directional indicator rather than an equal-footing measurement. Second, K-means and GMM converge on the same number of components (k = 15) through independent selection criteria (silhouette and BIC, respectively). For K-means, k = 15 is an interior optimum of the wider search grid {3, 5, 8, 10, 12, 15, 20} (the silhouette score peaks at k = 15 and decreases at k = 20), which provides a stronger indication that k = 15 reflects an intrinsic count rather than a grid-boundary effect. For GMM, k = 15 coincides with the upper boundary of its search grid {3, 5, 8, 10, 12, 15}; BIC may favor an even larger number of components if the grid were extended, so the GMM result alone would be inconclusive. The agreement between the two algorithms — one finding an interior optimum and the other reaching its boundary at the same value — is consistent with k = 15 being an intrinsic count, though extending the GMM grid would strengthen the conclusion further. Third, HDBSCAN identifies 21 components with the highest silhouette, where the selected minimum cluster size of 2,000 was the largest value in its search range and yields 16.5 percent of samples designated as noise; for downstream pseudo-labeling applications this noise designation is operationally problematic. Based on these considerations and to ensure consistency with the visualizations in subsequent subsections, we adopt K-means with k = 15 as the primary representation for the remainder of this study.

To assess whether the contrastive representation is necessary, or whether a simpler and computationally cheaper pipeline would suffice, we additionally clustered the same 162,731-record input using linear dimensionality reduction. Table IV compares K-means (k = 15) applied to PCA-reduced

and standardized process-variable representations against the SCARF embedding. Two patterns emerge. First, the SCARF embedding produces markedly more separable clusters: its silhouette score (0.366) is roughly twice that of any PCA or standardized-PV baseline (0.16–0.24), indicating that linear projection preserves the diffuse, overlapping structure of the raw process-variable space rather than resolving it. Second, the PCA baselines exhibit higher ARI against the PV-space K-means partition (0.47–0.51 versus 0.354 for SCARF), which is expected: a linear projection largely reproduces the partition of the space it was derived from, whereas the SCARF embedding deliberately departs from it. This combination — substantially higher cluster separation together with lower agreement with the raw-PV partition — indicates that SCARF does not merely re-express the PV-space regimes more compactly but recovers a finer, better-separated regime structure that the simpler linear pipelines do not capture, justifying the additional cost of contrastive pretraining.

TABLE IV. SIMPLER DIMENSIONALITY-REDUCTION BASELINES VERSUS THE SCARF REPRESENTATION (K-MEANS, K = 15).

Representation	Dim.	Silhouette	ARI vs PV
Standardized process variables (no reduction)	40	0.161	0.474
PCA (95% variance retained)	32	0.174	0.513
PCA (compact)	10	0.236	0.482
SCARF embedding	**128**	**0.366**	**0.354**

[d] All methods cluster the same 162,731-record input (37 standardized process variables plus three mill one-hot indicators) with K-means (k = 15). Silhouette is computed on a fixed 20,000-record subsample; ARI is computed on all records against the k = 8 PV-space reference clustering of Section IV-B.

B. Relationship to PV-Space Regimes

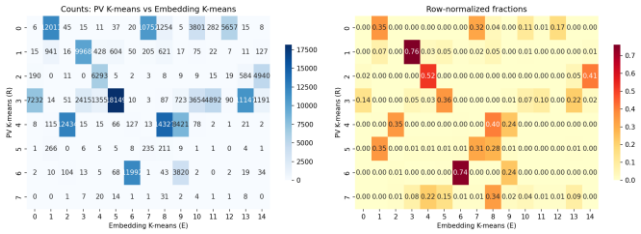

Fig. 5. Cross-tabulation between PV K-means regimes (rows) and embedding K-means clusters (columns). Left: counts; right: row-normalized fractions.

Fig. 5 shows the cross-tabulation between PV-space K-means regimes (R0–R7) and embedding-space K-means clusters (E0–E14), both as raw counts and row-normalized fractions. Two structural patterns are observed. First, certain PV regimes map cleanly to single embedding clusters. PV regime R1 has 76 percent of its samples in embedding cluster E3; PV regime R6 has 74 per cent in E6. These cases correspond to operating regimes that the raw PV space already separates well, and SCARF reinforces this separation. Second, other PV regimes split across multiple embedding clusters. PV regime R0, the largest in the raw PV space, distributes across four embedding clusters (E1, E7, E10, E12) with the largest fraction at 35 percent. PV regime R5 splits across three (E1, E7, E8). This finer subdivision indicates that within what raw PV clustering treats as a single coarse regime, the SCARF embedding identifies sub-regimes that share gross PV characteristics but differ in finer operational structure that the contrastive objective deemed discriminative.

C. Mill Specificity of Embedding Clusters

Fig. 6 displays the mill distribution within each embedding K-means cluster. The pattern is striking: 14 of the 15 clusters are dominated by a single mill (CM2 in clusters 0, 7, 11, 12, 13, 14; CM3 in clusters 1, 3, 5, 10; CM4 in clusters 2, 6, 8, 9). Cluster 4 is the only cluster with appreciable mill mixing, containing approximately 75 percent CM2 and 25 percent CM3 records. Cluster 8 is CM4-dominated (approximately 99 per cent CM4) with a small marginal CM3 component.

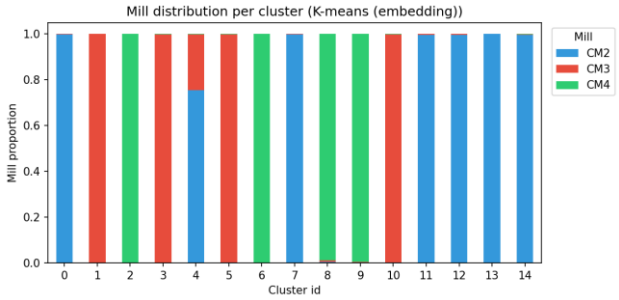

Fig. 6. Mill composition of each embedding K-means cluster. Nearly all clusters are dominated by a single mill, indicating strong mill-specific operating patterns captured by SCARF.

This pattern indicates that SCARF, despite receiving mill identifier only as a 3-dimensional one-hot feature alongside 37 process variables, has learned an embedding in which mill-specific operating patterns dominate. The contrastive objective evidently treats inter-mill differences as larger discriminative signals than within-mill regime differences. Cluster 4, the single mixed cluster, is operationally interpretable: it represents a region of the embedding space where CM2 and CM3 operating modes converge, plausibly indicating a shared operational state achievable on both mills (for example, similar feed composition and similar grinding fineness target).

D. Temporal Evolution of Embedding Clusters

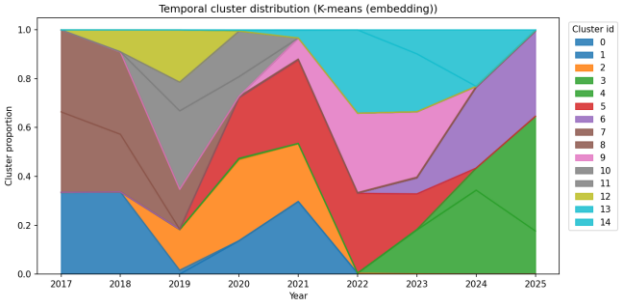

Fig. 7. Year-wise stacked area plot of embedding K-means cluster proportions, showing the progressive evolution of operating modes.

Fig. 7 displays a stacked area plot of cluster proportions by year. The visualization reveals a progressive temporal evolution of operational modes. In 2017 and 2018, clusters 7 and 8 dominate, together accounting for approximately 80 per cent of samples. From 2019 onward, additional clusters (notably clusters 11 and 12) gain prominence and the dominance of

cluster 7 begins to decline. From 2020 to 2021, mid-period clusters (clusters 2 and 5) become prominent. From 2022 onward, a further wave of clusters appears, including clusters 6, 9, 13, and 14. By 2024 and 2025, late-period clusters such as cluster 4 and cluster 6 dominate. The specific color–cluster mapping is shown in the figure legend.

The temporal pattern in Fig. 7 corresponds with the change points reported in Section IV. The first major transition, around 2019, coincides with PELT change points in multiple variables across all three mills. The second major transition, around 2022, coincides with PELT change points in CM2 and CM3. The most recent transition, around 2024, coincides with the latest PELT change point. The combined evidence from PELT (which uses purely temporal information) and SCARF clustering (which uses no temporal information except indirectly through the data distribution) thus converges on the same coarse drift structure, providing independent cross-method validation that the discovered structure reflects genuine operational evolution. We note that the alignment is presented qualitatively (visual coincidence in time) rather than through a formal alignment statistic; a quantitative alignment indicator is discussed as future work in Section VII F.

To quantitatively confirm that the embedding-derived regimes reflect genuine operational differences rather than artifacts of the contrastive learning process, we tested whether the 15 embedding regimes are statistically separable in the original process-variable space. A Kruskal–Wallis test across the regimes was significant for all 37 process variables ($p < 0.001$ in every case), with a mean effect size of $\eta^2 = 0.43$ and values reaching $\eta^2 = 0.79$ for bag-filter differential pressure (MILL_186_BF_DP) and 0.78 for bag-filter pressure (MILL_186_BF_PRESSURE). Because these regimes were discovered purely in the learned embedding space — without access to the raw process-variable distributions during clustering — their strong and uniform separability in process-variable space provides quantitative evidence that the discovered structure corresponds to physically distinct operating modes rather than to learning artifacts.

VII. Discussion

A. Implications for Pre-2023 Data Treatment

The analysis above directly addresses the central methodological question raised in the introduction. The initial restriction to the 2023 to 2025 period was motivated by observations of substantial distributional deviation in pre-2023 Blaine measurements relative to post-2023 records. The present analysis shows that, under a wider valid-range filter applied uniformly across the full 2017 to 2025 period, a meaningful fraction of pre-2023 records does pass both Blaine and 44 μmR range conditions and can be admitted to the labeled set. More importantly, the records that lack valid quality labels (and therefore enter D_unlab) still contain coherent operational structure: PELT detects multiple change points within the pre-2023 period itself (for example, CM3 MILL_SEPOL_SEPOL has six change points distributed across 2017 to 2023), and the SCARF embedding identifies multiple distinct operational clusters within this period (clusters 7, 8, 11, 12 dominate 2017 to 2020). The pre-2023 records thus contribute distinct operational regimes that, if discarded entirely, would represent a substantial loss of information for downstream tasks that benefit from operational diversity, even when those records cannot directly serve as supervised labels.

B. Validity of Embedding-Derived Regimes

The validity of the 15-cluster embedding-derived regime structure is supported by three lines of evidence, each with its own caveat. First, two clustering algorithms with different selection criteria (K-means with silhouette, GMM with BIC) converge on the same number of components ($k = 15$). For K-means, $k = 15$ is an interior optimum of the search grid {3, 5, 8, 10, 12, 15, 20}, which provides direct evidence for $k = 15$. For GMM, $k = 15$ coincides with the upper boundary of its search grid; the agreement is consistent with an intrinsic count but extending the GMM grid would further strengthen this conclusion. Second, the embedding-space silhouette score (0.37) substantially exceeds the raw PV-space score (0.16), although as noted in Section VI A, this comparison is across spaces of different dimensionality and the embedding directly optimizes for contrastive compactness. Third, the temporal evolution of embedding clusters aligns with the PELT change-point locations obtained from a completely independent algorithm using only daily-aggregated time series of three variables. Of the three lines, the third provides the strongest independent corroboration because PELT and SCARF use disjoint information (PELT uses time only on three signals, SCARF uses no time information on 37 signals). The convergence of these assessments provides reasonable, though not definitive, confidence that the discovered regime structure is operationally meaningful.

C. Mill Specificity and Cross-Mill Generalization

The strong mill specificity in Fig. 6 has implications for downstream prediction tasks. If 14 of 15 operating regimes are mill-specific, then models that share parameters across mills must implicitly learn mill-conditional behavior. Cluster 4, the one mixed cluster (CM2/CM3 = 75:25), suggests that some operational states are reachable across mills and that cross-mill transfer is plausible in those regions of the operating space. Future work should investigate whether cross-mill pseudo-labeling within shared operational clusters (such as cluster 4) yields better generalization than facility-wide pseudo-labeling that ignores mill structure.

D. Downstream Quality Prediction Benefit

While the central analysis of this study concerns operational regime structure, we additionally verify that the learned representation provides measurable benefits for the intended downstream task. Using the same labeled set D_l and the SCARF embeddings characterized above, we trained two state-of-the-art deep tabular regressors (FT-Transformer and SAINT) to predict Blaine fineness and 44 μmR, comparing models that receive the raw 40-dimensional input against models that additionally exploit the SCARF representation together with cluster-conditional pseudo-labeling of the unlabeled records. As summarized in Table V, incorporating the learned representation improves test R^2 for every target–model pair, raising Blaine R^2 from 0.524 to 0.567 (FT-Transformer) and from 0.483 to 0.557 (SAINT), and 44 μmR R^2 from 0.836 to 0.852 and from 0.825 to 0.844, respectively. The corresponding reductions in prediction error range from 9.1% to 14.3% and are statistically

significant for all four pairs under both the Wilcoxon signed-rank test and a paired t-test ($p < 0.01$; $n = 7{,}691$). The larger relative gain on Blaine, the harder chemically-mediated target, indicates that the representation is most valuable precisely where raw process variables are least informative. These results confirm that the regime structure recovered through self-supervised pretraining is not merely descriptive but translates into improved predictive performance. A complete end-to-end evaluation of the prediction system — including temporal (chronological) generalization and a systematic study of the pseudo-labeling strategy — is beyond the scope of the present characterization study and is pursued in a separate work.

TABLE V. DOWNSTREAM QUALITY PREDICTION WITH AND WITHOUT SCARF REPRESENTATION

Target	Model	Test R^2 (raw PV)	Test R^2 (+SCARF)	ΔR^2	RMSE (raw→+SCARF)	Wilcoxon p
Blaine	FT-Transformer	0.524	0.567	+0.043	100.7 → 96.0	$<10^{-63}$
Blaine	SAINT	0.483	0.557	+0.074	105.0 → 97.2	$<10^{-89}$
44 µmR	FT-Transformer	0.836	0.852	+0.015	0.521 → 0.496	$<10^{-66}$
44 µmR	SAINT	0.825	0.844	+0.019	0.538 → 0.508	$<10^{-44}$

[e.] Three-seed means: "raw PV" = 40-dimensional input used directly, "+SCARF" = same input with the SCARF representation and cluster-conditional pseudo-labeling.

E. Limitations

Seven limitations should be noted. First, the analysis is conducted on a single facility with three mills; multi-facility validation is essential for assessing generalizability across cement plants with different equipment vendors and operational practices. Within this single facility, however, the three mills (CM2, CM3, and CM4) differ substantially in their operating behavior — as evidenced by the strong mill specificity reported in Section VI C, where 14 of 15 embedding clusters are dominated by a single mill — so the present study already evaluates the method across three distinct operating environments rather than a single homogeneous process. The contribution of this work is methodological: to demonstrate that a coherent operational regime structure can be recovered from multi-year data of a given facility, rather than to claim cross-plant universality of the specific regimes discovered. Validation on independent plants with different equipment vendors remains essential future work to establish broader generalizability. Second, our PELT analysis is restricted to three process variables; a more comprehensive multivariate change-point analysis covering all 37 variables jointly may reveal additional regime transitions not visible in any single variable. Third, the choice of the L2 cost model in PELT assumes mean-shift transitions; transitions characterized by variance changes or covariance shifts may be missed. Fourth, the SCARF contrastive objective treats all feature corruptions as equally informative; feature-specific corruption rates (for example, higher corruption for derived variables and lower for raw sensor readings) may produce more informative embeddings. More broadly, the SCARF hyperparameters used here — the 128-dimensional embedding, the 60 per cent corruption rate, the three-layer encoder, and the contrastive temperature — follow the standard configuration recommended for SCARF rather than values tuned on this dataset; a systematic ablation over these design choices is a natural next step but lies outside the scope of the present characterization study, whose aim is to establish whether a coherent operational regime structure can be recovered rather than to optimize representation-learning hyperparameters. Relatedly, this study evaluates a single self-supervised method (SCARF), which was chosen as a representative contrastive approach well suited to the heterogeneous, mixed-scale process variables of finish milling; a controlled benchmark of SCARF against other self-supervised tabular paradigms — such as the reconstruction-based VIME [9] and SubTab [11], or the attention-based TabTransformer [12] — on the same industrial dataset would help establish which self-supervised inductive bias best captures operational-regime structure and is left to future work. Fifth, while Section VII-D confirms that the learned representation improves downstream quality prediction, a complete end-to-end predictive evaluation — including strictly chronological temporal generalization and a systematic analysis of the pseudo-labeling strategy — is left to separate work. Sixth, the SSL pretraining set described in Section V combines D_1 (including its test split) with D_unlab, which is acceptable for the unsupervised analysis presented in this study but would create a label-free form of test exposure if the same embeddings were reused without modification for downstream supervised evaluation; subsequent supervised studies will retrain the SSL encoder with the supervised test split excluded. Seventh, the regime-stratified random split of D_1 described in Section III-B places temporally adjacent records into different subsets, so any held-out test split constructed from D_1 provides an optimistic estimate of temporal generalization relative to a strictly chronological split; this protocol is adopted in the present study to ensure regime-balanced evaluation across the full 2017 to 2025 data span, and a strictly chronological split is recommended for any downstream supervised study that aims to assess temporal generalization on its own merits.

F. Toward Quantitative Alignment Indicators

The PELT–SCARF alignment reported in Section VI D is presented qualitatively. A quantitative indicator could be constructed by computing, for each PELT change-point date, the local Jensen–Shannon divergence between cluster assignment distributions in fixed-width windows before and after the change point, or by computing the ARI between cluster assignments in different temporal segments. Development of such indicators is left as future work.

VIII. CONCLUSION

This study has characterized the operational drift structure in approximately nine years of cement finish milling DCS data (188,858 hourly records across three industrial mill units) and demonstrated that self-supervised pretraining can recover this structure for downstream applications. PELT change-point detection identifies between 12 and 21 detected drift events per mill, with effect sizes (Cohen's d) consistently satisfying $|d| > 1.0$ for the majority of transitions. SCARF contrastive learning

on the combined labeled and unlabeled set (162,731 records) yields stable 128-dimensional embeddings (validation InfoNCE 6.93 ± 0.02 across three random seeds). Three independent clustering algorithms on the embedding space (K-means, GMM, HDBSCAN) consistently identify 15 to 21 operational regimes with silhouette scores between 0.36 and 0.41, substantially exceeding the raw PV-space silhouette of 0.16 (with the caveats on across-space comparison noted in Section VI-A). The embedding-space K-means regimes exhibit strong mill specificity (14 of 15 clusters dominated by a single mill) and show temporal evolution that aligns with the independently detected PELT change-point boundaries. These findings establish that long-term cement process data contains a richer operational regime structure than implied by raw PV clustering, and that contrastive self-supervised pretraining recovers this structure efficiently from unlabeled records, providing a representation suitable for use in downstream quality prediction tasks (downstream supervised performance is the subject of separate ongoing work).

Two directions for future work follow directly from these results. First, the cluster-conditional pseudo-labeling of the unlabeled subset, using the embedding-derived regimes as conditioning variables, is currently being investigated as a means of enabling state-of-the-art deep tabular models (FT-Transformer, SAINT) to close the performance gap with tree-based ensembles documented in the tabular learning literature; full empirical results will be reported in a forthcoming study. Second, the multi-facility generalization of the discovered regime structure remains an open question; comparison of embeddings across cement facilities with different equipment vendors would clarify whether the SCARF representation captures facility-specific or process-universal regime information.

Digital-to-Physical Transfer of Adversarial Patches for Aerial Vehicle Detection

Jung Heum Woo, Eun-Kyu Lee*
College of Information Technology, Incheon National University, Incheon, Republic of Korea

***Abstract*—Deep neural network (DNN)-based object detectors are widely used for analyzing aerial and satellite imagery in applications such as environmental monitoring and urban analytics. Despite their strong performance, these models are known to be vulnerable to adversarial examples, and physical adversarial attacks using printable patterns pose realistic security threats. This study evaluates physical adversarial patch attacks against an aerial vehicle detector by bridging digital optimization and real-world deployment. Adversarial patches are optimized in the digital domain using a loss function that minimizes the maximum objectness score while incorporating non-printability score (NPS) and total variation (TV) constraints to ensure both printability and spatial smoothness. The optimized patches are printed and deployed in three configurations: ON, OFF, and OFF-Side. Experiments using a YOLOv3 detector show that while the OFF patch achieves the highest effectiveness in the digital domain (85.51% Average Objectness Reduction Rate (AORR)), the ON patch demonstrates superior robustness in physical environments (0.197–0.343 Objectness Score Ratio (OSR)) due to its consistent visibility. Furthermore, the results indicate that weather-based augmentation does not necessarily improve patch optimization in this domain. These findings provide critical insights into the practical vulnerabilities of aerial object detection systems.**

I. Introduction

The rapid growth of aerial and satellite imagery has significantly expanded the use of automated visual analysis systems in a wide range of applications, including environmental monitoring, urban planning, traffic analysis, and disaster response. To efficiently analyze such large-scale image data, DNN-based object detection models have been widely adopted. Modern object detectors have demonstrated strong performance in identifying objects such as vehicles, buildings, and infrastructure in aerial imagery. Among these models, YOLOv3 has been widely used due to its high detection accuracy and real-time inference capability [1].

Despite their strong performance, DNN-based detectors are known to be vulnerable to adversarial examples, which are carefully crafted perturbations designed to manipulate model predictions. Previous studies have shown that adversarial perturbations can significantly degrade the performance of both image classification and object detection models. While early research mainly focused on digital adversarial attacks that directly modify pixel values in images, recent work has demonstrated the feasibility of physical adversarial attacks, in which adversarial patterns are printed and placed in real-world environments to influence camera-captured inputs.

However, most existing studies on physical adversarial attacks have focused on ground-based scenarios, such as autonomous driving systems or surveillance cameras. In contrast, aerial and satellite imagery present unique challenges due to large observation distances, varying viewing angles, scale variations, and environmental conditions such as illumination changes and weather effects. As a result, the effectiveness and transferability of physical adversarial attacks in aerial imagery remain relatively underexplored.

Unlike ground-level photography, aerial and satellite imagery is captured through long atmospheric paths, making it susceptible to visibility degradation caused by weather conditions such as fog, haze, and fluctuating illumination. Such environmental variability can significantly undermine the effectiveness of adversarial patches when they are transferred from digital optimization to physical deployment. To address this, this study incorporates weather-based augmentation into the patch optimization pipeline to simulate atmospheric effects and environmental noise, thereby investigating its impact on ensuring the robustness of adversarial attacks under diverse real-world capture conditions.

Building on this motivation, this study evaluates physical adversarial patch attacks against an aerial vehicle detector by developing and analyzing a practical attack pipeline that bridges digital optimization and real-world deployment. Adversarial patches are first optimized in the digital domain and then physically printed and deployed in real environments to evaluate their impact on object detection performance. The evaluation considers three patch configurations: ON patch placed directly on the vehicle roof, OFF patch placed around the vehicle, and OFF-Side patch in which two patches are placed on both sides of the vehicle. The target detector is pre-trained on the Microsoft COCO dataset [2] and fine-tuned on the Cars Overhead With Context dataset [3] for aerial vehicle detection.

The experimental results yield several critical insights into the physical robustness of aerial vehicle detectors. First, a significant discrepancy is observed between domains: while the OFF patch configuration—which manipulates contextual information—is most effective in digital simulations (achieving up to 85.51% AORR), the ON patch demonstrates superior effectiveness and robustness in real-world environments, reaching a minimum OSR of 0.197. Second, the analysis indicates that weather-based augmentation during the optimization stage does not necessarily improve attack performance and can even hinder the generation of effective adversarial patterns in this specific domain. Finally, moderate total variation (TV) regu-

larization is shown to be essential for balancing the trade-off between physical printability and adversarial potency. These findings provide insights into the practical vulnerabilities of aerial object detection systems under real-world physical perturbations.

Main contributions of this study are as follows:

- This study presents a digital-to-physical evaluation of adversarial patch attacks for aerial vehicle detection, focusing on the practical transfer gap between digital optimization and real-world aerial capture.
- Object-level and context-level patch deployment strategies, including ON, OFF, and OFF-Side configurations, are compared to show that the most effective strategy differs between digital and physical domains.
- Weather-based augmentation and TV regularization are analyzed in aerial patch optimization, providing empirical evidence that environmental augmentation does not necessarily improve attack effectiveness in this setting.

II. Background and Related Work

A. Aerial Image Object Detection

Object detection in aerial and satellite imagery has become an important research topic due to its wide range of applications, including urban analysis, environmental monitoring, and traffic understanding. Compared with natural-image object detection, aerial image detection is more challenging because target objects often appear very small, densely distributed, and visually ambiguous under varying viewpoints and imaging conditions. To address these challenges, convolutional neural network (CNN)-based detectors have been widely adopted in remote sensing tasks.

Among early large-scale applications, Albert et al. [4] demonstrated that convolutional networks combined with satellite imagery can effectively capture large-scale urban patterns, showing the practical value of deep learning for aerial scene understanding. In addition, Ji et al. [5] proposed a vehicle detection framework for remote sensing imagery that integrates super-resolution with object detection to improve the detection performance of small vehicles in aerial images. These studies demonstrate that deep learning-based approaches have become the dominant paradigm for aerial object detection.

Recent studies have further improved aerial and remote sensing object detection by addressing the unique characteristics of overhead imagery. Cai et al. [6] proposed PKINet to capture multi-scale local features and long-range contextual information for remote sensing detection. Huang et al. [7] investigated detection pre-training for remote sensing scenes and showed that object-level representation alignment can improve transfer performance, especially under limited annotation settings. These advances indicate that aerial object detectors are becoming increasingly specialized for scale variation, dense object layouts, and arbitrary orientations.

More broadly, the success of deep neural networks in aerial imagery has motivated the development of detection systems for vehicles and other small objects observed from overhead viewpoints. In this context, aerial object detection serves as a critical foundation for many downstream tasks, and its reliability is particularly important when the detection results are used in real-world monitoring or decision-making systems.

Despite their strong performance, aerial image detectors remain vulnerable to distribution shifts caused by viewpoint variation, scale change, illumination, and environmental conditions. These limitations become even more critical in adversarial settings, where carefully designed perturbations can exploit the detector's sensitivity. Therefore, understanding the vulnerability of aerial object detectors is necessary not only from the perspective of model accuracy, but also from the viewpoint of security and robustness.

B. Adversarial Attacks on Object Detection

Adversarial examples are intentionally crafted perturbations that cause machine learning models to produce incorrect predictions. Goodfellow et al. [8] established one of the foundational formulations of adversarial examples and showed that deep neural networks are highly vulnerable even to small, human-imperceptible perturbations. Subsequent studies such as DeepFool and Universal Adversarial Perturbations further expanded this line of work by proposing effective optimization-based attack methods and demonstrating that perturbations can generalize across many inputs [9], [10]. Carlini and Wagner [11] later introduced stronger optimization-based attacks that became a standard benchmark for evaluating model robustness.

While many early studies focused on image classification, later work extended adversarial attacks to object detection, which is a more complex task involving both localization and classification. Eykholt et al. [12] examined attacks on object detectors using adversarial stickers, while Song et al. [13] further discussed physical adversarial examples against object detection models. Chen et al. [14] proposed ShapeShifter, a robust physical adversarial attack against Faster R-CNN, showing that detector-specific attacks can remain effective under transformations. Lee and Kolter [15] also investigated physical adversarial patches for object detection, emphasizing the challenges of patch placement and transferability in detection scenarios.

In the aerial domain, den Hollander et al. [16] explored adversarial patch camouflage against aerial detection, suggesting that object detectors operating on overhead imagery are also susceptible to localized perturbations. Similarly, Czaja et al. [17] discussed adversarial examples in remote sensing and highlighted the importance of studying adversarial robustness in aerial and satellite imagery. These studies indicate that adversarial attacks on object detection are not limited to ground-based scenes and that overhead detection systems constitute an important yet relatively underexplored attack surface.

C. Physical Adversarial Patch Attacks

Physical adversarial patch attacks aim to preserve adversarial effectiveness after digital perturbations are transferred into the real world through printing, placement, and image recapture. Kurakin et al. [18] presented one of the earliest demonstrations that adversarial examples can survive the physical imaging process, although their effectiveness may degrade due to viewpoint and environmental variations. To address these

limitations, Brown et al. [19] introduced the adversarial patch paradigm, showing that a localized patch can be optimized to produce universal and robust attack behavior under different transformations. This work became a key foundation for later physical patch attacks.

Subsequent studies improved the realism and robustness of physical adversarial patches by explicitly considering printability, smoothness, and physical-world constraints. Komkov and Petiushko [20] proposed AdvHat, in which physically wearable adversarial patterns were designed to attack face recognition systems. In the object detection domain, many studies extended the patch-based attack setting to detection models, demonstrating that adversarial patterns can suppress or alter detections when placed in physically meaningful regions of the scene [12], [13], [14], [15], [21].

Recent studies have further expanded physical adversarial attacks by considering more realistic deployment factors. Guesmi et al. [22] proposed a dynamic adversarial patch that maintains a naturalistic appearance while improving robustness to transformations such as clothing creases. Wei et al. [23] revisited physical patch attacks from the perspective of camera image signal processing and showed that cross-camera variability can strongly affect attack stability. Long et al. [24] extended printable patch attacks from frame-level detection to multiple object tracking by disrupting both detection and temporal identity association. Liang et al. [25] proposed adversarial camouflage that addresses viewpoint conflicts, illumination changes, and texture smoothness for physical object detection evasion. These studies indicate that physical adversarial attacks are increasingly moving toward realistic imaging, motion, and environmental constraints.

Compared with ground-level physical attacks, physical patch attacks in aerial imagery are more challenging because the attack must remain effective across larger observation distances, severe scale changes, viewpoint differences, and environmental factors such as illumination and weather. Literatures provided early evidence that remote sensing models can be attacked using adversarial perturbations [17], [16]. More recent remote-sensing studies have begun to focus specifically on the digital-to-physical transfer problem. Chen et al. [26] addressed visual inconsistency between digitally optimized patches and their physical appearance by incorporating image harmonization into patch generation, while Li et al. [27] proposed a physical adversarial background patch for aerial object detection that balances attack effectiveness and patch area using Pareto-efficient optimization. Therefore, physical adversarial patch attacks on aerial object detectors represent an important research direction for understanding the real-world security limitations of overhead vision systems.

III. Threat Model

This study considers a threat model in which an attacker attempts to degrade the performance of an aerial vehicle detector using physically deployable adversarial patches. The attacker places adversarial patterns either directly on the target vehicle or around the vehicle so that the detector fails to recognize the object from aerial imagery. The objective of this threat model is to evaluate whether adversarial patches optimized in the digital domain can be effectively transferred to the physical domain and remain effective under real-world aerial capture conditions.

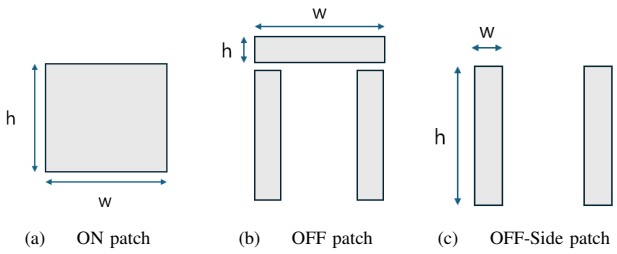

Fig. 1. Illustration of the three patch configurations: (**a**) ON patch, (**b**) OFF patch, and (**c**) OFF-Side patch.

1) Adversarial goal: The primary objective of the attacker is to reduce the detection confidence of an aerial vehicle detector. Specifically, the attacker aims to minimize the objectness score predicted by the detector so that the target vehicle is either not detected or detected with significantly reduced confidence. By decreasing the objectness score, the attack seeks to suppress the detector's confidence in the presence of the vehicle.

2) Knowledge: This study assumes a white-box threat model in which the attacker has full knowledge of the target detection model, including its architecture, parameters, and loss function. Under this assumption, the attacker can optimize adversarial patches directly against the target detector during the digital optimization stage. This setting allows the attack to evaluate the upper bound of adversarial vulnerability under physically realizable patch constraints.

3) Capability: The attacker is capable of generating adversarial patches in the digital domain and deploying them in the physical world. First, the patch is optimized digitally using the target detector. The optimized patch is then printed as a physical pattern and placed in the scene. In this study, three placement strategies are considered: an ON patch placed on the roof of the target vehicle, an OFF patch positioned around the vehicle, and an OFF-Side patch in which two patches are placed on both sides of the vehicle.

4) Strategy: During the optimization, the attacker iteratively updates the adversarial patch so as to minimize the objectness score predicted by the detector. By suppressing the objectness score of the target object, the patch reduces the probability that the detector correctly recognizes the vehicle in aerial imagery. This strategy focuses on degrading detection confidence rather than causing misclassification to another object category.

Under this threat model, the analysis evaluates whether digitally optimized adversarial patches can effectively transfer to the physical domain and degrade the performance of aerial object detectors in real-world capture scenarios.

IV. Attack Method

A. Patch Configuration

To evaluate the effectiveness of adversarial patches under different placement strategies, three patch configurations are

considered in this study, as illustrated in Fig. 1. These configurations represent different physical deployment scenarios that may influence the performance of aerial object detectors.

1) ON patch: The ON patch is placed directly on the roof of the target vehicle. This configuration aims to interfere with the detector by modifying the visual appearance of the object itself. In the digital domain, the ON patch has a size of 200×160 pixels. For physical deployment, the optimized patch is printed at approximately 1189×841 mm so that it covers a substantial portion of the vehicle roof and remains visible from aerial viewpoints.

2) OFF patch: In contrast, the OFF patch is placed around the vehicle rather than directly on it. This configuration attempts to manipulate the contextual information surrounding the target object, thereby affecting the detector's perception of the scene. In the digital domain, the OFF patch is designed as a rectangular strip of size 400×25 pixels. For physical deployment, the patch is printed at approximately 3200×200 mm and arranged around the vehicle to influence the detection process.

3) OFF-Side patch: The OFF-Side patch differs from the OFF patch in both the number and spatial arrangement of the deployed patches. While the OFF patch surrounds the vehicle with three rectangular patches arranged in a Π-shaped structure, the OFF-Side patch places only two patches on the left and right sides of the vehicle. Similar to the OFF configuration, the OFF-Side patch aims to manipulate the contextual region surrounding the vehicle rather than the vehicle surface itself. By perturbing the side regions of the vehicle, this configuration attempts to influence the detector's contextual perception while using fewer patches than the OFF configuration.

These three patch configurations support investigation of how the placement of adversarial patterns affects the robustness of aerial object detectors in both digital simulations and real-world environments. By comparing the ON, OFF, and OFF-Side configurations, this study analyzes the relative effects of object-level perturbations and contextual perturbations on detection performance.

B. Adversarial Patch Optimization

The overall pipeline of the adversarial patch optimization process is illustrated in Fig. 2. To generate adversarial patterns that remain effective in real-world environments, the adversarial patches are first optimized in the digital domain before being deployed in the physical domain. The optimization process aims to reduce the confidence of the object detector by minimizing the objectness score of the target object while ensuring that the generated patch can be reliably printed and physically deployed.

Let P denote the adversarial patch applied to an input image x. During optimization, the patch is iteratively updated to minimize the maximum objectness score produced by the detector. The optimization objective is defined as follows:

$$L_i(P) = \max(\hat{S}_i^u) + \delta \cdot \mathrm{NPS}(P) + \gamma \cdot \mathrm{TV}(P), \qquad (1)$$

where, $\max(\hat{S}_i^u)$ encourages the patch to reduce the highest objectness score in the i-th image, thereby suppressing the detector's confidence for the target object. The second term,

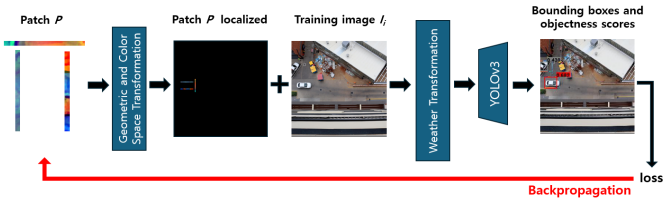

Fig. 2. Overview of the adversarial patch optimization process.

$\mathrm{NPS}(P)$, denotes the Non-Printability Score, which penalizes colors that cannot be reliably reproduced by physical printers. This constraint ensures that the optimized patch remains realizable when printed. The third term, $\mathrm{TV}(P)$, represents total variation regularization, which encourages spatial smoothness by reducing abrupt color changes between neighboring pixels in the patch.

The weighting coefficients δ and γ control the influence of the printability and smoothness constraints, respectively. In the experiments, these parameters are set to $\delta = 0.01$ and $\gamma = 2.5$, following prior work on physical adversarial patches.

In this study, the NPS term is treated primarily as a printability constraint rather than as a main factor for improving adversarial effectiveness. Accordingly, the NPS coefficient is fixed to encourage the optimized patch colors to remain within a physically printable range. In contrast, the TV coefficient is analyzed in more detail because TV regularization directly controls the spatial smoothness of the patch and visibly affects both the optimized patch structure and attack performance. This setting does not fully reveal the interaction between the NPS and TV terms during optimization; therefore, a joint ablation of both coefficients remains an important direction for future work. The default value $\gamma = 2.5$ is selected because, in preliminary experiments, $\gamma = 1.0$ and $\gamma = 2.5$ produced patches that appeared less visually unnatural while maintaining competitive attack performance. Among them, $\gamma = 2.5$ provided a favorable trade-off between visual naturalness and adversarial effectiveness.

To improve robustness against environmental variations, several transformations are applied during patch optimization. These transformations simulate changes that may occur during real-world image capture. Specifically, geometric transformations such as random scaling and rotation are applied to account for viewpoint variations. In addition, color-space transformations, including brightness and contrast adjustments, are introduced to simulate illumination changes. Weather-related perturbations are also considered to approximate atmospheric effects such as lighting variations and environmental noise.

Through this optimization process, the generated adversarial patch is designed to remain effective under both digital evaluation and real-world physical deployment conditions.

V. Detection Model and Dataset

A. Target Detector

This study targets a vehicle detection model designed for aerial imagery. The detector is based on YOLOv3 [1], which is a widely used one-stage object detector known for its efficiency and strong detection performance. YOLOv3 predicts bounding

boxes and objectness scores directly from multi-scale feature maps, making it suitable for detecting small objects such as vehicles in aerial images.

YOLOv3 is selected as the target detector for three main reasons. First, its one-stage detection structure provides efficient inference, which is important for aerial monitoring scenarios where a large number of image frames must be processed. Second, YOLOv3 explicitly predicts objectness scores, which directly align with the objective of this study: suppressing the detector's confidence in the presence of vehicles. This makes the relationship between the optimization loss and the AORR/OSR evaluation metrics transparent and interpretable. Third, although YOLOv3 is not the most recent detector, its explicit objectness-based detection formulation makes it particularly suitable for analyzing adversarial patch optimization and digital-to-physical transferability in the considered aerial vehicle detection setting.

To construct the target detector, the model is first pre-trained on the Microsoft COCO dataset [2], which contains diverse object categories and large-scale visual data. This pre-training stage enables the detector to learn general visual features for object recognition. The detector is then fine-tuned for aerial vehicle detection using the Cars Overhead With Context (COWC) dataset [3]. After fine-tuning, the trained detector is used as the target model for evaluating adversarial patch attacks in both the digital and physical domains.

B. Training Dataset

The target detector is trained using a two-stage dataset configuration consisting of a general-purpose pre-training dataset and an aerial-domain fine-tuning dataset. First, the detector is pre-trained on the Microsoft COCO dataset [2], which is a large-scale benchmark for object detection containing a wide variety of object classes and scene types. This stage provides the detector with general feature representations that are useful for downstream detection tasks.

After pre-training, the detector is fine-tuned on the COWC dataset [3], which is specifically designed for vehicle detection in overhead imagery. The COWC dataset contains more than 25,000 color image patches captured from aerial viewpoints in diverse urban environments. Each image has a spatial resolution of 256×256 pixels and includes vehicle annotations for detection tasks. Since the dataset focuses on overhead vehicle imagery, it is well suited for adapting the detector to the aerial detection setting considered in this study.

Examples from the training data are shown in Fig. 3, including representative scenes from the COWC dataset such as Selwyn and Utah. These images illustrate the overhead viewpoint, small object scale, and scene complexity that characterize aerial vehicle detection.

C. Physical Evaluation Dataset

To evaluate the real-world effectiveness of adversarial patches, additional aerial images are collected in two physical scenarios: *Side Street* and *Car Park*. These datasets are used exclusively for physical-domain evaluation and are intended to assess whether digitally optimized adversarial patches remain effective after physical deployment.

(a) COWC–Selwyn (b) COWC–Utah

(c) Car Park (d) Side Street

Fig. 3. Example images from the datasets used in this study: (**a**) COWC–Selwyn, (**b**) COWC–Utah, (**c**) Car park, and (**d**) Side street.

In the Side Street scenario, aerial images are captured from approximately the height of a ten-story building, corresponding to an observation height of about 40 m. In the Car Park scenario, aerial images are collected using an unmanned aerial vehicle (UAV) flying at an altitude of approximately 60 m. These two settings provide different viewpoints and scene structures, allowing the robustness of the adversarial patches to be evaluated under varying environmental conditions.

During physical data collection, three controlled vehicles are used, namely gray, white, and blue vehicles, depending on the scenario. The images and videos are recorded under multiple environmental conditions, including direct sunlight and shade, as well as static and moving vehicle states. The resulting physical evaluation dataset consists of 5,225 frames for the Side Street scenario and 2,126 frames for the Car Park scenario. Example images from these physical evaluation environments are also shown in Fig. 3.

These datasets enable a comprehensive evaluation of adversarial patch transferability from digital optimization to physical deployment under realistic aerial capture conditions.

VI. Experimental Setup

All experiments in this study were conducted on a workstation equipped with an NVIDIA GeForce RTX 4070 GPU. The models were implemented and trained using PyTorch 2.5.1 with CUDA 12.1.

A. Attack Settings

To evaluate the effectiveness of adversarial patches against aerial vehicle detectors, the patches are first optimized in the

digital domain and then deployed in the physical domain. During optimization, each patch is iteratively updated to minimize the objectness score predicted by the target detector while satisfying the printability and smoothness constraints described in Eq. (1). The optimization objective combines the maximum objectness term with the Non-Printability Score (NPS) and Total Variation (TV) regularization in order to generate adversarial patterns that are both physically realizable and robust under real-world capture conditions.

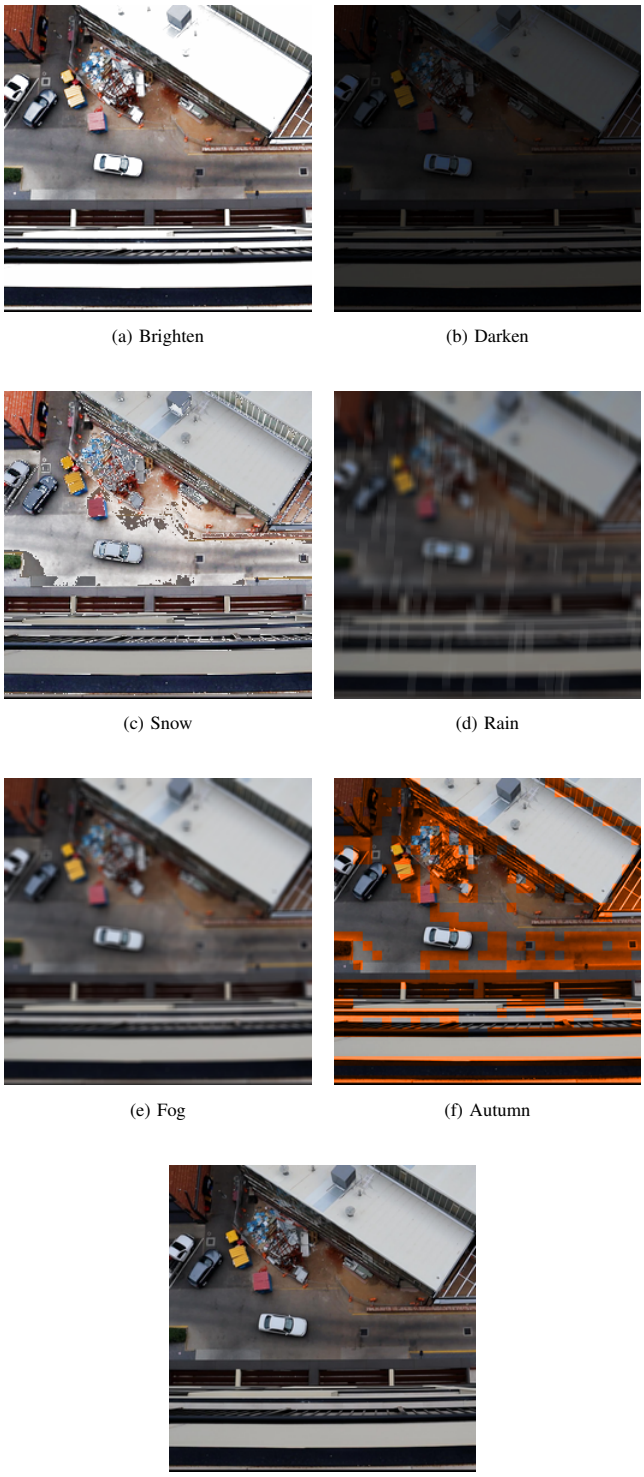
During patch training, several transformations are applied to improve robustness against environmental variations. Specifically, geometric transformations such as random scaling and rotation are used to simulate viewpoint changes in aerial imagery. In addition, color-space transformations including brightness and contrast adjustments are introduced to account for illumination variations. Weather-based augmentation is also incorporated to approximate environmental disturbances such as atmospheric effects and lighting variation.

To analyze the effect of augmentation strategies during patch optimization, three training pipelines are considered in this study: *G/C+W*, *G/C*, and *Control*. The *G/C+W* setting includes geometric transformations, color-space transformations, and weather augmentation. The *G/C* setting includes only geometric and color-space transformations. The *Control* setting uses a random patch without adversarial optimization. In addition, three patch placement strategies are evaluated, namely the ON, OFF, and OFF-Side configurations described in the previous section. These settings allow us to compare how augmentation strategies and patch placement affect attack performance in both digital and physical environments.

B. Weather Augmentation

To evaluate the robustness of adversarial patches under environmental appearance changes, image-level weather augmentation is applied during both patch training and digital testing when weather augmentation is enabled. In this process, the adversarial patch is first geometrically transformed according to the target object location and pasted onto the clean image. Then, the weather transformation is applied to the entire patched image before resizing it to the YOLOv3 input resolution. Therefore, the weather effect influences both the background scene and the adversarial patch, which better approximates physical deployment conditions where illumination, rain, fog, and color shifts affect the whole captured image.

For each image, one weather condition is randomly selected with uniform probability from seven candidates: brightening, darkening, snow, rain, fog, autumn color shift, and identity transformation. This selection corresponds to sampling an integer value from 0 to 6, where the seven cases denote brightening, darkening, snow, rain, fog, autumn color shift, and no transformation, respectively. The same weather augmentation policy is used during digital testing under the *STD+W* setting. Representative examples of the seven weather augmentation cases are shown in Fig. 4.



(a) Brighten (b) Darken

(c) Snow (d) Rain

(e) Fog (f) Autumn

(g) Identity

Fig. 4. Examples of the seven image-level weather augmentation cases used in patch training and digital testing: (**a**) brighten, (**b**) darken, (**c**) snow, (**d**) rain, (**e**) fog, (**f**) autumn color shift, and (**g**) identity transformation.

The brightening and darkening transformations are performed in the HLS color space by modifying the lightness channel. For brightening, the lightness coefficient is sampled as $1+\mathcal{U}(0,1)$, resulting in a scaling factor in the range $[1.0, 2.0]$. For darkening, the coefficient is sampled as $1-\mathcal{U}(0,1)$, producing a scaling factor in the range $[0.0, 1.0]$. The snow transformation increases the lightness of relatively dark pixels. Its threshold is sampled as $\mathcal{U}(0,1) \times 255/2 + 255/3$, corresponding approximately to the range $[85, 212]$, and pixels

below this threshold are brightened using a fixed coefficient of 2.5.

The rain transformation generates random rain streaks over the image. The slant of the streaks is selected from the integer range $[-10, 10]$, while the default drop length, drop width, and drop color are set to 20, 1, and $(200, 200, 200)$, respectively. The number of rain drops is proportional to the image area and is computed as the image area divided by 600. After drawing the rain streaks, a blur operation with a 7×7 kernel is applied, and the lightness channel is multiplied by 0.7 to simulate darker rainy conditions. The fog transformation overlays semi-transparent white circular haze patterns, with the fog coefficient sampled from $\mathcal{U}(0.3, 1.0)$. The haze size is determined as one third of the image width multiplied by the fog coefficient, and the final image is blurred using a kernel size proportional to the haze size. Finally, the autumn transformation divides the image into local 8×8 regions and changes the hue of selected low-green regions to one of four autumn-like hue values, $\{1, 5, 9, 11\}$, thereby simulating seasonal background color shifts.

Overall, the processing order for weather-based experiments is as follows: the clean image is padded to a square shape, the transformed adversarial patch is pasted, weather augmentation is applied to the patched image, the image is resized to 256×256, and YOLOv3 inference is then performed. For non-weather experiments, the same procedure is used except that the weather augmentation step is skipped.

C. Evaluation Metrics

To quantitatively evaluate the effectiveness of adversarial patch attacks, this study adopts objectness-based metrics for both digital-domain and physical-domain experiments. In the digital domain, the attack performance is measured using the Average Objectness Reduction Rate (AORR), which quantifies the relative decrease in objectness score after applying the adversarial patch. AORR is defined as

$$\mathrm{AORR}(T^v, \hat{T}^v) \triangleq \frac{1}{NE_j} \sum_{j=1}^{N} \sum_{l=1}^{E_j} \frac{s^v_{j,l} - \hat{s}^v_{j,l}}{s^v_{j,l}}, \tag{2}$$

where, T^v denotes the set of detection results for all images in the test set v, N is the number of test images, and E_j represents the number of detected objects in the j-th image. The term $s^v_{j,l}$ denotes the original objectness score of the l-th detection in the j-th image, whereas $\hat{s}^v_{j,l}$ denotes the corresponding objectness score after applying the adversarial patch. A higher AORR value indicates a stronger attack effect because it reflects a larger reduction in the detector's confidence.

AORR is used because the adversarial patch is optimized to directly suppress the objectness score of the target detector. Therefore, AORR measures the relative change in the same confidence signal that is minimized during patch optimization and provides a direct view of whether the learned patch successfully weakens the detector's vehicle-related response. Standard detection metrics such as mAP remain important for assessing final detection performance, but they can be affected by thresholding, non-maximum suppression, and localization changes. In contrast, AORR captures confidence degradation before and after patch application at the objectness score level. For this reason, AORR is reported as the primary attack-oriented metric, and mAP is additionally reported in the digital-domain evaluation to verify whether objectness suppression also leads to actual detection-performance degradation.

For physical-domain evaluation, the Objectness Score Ratio (OSR) is used, which measures the relative reduction in detection confidence after deploying the printed adversarial patch. OSR is defined as

$$\mathrm{OSR}(\hat{S}, S) \triangleq \frac{\frac{1}{\alpha} \sum_{f=1}^{\alpha} \hat{S}_f}{\frac{1}{\beta} \sum_{g=1}^{\beta} S_g}, \tag{3}$$

where, S_g denotes the original objectness score of the target object, and $\hat{S}_f$ represents the objectness score after the adversarial patch is applied. The parameter α denotes the total number of frames captured when the adversarial patch is physically deployed, whereas β denotes the total number of frames captured without the adversarial patch. A lower OSR value indicates a more effective physical attack.

OSR is used in the physical-domain evaluation because perfectly paired clean and patched images are difficult to obtain in real aerial capture. Unlike the digital setting, where the same image can be evaluated before and after inserting a patch, physical experiments are affected by small changes in viewpoint, illumination, vehicle position, camera motion, and environmental conditions. Therefore, directly computing an image-wise objectness reduction rate analogous to AORR is not reliable in the physical domain. Instead, OSR compares the average objectness score of frames captured with the printed patch to that of frames captured without the patch, providing a practical measure of confidence reduction under real deployment conditions.

D. Digital-Domain Evaluation

In the digital-domain experiments, adversarial patches are directly inserted into test images to evaluate their effectiveness without physical deployment. The experiments are conducted using the aerial vehicle detector described in the previous section, which is based on the YOLOv3 architecture.

To evaluate the robustness of the optimized patches under different testing conditions, two testing regimes are considered. The first regime, denoted as *STD*, measures AORR on the original test dataset without additional perturbation. The second regime, denoted as *STD+W*, applies weather effects to the test images before evaluation. These two settings allow us to analyze whether the optimized patches remain effective when environmental variations are introduced during testing.

The digital-domain evaluation is performed on the Side Street dataset. The same digital analysis is not conducted on the Car Park dataset because vehicles in that environment are parked very close to one another, causing visual interference among multiple patches and making it difficult to isolate the effect of each patch configuration. For each training pipeline and patch configuration, the attack performance is measured using AORR under both the *STD* and *STD+W* settings.

E. Physical-Domain Evaluation

To evaluate real-world attack effectiveness, this study uses the physical deployment settings provided by the benchmark in [28]. The physical experiments are conducted in two scenarios: *Side Street* and *Car Park*. In the Side Street scenario, images are captured from approximately 40 m above the ground, corresponding to the height of a ten-story building. In the Car Park scenario, aerial images are collected using a UAV flying at an altitude of approximately 60 m.

In this benchmark, the adversarial patches are printed on 160 gsm coated paper and placed either on the roof of the vehicle (ON patch) or around the vehicle (OFF patch). The OFF-Side configuration is considered in digital-domain analysis, whereas the physical-domain experiments mainly focus on the printed ON and OFF configurations. During data collection, the vehicles are recorded under varying environmental conditions, including direct sunlight and shade, as well as static and moving states.

The captured aerial images and video frames are processed by the target detector to obtain objectness scores for the target vehicle. The effectiveness of the adversarial attack is then measured using the OSR metric defined in Eq. (3). Through this evaluation protocol, the analysis assesses whether digitally optimized adversarial patches can maintain their effectiveness after physical printing, placement, and aerial image capture.

VII. Results and Analysis

A. Digital-Domain Results

Digital-domain evaluation reports results only on the Side Street dataset. Analyses on the Car Park dataset are omitted because vehicles in that environment are parked very close to one another, causing multiple patches to visually interfere with each other. This inter-patch interference makes it difficult to isolate the effect of each patch configuration and may distort the evaluation of attack effectiveness.

Table I summarizes the AORR results for the three patch configurations under different training pipelines. Overall, the *G/C* pipeline consistently outperforms the *G/C+W* pipeline for all patch types under both the *STD* and *STD+W* evaluation settings. This result suggests that incorporating weather-based augmentation does not improve adversarial patch optimization in this setting and may even degrade attack effectiveness. Out of the three patch configurations, the OFF patch achieves the strongest overall attack performance in the digital domain. In particular, the OFF patch trained with the *G/C* pipeline attains the highest AORR values, reaching 85.51% under *STD* and 78.02% under *STD+W*. These results indicate that perturbing the contextual region around the vehicle is more effective in the digital domain than directly modifying the appearance of the vehicle itself. The OFF-Side patch also exhibits meaningful attack performance, but it does not surpass the OFF patch. Specifically, the OFF-Side patch achieves 67.43% under *STD* and 62.43% under *STD+W* with the *G/C* pipeline, which is higher than the ON patch in some cases but still lower than the OFF patch overall. These results suggest that attack effectiveness varies depending on the number and spatial arrangement of the deployed patches.

Table I also shows that applying adversarial patches substantially decreases the detection accuracy compared with the clean baseline. Under the *STD* setting, the clean image achieves 56.22% mAP, whereas the adversarially optimized patches reduce the mAP to 5.98%, 7.46%, and 10.85% for the ON, OFF, and OFF-Side configurations with the *G/C* pipeline, respectively. A similar degradation is observed under the *STD+W* setting, where the clean mAP is 34.15%, but the adversarial patch cases remain much lower, ranging from 6.38% to 13.50% depending on the patch configuration and training pipeline. These mAP reductions are consistent with the AORR results: patch configurations with large objectness reduction generally produce severe detection-performance degradation. For example, the OFF patch with the *G/C* pipeline achieves the highest AORR under both *STD* and *STD+W*, while also reducing mAP far below the clean baseline. This consistency indicates that the AORR metric reflects not only confidence suppression but also practical degradation in detection performance. In contrast, the control patches generally retain higher mAP values or exhibit lower AORR values than the adversarially optimized patches, indicating that the performance drop is mainly caused by the optimized adversarial patterns rather than by simple occlusion or patch placement alone.

Overall, the digital-domain results reveal three key findings: 1) weather-based augmentation is not beneficial for patch optimization in this setting, 2) the OFF patch is the most effective configuration in the digital domain, and 3) attack performance changes according to the number and spatial extent of the deployed patches.

B. Physical-Domain Results

The physical-domain results in Table II are based on the aerial patch deployment benchmark reported in [28]. In this benchmark setting, the optimized adversarial patches are printed on 160 gsm coated paper, and aerial videos are recorded at 25 FPS for both the Car Park and Side Street scenarios. During data collection, three controlled vehicles, namely gray, white, and blue vehicles, are equipped with the printed adversarial patches. The resulting dataset consists of 2,126 frames for the Car Park scenario and 5,225 frames for the Side Street scenario.

Table II summarizes the physical-domain attack results. Overall, the deployed patches significantly reduce the detector's objectness scores across different vehicles and environmental conditions. The measured OSR values range from 0.197 to 0.746, indicating substantial degradation in detection confidence after physical patch deployment. Unlike the digital-domain results, where the OFF patch achieves the best performance, the ON patch generally shows stronger effectiveness in the physical domain, with the lowest mean OSR of 0.197 in the Side Street scenario. In the Side Street scenario, the ON patch reduces the mean OSR to values between 0.197 and 0.343 depending on the vehicle, lighting condition, and motion state. In contrast, the OFF patch shows weaker performance in the same scenario, with OSR values of 0.429 and 0.748 in the evaluated settings. In the Car Park scenario, the ON patch also reduces the detector confidence, achieving OSR values of 0.208, 0.509, and 0.746 for different vehicles and lighting conditions.

TABLE I. DIGITAL-DOMAIN EVALUATION RESULTS OF ADVERSARIAL PATCHES ON THE SIDE STREET DATASET UNDER BOTH STD AND STD+W EVALUATION SETTINGS. FOR PATCHED CASES, BOLD AND UNDERLINE INDICATE THE BEST AND SECOND-BEST ATTACK RESULTS, RESPECTIVELY; LOWER MAP AND HIGHER AORR INDICATE STRONGER ATTACKS

Training pipeline	Patch type	mAP (STD) [%]	AORR (STD) [%]	mAP (STD+W) [%]	AORR (STD+W) [%]
–	Clean	56.22	–	34.15	–
G/C	ON	5.98	72.59	7.07	64.09
G/C+W	ON	**4.10**	53.76	**6.38**	54.44
Control	ON	20.01	29.06	16.48	34.75
G/C	OFF	7.46	**85.51**	9.52	**78.02**
G/C+W	OFF	<u>4.93</u>	<u>79.37</u>	<u>6.57</u>	<u>71.80</u>
Control	OFF	27.28	20.65	18.01	10.73
G/C	OFF-Side	10.85	67.43	13.50	62.43
G/C+W	OFF-Side	5.54	66.46	12.28	59.36
Control	OFF-Side	39.65	15.66	28.86	28.49

TABLE II. RESULTS OF ADVERSARIAL PATCHES IN THE PHYSICAL DOMAIN [28]

(a) Side Street

Car	Patch type	Lighting	Motion	Mean OSR
Gray	ON	Both	Moving	0.343
Gray	ON	Sun	Static	0.251
Gray	ON	Shade	Static	0.255
Gray	OFF	Sun	Static	0.429
White	ON	Both	Moving	0.286
White	ON	Sun	Static	0.285
White	ON	Shade	Static	0.197
White	OFF	Sun	Static	0.748

(b) Car Park

Car	Patch type	Lighting	Motion	Mean OSR
Gray	ON	Sun	Static	0.509
Blue	ON	Shade	Static	0.208
White	ON	Sun	Static	0.746

These results show that adversarial patches optimized in the digital domain can be transferred to real-world aerial environments and remain effective after physical deployment. At the same time, the results indicate that the most effective patch configuration differs between the digital and physical domains.

C. Effect of TV Regularization

To analyze the effect of the TV regularization term, the coefficient γ in the patch optimization loss is varied, and the OFF patch is evaluated under the *G/C+W* training pipeline. The results are summarized in Table III, and representative visual examples of the optimized patches are shown in Fig. 5.

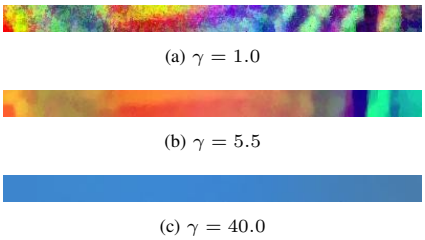
Overall, the attack performance strongly depends on the value of the TV loss coefficient. When $\gamma = 0.0$, the AORR is relatively low, reaching 33.18% under *STD* and 36.76% under *STD+W*, indicating that patches without smoothness regularization are less effective. Introducing TV regularization significantly improves the attack performance, with the best results observed around $\gamma = 1.0$ and $\gamma = 2.5$. Specifically, the highest AORR values are obtained at $\gamma = 1.0$ under *STD* and at $\gamma = 2.5$ under *STD+W*.

TABLE III. RESULTS OF ADVERSARIAL PATCHES UNDER THE G/C+W TRAINING PIPELINE WITH DIFFERENT TV LOSS COEFFICIENTS. BOLD AND UNDERLINE INDICATE THE BEST AND SECOND-BEST ATTACK RESULTS, RESPECTIVELY

TV loss coefficient (γ)	AORR (STD) [%]	AORR (STD+W) [%]
0.0	33.18	36.76
1.0	**80.79**	<u>71.32</u>
2.5	<u>79.37</u>	**71.80**
4.0	76.23	69.17
5.5	72.54	66.72
20.0	53.52	56.26
40.0	47.19	53.23

However, as the value of γ increases further, the attack performance gradually decreases. For example, when $\gamma = 20.0$ or $\gamma = 40.0$, the AORR drops substantially in both evaluation settings. This trend indicates that excessive TV regularization overly smooths the patch, thereby weakening the adversarial patterns that are necessary for suppressing the detector's objectness score.

The visual examples in Fig. 5 support this observation. When γ is small, the optimized patch contains diverse and high-frequency color patterns that effectively disrupt the detector. As γ increases, the patch becomes progressively smoother, and at very large values, such as $\gamma = 40.0$, the patch converges to a nearly uniform color pattern. These results indicate that moderate TV regularization is necessary to balance printability and attack effectiveness, whereas excessive smoothing degrades adversarial performance.



(a) $\gamma = 1.0$

(b) $\gamma = 5.5$

(c) $\gamma = 40.0$

Fig. 5. Visual examples of optimized patches under different TV loss coefficients: (**a**) $\gamma = 1.0$, (**b**) $\gamma = 5.5$, and (**c**) $\gamma = 40.0$.

VIII. Discussion

This study focuses on evaluating the digital-to-physical transfer of adversarial patches in aerial vehicle detection, where attacks are affected by overhead viewpoints, small object scale, long-distance capture, physical visibility, and context dependence. These factors distinguish the aerial setting from classic ground-based physical patch scenarios.

The experimental results provide several important observations regarding the transferability of adversarial patches from digital optimization to physical deployment in aerial vehicle detection. First, the digital-domain results show that the OFF patch achieves the strongest attack performance, whereas the physical-domain results indicate that the ON patch is generally more effective after real-world deployment. This discrepancy suggests that the attack effectiveness in the digital domain does not necessarily translate directly to the physical domain. One possible explanation for this difference is the distinct role of contextual perturbations and object-level perturbations under real-world imaging conditions. In the digital domain, the OFF patch is highly effective because it perturbs contextual cues around the vehicle, such as road texture, parking-lot structure, shadows, and local background contrast, while its position, scale, and visibility are precisely controlled. However, this context-dependent attack becomes less stable after physical deployment, where viewpoint changes, partial occlusion, scale variation, boundary misalignment, environmental noise, and small placement errors can alter the spatial relationship between the vehicle and the surrounding patch. Since the OFF patch is placed around the vehicle, nearby objects, occlusions, and shadows may further reduce its visibility and explain why the ON patch appears more effective in the physical setting. In contrast, the ON patch is attached directly to the vehicle body and moves together with the target object, maintaining more consistent visibility and object-level alignment across aerial frames. This explains why the ON patch is more robust in the physical domain, even though the OFF patch is stronger in digital evaluation. The OFF-Side configuration further shows the role of spatial coverage, as perturbing only the two side regions provides weaker contextual manipulation than the full OFF configuration. Since OFF-Side is mainly evaluated digitally in this study, a complete physical comparison among ON, OFF, and OFF-Side remains future work.

Second, the results show that weather-based augmentation during optimization does not improve attack performance and may even reduce it. In the digital-domain experiments, the *G/C* pipeline consistently outperforms the *G/C+W* pipeline for all patch configurations. This finding suggests that the additional variability introduced by weather augmentation might hinder the optimization of discriminative adversarial patterns in the considered setting. Rather than improving robustness, excessive augmentation may weaken the attack objective by forcing the patch to adapt to overly broad or unrealistic perturbation conditions. A possible mechanism behind this result is that the weather transformation perturbs both the adversarial patch and the surrounding scene after patch placement. Because the attack objective is based on suppressing objectness scores, the optimizer must learn patch patterns that consistently disturb vehicle-related features across many transformed appearances. Strong image-level weather effects such as fog, rain, snow, and large brightness changes can alter edge contrast, local texture statistics, and color distributions of the entire image. As a result, gradients obtained from different weather conditions may become less consistent across iterations, making the optimization less stable and reducing the emergence of sharp, discriminative adversarial patterns. In addition, weather augmentation may partially mask or smooth the patch itself, especially when haze, rain blur, or strong illumination changes are applied after patch insertion. This can weaken the feature perturbation produced by the patch and encourage the optimization to converge to patterns that are more generic but less effective against the detector's stable vehicle features. Therefore, in this setting, weather augmentation appears to increase appearance diversity but does not necessarily improve adversarial generalization. Instead, it can dilute the attack signal and reduce optimization efficiency. Therefore, the effect of weather augmentation should be interpreted as an empirical observation in this setting, and further analysis of convergence behavior, gradient stability, or detector feature responses would be needed to explain the underlying optimization mechanism.

Third, the ablation study on TV regularization demonstrates that moderate smoothness constraints are essential for effective physical adversarial patch generation. When the TV coefficient is too small, the optimized patch lacks sufficient structural regularity for stable physical deployment. On the other hand, when the coefficient becomes too large, the patch becomes overly smooth and loses the high-frequency patterns necessary for suppressing detector confidence. This result indicates that there is a trade-off between printability and adversarial effectiveness, and that an intermediate level of regularization provides the best balance.

Overall, these findings highlight several practical implications for aerial object detection security. They show that aerial detectors are vulnerable not only to digitally optimized perturbations but also to physically deployed patches that remain effective under real-world capture conditions. At the same time, the results reveal that the most effective attack strategy depends strongly on whether the evaluation is conducted in the digital or physical domain. Therefore, robustness assessment for aerial object detectors should not rely solely on digital experiments, but should also consider physical deployment scenarios and environmental variability.

Despite these findings, this study has limitations. First, the experiments are conducted using a single detector architecture, YOLOv3, and the generality of the results to other aerial object detectors remains to be verified. In particular, whether the observed digital-to-physical transfer behavior extends to anchor-free detectors or transformer-based detectors is not investigated in this study. Second, the physical evaluation is limited to a small number of vehicles and capture environments. Third, the OFF-Side configuration is mainly evaluated in the digital domain, and further physical experiments would provide a more complete comparison among all patch types. In addition, the optimization hyperparameters are fixed after preliminary experiments, and a full sensitivity analysis over learning rate, initialization strategy, and optimization duration is not conducted. The reported AORR and OSR values are descriptive averages, and repeated optimization runs, confidence intervals, standard deviations, and significance tests are not included. In addition, the current weather analysis does not explicitly consider dynamic shadows or partial patch occlusion caused

by buildings, trees, or changes in sun position, although such effects are important in real aerial photography. Future work should extend the analysis to additional detector architectures, more diverse aerial scenarios, dynamic shadow and partial-overlap conditions, and defense strategies for improving robustness against physical adversarial perturbations.

IX. Conclusion

This study investigated the transferability of adversarial patches from digital optimization to physical deployment for aerial vehicle detection. Adversarial patches were optimized in the digital domain using an objectness-based loss with Non-Printability Score and Total Variation regularization, and were then evaluated under three placement strategies: ON, OFF, and OFF-Side.

The experimental results showed that the OFF patch achieved the strongest attack effectiveness in the digital domain, indicating that contextual perturbations around the vehicle can strongly suppress detector confidence in simulation-based evaluation. In contrast, the ON patch was more effective in the physical domain, suggesting that object-level perturbations are more robust after printing and real-world deployment. In addition, weather-based augmentation did not improve patch optimization performance in this setting, and the TV loss coefficient was found to have a substantial influence on attack effectiveness.

These results demonstrate that digitally optimized adversarial patches can transfer to real-world aerial environments and significantly degrade the performance of aerial vehicle detectors. More importantly, the study reveals that the most effective patch configuration differs between digital and physical evaluations. This finding highlights the importance of considering physical deployment conditions when assessing the robustness of aerial object detection systems.

Overall, this work provides empirical evidence of the practical vulnerability of aerial object detectors to physical adversarial attacks and offers useful insights for future research on robust aerial perception and adversarial defense.

A Hybrid Ethereum-Based Architecture for Secure Electronic Health Records: Consent, Integrity Anchoring and Auditable Access

Rodica Doina Zmaranda, Attila-Imre Kovacs, Daniela Elena Popescu, Alexandrina Mirela Pater
Department of Computer Science and Information Technology, University of Oradea, Oradea, Romania

***Abstract*—Securing electronic health records (EHR) requires strong guarantees for confidentiality, integrity, access control, and auditability. Traditional centralized architectures rely on database-level protection and internal logging, which remain vulnerable to insider misuse and undetected data modification. This study proposes a practical hybrid architecture in which medical content is stored encrypted off-chain, while blockchain is used selectively as a governance and evidence layer. An Ethereum-based prototype was designed and implemented to support integrity anchoring of medical documents, patient-controlled consent management, and immutable audit trails for critical actions. In the implemented solution, the actual medical content is not stored on-chain. Instead, the blockchain stores only document-related metadata, cryptographic hashes, document references, and access-control information, while the sensitive medical data remains encrypted and stored off-chain. This design supports GDPR-oriented data minimization, since the immutable blockchain layer does not contain raw medical records or directly identifiable medical content. The prototype separates confidentiality from blockchain immutability. Medical document confidentiality is handled at the application and off-chain storage level, while the blockchain is used for integrity verification, consent management, and auditability. Encryption keys are not stored on-chain, which prevents the blockchain layer from becoming a repository of sensitive or directly exploitable medical information. Security mechanisms are integrated directly into application flows, including hash-based tamper detection and on-chain verification of access rights. The prototype is evaluated through realistic operational scenarios, analyzing security properties, performance, and transaction cost implications. Results show that, relative to a DB-only baseline, the hybrid approach provides structurally stronger support for integrity verification, traceability, and accountability without exposing sensitive medical data on-chain. The study also highlights practical limitations related to latency and costs in public blockchain environments, supporting a selective on-chain design focused on high-value operations.**

Keywords*—*Electronic Health Records (EHR); blockchain, ethereum; smart contracts; access control; consent management; auditable access

I. Introduction

Currently, the digitalization of the medical field through EHR is no longer just a problem of computerization, but one of data architecture and governance. In this context, the benefits of EHRs are real, but they are conditioned by the ability of the systems to securely manage sensitive data, to control access in a transparent way and to provide traceability of the actions performed on the data.

Blockchain represents a technology that proposes a distributed ledger in which transactions are recorded in a verifiable form, and the history is difficult to alter without the consensus of the network [1]. The concept was initially popularized by Bitcoin as a mechanism for maintaining a ledger resistant to unauthorized changes in the absence of a central authority [2]. Later, platforms such as Ethereum extended this paradigm by introducing smart contracts – programs that run on the blockchain and can implement business rules and access mechanisms in an automated and transparent way [3].

This study aims to analyze how blockchain technology can support the security and management of electronic health records (EHR), in a practical solution in which blockchain is used as a governance, evidence, and audit layer. From an implementation perspective, each document is registered through the smart contract by storing its hash and associated reference, while a corresponding event is emitted to create an auditable proof of registration. Access control is handled through explicit grant and revoke operations, which update the on-chain permission state and emit audit events for traceability. When a document is requested, the application verifies the current access permission through the smart contract before allowing the off-chain encrypted content to be retrieved and displayed. The approach was supported by the implementation of a functional prototype with a hybrid architecture (web application developed in Next.js, off-chain storage via Prisma/DB and on-chain component on Ethereum in a local test environment), used as a case study to practically validate the basic hypothesis: medical data (content) must be stored off-chain, and blockchain must be used selectively for integrity, consent and traceability, without exposing the medical content. Choosing Ethereum allows for the analysis of practical advantages and limitations of a blockchain solution, based on different criteria such as transaction costs, performance, and considerations regarding on-chain vs. off-chain data storage. The main contributions of this work are as follows:

1) We propose a hybrid Ethereum-based architecture for electronic health records (EHR) that separates sensitive medical data storage from the trust and verification layer. In this architecture, medical data is stored off-chain, while Ethereum is used for governance, integrity anchoring, consent management, and auditability.

This work was funded by the University of Oradea, Romania

2) We introduce a consent-driven access control model implemented through smart contracts, enabling patient-centric authorization workflows across multiple stakeholders. The prototype supports explicit access granting and revocation operations, and each relevant action is recorded through blockchain events to provide an auditable history.

3) We provide a practical design for integrity anchoring of medical records using cryptographic hashes stored on-chain. Each medical document can be linked to an on-chain hash, allowing later verification that the off-chain content has not been modified, while avoiding the exposure of sensitive medical data on the blockchain.

4) Unlike prior work that focuses mainly on permissioned blockchain environments such as Hyperledger Fabric, our approach evaluates the feasibility of using Ethereum as a deployment environment. The work includes a cost-oriented analysis based on gas consumption and varying gas price assumptions, highlighting the economic constraints of public blockchain deployment.

5) We present a prototype implementation and evaluate its performance characteristics in a local Ethereum-based testing environment. The evaluation highlights the difference between local testing conditions, where transaction execution is fast and cost-free, and public blockchain deployment, where latency, gas costs, and scalability constraints must be considered.

6) We discuss the architectural implications of key management and off-chain encryption for secure real-world deployment. In the implemented prototype, encryption and sensitive data handling are kept outside the blockchain layer, while the blockchain stores only hashes, references, permissions, and audit-relevant events. This separation reduces the exposure of sensitive medical information and supports a more GDPR-aligned system design.

The study is structured as follows: Section II presents the related work and the implementation gap that motivates the proposed architecture; Section III presents the architecture and security requirements of the Blockchain (Ethereum)-based EHR prototype; Section IV describes the security issues and their integration into the application functional flows; furthermore, a comprehensive analysis and discussions regarding advantages and limitations based on several criteria such as security, performance, scalability and costs, were presented in Section V. Finally, some conclusions were drawn.

II. Related Work and Identified Research Gap

Existing research on blockchain-based EHR systems can be grouped into three main directions: conceptual frameworks and literature reviews, prototype-oriented implementations, and studies focused on the trade-offs between on-chain and off-chain storage. The first group, represented by surveys and framework papers [4]-[9], confirms the relevance of blockchain for healthcare interoperability, privacy and auditability, but most contributions remain at an architectural or conceptual level and do not describe an executable application flow that combines encrypted off-chain storage, smart-contract consent and hash-based integrity verification in a single prototype.

A second group contains practical implementations, including solutions based on permissioned environments such as Hyperledger Fabric [10] or more general blockchain-based record-management prototypes [11]. These works are valuable because they show that blockchain can be integrated with healthcare workflows, but they often assume a controlled consortium setting, focus mainly on record registration, or do not explicitly analyze the cost implications of Ethereum-style public deployment. As a result, the specific operational tension between public-chain transparency, transaction fees, medical confidentiality, and GDPR-oriented data minimization remains insufficiently addressed.

The third direction discusses the general storage trade-off between keeping data on-chain and storing only proofs or references off-chain [12]. This literature motivates the hybrid design adopted in this study. However, the identified limitation is that the storage trade-off is frequently discussed independently from concrete EHR consent flows. The proposed prototype addresses this gap by combining three mechanisms in the same implemented case study: encrypted off-chain medical documents, on-chain consent state through grant/revoke operations, and on-chain integrity anchoring through cryptographic hashes and audit events.

Therefore, the purpose of this work is not to replace existing EHR platforms or to claim production-level scalability from a local prototype, but to validate a concrete hybrid security pattern and to analyze its practical implications. The novelty of the study lies in the integrated implementation and evaluation of consent, integrity anchoring, and auditable access in an Ethereum-compatible setting, while explicitly keeping sensitive medical content outside the blockchain layer.

III. Case Study – Blockchain (Ethereum) - Based EHR Prototype

A. Prototype Architecture

To analyze and evaluate a blockchain-based EHR solution, a functional Ethereum-based EHR prototype was developed in a local environment to analyze, in a reproducible way, how security advantages such as integrity, auditability, and consent-based access control can be obtained, as well as investigating the problems that such implementations raise from a practical implementation perspective.

The approach, based on a realistic design, tries to reduce exposure and avoid storing clinical content in raw form on a replicated ledger; for this reason, the prototype uses a hybrid architecture: off-chain for content (document content + operational metadata - local database via Prisma ORM [13]) and on-chain for governance and integrity (access rules, integrity proofs - hashes and audit trails - events). This pattern, frequently recommended in healthcare literature, balances confidentiality with verifiability [14].

The prototype is built around three functional modules, visible in the application interface as separate sections and reflected in the overall architecture presented in Fig. 1, which illustrates the explicit separation between the off-chain and on-chain areas as a main security requirement of the project:

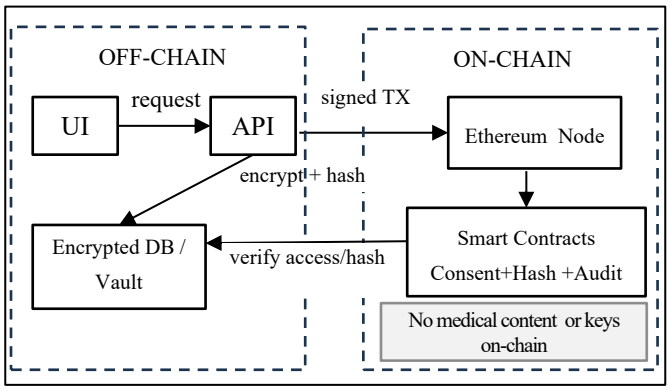

Fig. 1. Overall architecture with off-chain/on-chain storage.

- Document Vault (off-chain): upload, encrypted storage, metadata, indexing, document listing.
- Consent Manager (on-chain + application): grant/revoke access for doctors, with verifiable status on-chain.
- Audit Explorer (on-chain + application aggregation): visualization of events issued by smart contracts (registered document, granted/revoked access), as an "append-only" chronological log.

From the implementation perspective, the prototype is composed of several components. The web client (Next.js UI) is represented by an interface logically separated by roles (patient/doctor). UI offers: uploading documents (patient), listing own documents (patient), granting/revoking access to a doctor (patient), accessing allowed documents (doctor), viewing the audit (both roles, with different levels). Backend (Next.js server: API routes/server actions) performs security logic such as input validations, encryption/decryption, hash calculation, DB interaction (Prisma), calls to smart contracts (local Ethereum). Local blockchain (Ethereum in our test environment) implements contracts for permissions (grant/revoke), recording hashes, issuing audit events. Off-chain storage (DB + Prisma) keeps encrypted content, keeps metadata necessary for searching/listing, and keeps the link between an off-chain document and its on-chain proof (e.g. docId + hash + txHash / blockNumber).

B. Functional and Security Requirements

The functional requirements of the prototype include the following: register users with distinct roles (e.g. patient, doctor); upload medical documents (e.g. results, reports, medical letters) and associate them with the patient; grant access by the patient to a doctor (grant), with the possibility of revocation; consult documents by the doctor only if there is active permission; maintain an audit trail for critical actions (upload, grant, revoke, consult).

Security requirements (what the system must protect) are represented by:

- Confidentiality - medical content must not be exposed publicly; access must be conditioned and controlled.
- Integrity - any unauthorized modification of documents stored off-chain must be detected.
- Auditability / non-repudiation - relevant actions must be traceable (who granted access, when it was revoked, etc.).
- Data minimization - only strictly necessary data is stored on the blockchain (hashes, technical identifiers, events).
- Separation of responsibilities - neither the blockchain nor the database are sufficient on their own; security is achieved end-to-end (application + DB + contracts + keys).

1. User
id (UUID)
role (PATIENT / DOCTOR)
displayName
ethAddress (0x… associated with the wallet account)
createdAt
2. Document
id (UUID – internal docId)
ownerUserId (pacient)
type (ex: analyses, imaging, letter, recipe)
createdAt (moment upload)
ciphertext (blob / encrypted file) or internal pointer if storing in filesystem
cipherAlgo (ex: AES-256-GCM)
hashAlgo (ex: SHA-256)
contentHash (consistently calculated hash)
sizeBytes
anchorTxHash (tx on blockchain)
anchorBlockNo
status (ACTIVE / TAMPERED / REVOKED_BY_OWNER)
3. PermissionCache (optional, for UI performance)
patientUserId
doctorUserId
statusLocal (informational mirror)
lastCheckedAt

Fig. 2. Entity conceptual model.

The off-chain component is represented by a local database accessed through Prisma ORM. The reason for this choice is twofold: from a performance perspective, it ensures efficiency for searches, listings, and file/metadata storage, and from a security perspective it ensures increased confidentiality, with the medical content remaining in a controllable area, where classic policies can be applied (backup, encryption, access control, retention). In the prototype, the off-chain modelling aims to clearly separate the following elements:

- Application identity data: users, roles, mapping to an Ethereum address (for signing transactions).
- Medical documents: content (stored encrypted or in protected form), metadata (type, date, issuer).
- Access bindings: a local representation of permissions (optional), used for UX and caching, but the final decision is made based on the on-chain state.
- Application audit: useful internal logs (e.g., errors, requests), separate from the on-chain audit (which covers critical actions).

The on-chain model uses Ethereum/Ganache for governance, permissions, and audit; the component is represented by a set of smart contracts implemented in Solidity [15] and run on a local Ethereum network (Ganache [16]). Their

role is to be a verifiable registry for: access permissions (grant/revoke – formal decision, signed by the patient through a transaction); integrity proofs (the document hash, anchored in the registry); audit events – critical actions are reflected through events, so that the audit can be rebuilt.

The design of the contracts follows a strict principle: no medical content or explicit clinical information is stored on-chain. The contract only contains elements such as technical identifiers, such as document IDs, hashes, Ethereum addresses, logical timestamps, and events. It can be seen that the key to the approach is minimization: in the DB, only what is necessary for operation and security is kept, and in the blockchain, only the evidence/documents and rules are kept.

IV. Security Issues and Implementation into Functional Flows

Both on-chain and off-chain layers require specific approaches from the security point of view for implementation:

A. Security in the Off-Chain Data Model (Database)

In the prototype, the DB has the role of enforcing a series of security invariants: the medical content is stored encrypted; there is no "direct read" of the content without on-chain verification; the document is associated with a hash and with the reference to the on-chain proof; permissions are doubly conditional: on-chain state + integrity validation.

A conceptual model of tables/entities (compatible with our Next.js + Prisma implementation) is presented in Fig. 2.

The model clearly separates the identity and roles of users, the protected medical content, and the metadata necessary for operation, respectively, the verifiable link to the on-chain proofs. Thus, the medical content remains off-chain and encrypted (confidentiality), the integrity is verifiable through anchored hashes (integrity), and critical actions are linked to on-chain transactions and events (auditability and traceability).

It is noted that the User entity contains only the minimum information necessary for operation (id, role, display name) and a blockchain layer connection field (ethAddress), used for mapping between the application account and the address that signs transactions. Choosing this field allows auditability and non-repudiation for critical operations (grant/revoke/register), while keeping the detailed clinical identity off-chain (data minimization principle).

The Document entity is designed so that the medical content remains off-chain, protected: the ciphertext field (or an internal pointer to the encrypted file) allows the data to be stored in encrypted form, and the cipherAlgo and hashAlgo fields explicitly document the algorithms used (e.g., AES-256-GCM, SHA-256), increasing reproducibility and verifiability. The contentHash field represents the consistently calculated fingerprint of the content and is the key to the integrity mechanism: upon access, the recalculated hash from the DB is compared with the anchored value. The anchorTxHash and anchorBlockNo fields directly link the off-chain document to the on-chain transaction in which the proof was recorded, allowing independent verification of the moment and existence of the proof.

The status field (ACTIVE/TAMPERED/REVOKED etc.) is introduced to reflect the security state observed by the application (e.g. hash mismatch → TAMPERED) and to prevent displaying a suspicious document.

The PermissionCache entity is optional and has a strictly UI performance role: it can locally store the result of the last on-chain check (per patient–doctor–document), together with lastCheckedAt, to reduce repeated calls to the contract in fast navigation scenarios. Importantly, this entity is not the source of truth for permissions; the final access decision remains on-chain (hasAccess), and the cache is only an information mechanism that can be revalidated/invalidated based on events (AccessGranted/AccessRevoked) or upon expiration.

B. Security and On-Chain Layer: Smart Contracts and Executable Rules (consent + Audit)

In the prototype, the blockchain is used strictly as a governance and evidence layer. For clarity and a small attack surface, it is recommended to use a two-contract design.

Contract 1 – ConsentRegistry (used for permissions) has the following responsibilities: stores the state of permissions: patient → doctor → allowed/denied; optional: includes expiration (timestamp) and a minimal "scope" (document types). Typical functions are the following: grantAccess (address doctor, uint64 expiresAt) – called by the patient; revokeAccess(address doctor) – called by the patient; hasAccess(address patient, address doctor) – view (used by the server). Typical audit events: AccessGranted(patient, doctor, expiresAt); AccessRevoked(patient, doctor).

Contract 2 – DocumentAnchor (used for hashes), has the following responsibilities: records the proof of integrity for documents: (patient, docId) → hash; emits a DocumentAnchored event on each record. Typical functions: anchorDocument(bytes32 docId, bytes32 contentHash) – called by the patient (or by an authorized "uploader" on their behalf); getHash(address patient, bytes32 docId) – view. Typical events: DocumentAnchored(patient, docId, contentHash).

A justified design decision in this regard is that the events are intentionally minimal: they do not include diagnoses, results, document names, or other sensitive metadata, containing only technical identifiers and actions (grant/revoke/anchor).

C. Integrating Security Issues into Implementation Flows

One of the challenges of the implementation was to integrate security elements as smoothly as possible into the functional flows of the application.

Flow A – Document upload, off-chain protection, and on-chain anchoring of proof of integrity is shown in Fig. 3.

- Step 1 (UI – patient): patient uploads a .pdf file, e.g., analyses
- Step 2 (server): backend validates file type and size; generates a per-document symmetric key; encrypts the content (e.g., AES-256-GCM); calculates a hash (e.g., SHA-256) over encrypted content (or over original content – it is important to be consistent); saves in DB: ciphertext, contentHash, docId, metadata.

- Step 3 (on-chain): application sends transaction anchorDocument(docId, contentHash) to contract; contract records hash and issues DocumentAnchored.
- Step 4 (DB completion): DB is updated with anchorTxHash and anchorBlockNo.

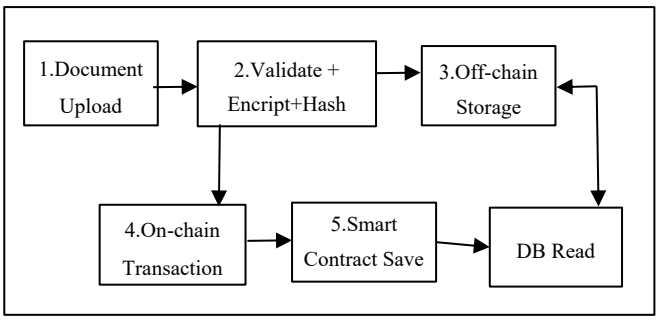

Fig. 3. Document upload, off-chain protection, and on-chain anchoring of proof of integrity.

Flow B – Granting access and document consultation sequence (permission + integrity check) is shown in Fig. 4.

- Step 1 (UI – patient): patient selects a doctor (e.g. 0xB2...) and sets duration (e.g. 7 days).
- Step 2 (on-chain): transaction grantAccess(doctor, expiresAt) is sent; contract updates permission state and issues AccessGranted.
- Step 3 (UI/Audit Explorer): event appears in log: AccessGranted – patient X → doctor Y.

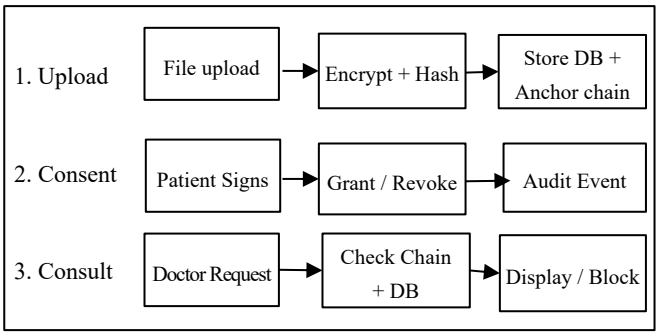

Fig. 4. Granting access and document consultation sequence (permission + integrity check).

Thus, in the prototype, a grant is a cryptographically signed transaction (patient wallet) and produces an on-chain event, which makes consent easier to prove and harder to challenge later (who, to whom, for what and when).

Flow C – doctor's document consultation (access control + integrity), involves the following steps:

- Step 1 (UI – doctor): the doctor requests the document docId = 7b2f.
- Step 2 (server): the application runs: hasAccess(patient, doctor) - view on-chain → if false, stops; retrieves ciphertext from DB; recalculates the hash on the content (same method as for upload); extracts the on-chain hash from getHash(patient, docId); compares hashes: if they do not match → status = TAMPERED, access blocked + alert; if everything is valid → decrypts and displays the content.

As an observation related to security, it should be mentioned here that the blockchain does not "keep" the document, but acts as a log: any subsequent change becomes detectable. At the time of upload, the document's cryptographic fingerprint (hash, e.g. SHA-256) is calculated, and this value is anchored on-chain (via registerDocument and/or the DocumentRegistered event). Subsequently, at each consultation, the application recalculates the hash on the document retrieved from off-chain storage and compares it with the anchored hash; if the file has been modified, replaced, or corrupted in the database, the recalculated hash will be different, and the discrepancy becomes an objective indicator of alteration, causing access to be blocked/decryption denied or the document to be marked as invalid.

Flow D – Access Revocation involves the following steps:

- Step 1 (UI – patient): the patient revokes the doctor's access.
- Step 2 (on-chain): a transaction revokeAccess(doctor) is made; an AccessRevoked event is generated.
- Step 3 (practical effect): any further consultations are blocked at Step 2 of scenario C (permission check).

An inherent limitation in this context is that revocation does not "erase" the fact that the doctor has already seen the document. It only stops future access; therefore, auditing and organizational policies remain necessary.

Flow E – Tamper detection: in this scenario, if an attacker (or operational error) modifies the ciphertext in the DB, then:

- upon access, the recalculated hash no longer matches the hash anchored on-chain;
- the application marks the document as TAMPERED;
- blocks decryption and display.

This is exactly where the prototype offers a structural advantage over a traditional DB-only implementation: there is an external, immutable proof of the "original state" (the hash anchored on-chain) that cannot be rewritten by accessing the off-chain infrastructure. In a traditional system, an attacker or a privileged administrator who compromises the DB can, at the same time, modify the document, update the metadata (including any hash stored internally), and adjust the application logs to reduce the chances of detection.

In the prototype implementation approach, even if the file in the DB is replaced or edited, the hash recalculated upon consultation will no longer coincide with the value recorded on-chain, and the discrepancy becomes an objective technical indicator of the alteration (tamper evidence). To "hide" the alteration, the on-chain evidence (the anchored hash) would also have to be modified, which is not possible retroactively without a new transaction visible in the history and, implicitly, without leaving audit trails (timestamp/block number). Therefore, the blockchain transforms integrity from a trust-based property into a verification-based property, where the document is accepted

only if it passes cryptographic validation reported to the on-chain anchor.

D. Privacy and GDPR Compliance

The proposed system operates in the context of electronic health records (EHR), which are classified as special category data under Article 9 of the General Data Protection Regulation (GDPR) [17]. As such, privacy protection and data minimization are fundamental requirements of the architecture.

A key challenge arises from the conflict between blockchain immutability and the "right to erasure" under Article 17 GDPR [17]. The proposed architecture mitigates this issue by ensuring that no raw personal data or medical records are stored directly on-chain. Instead, the blockchain stores only cryptographic hashes, document references, access permissions, and audit-relevant events, while the actual medical content is kept encrypted in off-chain storage. As a result, sensitive off-chain data can be deleted, modified, or made inaccessible when required, without needing to alter immutable blockchain records.

The system also supports a consent-driven authorization model. Patient consent is represented through smart contract-based access control operations, such as granting and revoking access to a medical document. These operations create a verifiable audit trail through blockchain transactions and events, allowing the system to demonstrate when access was granted, revoked, or checked.

Data minimization principles under Article 5 GDPR are addressed by limiting the information stored on-chain to technical verification data [17]. No direct identifiers, raw medical records, diagnoses, treatment details, or other sensitive health information are stored on the blockchain. The on-chain hash is used only as an integrity proof, allowing the application to verify whether the corresponding off-chain document has been altered.

Regarding cross-border data transfer under Article 44 GDPR, the use of public Ethereum infrastructure may introduce additional compliance risks, since blockchain nodes can be distributed across multiple jurisdictions [17]. For a real-world deployment, this risk could be mitigated by using controlled access gateways, EU-based node providers, private or consortium Ethereum-compatible networks, or infrastructure operated by trusted healthcare institutions.

Finally, encryption and key management remain critical for confidentiality. In the prototype, confidentiality is handled outside the blockchain layer: medical documents are stored off-chain in encrypted form, while the blockchain is used for integrity verification, access control, and auditability. Encryption keys are not stored on-chain, reducing the risk that immutable blockchain records could expose sensitive or directly exploitable medical information

E. Key Management and Data Protection

The security of the proposed system depends not only on the smart contract logic, but also on the protection of the off-chain medical data and the cryptographic material used to secure it. Since the blockchain is not used to store medical content directly, the confidentiality of the system relies on the encryption and access-control mechanisms implemented at the application and off-chain storage layers.

In the implemented prototype, medical document confidentiality is handled outside the blockchain layer. The blockchain stores only hashes, references, access permissions, and audit events, while the sensitive document content is stored off-chain. This separation ensures that the blockchain can provide integrity verification and auditability without becoming a repository of confidential medical information.

Encryption keys are not stored on-chain. This is an important design decision because any data written to a blockchain should be considered persistent and difficult or impossible to remove. Keeping keys outside the blockchain prevents unauthorized users from deriving access to medical content directly from blockchain data.

For a production-ready implementation, a more advanced key management model would be required. One possible approach is to encrypt each medical document using a document-specific symmetric key and then protect that key using the public keys of authorized users. Under such a model, only users with the corresponding private keys would be able to decrypt the medical data. However, this introduces additional requirements related to secure private key storage, recovery mechanisms, access revocation, and user usability.

Revocation of access is also an important practical consideration. In the prototype, access revocation is represented at the smart contract level by updating the on-chain permission state. This prevents a previously authorized user from passing future access checks through the application. However, in a real-world system, stronger revocation guarantees may require re-encryption of the off-chain data and redistribution of new keys to the remaining authorized users.

Therefore, the architecture assumes that blockchain-based authorization must be combined with secure off-chain key lifecycle management. Future improvements may include integration with hardware-backed keystores, hardware security modules, decentralized identity frameworks, or institutional key management services suitable for healthcare environments.

For a production deployment, the key lifecycle would need to be specified in more detail. Key rotation could be implemented through envelope encryption, where each document key is wrapped by user or institutional public keys and can be re-wrapped without rewriting the encrypted document itself. Multi-device access would require controlled enrollment of additional user keys, while emergency recovery or break-glass access would require explicit institutional policy, strong authentication, and additional audit events. Institutional delegation and insider threats should be handled through role separation, least privilege, hardware-backed key storage, and periodic access reviews. In practice, these controls would normally be implemented through a healthcare-grade KMS/HSM or institutional identity infrastructure rather than directly through the blockchain.

While the proposed architecture improves integrity, auditability, and transparency, several security considerations must be addressed before real-world deployment.

One potential risk is the use of application-level caching mechanisms for access permissions. If permission data is cached, there is a possibility of stale-state inconsistencies, for example when access has been revoked on-chain but the application still relies on an outdated cached permission state. This risk can be reduced through short cache lifetimes, explicit cache invalidation after grant or revoke operations, and periodic revalidation against the smart contract state.

Another important consideration is the reliance on off-chain storage. Since medical documents are not stored directly on-chain, the system depends on the availability and security of the external storage layer. This introduces trust assumptions regarding storage infrastructure, backup policies, and operational security. However, the impact of this risk is reduced by encrypting the off-chain content and verifying document integrity against the hash anchored on-chain.

The correctness of the smart contract logic is also essential. Functions responsible for document registration, access granting, revocation, and permission checking must be carefully designed to prevent unauthorized access or inconsistent authorization states. Since smart contract transactions are immutable once deployed, contract testing and validation are critical before deployment to a production blockchain environment.

Finally, the overall security of the system depends heavily on cryptographic key protection. If a user's private key or application-level encryption material is compromised, unauthorized access to medical documents may become possible. Therefore, secure key storage, recovery mechanisms, user awareness, and institutional security policies are necessary components of any real-world deployment.

V. Analysis and Discussions

A. Security Analysis and Evaluation

The security analysis based on the prototype case study is structured on the following criteria: confidentiality, integrity, availability, complemented by access control and auditability.

1) Threat model and security invariants: To make the security evaluation more explicit, the prototype can be interpreted under the following threat model: an attacker may attempt to read or modify off-chain stored documents, an unauthorized doctor may attempt to access a patient document without consent, a stale application cache may preserve an outdated permission state, or a privileged infrastructure actor may attempt to alter local database records or logs. The model does not claim to solve denial-of-service attacks, theft of a user's private key, or all smart-contract implementation bugs; these remain deployment risks that require additional operational controls.

The main security invariants enforced by the prototype are: I1 - raw medical content and encryption keys are never written on-chain; I2 - a document is displayed only if hasAccess(patient, doctor) returns an active permission state; I3 - the hash recalculated from the off-chain content must match the hash anchored on-chain before decryption/display; I4 - PermissionCache is never the source of truth and cannot override the smart contract state; I5 - grant, revoke and anchor operations generate auditable events that can be reconstructed independently from the application database.

Against these invariants, the defense mapping is concrete: database tampering is detected by the mismatch between the recalculated hash and the on-chain anchor; unauthorized access is blocked by the hasAccess check; stale-cache risk is mitigated by short cache lifetime, event-based invalidation and revalidation against the contract; modification of centralized logs does not remove the blockchain event history. Smart contract vulnerabilities are reduced by a small contract surface and testable state transitions, but formal verification and third-party audit would be required before production deployment.

Confidentiality is achieved by: off-chain storage of content; encryption at the application level (before DB); decryption conditional on on-chain verification + integrity. The specific blockchain risk (in public networks) is leakage through metadata and address correlations. In the prototype (local), the risk is low, but for a real system, mitigation measures should be mentioned: minimization of events, pseudonymization, avoiding including the on-chain document type, aggregation, and rate-limiting at the UI/API level. However, blockchain solution privacy remains dependent on encryption and key management (off-chain). Blockchain does not guarantee privacy by itself; it only reinforces it through a design that minimizes what is public.

Integrity is strengthened by on-chain anchored hash and verification at each access. This mechanism is simple, cheap to implement, and very strong as "proof": any difference between the stored content and the anchored proof becomes immediately visible at the time of access, without relying exclusively on centrally managed logs. From an integrity perspective, there is a clear advantage of the blockchain solution: integrity becomes verifiable through an external proof (on-chain hash), not just through trust in the administration.

Regarding access control and consent (non-repudiation and accountability), as shown in the prototype, consent is not a setting in the DB, but a verifiable state on-chain. This produces two effects: access becomes independently verifiable (at least at the system level) and actions become traceable and hard to deny (transaction signature). Grant/revoke actions are cryptographically signed transactions (address/key), and the change of permission state is recorded on-chain. This results in an important practical property: stronger non-repudiation for critical actions (who granted/revoked access and when). In addition, the prototype applies "double checking": even if the DB contains the document, actual access is conditional on on-chain permission verification + hash integrity verification. Thus, from an access control perspective, the blockchain solution reduces the risk of "invisible" abuse at the consent level and makes access decisions easier to prove later.

Audit is built on on-chain events (grant/revoke/anchor). The advantage over centralized logs is the append-only nature and transaction signing. Basically, even if the DB is compromised, the main history of critical actions remains reconstructable from the chain: on-chain events (DocumentAnchored, AccessGranted, AccessRevoked, etc.) are append-only and can be used to reconstruct a verifiable timeline of critical actions. Consequently, from the audit perspective, there is a real

auditability gain, especially for critical actions, in the hybrid blockchain model, as the on-chain log is harder to tamper with without a trace.

Because the content is still off-chain, the availability of documents still depends on the DB and the application. Blockchain does not replace storage and does not solve availability on its own. Thus, the hybrid blockchain approach does not eliminate the off-chain dependency: if the DB goes down, the documents are not accessible, even if the evidence is on the chain. Therefore, in a real architecture, availability remains largely a classic problem and relies on classical approaches (backup, replication, monitoring).

2) Qualitative comparison with a DB-only EHR baseline: The baseline considered for the security comparison is a conventional centralized EHR implementation in which the document, the stored hash, permission flags, and audit logs are all maintained inside the same administrative database or infrastructure domain. In such a baseline, a privileged compromise can modify the medical file and also rewrite the associated hash, permission record, or local audit trail. In the proposed hybrid architecture, the attacker would additionally have to change the previously anchored on-chain hash or remove historical grant/revoke events, which is not possible retroactively without creating a new visible transaction. Therefore, the improvement claimed in this study is a structural and verifiability-oriented improvement, not a quantitative throughput comparison against an independently implemented EHR system.

B. Performance and Scalability Analysis

The performance of a hybrid EHR (off-chain + on-chain) cannot be evaluated as a single "response time", because the flows have two distinct components: 1) off-chain operations, which dominate the user experience (upload, read, list), and 2) on-chain operations, which dominate the governance decision (consent, anchor, audit).

1) Measurement methodology: The measurements were performed in the local environment of the prototype, using the following approach: measured end-to-end time for each operation (from the action in the UI to the response received by the user); separation of times by stages, where relevant: 1) server processing (validation + encryption + hash), 2) DB operation (Prisma), 3) blockchain interaction (submit tx + confirmation), 4) access checks (hasAccess + getHash + compare).

For on-chain operations, two different values were measured: t_submit (how long it takes to send the transaction, until you receive txHash); t_confirm (how long it takes until the transaction is mined/confirmed and the event is available). This separation is important because the UX can be designed so that the user does not "wait in a blocking way" for confirmation in some cases (e.g., anchoring can run asynchronously), but for other cases confirmation is critical (e.g., grant/revoke must be confirmed to be considered active).

2) Example measurements on the prototype case-study: Table I summarizes average values measured on a set of common files and on typical scenarios (upload, grant, consultation).

TABLE I. AVERAGE TIMES PER PROTOTYPE (MS) – END-TO-END MEASUREMENT (LOCAL ENVIRONMENT)

Operation	Measurement results		
	Dominant Components	***Average Time (ms)***	***Observations***
Upload document 1 MB (off-chain)	encryption + DB write	~180–320	does not include on-chain confirmation
Hash calculation (SHA-256)1 MB	CPU (server)	~8–15	subdominant to IO
AES-256-GCM 1 MB encryption	CPU (server)	~25–60	depends on implementation
Save DB (Prisma) 1 MB	IO DB	~60–180	depends on local DB
Submit transaction anchor (txHash)	RPC + signing	~120–250	user sees "sent"
Confirm transaction (Ganache)	local mining	~400–900	stable in controlled environment
GrantAccess (submit)	RPC + signing	~120–250	similar to anchor
GrantAccess (confirm)	local mining	~400–900	becomes active after confirmation
Consult document (verify + display) 1 MB	hasAccess + DB read + compare + decrypt	~220–520	includes on-chain checks (view)

The values are indicative for the local environment and serve to highlight where costs arise and which components dominate. From measurements, we can notice that for off-chain operations, the cost is dominated by I/O (DB) and encryption. Hash is fast and does not represent a significant bottleneck. Also, for on-chain operations, confirmation is the most "visible" component if it is put directly into the clinical flow (the user waits). In the local prototype, confirmation is stable; in real public networks, this latency is variable and can increase significantly. Document consultation remains comparable to a traditional system in terms of access time, with a moderate overhead due to checks (hasAccess + getHash + compare), but with a security gain (integrity + verifiable access control).

3) Interpretation of local measurements and deployment limits: The measurements in Table I must be interpreted as prototype-level measurements obtained in a local Ganache environment. They validate the correctness of the implemented flows and identify the dominant components inside the prototype, but they do not prove public Ethereum feasibility. Ganache eliminates variable consensus latency, fee volatility,

and network congestion; therefore, the public deployment discussion in this study is limited to gas-based cost estimation and architectural implications. A real deployment would require additional testing on public test networks, layer-2 networks, or a controlled consortium network.

The prototype was not stress-tested with thousands of patients, concurrent doctors, or very large repositories. In a production architecture, high-frequency actions should remain off-chain, while on-chain operations should be limited to high-value state transitions such as document anchoring and consent updates. Operational resilience would also require transaction queues, retry and idempotency logic for pending blockchain operations, redundant blockchain RPC providers or nodes, database replication and backups, monitoring, and a fail-closed access policy when the system cannot verify current permission or integrity state.

Storage overhead introduced by the hybrid model is limited compared with the medical files themselves. For each document, the additional off-chain fields include an internal document identifier, content hash, hash/encryption algorithm identifiers, initialization vector and authentication tag for encryption, transaction hash, block number and status flags. These artifacts are typically below a few kilobytes per document, while the medical document can be several megabytes. The on-chain footprint is dominated by the stored hash/reference and event data, while detailed audit records and application logs should remain off-chain or be periodically anchored to avoid high costs.

The current evaluation uses fixed representative parameters, such as a 1 MB document and a moderate number of annual grant/revoke/access operations. A complete sensitivity analysis should vary document size, document frequency, transaction frequency, cache lifetime, encryption overhead, number of users, and concurrent requests. This limitation is acknowledged because the present study focuses on validating the security pattern and estimating cost order of magnitude, not on exhaustive capacity planning.

C. Costs Analysis

1) Premises for comparison (annual scenario): The cost estimations were made on a moderate scenario, realistic enough to estimate their order of magnitude. The assumptions on which the analysis was based are presented in Table II.

TABLE II. PREMISES FOR COST ASSESSMENT (ANNUAL SCENARIO, PER PATIENT)

Parameter	Value (scenario)	Observations
New documents / patient / year	10	e.g.: tests, imaging, medical letter
Average document size	1 MB	order of magnitude for common files
Stored volume / patient / year	10 MB	10 doc × 1 MB
Document requests / year	20	doctor requests for access
Access grants / year	4	access grants (consent)
Access revokes / year	4	revoke access

In public Ethereum, each on-chain operation has a transaction cost (fee), calculated by:

$$\text{fee (ETH)} = \text{gasUsed} \times \text{gasPrice} \quad (1)$$

where, gasPrice is in gwei (1 gwei = 10^-9 ETH).

In the local prototype (Ganache), this monetary cost is practically 0, but in a real scenario (public Ethereum) the cost becomes relevant. For example, we use a further estimation valid at present of price_eth = 2,212.07 EUR/ETH. Plausible estimates for minimalist contracts (mapping + events) were the following: document anchor (hash + event): 95,000 gas; grant access (grant + event): 60,000 gas; revoke access (revoke + event): 45,000 gas; log access (optional audit event): 35,000 gas. GasPrice scenarios (so as not to be "cosmetic numbers") could be chosen from the following: 10 gwei (low), 30 gwei (medium), 60 gwei (high). Consequently, the direct formula that we used will be:

$$\text{Cost (EUR)} = \text{gasUsed} \times \text{gasPrice(gwei)} \times 10^{-9} \times \text{price_eth (EUR/ETH)} \quad (2)$$

2) Costs comparison results: It can be seen from Table III that, in public Ethereum, there are significant cost per access, making a model where "everything is logged on-chain" unsustainable. This leads to the correct conclusion: on public networks, blockchain is suitable for rare high-value operations (anchors, critical consent), not for turning every access into a transaction. Therefore, for real adoption, some architectures preserve integrity/auditability, but drastically reduce the cost. One of the options is represented by off-chain audit + periodic on-chain anchoring or networks (predictable operational cost).

TABLE III. HYBRID EHR COST ESTIMATION ON PUBLIC ETHEREUM (10, 30, 60 GWEI VARIANTS)

Parameter	Costs Public Ethereum /year		
	10 gwei	***30 gwei***	***60 gwei***
10 document anchors/year/pacient	21 EUR	63 EUR	126 EUR
20 document requests / year (audit)/pacient	15,40 EUR	46,40 EUR	92,80 EUR
4 Access grants / year	5,32 EUR	15,92 EUR	31,84 EUR
4 Access revokes / year	4,00 EUR	11,96 EUR	23,92 EUR
TOTAL/pacient/year	**45,72 EUR**	**137,28 EUR**	**274,56 EUR**
TOTAL for 10000 pacients	**457.200 EUR**	**1.372.800 EUR**	**2.745.600 EUR**

VI. CONCLUSION

This study demonstrates that a hybrid blockchain architecture provides a robust framework for Electronic Health Records (EHR), where integrity stands out as the most direct and demonstrable benefit. The developed prototype confirms that blockchain serves as an essential tamper-evident mechanism, making any modification, replacement, or corruption of documents within the database objectively detectable. Through this approach, consent and access control transcend being internally modifiable states; they become a transparent set of actions with verifiable traces, documenting precisely who granted access, to whom, for which document, and when.

Regarding regulatory compliance and data protection, the architecture was designed to support GDPR-oriented requirements by enforcing a strict separation between sensitive medical data and immutable blockchain records. The implemented prototype does not store raw personal information or medical content on-chain. Instead, the blockchain layer stores only cryptographic hashes, document references, access permissions, and audit-relevant events, while the actual medical documents remain encrypted and stored off-chain. This design supports the principle of data minimization and reduces the risk of exposing sensitive health information through immutable blockchain records.

Privacy is therefore not treated as an inherent blockchain feature, but as an end-to-end architectural responsibility. The blockchain is used for integrity verification, consent management, and auditability, while confidentiality is handled at the application and off-chain storage layers. During document retrieval, the application verifies the current on-chain access permission and the integrity of the requested document before allowing the encrypted off-chain content to be accessed and displayed. Encryption keys are not stored on-chain, which prevents the blockchain layer from becoming a source of sensitive or directly exploitable medical information.

The feasibility of this model depends on a selective on-chain design. To mitigate the high costs and variable fees associated with public Ethereum transactions, only the critical minimum—cryptographic evidence, consent updates, and essential events—is recorded on-chain. Detailed auditing and intensive data operations remain off-chain to maintain a controllable cost profile and competitive user experience (UX) performance.

While the current evaluation was conducted in a local Ganache environment, the prototype provides a functional proof of concept for the proposed architecture, including document registration, hash-based integrity anchoring, access granting, access revocation, and permission verification. The local environment was suitable for validating the correctness of the smart contract logic and the interaction between the application layer and the blockchain layer, but it does not fully capture the operational characteristics of a public Ethereum network.

Consequently, the results should be interpreted as a functional proof of concept and as an order-of-magnitude cost and security analysis. They should not be read as evidence that the same performance would be obtained on public Ethereum or under large healthcare workloads without further load testing, operational hardening, and production-grade key management.

Further research will also explore the adoption of permissioned or consortium networks for increased identity control and the integration with medical standards such as FHIR/HL7. Ultimately, this hybrid approach proves that blockchain can effectively serve as a specialized consent and audit layer, seamlessly integrating with existing healthcare infrastructures while ensuring security, accountability, and legal compliance.

Using Artificial Intelligence Techniques for Error Detection and Repair in Software Development

Abdulaziz Aladwani, Sultan Alsamaani, Turki Alrumaykhani, Mohamed Tahar Ben Othman
Department of Computer Science-College of Computer, Qassim University, Qassim, Saudi Arabia

***Abstract*—Software bugs remain one of the most costly challenge in software engineering, consuming significant development time and resources. Recent advances in Artificial Intelligence (AI), particularly deep learning and large language models (LLMs), have shown remarkable potential in automating the detection and repair of software errors. This study presents a comprehensive survey and comparative analysis of AI-based techniques for error detection and automated program repair (APR). We categorize existing approaches into traditional search-based methods, learning-based neural machine translation models, and emerging LLM-based repair systems. We evaluate these techniques across standard benchmarks, including Defects4J and SWE-bench, comparing their effectiveness in terms of bugs fixed, patch correctness, and scalability. Our analysis reveals that while LLM-based approaches significantly outperform traditional methods in repair capability, challenges remain in patch correctness validation, computational cost, and generalization to real-world codebases. Our results show that LLM-based tools, such as ChatRepair, can correctly fix 114 out of 395 benchmark bugs at just $0.42 per fix, fixing 2.6× as many bugs as the best traditional method (a 165% increase). We discuss open challenges and propose future research directions toward more reliable AI-assisted software development.**

Keywords*—Automated program repair; bug detection; deep learning; large language models; software engineering; neural machine translation; defect prediction; code analysis

I. Introduction

Software defects are an inherent part of the software development lifecycle, costing the global economy an estimated $1.56 trillion annually, according to the Consortium for Information and Software Quality (CISQ). Debugging and fixing software errors account for a substantial portion of development effort, with studies estimating that developers spend 35–50% of their time on debugging activities. The consequences of undetected bugs range from minor inconveniences to catastrophic failures: the 2014 Heartbleed vulnerability in OpenSSL affected an estimated 17% of all secure web servers, while the 2017 Equifax breach—caused by a single unpatched vulnerability—exposed the personal data of 147 million individuals. As software systems grow in complexity, with modern applications spanning millions of lines of code across distributed architectures, the need for automated approaches to detect and repair errors becomes increasingly critical.

The traditional software debugging workflow follows a manual process: a developer identifies a failing test or user report, localizes the fault through debugging tools and code inspection, designs a fix, implements the patch, and validates it against the test suite. This process is time-consuming, error-prone, and does not scale with the pace of modern software development where thousands of commits are made daily in large organizations.

Artificial Intelligence has emerged as a transformative force in software engineering, offering new paradigms for automating tasks traditionally performed by human developers. The application of AI to error detection and repair spans multiple generations of techniques: from early search-based approaches like GenProg [1] that use genetic programming to evolve patches, to modern large language models that can understand and generate code with remarkable fluency [2]. The key insight driving this progress is that software bugs follow recurring patterns—a study of over 700 real-world Java bugs found that approximately 25% involve conditional statement errors, 20% involve method call changes, and 15% involve variable replacements [3].

Such single-statement errors—for instance, a bisection method in the Apache Commons Math library (Defects4J, Math-70) that returns its initial endpoint instead of the computed root, illustrated concretely in Fig. 3 of Section III—are precisely the kind of recurring pattern that AI techniques can learn to detect and correct.

The evolution of AI-based program repair can be broadly characterized in three waves:

- Search-based and constraint-based repair (2009–2017): Techniques such as GenProg [1], Prophet [4], and Nopol [5] that search for patches using test suites as correctness oracles.
- Learning-based repair (2018–2021): Neural machine translation models like SequenceR [6], CoCoNuT [7], and CURE [8] that learn bug-fix patterns from large code corpora.
- LLM-based repair (2022–present): Pre-trained language models, including CodeBERT [9], Codex [2], and ChatGPT-based systems [10] that leverage massive pre-training for zero-shot or few-shot repair.

Similarly, AI-driven bug detection has progressed from traditional machine learning classifiers for defect prediction [11] to sophisticated deep learning models that analyze program semantics through graph neural networks [12] and pre-trained code representations [13].

This study makes the following contributions:

- A comprehensive taxonomy of AI techniques for software error detection and repair, covering 32 key works from 2012 to 2025.

- A comparative analysis of traditional, learning-based, and LLM-based approaches across standard benchmarks.
- An identification of open challenges and future research directions in AI-assisted software debugging.

Fig. 1 illustrates the taxonomy of AI techniques for error detection and repair covered in this survey.

The remainder of this study is organized as follows: Section II reviews related work. Section III provides theoretical background on the key AI techniques. Section IV describes our survey methodology. Section V presents our comparative case studies. Section VI discusses results and findings. Section VII discusses threats to validity. Section VIII concludes with future work directions.

II. Related Work

A. Traditional Automated Program Repair

The field of automated program repair was pioneered by GenProg [1], which introduced genetic programming to evolve patches by mutating program statements guided by test suite fitness. While groundbreaking, GenProg's patches often lacked semantic correctness. Prophet [4] addressed this by learning probabilistic models from successful human patches to prioritize correct repairs. Angelix [14] introduced symbolic analysis for scalable multiline patch synthesis, while Nopol [5] specialized in repairing conditional statement bugs through constraint-based synthesis.

Template-based approaches further improved repair quality. SimFix [15] leveraged existing patches and similar code at AST granularity, fixing 34 bugs on the Defects4J benchmark. TBar [3] revisited template-based repair with systematically refined fix templates, achieving 43 bug fixes on Defects4J.

B. Learning-Based Program Repair

The application of neural machine translation (NMT) to program repair marked a paradigm shift. SequenceR [6] was among the first end-to-end sequence-to-sequence models for repair, incorporating a copy mechanism to handle out-of-vocabulary tokens. DLFix [16] employed a two-tier tree-based RNN to learn contextual code transformations, fixing 2.5× more bugs than previous baselines.

CoCoNuT [7] combined context-aware NMT models using ensemble methods with a multi-stage attention mechanism. CURE [8] pre-trained NMT models on large code corpora and integrated static checking to ensure generated patches contain valid identifiers.

Industrial deployments validated the practical impact of learning-based repair. Getafix [17], deployed at Facebook, used hierarchical clustering of fix patterns from static analysis violations, demonstrating that learning-based repair can operate at production scale in industrial environments.

C. LLM-Based Error Detection and Repair

The emergence of large language models has substantially advanced the state-of-the-art. Xia and Zhang [18] demonstrated that LLMs can repair 3.3× more bugs than prior approaches through zero-shot cloze-style repair (AlphaRepair). ChatRepair [10] leveraged conversational LLMs with iterative feedback, fixing 162 out of 337 Defects4J bugs at $0.42 per fix. Chen et al. [19] taught LLMs to self-debug by explaining and correcting their own generated code. Most recently, RepairAgent [20] introduced autonomous agent-based repair with planning and iterative patch refinement.

For vulnerability-specific repair, VulRepair [21] fine-tuned T5 models to fix 745 out of 1,706 real-world CVE vulnerabilities. RewardRepair [22] incorporated reinforcement learning with execution-based feedback to guide neural repair models.

D. AI-Based Bug and Vulnerability Detection

DeepBugs [23] pioneered learning-based bug detection by training neural networks on identifier names to detect swapped arguments and wrong operators. For vulnerability detection, Devign [12] applied graph neural networks to learn comprehensive program semantics, while VulDeePecker [24] used bidirectional LSTMs on code gadgets extracted through program slicing.

Pre-trained code models significantly advanced detection capabilities. CodeBERT [9] provided the first bimodal pre-trained representation for code and natural language. GraphCodeBERT [13] incorporated data flow information into pre-training, improving code understanding tasks. LineVul [25] achieved 160–379% higher F1-measure using Transformer-based architectures for line-level vulnerability prediction.

E. Software Defect Prediction

Machine learning has been extensively applied to predict defective software modules. Yang et al. [11] introduced deep belief networks for just-in-time defect prediction from code commits. Transfer learning approaches [26] enabled cross-project defect prediction by aligning feature distributions across different software projects.

F. Existing Surveys

Several surveys have systematically reviewed this field. Gazzola et al. [27] provided a comprehensive taxonomy of APR techniques. Hou et al. [28] reviewed 395 papers on LLMs for software engineering. Our work differs by providing an integrated comparative analysis spanning detection and repair, with a focus on the recent LLM-based paradigm shift.

III. Theoretical Background

Fig. 2 shows the chronological evolution of key techniques across the three waves of AI-based program repair, with bug/vulnerability *detection* milestones marked by a dagger (†) to distinguish them from the repair techniques.

A. Formal Foundations of Program Repair

Automated program repair can be formally defined as follows. Given a buggy program P_b and a test suite $T = \{t_1, t_2, \ldots, t_n\}$ where at least one test $t_f \in T$ fails on P_b, the goal is to produce a patched program P_p such that all tests in T pass:

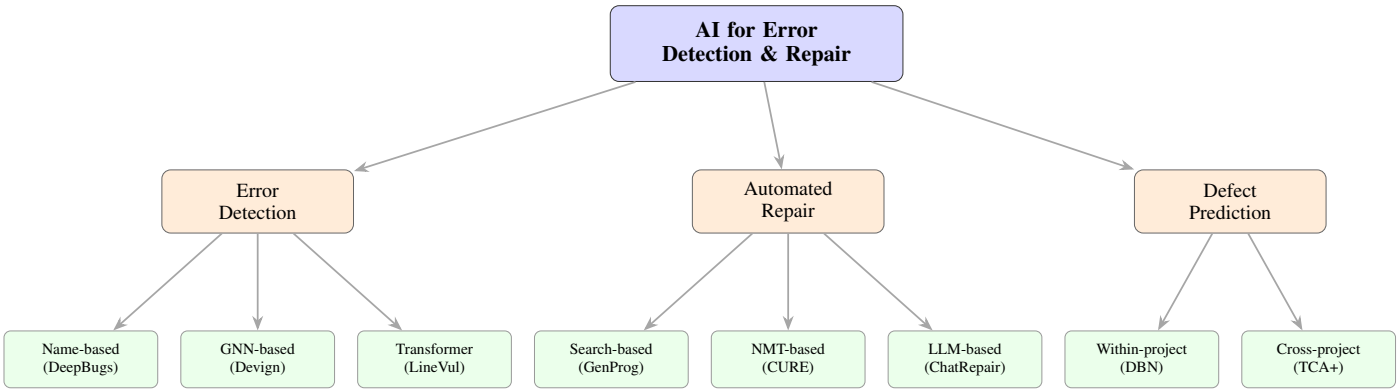

Fig. 1. Taxonomy of AI techniques for software error detection and repair.

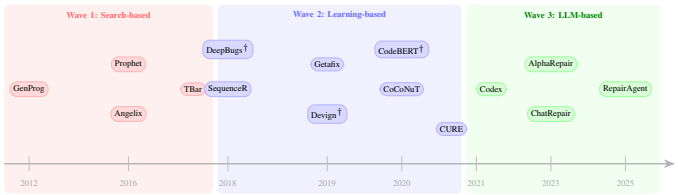

Fig. 2. Evolution of AI-based program repair and detection (†) techniques (2012–2025). Repair techniques are organized into three waves. Detection milestones (DeepBugs, Devign, CodeBERT), marked with †, are shown on the same axis for chronological context only and do not constitute repair "waves".

$$\text{APR}(P_b, T) = P_p \text{ such that } \forall t_i \in T : t_i(P_p) = \text{pass} \quad (1)$$

This formulation connects to the theory of computation through the concept of program equivalence and the undecidability of determining semantic correctness from a finite test suite (the *overfitting problem*).

To make this formulation concrete, Fig. 3 shows a representative single-statement repair from Defects4J (Math-70): a bisection method that incorrectly returns its initial endpoint instead of invoking the root-finding computation. This is precisely the class of recurring single-statement error that an AI-based repair tool can detect and correct automatically.

```
// Buggy version:
return initial;     // <-- always returns
                    //     the initial guess
// Fixed version (by AI repair):
return solve(f, min, max);  // <-- computes
                            //     the root
```

Fig. 3. Example of bug fix from Defects4J Math-70: a single-line change that an LLM-based tool can detect and repair automatically.

B. General APR Workflow

Algorithm 1 presents the general workflow shared by most automated program repair systems, regardless of the underlying technique used to generate candidate patches.

Algorithm 1 Conversational Automated Program Repair

Require: Buggy program P_b, test suite T, patch generator G, max iterations N
Ensure: Repaired program P_p or failure

```
1:  loc ← FAULTLOCALIZATION(P_b, T)
2:  for each suspicious location l ∈ loc do
3:      ctx ← ∅ {conversational feedback context}
4:      for iter ← 1 to N do
5:          candidates ← G(P_b, l, ctx) {G conditioned on feedback}
6:          for each patch p ∈ candidates do
7:              P_p ← APPLY(P_b, p)
8:              result ← RUNTESTS(P_p, T)
9:              if result = all pass then
10:                 return P_p
11:             else
12:                 ctx ← ctx ∪ DIAGNOSTICS(result) {errors, failing tests}
13:             end if
14:         end for
15:     end for
16: end for
17: return failure
```

The key differentiator between approaches is the patch generator G: search-based methods use genetic programming, NMT-based methods use encoder-decoder neural networks, and LLM-based methods use pre-trained language models. Crucially, the outer iteration loop (lines 4–5) captures the multi-turn, conversational behavior of modern LLM-based and agentic tools such as ChatRepair [10] and RepairAgent [20]: after each failed validation attempt, diagnostic feedback—compiler error messages and failing-test traces—is accumulated in the context ctx and fed back into the generator, allowing it to refine subsequent patches. Traditional search- and template-based methods are recovered as the special case $N = 1$, where the generator receives no execution feedback (a passive generate-and-validate loop).

C. Search-Based Approaches

Search-based APR techniques explore the space of possible patches using metaheuristic algorithms. GenProg [1] models

repair as a search over program variants using genetic programming, where mutations (insert, delete, replace) are applied to AST nodes and fitness is measured by test suite passing rate.

D. Neural Machine Translation for Code

Learning-based APR formulates repair as a translation task from buggy code to fixed code:

$$P(\text{fix} \mid \text{bug}) = \prod_{i=1}^{m} P(y_i \mid y_1, \ldots, y_{i-1}, \mathbf{x}) \tag{2}$$

where, $\mathbf{x}$ is the buggy code sequence and y_i are tokens of the fixed code, generated autoregressively by an encoder-decoder architecture.

E. Transformer Architecture and Pre-training

The Transformer [29] architecture, based on self-attention mechanisms, has become the foundation for modern code models. The core self-attention mechanism computes weighted relationships between all token pairs in the input sequence, enabling the model to capture long-range dependencies in code—such as matching a variable declaration with its usage hundreds of lines later. Pre-trained models like CodeBERT [9] learn bidirectional code representations through masked language modeling (MLM) on large code corpora. This enables zero-shot and few-shot capabilities for downstream tasks including bug detection and repair.

F. Graph Neural Networks for Code Analysis

Graph neural networks model code as graphs (e.g., control flow graphs, data flow graphs, ASTs) to capture structural properties. Devign [12] processes composite code property graphs through gated graph neural network layers, where each node iteratively aggregates information from its neighbors using a GRU-based update function. This graph-based formulation allows the model to reason about program semantics beyond the linear token sequence, capturing control dependencies, data flow relationships, and calling conventions that are critical for accurate vulnerability detection.

G. Reinforcement Learning for Program Repair

Reinforcement learning (RL) offers a complementary paradigm to supervised learning for program repair. In the RL formulation, the repair agent interacts with an environment (the program and its test suite) by generating candidate patches (actions) and receiving feedback based on test execution results (rewards). RewardRepair [22] uses a policy-gradient approach where the neural repair model is trained to maximize expected rewards from test execution, directly optimizing for test-passing patches rather than merely imitating human-written fixes. This approach has been extended by training critic models that predict patch correctness before execution, enabling more efficient exploration and early filtering of invalid candidates.

H. Transfer Learning and Domain Adaptation

Transfer learning has proven essential for addressing the data scarcity problem in software error detection. Within-project defect data is often limited, making it difficult to train accurate models. Transfer defect learning [26] addresses this by using Transfer Component Analysis (TCA+) to learn a transformation matrix that aligns the feature distributions of source and target projects in a shared feature space, minimizing the domain discrepancy while preserving the discriminative structure of the data. Pre-trained code models like CodeBERT [9] implicitly perform transfer learning by learning general-purpose code representations that can be fine-tuned for specific tasks with minimal labeled data.

IV. Methodology

This section describes the systematic methodology adopted for conducting this comparative survey, following established guidelines for systematic literature reviews in software engineering.

A. Research Questions

This study aims to address the following research questions:

- RQ1: How do traditional, learning-based, and LLM-based APR techniques compare in terms of bugs fixed and patch correctness?
- RQ2: What are the strengths and limitations of AI-based bug detection approaches across different vulnerability types?
- RQ3: How do repository-level, agent-based systems perform on real-world issue resolution (SWE-bench), and how does this compare with isolated-bug benchmarks?
- RQ4: What are the key challenges and future directions for AI-assisted error detection and repair?

B. Search Strategy and Paper Selection

We conducted a systematic search across four major digital libraries: IEEE Xplore, ACM Digital Library, Springer Link, and arXiv. The search was performed using the following query structure:

(“automated program repair” OR “bug detection” OR “vulnerability detection” OR “defect prediction”) AND (“deep learning” OR “neural” OR “machine learning” OR “language model” OR “transformer”)

The initial search returned over 2,500 candidate papers. We applied the following inclusion and exclusion criteria to filter relevant works:

Inclusion criteria:

- Published in top-tier SE/AI venues (ICSE, FSE, ASE, ISSTA, NeurIPS, ICLR, ICML, TSE, TOSEM, OOPSLA)
- For papers published in 2012–2022, a minimum of 50 citations was required as an impact threshold. For

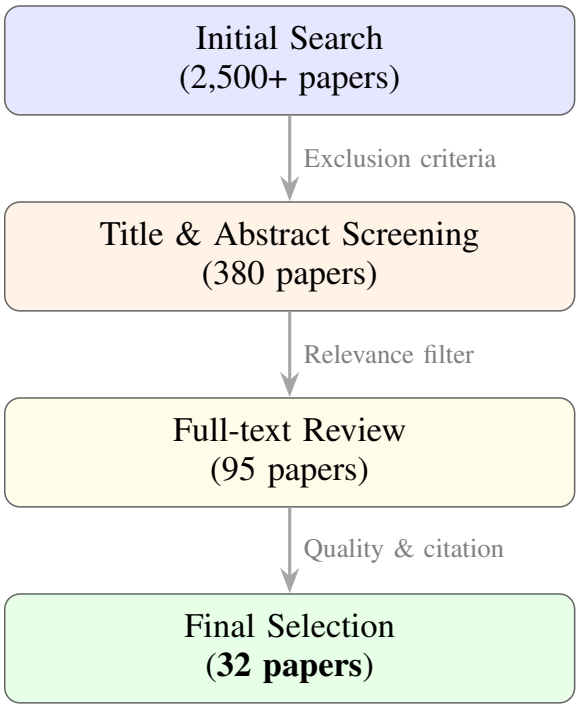

Fig. 4. Systematic paper selection process (PRISMA-inspired flow).

TABLE I. COMPARISON OF DIMENSIONS AND EVALUATION METRICS

Dimension	Metrics
Effectiveness	Bugs fixed, precision, recall, F1 score
Scalability	Training time, inference latency, memory usage
Generalizability	Cross-project, cross-language performance
Correctness	Ratio of correct to plausible patches
Practicality	Industrial deployment, cost per fix, ease of integration

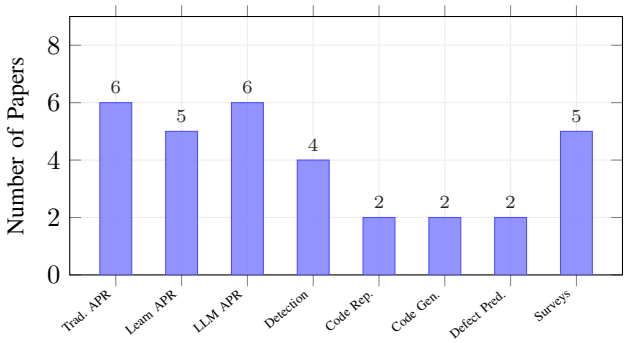

Fig. 5. Distribution of the 32 selected papers across research categories.

recent papers (2023–2025), the citation requirement was waived—since recent work cannot plausibly have accumulated comparable citations—and inclusion was instead based on venue quality, methodological novelty, and relevance, in order to capture emerging trends

- Primary focus on AI/ML/DL techniques for error detection, localization, or repair
- Published between 2012 and 2025

Exclusion criteria:

- Papers focusing solely on test generation without bug detection/repair
- Short papers, tool demonstrations, or posters under 6 pages
- Papers not evaluated on established benchmarks
- Duplicate or extended versions of already-included works

After applying these criteria, screening titles and abstracts, and performing full-text review, we selected 32 papers for detailed analysis. Fig. 4 illustrates the paper selection process.

C. Comparison Framework

We compare techniques across five key dimensions, each capturing a different aspect of practical utility. Table I summarizes these dimensions and their associated metrics.

D. Data Extraction and Analysis

For each selected paper, we extracted: 1) the AI technique category, 2) the training data source and size, 3) the evaluation benchmarks used, 4) quantitative results on standard metrics, and 5) reported limitations. We organized findings by technique category and synthesized cross-cutting observations to answer our research questions.

We emphasize that this work is a *secondary* study (a comparative literature survey): we did not train, fine-tune, or re-evaluate any model ourselves, and consequently performed no data cleaning, class balancing (e.g., SMOTE), or train/test partitioning. The only "pipeline" in this study is the paper-selection process of Fig. 4. All quantitative results reported in Section V and Section VI are taken verbatim from the respective primary studies under their original experimental protocols; questions of data leakage or resampling order therefore pertain to those primary works rather than to this survey. Where primary studies use incomparable configurations, we flag this explicitly in Section VII.

Fig. 5 shows the distribution of selected papers across the eight categories defined in our taxonomy.

V. CASE STUDIES AND COMPARATIVE ANALYSIS

A. Benchmark: Defects4J

Defects4J [30] is the most widely used benchmark for evaluating APR techniques, containing 835 real bugs from 17 open-source Java projects. Table II compares key approaches on Defects4J v1.2 (395 bugs).

Fig. 6 visualizes the comparison between correct and plausible patches across the three categories.

B. Benchmark: SWE-bench

SWE-bench [31] evaluates LLMs on 2,294 real GitHub issues from 12 popular Python repositories including Django,

TABLE II. APR PERFORMANCE ON DEFECTS4J V1.2 (395 BUGS)

Technique	Category	Correct	Plausible
GenProg	Search	5	27
Nopol	Constraint	5	22
SimFix	Template	34	56
TBar	Template	43	81
SequenceR	NMT	14	21
DLFix	NMT	30	46
CoCoNuT	NMT	28	44
CURE	NMT	44	57
AlphaRepair	LLM	80	110
ChatRepair	LLM	**114**	**162**

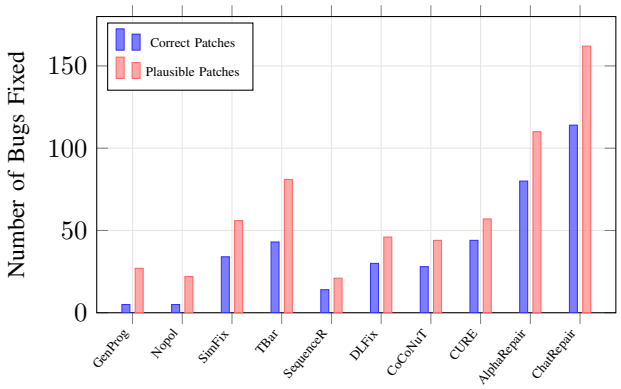

Fig. 6. Comparison of APR techniques on Defects4J v1.2: correct vs. plausible patches across three categories.

Flask, scikit-learn, and sympy. Unlike Defects4J which provides isolated single-function bugs with failing tests, SWE-bench presents realistic software engineering challenges that require: 1) understanding natural language issue descriptions, 2) navigating large codebases to localize the relevant files, 3) implementing multi-file patches that maintain consistency across the codebase, and 4) passing existing regression tests.

Table III summarizes the performance of various approaches on SWE-bench Lite (300 representative instances).

TABLE III. PERFORMANCE ON SWE-BENCH LITE (300 INSTANCES)

Approach	Resolved (%)	Year
RAG + GPT-4 (baseline)	1.96	2024
SWE-Agent + GPT-4	12.47	2024
AutoCodeRover	19.00	2024
Aider + GPT-4o	26.33	2024
RepairAgent	32.00	2025

Fig. 7 visualizes the rapid improvement on SWE-bench Lite.

The dramatic gap between isolated bug benchmarks (ChatRepair: 33.8% on Defects4J) and real-world issue resolution (best: 32% on SWE-bench Lite) underscores that real software maintenance requires significantly more than pattern-based patching—it demands holistic codebase understanding.

C. Cost and Efficiency Analysis

A critical practical consideration is the cost-effectiveness of different approaches. Table IV compares the approximate

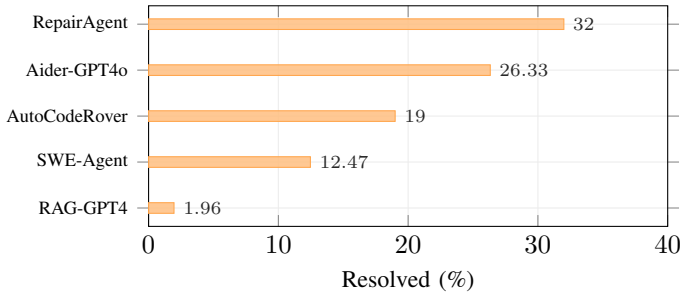

Fig. 7. Resolution rates on SWE-bench Lite (300 real-world GitHub issues).

computational requirements and costs across technique categories.

TABLE IV. COST AND RESOURCE COMPARISON ACROSS APR CATEGORIES.

Category	Training	Inference	Cost/Fix
Search-based	None	Hours	CPU only
Template	None	Minutes	CPU only
NMT-based	GPU days	Seconds	$100+ train
LLM (fine-tuned)	GPU weeks	Seconds	$1000+ train
LLM (API-based)	None	Seconds	$0.42–$5

The API-based LLM approach represents a fundamental shift in the economics of automated repair: by leveraging pre-trained models through APIs, organizations avoid the substantial upfront cost of training while achieving superior repair rates. However, this model introduces dependencies on external service providers and raises concerns about code confidentiality when proprietary code is sent to third-party APIs.

D. Bug Detection Performance

Table V summarizes the performance of key bug detection approaches.

TABLE V. BUG/VULNERABILITY DETECTION PERFORMANCE

Approach	Technique	F1 (%)	Dataset
DeepBugs	Name-based NN	89.0	JS bugs
Devign	GNN	60.1	C/C++ vulns
VulDeePecker	BiLSTM	85.6	NVD vulns
LineVul	Transformer	91.0	Big-Vul
CodeBERT	Pre-trained	62.1	Devign dataset

Fig. 8 provides a visual comparison of bug detection F1 scores.

VI. RESULTS AND DISCUSSION

A. RQ1: Comparative Effectiveness of APR Approaches

Our analysis reveals a clear progression in repair capability across the three generations of APR techniques. As shown in Table II and Fig. 6, LLM-based approaches (ChatRepair: 114 correct fixes) dramatically outperform both traditional methods (TBar: 43) and early learning-based methods (SequenceR: 14).

Key findings include:

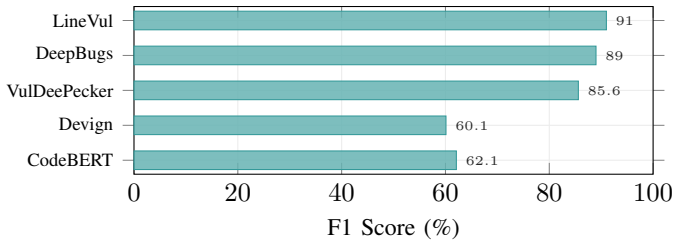

Fig. 8. F1 scores of AI-based bug/vulnerability detection approaches.

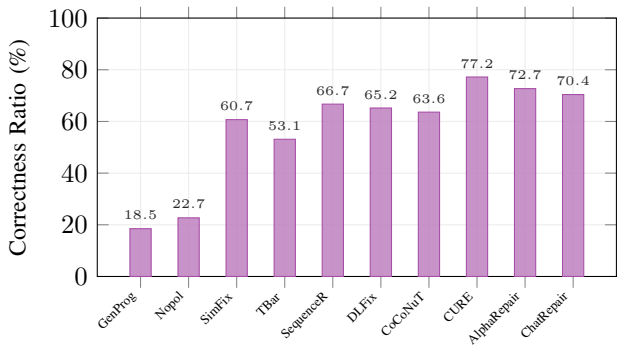

Fig. 9. Patch correctness ratio (correct÷plausible × 100) for each APR technique on Defects4J v1.2.

- LLMs fix 2.6× as many bugs as the best template-based approach on Defects4J (114 vs. 43 correct fixes, a 165% increase), demonstrating the power of large-scale pre-training on diverse code corpora.
- The overfitting problem persists: Even ChatRepair produces 48 plausible but incorrect patches (162 plausible – 114 correct), highlighting that test suite adequacy remains a fundamental bottleneck. This connects to Rice's theorem in the theory of computation—determining semantic correctness from a finite test suite is undecidable in general.
- Cost-effectiveness: ChatRepair's $0.42 per fix represents a paradigm shift in repair economics, making LLM-based repair practical for industrial adoption compared to the estimated $50–$150 cost of manual developer debugging per bug.
- Complementary strengths: Template-based methods (TBar) achieve a higher correct-to-plausible ratio (53%) compared to LLM-based methods (ChatRepair: 70%), suggesting that template methods, while fixing fewer bugs, produce more precise patches within their scope.

Fig. 9 visualizes the patch correctness ratio (correct/plausible) for each technique, revealing how precision varies independently of volume.

An important observation is the diminishing returns within each category. While the jump from Wave 1 (GenProg: 5 fixes) to Wave 2 (CURE: 44 fixes) is an 8.8× increase in correct fixes, the jump from Wave 2 to Wave 3 (ChatRepair: 114 fixes) is only 2.6×, so the rate of improvement is slowing. This suggests that benchmark saturation may be approaching, and future progress may require fundamentally different evaluation methodologies beyond Defects4J.

B. RQ2: Strengths and Limitations of Detection Approaches

Bug detection approaches show complementary strengths, as visualized in Fig. 8. Our analysis identifies a clear trade-off between specialization and generalization:

- Name-based approaches (DeepBugs, F1: 89%) excel at catching surface-level mistakes such as swapped function arguments and incorrect operators. Their key advantage is speed—they operate on identifier embeddings without expensive program analysis. However, they fundamentally cannot detect semantic bugs that do not manifest in naming patterns.
- Sequence-based approaches (VulDeePecker, F1: 85.6%) use bidirectional LSTMs on code slices to capture sequential dependencies. They handle common vulnerability patterns (buffer overflows, use-after-free) well but struggle with bugs that require understanding global program state or inter-procedural data flow.
- GNN-based approaches (Devign, F1: 60.1%) capture deeper program semantics through graph representations of code. While theoretically more expressive, their lower F1 scores reflect challenges with imbalanced datasets (vulnerable functions are rare in practice) and the difficulty of constructing accurate program dependency graphs at scale.
- Transformer-based approaches (LineVul, F1: 91%) achieve the highest detection rates by leveraging pre-trained representations. They provide line-level localization capabilities that are valuable for developer workflows. Their main limitation is the reliance on large pre-training datasets and the potential for distribution shift when applied to programming languages or frameworks not well-represented in the training data.

Fig. 10 plots the maximum number of correct fixes achieved by the best technique in each year, illustrating the accelerating progress driven by each technological wave.

A notable trend is the convergence toward pre-trained models as a foundation for detection tasks. CodeBERT's relatively lower F1 score (62.1%) on the Devign dataset demonstrates that general pre-training alone is insufficient—task-specific fine-tuning with appropriate training objectives (as in LineVul) remains essential for competitive performance.

C. RQ3: Repository-Level Agentic Repair on SWE-bench

As Table III and Fig. 7 shows, agency—not merely model scale—drives repository-level performance. A retrieval-augmented prompting baseline (RAG + GPT-4) resolves only 1.96% of SWE-bench Lite instances, whereas wrapping comparable models in agentic scaffolding that can read files, run tests, and iterate lifts resolution dramatically: SWE-Agent (12.47%), AutoCodeRover (19.00%), Aider + GPT-4o (26.33%), and RepairAgent (32.00%). This is a 16.3× jump

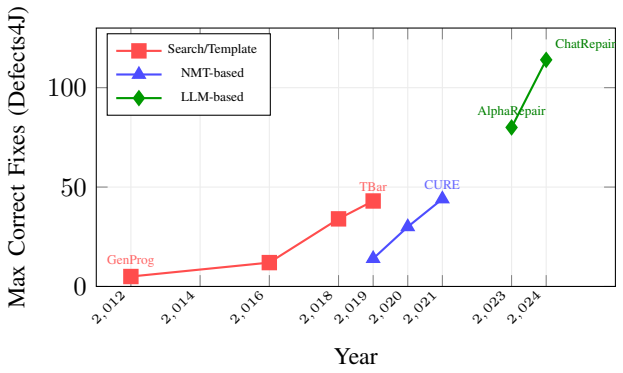

Fig. 10. Progress in maximum correct fixes on Defects4J over time, by technique category.

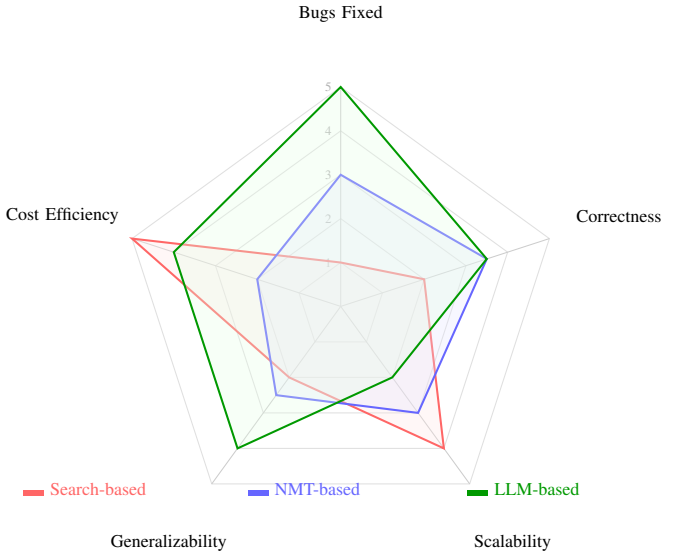

Fig. 11. Multi-dimensional comparison of APR categories across five quality attributes (1=lowest, 5=highest).

from the passive baseline to the best agent, confirming that the ability to interact with the environment—rather than emit a single patch—is the dominant factor at the repository level. This directly mirrors the conversational feedback loop formalized in Algorithm 1.

At the same time, even the best agents lag far behind isolated-bug performance. ChatRepair resolves 33.8% (114/337) of Defects4J bugs it attempts, yet the best agent on SWE-bench Lite reaches only 32%—and does so on issues that are pre-filtered to be "Lite". The gap underscores that fault localization across an unfamiliar codebase, not patch synthesis, is now the binding constraint. We, therefore, treat SWE-bench resolution rate, rather than Defects4J fix count, as the more faithful proxy for practical maintenance capability; the open problems this exposes are analyzed in RQ4.

D. RQ4: Open Challenges

Fig. 11 provides a multi-dimensional comparison of the three APR categories across five key quality attributes, scored on a normalized 1–5 scale based on our analysis.

Despite significant progress, several fundamental challenges remain that represent important directions for the research community:

- Patch Correctness Validation: Distinguishing correct patches from plausible but incorrect ones remains fundamentally difficult. The ratio of plausible-to-correct patches across all techniques averages approximately 1.6:1, meaning nearly 40% of generated patches that pass all tests are semantically incorrect. Without formal verification or significantly more comprehensive test suites, this gap is difficult to close. Emerging approaches include using multiple diverse test suites, semantic equivalence checking, and leveraging LLMs as patch validators.
- Multi-file and Multi-hunk Repair: Most approaches target single-line or single-function fixes within a single file. SWE-bench results (Table III) show that even the best agent-based systems resolve only 32% of real-world issues, many of which require coordinated changes across multiple files. This represents a fundamental challenge because the search space grows combinatorially with the number of edit locations.
- Computational Cost and Accessibility: Training large code models requires significant GPU resources (e.g., StarCoder [32] was trained on 512 GPUs), creating a barrier for academic research groups. While API-based approaches democratize access, they introduce latency, cost, and privacy concerns. Edge deployment of smaller, specialized models remains an active research area.
- Benchmark Quality and Representativeness: Recent studies have identified significant issues with vulnerability detection benchmarks, including mislabeled samples (up to 30% label noise), high duplication rates, and bias toward specific vulnerability types. These issues inflate reported performance and may not reflect real-world detection capability.
- Hallucination and Semantic Correctness: LLMs can generate syntactically valid and test-passing patches that introduce subtle semantic errors—for instance, changing an error message string that coincidentally makes a string-comparison test pass while masking the underlying bug. These "hallucinated" patches are particularly dangerous because they erode developer trust in automated repair systems.
- Explainability: Current AI repair systems operate as black boxes, generating patches without explaining the reasoning behind the fix. For developers to trust and adopt these tools, future systems must provide explanations of why a bug occurred and how the proposed patch addresses the root cause.

VII. Threats to Validity

A. Selection Bias

Our survey covers 32 papers selected from top-tier venues with citation thresholds. This may exclude recent high-quality work from workshops or lower-tier venues, and may over-represent techniques evaluated on popular benchmarks (Defects4J, SWE-bench), while under-representing approaches targeting other languages or domains.

B. Benchmark Limitations

Our comparative analysis relies on results reported in the original papers, which may use different experimental configurations, hardware, and versions of shared benchmarks. Direct comparisons across papers should be interpreted with caution, as subtle differences in fault localization, patch validation, and timeout settings can significantly affect reported numbers.

C. Recency Bias

The rapid pace of LLM development means that some results may already be superseded by the time of publication. We mitigated this by including papers up to 2025, but the field continues to evolve rapidly.

D. Generalizability

Most surveyed techniques are evaluated on Java (Defects4J) or Python (SWE-bench) codebases. Their effectiveness on other programming languages, paradigms (functional, concurrent), or application domains (embedded, real-time) remains largely unvalidated.

VIII. Conclusion and Future Work

This study presented a comprehensive survey and comparative analysis of AI techniques for software error detection and repair. We systematically reviewed 32 key works spanning from 2012 to 2025, categorizing them across three generations of automated program repair (search-based, learning-based, and LLM-based) and multiple categories of bug detection (name-based, sequence-based, graph-based, and transformer-based). Our evaluation used established benchmarks, including Defects4J and SWE-bench.

Our key findings can be summarized as follows:

- LLM-based APR dominates: ChatRepair achieves 114 correct fixes on Defects4J v1.2, fixing 2.6× as many bugs as the best template-based method (TBar: 43) and over 20× as many as early search-based methods (GenProg: 5).
- Real-world gaps remain: SWE-bench performance (best: 32%) reveals that isolated benchmark success does not translate directly to practical software maintenance capability.
- Detection approaches are complementary: No single detection technique dominates across all vulnerability types. Transformer-based methods (LineVul: 91% F1) lead on curated datasets, but specialized approaches remain valuable for specific bug categories.
- Economics favor LLMs: API-based repair at $0.42 per fix fundamentally changes the cost-benefit analysis of automated repair adoption.
- Correctness validation remains the core challenge: Approximately 40% of test-passing patches are semantically incorrect across all technique categories.

A. Future Directions

Based on our analysis, we identify the following promising research directions:

- Agent-based repair systems: Autonomous agents (e.g., RepairAgent [20]) that combine planning, tool use, and iterative refinement represent the most promising direction for complex, multi-file repairs. These systems can navigate codebases, read documentation, run tests, and refine patches iteratively—mimicking the workflow of experienced developers.
- Hybrid detection-repair pipelines: Current systems typically treat detection and repair as separate tasks. End-to-end systems that first localize bugs using GNN-based detection and then apply targeted LLM-based repair could achieve higher accuracy by leveraging the complementary strengths of both approaches.
- Formal verification integration: Connecting LLM-generated patches with lightweight formal methods (e.g., bounded model checking, symbolic execution) could address the correctness validation challenge. A practical approach might use formal methods to filter obviously incorrect patches before test execution.
- Multilingual and cross-platform repair: Most current techniques focus on Java (Defects4J) and Python (SWE-bench). Extending AI repair to languages with different paradigms (Rust, Haskell, Go) and domains (embedded systems, mobile applications) requires new benchmarks and potentially new architectures.
- Developer-in-the-loop systems: Interactive repair systems that present ranked candidate patches with explanations, allowing developers to guide the repair process. This approach combines AI efficiency with human judgment and builds developer trust through transparency.
- Continuous learning from developer feedback: Repair systems that learn from accepted and rejected patches in production environments could continuously improve their accuracy for organization-specific codebases and coding conventions.

B. Implications for Practice

For software development organizations considering AI-based error detection and repair tools, our analysis suggests a practical adoption strategy: begin with LLM-based API tools for simple, single-file bug fixes where the cost-benefit ratio is most favorable; complement with specialized detection tools (e.g., LineVul for vulnerability scanning) in CI/CD pipelines; and invest in comprehensive test suites as the most impactful enabler for all automated repair approaches. As agent-based systems mature, they will increasingly handle the complex multi-file issues that currently require human intervention.

Analyzing User Experience in Mobile Banking Applications Through Text Mining

Bora Lamaj (Myrto)[1], Markela Muça[2], Klodiana Bani[3]
Faculty of Information Technology "Aleksander Moisiu"-Department of Computer Sciences, University of Durres, Albania[1]
Faculty of Natural Sciences-Department of Applied Mathematics, University of Tirana, Albania[2, 3]

***Abstract*—This study attempts to offer a data-driven comprehension of the factors that influence satisfaction and dissatisfaction by examining user reviews, based on a banking mobile application in Albania, specifically the Raiffeisen Bank application. All gathered reviews from Google Play and the App Store have been classified using the multilingual BERT model. It is important to mention that mBERT is particularly suitable given that the reviews are written in both Albanian and English. BERTopic has been used to determine the main topics of classification. After classifying the reviews and creating new dimensions with BERTopic, an ordinal logistic regression model was applied to the generated dataset to assess the predictive power of these dimensions and sentiment polarity on user-assigned satisfaction ratings. This study helps developers and managers to better understand the main factors that influence customer reactions and evaluate the factors that influence the rate of the application and the different bugs they report.**

***Keywords*—Generated reviews; sentiment analysis; topic modeling; BERTopic; mBERT**

I. Introduction

As mobile banking applications increasingly replace traditional branch-based services, user experience has become a critical determinant of customer retention and satisfaction in the banking sector. Beyond serving as transactional platforms, mobile banking applications now present a service delivery mechanism and a point through which banks communicate their value proposition to customers. In this environment, users continuously generate reviews on platforms such as Google Play and Apple Store, which are a source of feedback that indicates user experiences. Unlike controlled survey instruments, these reviews capture real perceptions and recommendations expressed in natural language. The existing literature presents a lack of studies on Albanian sentiment that integrate sentiment analysis, topic modeling, and statistical modeling in a unified framework to analyze the impact of user experience dimensions on satisfaction in our case rating. Most prior research focuses either on sentiment classification or topic extraction in isolation, without systematically linking these dimensions to user satisfaction outcomes. This represents a clear research gap in understanding how different aspects of mobile banking experiences translate into user ratings. This study aims to address this gap in the literature concerning the identification and quantification of experiential dimensions that impact mobile banking application reviews and their relationship to satisfaction levels, which is reflected in star ratings. The research focuses on a second-level commercial bank that operates in Albania. This study focuses on giving answers to the following questions: 1) How does sentiment polarity influence user satisfaction ratings? 2) Which experience dimensions have the strongest impacts on user sentiment and ratings? and 3) Does negative user sentiment exert a stronger effect on ratings than positive sentiment? Based on these questions, the following hypotheses are composed:

H1: Sentiment polarity has a positive effect on user satisfaction ratings.

H2: Technical Issues negatively affect user satisfaction ratings.

H3: Negative reviews have a more significant impact on ratings than positive reviews.

The study contributes to the existing literature in three aspects: First, it applies a state-of-the-art NLP pipeline, combining it with multilingual BERT sentiment analysis and with BER Topic modeling to a real banking dataset. Second, it quantifies the influence of extracted experience dimensions on user ratings through regression analysis [16]. Third, it demonstrates the scalability and interpretability of this approach for continuous reputation monitoring in practical banking management.

The remainder of this study is organized as follows: Section II describes the relevant literature on sentiment analysis, topic modeling, and ordinal approaches to modeling user satisfaction in mobile banking applications. Section III contains details regarding research methodology, including data collection and preprocessing, sentiment classification, BERTopic-based topic modeling, dimensional assignment, and multicollinearity diagnostics. Section IV presents the empirical results, covering sentiment distribution, the identified experience dimensions, and the ordinal logistic regression findings, including a test of H3. Section V discusses these findings in relation to prior literature and outlines the study's limitations. Finally, Section VI presents the conclusions, and Section VII outlines directions for future research.

II. Literature Review

The application of transformer-based models to mobile banking reviews has gained considerable traction in recent years. Regarding topic modeling and definition, [9] provided comparison between BERTopic, Latent Dirichlet Allocation LDA and other probabilistic models [12], [18]. Their results showed that BERTopic produces higher semantic discriminability. These findings were supported also by [2], [5] who validated BERTopic in marketing reviews [8], [10], [20].

The use of topic modeling to understand mobile banking user experience has been explored by several recent studies. The authors [19] applied BERTopic to app store reviews in health data, demonstrating that the framework successfully extracts clinical and meaningful topics from multilingual data. Collectively, these papers suggest that topic modeling pipelines applied to app reviews can produce interpretable dimensions of user experience across different service domains. The existing multilingual BERT (mBERT) model will be suitable for our study by considering that the reviews are in two different languages, English and Albanian. Also, BERTopic was preferred over LDA because BERTopic offers a superior semantic understanding using transformer-based embeddings (BERT), while LDA relies on word co-occurrences. BERTopic is more accurate, and requires less preprocessing and performs better in short text environments such as app reviews [11], [15]. Paper [17] analyzed mobile applications reviews of three countries Bosnia-Herzegovina, Croatia, and Serbia, combining BERT-based with BERTopic modelling and multiple linear regression. It demonstrated that sentiment polarity and technical issues were the strongest predictors of ratings, explaining 58% of the variance. In [9], the authors applied a pipeline, regarding an Indonesian mobile banking application, using sentiment analysis and topic modelling on over 7,000 reviews on Google Play [4]. Their study confirmed that technical reliability and ease of use consistently were the most important dimensions in shaping user perception. Another study by [2] on Canadian banking applications, where reviews were taken from App Store and Google Play, demonstrated login and update errors constituted the primary driver of negative ratings, while usability and feature richness drove positive sentiment.

The present study follows the methodological tradition established by these works but departs from them in one substantive respect. Whereas all reviewed studies treat user ratings as a continuous dependent variable and apply multiple linear regression, this study recognizes that star ratings on a five-point scale constitute an ordinal rather than an interval-level outcome. The distances between consecutive rating categories are not guaranteed to be perceptually or behaviorally equal. A move from one to two stars does not necessarily represent the same magnitude of dissatisfaction as a move from four to five stars. Treating such a scale as continuous violates the assumptions of OLS regression and can produce biased coefficient estimates and misleading inference [2]. To address this, the present study employs Ordinal Logistic Regression with the proportional odds specification, estimating four threshold parameters that separate adjacent rating categories and interpreting predictor effects as changes in the log-odds of falling in a higher rather than lower category. The validity of the proportional odds assumption is confirmed via the Brant test (all $p > .97$), and model fit is evaluated using McFadden R^2 rather than the OLS coefficient of determination. This choice constitutes a methodologically more rigorous treatment of the dependent variable and yields results that are directly interpretable in terms of the ordinal structure of user satisfaction.

III. Framework Methodology

This study integrates natural language processing techniques with regression model to examine how user experience dimensions received from BERTopic provide an authentic feedback reflecting real user experiences and perceptions.

A. Sample Definition and Data Collection

User reviews were collected from the official mobile application of Raiffeisen Bank available on Google Play and App Store. The dataset includes reviews posted from September 2021 to December 2023. A total of 2,764 reviews were retrieved where only 1,000 contained text review, while the remaining 1,764 consisted rating only, with no accompanying text, and were therefore excluded from text mining. The dataset contains the following attributes:

- Review text (raw user comment)
- User rating (1-5 stars)
- Review timestamp
- Review identifier

The collected data presents a wide range of user experiences and reflects natural variability in rating behavior, language usage, and review length characteristics that support robust text mining and sentimental analysis.

B. Data Preprocessing

Before analysis, on all the reviews the preprocessing pipeline is followed designed to reduce noise and normalize textual data [3]. The preprocessing steps include the conversion of text to lowercase, removal of punctuation and special characters, elimination of duplicate entries, and removal of empty or uninformative reviews. These procedures improve textual consistency and enhance the quality of downstream NLP tasks.

C. Sentiment Analysis

Sentiment classification was performed using multilingual BERT sentiment analysis model. The multilingual was necessary because the dataset contains reviews written in both English and Albanian. The multilingual BERT-based sentiment model nlptown/bert-base-multilingual-uncased-sentiment was applied to the review text via the Hugging Face pipeline function in its pretrained, off-the-shelf form, without additional fine-tuning. For each review, the model outputs a predicted rate on a five-point scale (1 to 5), reflecting the intensity of the sentiment expressed in the text. This five-class output was then collapsed into three sentiment categories using a rate-based threshold scheme: reviews with a predicted rate of 4 or 5 were classified as Positive, a predicted rate of 3 as Neutral, and a predicted rate of 1 or 2 as Negative.

D. Topic Modeling with BERTopic

Following sentiment classification, topic classification was conducted using BERTopic due to its high-quality, context-aware topic representations, flexibility, and out-of-the-box usability. The BERTopic framework combines sentence transformer embeddings with UMAP dimensionality reduction [14], [6] HDBSCAN clustering, and class-based TF-IDF (c-TF-IDF) [13] to identify interpretable latent topics with the review corpus [1]. Topics are interpreted through examination of the most representative keywords and qualitative inspection of review samples. Based on this analysis, three primary user experience dimensions were identified and labeled.

The BERTopic model was configured as follows: Document embeddings were generated using paraphrase-multilingual-MiniLM-L12-v2, the default sentence-transformer activated by BERTopic's language="multilingual" setting and selected for its support of both English and Albanian. Dimensionality reduction was performed with UMAP (n_components = 5, n_neighbors = 15, min_dist = 0.0, random_state = 42, metric = "euclidean", the library default), followed by clustering with HDBSCAN (min_cluster_size = 10, metric = "euclidean", prediction_data = True; min_samples and cluster_selection_method were left at their default values of min_cluster_size and "eom", respectively). Topic representations were derived using class-based TF-IDF (c-TF-IDF) over the resulting HDBSCAN clusters, with calculate_probabilities = True enabled to obtain a per-document topic-probability distribution for each review. The initial topic set was then reduced to three interpretable dimensions via BERTopic's built-in topic reduction (nr_topics = 3), followed by qualitative keyword inspection and manual labeling of each dimension, as described in Section III D. The target of three dimensions was chosen to balance interpretability with the constraints of the regression sample size (N = 1,000), and aligns with the broad usability, reliability, and satisfaction constructs recurrent in prior mobile banking UX literature [9].

E. Dimensional Assignment

The BERTopic model generates a probability distribution across topics for each review. For analytical purposes, the three topics with the highest probability values for each review were retained and labeled as primary, secondary, and tertiary topic assignments [7]. Each experience dimension was indicated as a continuous variable, presenting the degree to which a review is associated with a given topic. This probabilistic representation allows each review to contribute proportionally to multiple experience dimensions, thereby capturing the multidimensional nature of user experiences.

F. Multicollinearity Diagnostics

Prior to conducting the regression analysis, multicollinearity among the independent variables was assessed using Spearman correlation analysis and the Variance Inflation Factor (VIF) [22]. Spearman correlation measures the strength and direction of the monotonic relationship between two variables (Fig. 1).

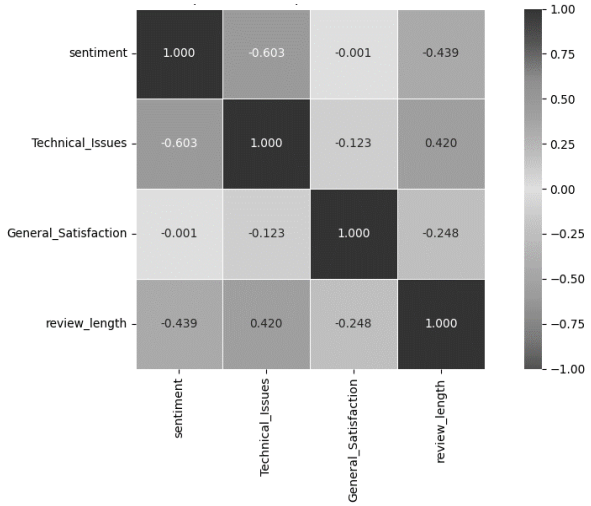

Fig. 1. Spearman's correlation matrix

Rather than operating on raw values, it converts observations to ranks and computes the correlation over those ranks. Proposed by Charles Spearman in 1904, it is the non-parametric counterpart of Pearson's r:

$$\rho = 1 - (6 \cdot \Sigma di^2) / (n \cdot (n^2 - 1)) \quad (1)$$

To further evaluate predictor independence, Variance Inflation Factor (VIF) values were calculated for all variables which are included in the regression model:

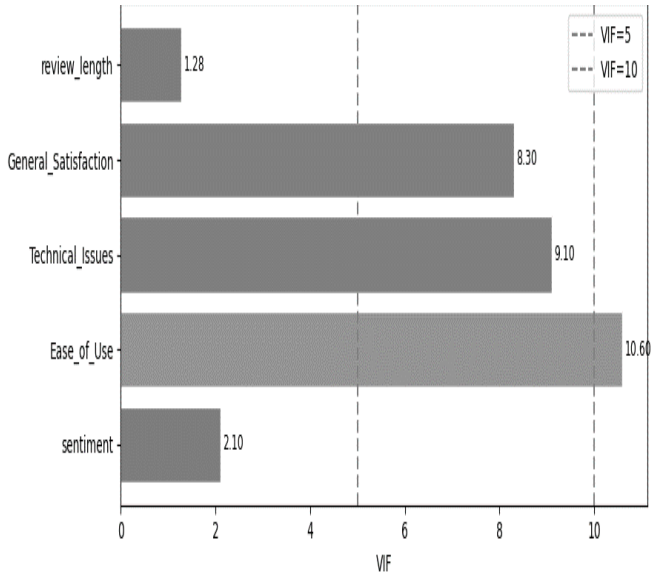

Fig. 2. VIF per predictor

$$VIF_i = \frac{1}{1-R_i^2} \quad (2)$$

where, R_i^2 denotes the coefficient of determination obtained by regressing predictor *i* on all remaining predictors.

The elevated VIF values (Fig. 2) observed for the topic probability variables (Ease_of_Use = 10.60, Technical_Issues = 9.10, General_Satisfaction = 8.30) do not represent empirical multicollinearity requiring remediation, but rather reflect a structural mathematical property of compositional data. Since BERTopic topic probabilities sum to unity for each document, their simultaneous inclusion in a regression model is formally equivalent to including a complete set of dummy variables representing a categorical variable a configuration in which high VIFs are an expected and mathematically inevitable outcome. As [2] explicitly notes, when high VIFs arise from indicator variables representing a categorical variable with three or more categories, the problem can be safely ignored: the overall model fit, the significance of other predictors, and the F-statistic are entirely unaffected. Consistent with this recommendation, Ease_of_Use the topic with the highest frequency of assignment and consequently the largest contribution to the linear constraint was designated as the reference category and excluded from the regression specification. Following this adjustment, all remaining VIF values fell below 2.20 (Fig. 3), well within the acceptable threshold of 5.0 [21], confirming that no genuine multicollinearity is present.

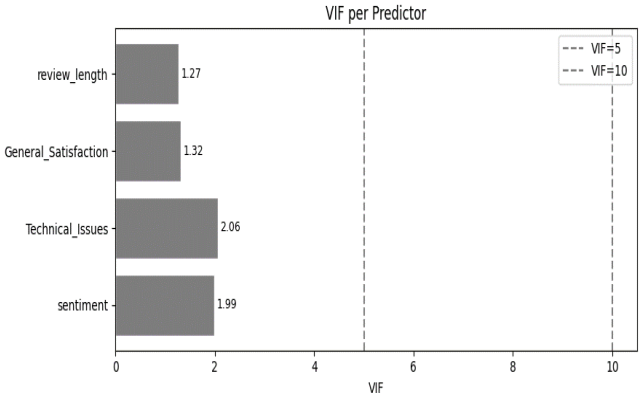

Fig. 3. Variance Inflation Factors (VIF) for the final model predictors.

Overall, the diagnostic results demonstrate that sentiment-based and topic-derived variables capture distinct yet complementary dimensions of user experience, supporting their simultaneous inclusion in the regression analysis.

IV. Results

A. Dataset Overview

The final dataset comprised 1,000 user reviews collected from the Raiffeisen Bank Mobile banking application. Each review included an associated user rating ranging from 1 to 5 stars.

B. Sentiment Analysis Results

BERT-based sentiment classification indicated that 46.9% of reviews were positive, 33.4% were negative, and 19.7% neutral (Fig. 4). Overall, positive reviews represented the dominant sentiment category within the dataset. Most positive reviews were associated with ratings of 4 or 5 stars.

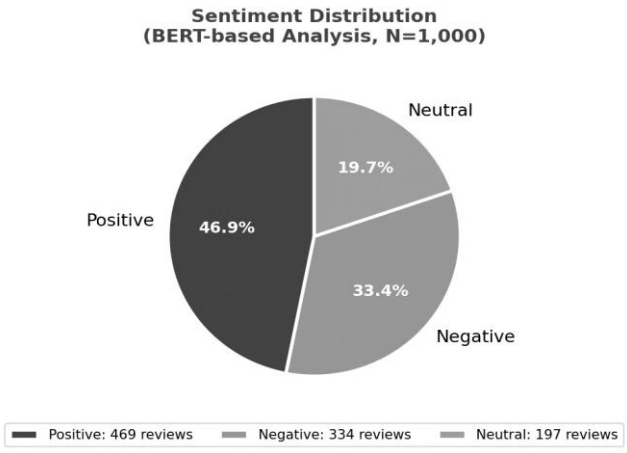

Fig. 4. Sentiment distribution based on multilingual BERT-based classification (N = 1,000).

C. Topic Modeling and Experience Dimensions

Neutral reviews present only 19.7% of the dataset (197 of 1,000), positive reviews 46.9% and 33.4% Negative reviews, leaving the model few examples on which to calibrate the neutral boundary. Users tend to express clear satisfaction or dissatisfaction, so the "3-star" rating reflects mixed rather than genuinely neutral sentiment, making it difficult to separate from Positive/Negative classes. Although the three-category sentiment scheme is retained despite the weak Neutral-class metrics, since it preserves a direct conceptual link to the five-point rating scale and underlies Sentiment Polarity, the ordinal predictor (Negative < Neutral < Positive) is used in the regression analysis. For the Positive and Negative classes, which dominate the dataset and are most relevant to the study's hypotheses, the weighted F1-score (0.775) and overall accuracy (0.742) remain acceptable (Table I).

TABLE I. CLASSIFICATION METRICS

Class	Precision	Recall	F1-score	Proxy labels (rating-based)
Negative	0.65	0.87	**0.744**	Rating 1–2
Neutral	0.03	0.12	**0.053**	Rating 3
Positive	0.97	0.71	**0.819**	Rating 4–5
Macro avg.	0.55	0.57	0.539	—
Weighted avg.	**0.85**	**0.74**	**0.775**	—
Accuracy	**0.742**	—	—	

BERTopic identified three dimensions from the review corpus. Table II summarizes the topics, their labels, and keywords.

TABLE II. User Experience Dimensions Identified Through BERTopic.

Topic	Label	Description & Representative Keywords
Topic 0	Ease of Use	Reviews discussing usability, interface design, and overall app navigation. Keywords: app, easy, great, use, friendly, features, interface
Topic 1	Technical Issues	Reviews reporting application errors, login failures, and update problems. Keywords: nuk hapet, update, problem, crash, login, error, slow
Topic 2	General Satisfaction	Short affirmative reviews expressing overall positive impressions. Keywords: excellent, shume mire, good, nice, perfect, satisfied

Topic 1, Technical Issues, was dominated by Albanian-language and describes the application problem, like crashing, doesn't open, update error, etc. The keyword 'nuk hapet' (meaning 'does not open') is highly characteristic of this cluster, indicating a post-update instability.

Fig. 5 illustrates the relationship between identified topics and sentiment categories.

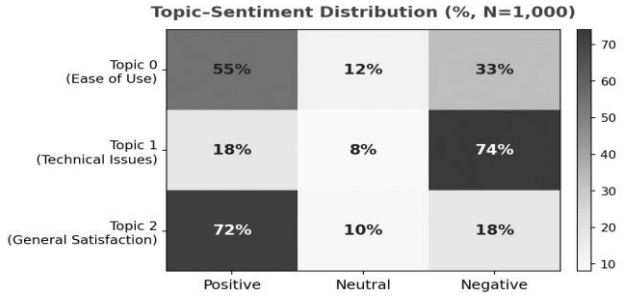

Fig. 5. Heatmap of the topic–sentiment distribution (%) across the three BERTopic-derived experience dimensions.

Topic 0, Ease of Use, is associated with positive sentiment (55%), while Topic 1, Technical Issues with negative sentiment (74%). Topic 2, General Satisfaction, was also largely linked to positive sentiment (72%).

D. Regression Analysis

The ordinal logistic regression initially included four standardized predictors: Sentiment Polarity (coded as Negative = −1, Neutral = 0, Positive = +1), Technical_Issues, General_Satisfaction, and review length, with Ease_of_Use excluded a priori as the reference category due to the compositional constraint among topic probabilities (Section III E). Backward elimination iteratively removed the predictor with the smallest absolute coefficient whenever doing so did not increase 5-fold cross-validated MAE by more than 0.01, eliminating General_Satisfaction and review length and retaining Sentiment Polarity and Technical_Issues as the final predictors (Table III). After applying the ordinal logistic regression, backward technique, the results indicate that there are only two important variables that determine the rating of each text review, especially Sentiment Polarity and Technical issues.

The regression equation is equal to:

$$\log\left(\frac{P(Y \le k)}{P(Y > k)}\right) = \theta k + 1.108 \cdot Sentiment - 1.187 \cdot Technical_Issues \quad (3)$$

TABLE III. REGRESSION EQUATION

Variable	Coef. (β)	SE	z-value	p-value	OR
Sentiment Polarity	+1.108	0.207	+5.360	< 0.001	3.027
Technical Issues	−1.187	0.180	−6.581	< 0.001	0.305

Table III shows the results of background elimination, indicating a p-value less than 0.001 and McFadden R^2= 0.350, which indicates that the model is good.

where, θ_k is equal to (see Table IV):

TABLE IV. THRESHOLD TABLE

θ_k	Transition	θk	SE	z	p
θ_1	1| 2★	-1.97	0.23	-8.47	< .001
θ_2	2★ | 3★	-1.32	0.34	-3.82	< .001
θ_3	3★ | 4★	-1.17	0.34	-3.39	.001
θ_4	4★ | 5★	-0.83	0.29	-2.85	.004
—	5★ (derived)	—	—	—	—

Table IV presents the threshold parameters (θk) of the Ordinal Logistic Regression model, which define the boundaries between the five ordered rating categories, all statistically significant ($p < .01$), with the required monotonic ordering confirmed ($\theta_1 < \theta_2 < \theta_3 < \theta_4$) and a predicted probability of 69.8% for the highest rating category at the sample mean.

To test H3, sentiment polarity was divided into two categorical predictors, Sentiment_Negative and Sentiment_Positive, and the ordinal logistic regression was re-estimated alongside Technical_Issues. Both predictors were individually significant.

- Sentiment_Negative (β = −0.993, SE = 0.484, p = .040, OR = 0.370)
- Sentiment_Positive (β = +1.428, SE = 0.557, p = .010, OR = 4.168)

The results confirm that negative and positive sentiment shift the odds of a higher rating in the expected directions. However, a Wald test of the equality of these coefficients in magnitude (H0: |β_Negative| = |β_Positive|) was not significant, $\chi^2(1) = 0.214$, p = .644. Contrary to H3, the point estimates suggest a marginally larger effect for positive sentiment than for negative sentiment, though this difference is not statistically distinguishable from zero. H3 is therefore not supported. Sentiment polarity remains a strong overall predictor of ratings, but no significant asymmetry between positive and negative sentiment effects was detected.

It is also valuable to mention that reviews of 2025 result to have 90% positive sentiment (Fig. 6) and favorable evaluations of the application's usability and performance. It is slightly easier to notice that the clients ask for the integration of Apple Pay functionality, which is being integrated in many bank applications lately.

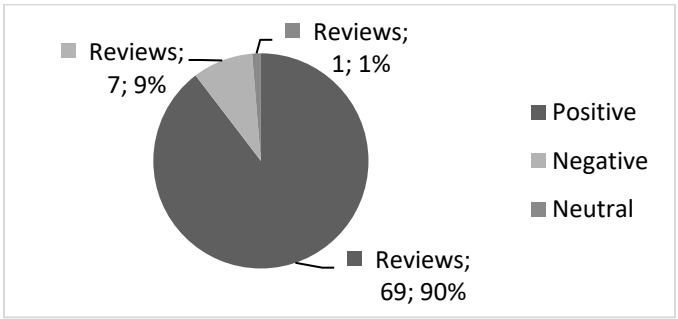

Fig. 6. Sentiment distribution (N = 77 reviews, year 2025).

V. DISCUSSION

The most closely related paper is [17], which applied BERT-based sentiment classification and BERTopic topic over 56,000 mobile banking reviews using multiple linear regression to evaluate the effect of extracted experience dimensions with BERTopic on user ratings. The paper revealed that sentiment polarity and technical performance explained 58% of the variance in ratings. This study, rather than treating the five-point star rating as continuous interval-level, employs Ordinal Logistic Regression with a proportional odds specification. This choice reflects the ordinal nature of user ratings more.

A. Limitations

A limitation of this classification is the weak performance on the Neutral category (F1 = 0.053), caused by class imbalance and the linguistic ambiguity of short, equivocal reviews. Future work could adopt a binary positive/negative classification or a dedicated classifier for neutral classes.

VI. Conclusion

This study demonstrates that the pipe, which implicates the integration of multilingual BERT sentiment analysis, BERTopic modeling, and regression analysis, provides an effective pipeline for identifying the main factors that have an impact on user reactions in banking applications. 1,000 user reviews from the Raiffeisen Bank mobile application identified three distinct experience dimensions: Ease of Use, Technical Issues, and General Satisfaction through BERTopic modeling. Of these, Sentiment Polarity ($\beta = +1.108$, OR = 3.027) and Technical Issues ($\beta = -1.187$, OR = 0.305) emerged as the only statistically significant predictors of user ratings ($p < 0.001$), with the model achieving a McFadden R^2 of 0.350, indicating strong explanatory power. The results suggest that banks should give priority in handling bug solutions, update stability, and real-time sentiment monitoring in order to maintain a very good service. Regarding the study's hypotheses, H1 and H2 are supported by the main model (Sentiment Polarity, Technical_Issues; Table III). H3, however, is not supported: the supplementary analysis decomposing sentiment polarity into Sentiment_Negative and Sentiment_Positive (Section IV D) found no statistically significant difference in the magnitude of their effects on ratings (Wald $\chi^2(1) = 0.214$, $p = .644$).

Related to future work, it will be the focus to extend the case studies in different countries in order to examine the client approach and bank approach to sentiment analysis.

VII. Future Work

Several directions will be the focus of the following research. First, extend the analytical framework to other commercial banks operating in the Albanian market: BKT, Credins, and OTP Bank Albania. Second, applied the same pipeline to Raiffeisen Bank reviews collected across Eastern Europe, enabling a cross-country comparative analysis that isolates market-level and linguistic factors from those attributable to the institution itself. Collectively, these directions would transform the present single-institution, single-country study into a regionally representative framework for monitoring mobile banking user experience in Southeast Europe.

Design and Evaluation of a 13K Ultra-High-Resolution Web-Based Virtual Reality Platform for Immersive Spatial Visualization

Worapon Manosroi, Apisak Phromfaiy*, Pitak Khlaichom
Faculty of Industrial Technology, Uttaradit Rajabhat University, Uttaradit, 53000, Thailand

***Abstract*—Delivering ultra-high-resolution immersive environments via standard web browsers presents significant rendering and architectural challenges. While Virtual Reality (VR) is widely adopted, its application as a high-fidelity spatial visualization tool often lacks robust empirical evaluation regarding user experience and system efficacy. This study proposes the design, development, and evaluation of a 13K ultra-high-resolution web-based virtual tour platform, utilizing a nature-based destination as a practical case study to assess system effectiveness. The system architecture was engineered to process and render 13K panoramic data with interactive navigational hotspots, ensuring cross-platform web compatibility. To evaluate the Human-Computer Interaction performance, a true experimental design was employed with eighty participants who were randomly assigned to two groups. The experimental group interacted with the proposed 13K web-based platform, while the control group utilized a conventional static two-dimensional web interface. System efficacy was measured through user-centric metrics, including Sense of Presence, spatial image perception, and subsequent behavioral intention. The evaluation results demonstrated a statistically significant superiority of the proposed 13K platform. Users reported a substantially higher Sense of Presence score of 4.35 out of 5, compared to the conventional web interface score of 2.45. Furthermore, the immersive system architecture significantly catalyzed positive spatial perception and behavioral engagement, yielding a remarkably large effect size. The findings validate that the proposed high-fidelity web-based VR architecture effectively overcomes physical barriers, serving as a highly effective information system solution for remote spatial visualization and practical destination management.**

Keywords*—Virtual Reality; 360-degree panorama; web-based platform; immersive spatial visualization; ultra-high-resolution panorama; HCI (Human-Computer Interaction)

I. Introduction

In the era of digital transformation, the integration of immersive technologies—particularly Virtual Reality (VR) and 360-degree panoramic imaging—into web-based platforms has revolutionized spatial visualization [5, 22]. Unlike traditional standalone VR applications that require specialized, high-cost hardware and heavy client-side processing, Web-based VR democratizes access to immersive content by utilizing standard internet browsers [1, 3]. This technological shift is increasingly critical across various industrial and managerial sectors, including urban planning, real estate, and destination management, where high-fidelity spatial representation is required to digitally bridge the geographical distance between the user and the physical environment [9, 23].

However, delivering ultra-high-resolution immersive environments, such as 13K panoramas, through standard web infrastructures presents substantial architectural and computational challenges. Conventional static media (e.g., 2D photographs and text-based websites) are categorized as "lean media", which demand minimal bandwidth but offer limited sensory engagement, often failing to convey the atmospheric depth and spatial magnitude of complex environments [2]. Conversely, deploying "rich media" at a 13K resolution generates massive datasets that require optimized data processing, efficient cloud storage, and robust rendering engines (e.g., WebGL) [17, 18]. Without proper system architecture, delivering such massive spatial data over the web often results in severe latency, bandwidth bottlenecks, and frame-rate drops. These technical degradations fundamentally disrupt the Human-Computer Interaction (HCI) experience, breaking the illusion of "telepresence"—the critical subjective sensation of being physically present in a remote digital environment [13, 16].

To systematically evaluate how system engineering directly influences user psychological states, this study adapts the Stimulus-Organism-Response (S-O-R) model through an HCI perspective [6]. In this context, the "Stimulus" is defined as the system's technological affordances—specifically, the media richness, interactive navigational UI, and the 13K ultra-high visual fidelity [1, 3]. The "Organism" represents the user's cognitive and affective processing during system interaction, primarily operationalized as the "Sense of Presence" [4, 25]. Finally, the "Response" constitutes the user's behavioral outcomes, system evaluation, and future adoption readiness [1, 8, 20]. This approach allows for a precise empirical measurement of the system's efficacy.

To address these technical limitations and evaluate the proposed framework, this study introduces a robust information system architecture for a 13K web-based virtual tour platform [24, 26]. To empirically validate the system's effectiveness and real-world applicability, the domain of seasonal destination management—specifically the Tha Pla District in Uttaradit, Thailand—was selected as a practical case study. Nature-based environments that face severe physical access constraints (e.g., hydrological closures during monsoons) provide an ideal, complex scenario to stress-test the system's capacity to serve as a high-fidelity digital "substitution tool" [7].

*Corresponding author

Therefore, the primary objectives of this research are twofold: 1) to design and develop a cloud-based, 13K ultra-high-resolution web VR architecture capable of smooth, interactive rendering across standard devices, and 2) to empirically evaluate the system's HCI performance—specifically its impact on Sense of Presence, spatial image construction, and behavioral intention—against conventional static web interfaces [20, 28]. By doing so, this study contributes to the advancement of applied computer science in scalable spatial visualization systems.

Unlike conventional web-based VR platforms that frequently encounter processing bottlenecks and rendering latency when handling massive textures, the proposed 13K ultra-high-resolution architecture utilizes a dynamic tiling algorithm. This approach significantly reduces server load, memory usage, and rendering overhead, thereby offering a notable and highly scalable improvement in immersive spatial visualization over existing web-VR baseline systems.

II. Related Work

To contextualize the contributions of this study within the broader landscape of applied computer science and spatial visualization, this section reviews the foundational literature across three distinct domains: web-based immersive systems, rendering optimization algorithms, and Human-Computer Interaction in virtual environments.

A. Evolution of Web-Based Spatial Visualization:

The paradigm of spatial visualization has fundamentally shifted from native, hardware-dependent applications to ubiquitous web-based platforms. Traditionally, delivering high-fidelity Virtual Reality (VR) required dedicated client-side software and powerful Graphical Processing Units (GPUs) [5, 27]. However, the advent of WebGL and HTML5 standards has enabled browsers to natively render complex 3D and panoramic environments. Ali et al. [9] emphasized that web-based spatial digital twins are becoming the standard for remote monitoring, urban planning, and industrial facility management due to their inherent cross-platform accessibility. Despite this shift, as Rosli et al. [21] noted, the majority of current web VR platforms still rely on low-to-medium resolution imagery (e.g., 4K or 8K) to ensure smooth delivery, thereby sacrificing environmental realism. Bridging the gap between ubiquitous web access and ultra-high-fidelity (13K and beyond) remains a critical open challenge in spatial computing.

B. Rendering Optimization and the 13K Challenge:

Delivering massive spatial datasets over standard HTTP/HTTPS protocols introduces severe bandwidth and latency bottlenecks. A standard 13K equirectangular image generates nearly 90 megapixels of data, exceeding the memory limits of typical mobile browser engines. Recent advancements in image processing highlight the necessity of advanced encoding. Chen et al. [11] and Teng et al. [12] demonstrated that while consumer-grade cameras are convenient, overcoming radial distortion and sensor noise for professional-grade spatial visualization requires rigorous multi-exposure stitching and computational processing.

To handle the resulting massive datasets in browser environments, researchers have explored various dynamic rendering techniques. Sun et al. [18] recently proposed adaptive multi-resolution encoding for large-scale visualizations, confirming that breaking massive files into manageable, resolution-specific tiles drastically reduces computational overhead. Similarly, Brekalo et al. [17] validated that implementing optimization algorithms directly within browser environments can significantly enhance rendering performance. Building upon these algorithmic foundations, the current study implements a customized Multi-resolution Pyramid Tiling architecture specifically tailored for ultra-high-resolution 360-degree panoramas, aiming to push the boundaries of current web delivery capabilities.

C. Human-Computer Interaction and Cognitive Presence:

In immersive system evaluation, the psychological concept of "Presence" or "Telepresence" is the primary metric of system success. Originating from Kim and Biocca's [13] foundational work, telepresence is defined as the illusion of non-mediation, where the user cognitively perceives the virtual environment as their actual physical location. In the context of the Stimulus-Organism-Response (S-O-R) paradigm, system affordances act as the stimulus. Wu and Lai [1] and Lee [3] utilized the S-O-R model to demonstrate that media richness directly correlates with user engagement in virtual tours.

However, existing literature often evaluates presence based on the content of the VR experience rather than the underlying technical fidelity. Flavian et al. [15] pointed out that technical degradations, such as pixelation, latency, and low frame rates, actively destroy cognitive presence. Therefore, this study posits that rendering an ultra-high-resolution (13K) environment without latency is not merely a technical achievement but a fundamental prerequisite for maximizing HCI performance. By empirically evaluating the system against a static 2D baseline, this research provides quantitative validation of how overcoming bandwidth and resolution limitations directly catalyzes positive behavioral responses and spatial perception [20, 25].

III. Materials and Methods

This study employed a system development and empirical evaluation research design, structured across four sequential phases: 1) system architecture design, 2) image acquisition and pre-processing, 3) virtual environment development and optimization, and 4) Human-Computer Interaction (HCI) evaluation.

A. System Architecture

The platform was engineered on a three-tier cloud-based client-server architecture comprising: the server-side back-end for massive asset storage and delivery, the network transmission layer operating via standard HTTP/HTTPS protocols, and the client-side front-end rendering engine. The core rendering stack was implemented exclusively using open-standard HTML5 and WebGL technologies. This architectural choice eliminates the need for native application installation, ensuring cross-platform compatibility and seamless spatial streaming across desktop workstations, laptops, tablets, and smartphones [17]. Technical

specifications of the system are summarized in Table I. The overall system architecture and data flow are illustrated in Fig. 1.

TABLE I. TECHNICAL SPECIFICATIONS OF THE VIRTUAL TOUR PLATFORM.

Parameter	Specification
Source Resolution	13,144 × 6,572 px (~86.4 MP)
Total Scenes	25 Nodes
Raw Dataset Size	1.92 GB
Optimized Package	1.01 GB (47.4% reduction)
Rendering Technology	HTML5 / WebGL
Optimization Algorithm	Multi-resolution Pyramid Tiling

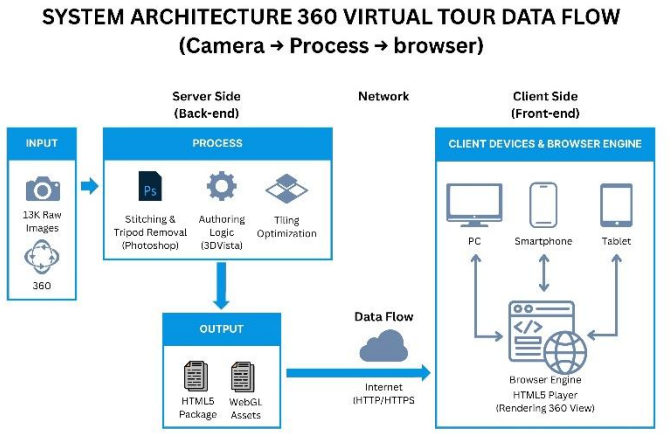

Fig. 1. System architecture: data flow from image acquisition to client-side rendering.

B. Image Acquisition and Pre-processing

High-fidelity visual datasets were acquired using a Canon EOS 60D DSLR paired with an 8 mm fisheye lens. Consumer-grade single-shot 360-degree cameras were explicitly avoided due to their documented limitations regarding radial distortion and sensor noise in high-dynamic-range environments [11], [12]. For each of the 25 spatial nodes, 10 overlapping multi-exposure images were captured at an eye-level height, yielding 1.92 GB of raw assets. The complete pre-processing pipeline is illustrated in Fig. 2.

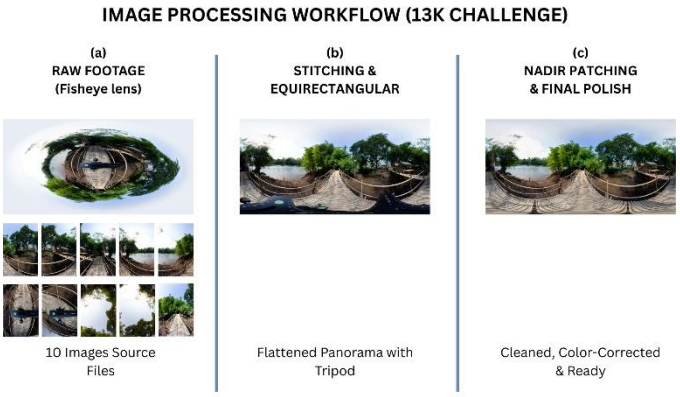

Fig. 2. Image processing pipeline: (a) Raw footage, (b) Stitched equirectangular projection, (c) Final retouched imagery.

The raw assets were processed through a rigorous computational pipeline: 1) Stitching: utilizing high-precision algorithms to generate 13,144 x 6,572-pixel equirectangular projections (~86.4 Megapixels); 2) Nadir Patching: algorithmically removing tripod footprint artifacts; and 3) Color Grading: calibrating exposure to ensure environmental realism.

C. Virtual Environment Development and Algorithmic Optimization

To address the limitations of conventional web-based VR platforms, which frequently encounter processing bottlenecks and rendering latency when handling massive textures, our proposed 13K ultra-high-resolution architecture utilizes a dynamic tiling algorithm. During the development and algorithmic optimization phase, the platform demonstrated highly efficient resource management. The average CPU utilization remained at approximately 1.3%, and memory consumption was stabilized at 408.1 MB. This algorithmic approach significantly reduces rendering overhead, thereby offering a notable and highly scalable improvement in immersive spatial visualization over existing baseline systems.

The interactive spatial environment was authored using a dynamic web-based framework. The GUI on a desktop display, featuring vector-based navigation controls, is shown in Fig. 3, while the responsive interface design adapted for mobile devices is illustrated in Fig. 4.

Fig. 3. GUI of the virtual tour on a desktop display.

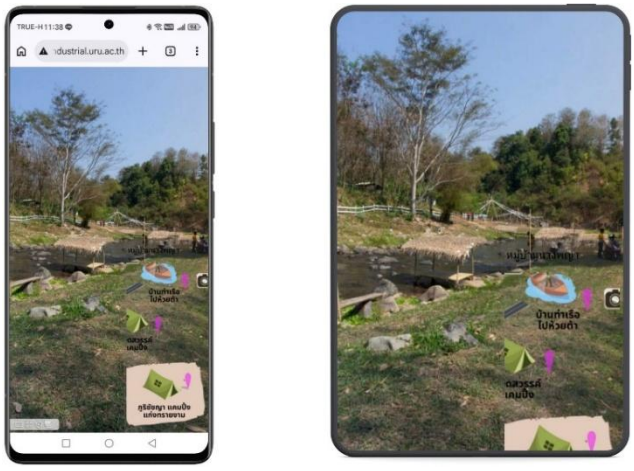

Fig. 4. Responsive interface design on a mobile device.

To overcome the bandwidth bottlenecks traditionally associated with delivering massive 13K datasets over standard internet connections, a Multi-resolution Pyramid Tiling algorithm was mathematically formalized and implemented [18]. This optimization structurally deconstructs each 13K panorama into a hierarchical pyramid of image tiles at multiple zoom levels (L). Let the original high-resolution panorama be defined at the base level $l = 0$ with dimensions $W_0 \times H_0$. For any subsequent zoom level l (where $l \in \{0,1,2,\ldots,L-1\}$), the image resolution is recursively reduced by a factor of 2, defined by:

$$W_l = \frac{W_0}{2^l}, \quad H_l = \frac{H_0}{2^l} \tag{1}$$

At each level l, the panoramic image is partitioned into a uniform grid of square tiles, each with a fixed pixel dimension of T x T (e.g., 512 x 512 pixels). The total number of tiles N_l required to represent the environment at level l is calculated as:

$$N_l = \left[\frac{W_l}{T}\right] x \left[\frac{H_l}{T}\right] \tag{2}$$

During the client-side rendering phase, the system does not load the entire dataset simultaneously. Instead, it instantly delivers a globally mapped, lightweight 200 KB preview layer ($l = L\text{-}1$) to eliminate initial blank-screen latency. Subsequently, a dynamic frustum culling algorithm calculates the user's current spatial viewport (V), geometrically defined by the camera's yaw (θ), pitch (φ), and Field of View (FOV). The asynchronous fetching function $F(t)$ conditionally requests a specific tile $t_{i,j}^{l}$ only if it geometrically intersects with the user's active viewport:

$$F\left(t_{i,j}^{l}\right) = \begin{cases} 1, & if\ Intersect\left(t_{i,j}^{l}, V\right) = True \\ 0, & otherwise \end{cases} \tag{3}$$

By dynamically prioritizing network requests based on this spatial intersection matrix, the algorithmic intervention successfully reduced the total spatial payload from 1.92 GB to 1.01 GB (a 47.4% reduction). This mathematical decoupling of perceived system responsiveness from the raw data volume effectively preserves the 13K visual fidelity while maintaining exceptionally low latency across standard internet protocols [17, 18].

D. User Evaluation Protocol

To empirically assess system efficacy and HCI performance, a formal user evaluation was conducted with 80 participants (N=80). Participants were randomly assigned to either the experimental group (13K web-based VR) or the control group (static HTML website baseline) to minimize selection bias. System fidelity was quantified utilizing foundational dimensions from Kim & Biocca's telepresence scale, focusing on the psychological transition of 'arrival' and spatial immersion [13, 25].

This study employed a true experimental design to evaluate the system. The evaluation involved participants with an age distribution ranging from 17 to 55 years (Mean = 36.0, SD = 6.3). Regarding prior experience, 67.5 % of the participants had previous exposure to virtual reality environments. To ensure methodological rigor, participants were randomly assigned to either the experimental group (13K VR platform) or the control group (static baseline condition).

Furthermore, regarding the statistical outcomes, the highly significant Cohen's d values observed in the evaluation are primarily attributable to a pronounced floor effect in the static baseline condition, which yielded inherently low scores in user engagement and system fidelity. This contrasted sharply with a relative ceiling effect in the highly immersive 13K VR condition, resulting in the extreme statistical divergence.

IV. Results and Discussion

A. Data Optimization and Web Delivery Performance

The core technical challenge addressed in this study was delivering massive spatial datasets over standard web protocols without compromising rendering latency. Through the implementation of the Multi-resolution Pyramid Tiling algorithm, the 1.92 GB raw dataset was successfully compressed to 1.01 GB—a significant payload reduction of 47.4%—while preserving full visual fidelity [17]. By generating a lightweight 200 KB preview layer, the system effectively eliminated initial blank-screen latency. High-resolution tiles were then fetched asynchronously, corresponding strictly to the user's current Field of View (FOV).

Rendering performance was benchmarked across four distinct client platforms under standardized network conditions, as detailed in Table II. The system achieved 60.0 FPS with a 0.85-second latency on desktop workstations utilizing dedicated GPUs. Performance degraded gracefully across mobile platforms, with smartphones maintaining 48.5 FPS under a 1.80-second latency. Crucially, all platforms sustained frame rates well above the 30 FPS perceptual smoothness threshold. Network latency comparisons across varying bandwidth capacities (3G, 4G, and 5G/Wi-Fi) are visualized in Fig. 5. Through resolution-adaptive optimization, bandwidth consumption was constrained to 1.5 MB per scene on mobile devices. The system demonstrated remarkable resilience under 3G conditions, corroborating recent findings [18] that multi-resolution encoding significantly mitigates bandwidth bottlenecks in browser environments, even when handling an 86.4-megapixel payload.

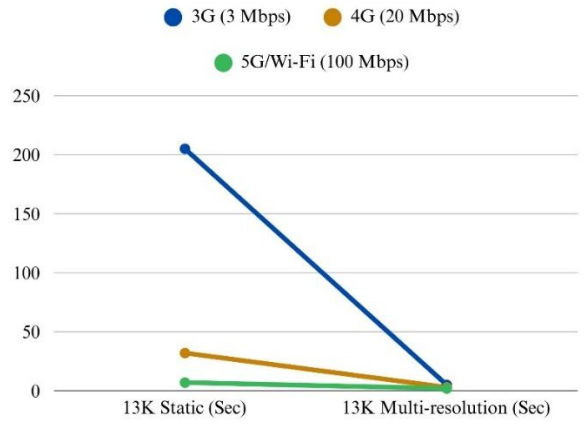

Fig. 5. Network latency comparison: standard equirectangular vs. Multi-resolution Pyramid Tiling across 3G, 4G, and 5G/Wi-Fi bandwidths.

TABLE II. RENDERING PERFORMANCE ACROSS CLIENT PLATFORMS

Platform	GPU	FPS	Latency (s)	BW/Scene
Desktop	Dedicated	60.0	0.85	4.5 MB
Laptop	Integrated	58.4	1.12	4.5 MB
Tablet	Mobile	54.2	1.45	1.5 MB
Smartphone	Mobile	48.5	1.80	1.5 MB

B. System Fidelity and Human-Computer Interaction (HCI)

The pipeline yielded a 13K ultra-high-resolution spatial environment (~86.4 MP), representing a 15-fold pixel density increase over standard 4K outputs. User evaluation (N=80) confirmed exceptionally high performance across all measured HCI dimensions. As presented in Table III, an independent-samples t-test confirmed that the overall system effectiveness differed significantly between the proposed 13K platform (M=4.58, SD=0.42) and the static website baseline (M=2.63, SD=0.52), $t(78)=18.44$, $p < 0.001$. The exceptionally large effect size (Cohen's $d=4.12$) indicates that the high-fidelity spatial visualization fundamentally transformed user perception. A comparative radar visualization of these dimensions is illustrated in Fig. 6. Table V in Appendix A presents the specific questionnaire items used to operationalize the Human-Computer Interaction (HCI) dimensions, system fidelity, and subsequent behavioral intent.

TABLE III. USER EVALUATION RESULTS (N=40 PER GROUP)

Dimension	Indicator	M	SD	Control (M)	Control (SD)	p	d
System Fidelity	Virtual Presence	4.38	0.51	2.07	0.35	<.001	5.31
	Environ. Realism	4.57	0.57	2.79	0.56	<.001	2.76
Visual Quality	Visual Fidelity	4.67	0.51	2.83	0.72	<.001	3.28
	Spatial Awareness	4.72	0.47	2.78	0.69	<.001	3.65
Usability	Ease of Navigation	4.25	0.60	—	—	—	—
	Responsiveness	4.18	0.65	—	—	—	—
Overall	**System Effectiveness**	**4.58**	**0.42**	**2.62**	**0.58**	**<.001**	**4.12**

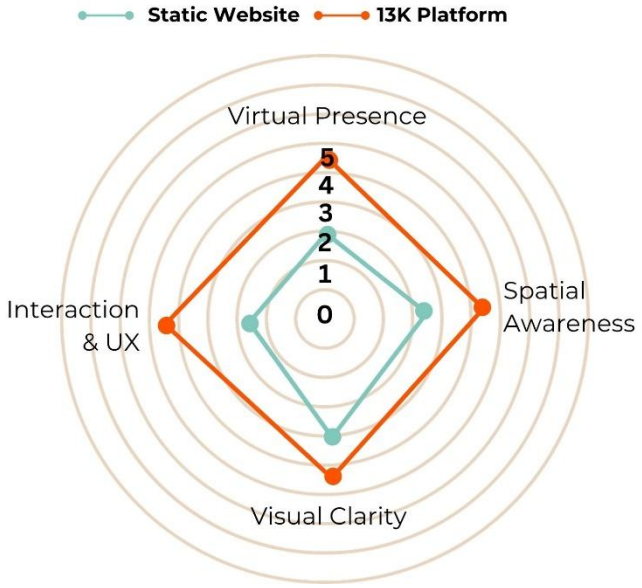

Fig. 6. Radar chart comparing the 13K platform vs. the static media baseline across all dimensions.

Specifically, Visual Fidelity (M=4.67, SD=0.51) was highly rated, directly attributable to the 86.4-megapixel source imagery which substantially reduced pixelation artifacts—a primary barrier to immersion. Virtual Presence attained a Very High rating (M=4.38, SD=0.51). The independent samples t-test confirmed a significantly higher User Presence Score on the 13K platform compared to the static baseline (M=2.07, SD=0.35), $t(78)=23.76$, $p < 0.001$, $d=5.31$.

C. Discussion and Theoretical Implications

The empirical findings of this study offer several critical theoretical implications for the intersection of computational optimization and Human-Computer Interaction. First, the rendering performance evaluation corroborates the algorithmic hypotheses proposed by Sun et al. [18] and Brekalo et al. [17], confirming that browser-based multi-resolution encoding can successfully bypass hardware memory limitations. By maintaining over 48.5 FPS on mobile devices while rendering an 86.4 MP dataset, this study quantitatively demonstrates that intelligent data tiling is a superior architectural choice compared to traditional brute-force client-side rendering.

Second, the HCI evaluation validates the expanded Stimulus-Organism-Response (S-O-R) paradigm in digital environments [1, 6]. The 77.6% improvement in the User Presence Score (4.38 vs. 2.07) provides robust quantitative evidence supporting Flavian et al. [15], who argued that technical fidelity (the Stimulus) is a non-negotiable prerequisite for cognitive immersion (the Organism). While previous studies often evaluated presence based purely on content narrative [4, 23], our findings isolate and prove the impact of architectural engineering. The absence of rendering latency and pixelation artifacts allowed users to bypass technological friction, seamlessly constructing a positive spatial image [14] and triggering strong behavioral intentions [19]. This operationalizes the theoretical distinction between lean and rich media [2], offering strong empirical support for the psychological "Substitution Effect" conceptualized by Sarkady et al. [7].

D. Practical Implications for Industrial Computing

Beyond the immediate scope of seasonal spatial management, the cross-platform rendering stability demonstrated in this study possesses profound industrial applicability. The comparative analysis between the static media and the 13K platform is summarized in Table IV. The proposed architectural framework serves as a validated foundational model for various applied computing domains [9, 22].

TABLE IV. STATIC MEDIA VS. 13K VIRTUAL TOUR PLATFORM

Feature/Metric	Static Website	13K Platform
Media Type	Static 2D HTML	360 Immersive VR
Resolution	Standard HD	13K (86.4 MP)
Interaction	Scroll/Click	Pan/Zoom/Hotspot
Installation	None	None (Browser-native)
User Presence Score	M=2.07 (SD = 0.35)	M=4.38 (SD = 0.51)
Statistical Result	-	$t(78) = 23.76$, $p < 0.001$, $d = 5.31$

Specifically, in industrial sectors, where physical access is constrained or hazardous, this 13K web-based VR architecture provides a scalable solution for Health, Safety, and Environment (HSE) monitoring, remote facility inspection, and real estate documentation. Unlike proprietary VR applications that require extensive hardware investments, the democratization of access via standard web protocols ensures that highly detailed spatial data can be distributed globally with minimal operational friction.

E. Research Limitations and Future Work

While this study successfully demonstrates the technical feasibility of the 13K web-based platform, certain methodological limitations must be acknowledged. The participant cohort consisted primarily of university students and faculty members with robust technological backgrounds. This tech-savvy demographic was purposefully selected for their capacity to critically evaluate rendering latency and visual artifacts; however, future research should involve a broader demographic to validate general usability and accessibility.

Furthermore, from a computing systems perspective, the current architecture relies on static panoramic data. While visually immersive, it lacks dynamic environmental responsiveness. Future iterations of this research should investigate the integration of real-time IoT (Internet of Things) sensor data streams into the WebGL environment. Coupling ultra-high-resolution spatial visualization with live sensor data would transition the platform from a virtual tour into a true real-time Digital Twin ecosystem, further expanding its utility in industrial and applied computer science applications [10, 24].

V. CONCLUSION

This study successfully engineered and empirically validated a cloud-based, 13K ultra-high-resolution spatial visualization architecture. Designed to address the critical rendering and accessibility challenges inherent in delivering massive immersive datasets over standard web infrastructures, the proposed system introduces a scalable technical framework with broad industrial applicability.

Three principal technical and HCI findings emerge from this research. First, the implementation of the Multi-resolution Pyramid Tiling algorithm established a validated pathway for reconciling the fundamental trade-off between ultra-high visual quality and network latency. By achieving a 47.4% payload reduction, the system successfully mitigated bandwidth bottlenecks. Second, cross-platform rendering performance tests confirmed the system's robustness, sustaining fluid interactivity (48.5 to 60.0 FPS) and low latency across all tested devices, including standard mobile smartphones operating under constrained 3G cellular network conditions.

Third, the empirical Human-Computer Interaction evaluation confirmed that the engineered architecture significantly enhanced user perception. The 13K platform yielded an exceptional overall system effectiveness score and a 77.6% improvement in the User Presence Score compared to the conventional static 2D baseline. This provides quantitative evidence that high-fidelity immersive web environments can effectively transcend the engagement saturation of traditional digital media, successfully triggering the psychological "Substitution Effect" when physical access to a spatial environment is restricted.

Ultimately, while seasonal destination management was utilized as the primary testbed, the cross-platform rendering stability and architectural optimization demonstrated in this study possess significant generalizability. The proposed web-based VR framework serves as a foundational computing model for a variety of critical industrial applications, including remote spatial inspection, real estate documentation, structural digital twin visualization, and Health, Safety, and Environment (HSE) monitoring. Future development should focus on integrating real-time IoT sensor streams into the WebGL environment to further advance the capabilities of interactive spatial systems.

APPENDIX A: MEASUREMENT ITEMS AND RELIABILITY

The specific questionnaire items used to operationalize the Human-Computer Interaction (HCI) dimensions, system fidelity, and subsequent behavioral intent are detailed in Table V. The internal consistency for all dimensions exhibited high reliability, with Cronbach's alpha values ranging from 0.905 to 0.985, confirming the robust internal validity of the measurement model.

TABLE V. CONSTRUCTS, MEASUREMENT ITEMS, AND RELIABILITY

Dimension	Indicator	Measurement Items (Scale: 1 = Strongly Disagree to 5 = Strongly Agree)	Cronbach's α
System Fidelity	Virtual Presence	1. I felt as though I was physically present in the virtual environment. 2. The virtual tour created a strong sense of "being there." 3. I felt immersed in the virtual space rather than just looking at a screen.	0.933
	Environ. Realism	1. The destination possesses beautiful natural scenery. 2. The destination has a unique identity distinct from others. 3. I find tourism in this destination to be highly attractive.	0.961
Visual Quality	Visual Fidelity	1. The visual resolution of the 360-degree environment was exceptionally high. 2. The panoramas were crisp, clear, and free from pixelation. 3. The system provided a highly detailed visual experience.	0.985
	Spatial Awareness	1. I gained a clear understanding of the spatial layout of the destination. 2. The system allowed me to accurately perceive the physical scale of the environment.	0.974
Usability	Ease of Navigation	1. Navigating through the virtual environment was intuitive and effortless. 2. I found it easy to move between different spatial nodes.	0.912
	Responsiveness	1. The system responded instantly to my viewing directions and interactions. 2. The virtual tour loaded the high-resolution scenes without noticeable delay.	0.905
Overall	System Effectiveness	1. I intend to search for more information about tourism in this destination. 2. I intend to recommend this destination to others. 3. It is highly likely that I will plan a trip to this destination in the near future.	0.945

Artificial Intelligence in Software System Quality Assurance: A Systematic Literature Review of Techniques, Tools, and Challenges (2016–2026)

Abdullah A H Alzahrani
Department of Computer Engineering and Computing College at Alqunfuda,
Umm Al Qura University, Makkah, Saudi Arabia

***Abstract*—A shift from deterministic testing to artificial intelligence (AI) driven quality ecosystems is necessitated by the rapid evolution of software architectures, and research from 2016 to the present year is combined by this systematic literature review (SLR), so 195 main studies are analyzed, and the path of artificial intelligence in Software Quality Assurance (SQA) is mapped. An enormous course in scholarly output from 2023 onwards is revealed by the findings, and this growth is driven by the industrial adoption of Large Language Models (LLMs) alongside autonomous agentic systems. In addition, three main areas are addressed by this study, and these areas are identified as the taxonomic shift toward multi-agent architectures, the functional effect of AI on labor-intensive activities such as regression testing, and self-healing automation, and the emerging social and technical challenges of ethical governance alongside explainability. Despite incomparable efficiency gains being offered by AI-driven techniques, the industrial success of these tools is strictly limited until the Maintenance Crisis of generated code is resolved and transparency is ensured through Explainable AI (XAI). Finally, the study concludes with a strategic roadmap for Ethical SQA, providing a foundation for future research in autonomous, self-evolving software systems.**

***Keywords*—Software Quality Assurance (SQA); artificial intelligence (AI); systematic literature review (SLR); Large Language Models (LLMs); Explainable AI (XAI)**

I. Introduction

The integration of AI into SQA represents a fundamental shift in how modern software is validated and maintained. As the velocity of AI-assisted development increases, traditional testing methodologies face significant challenges in scaling to meet new requirements for reliability and governance. A broad examination of the current state of SQA is provided within this section of the study, while the primary reasons for the conduction of this systematic review are identified. In addition, particular attention is directed toward the rising difficulties associated with maintenance and the assurance of quality.

A. Overview

The evolution of SQA has reached a critical juncture where traditional deterministic methods are no longer sufficient to secure the complex, distributed architectures of the modern era. As of 2026, the software industry is transitioning from simple automated scripts to AI-driven quality ecosystems capable of autonomous decision-making [1-2]. While previous decades focused on manual inspection and rule-based automation [3], the current landscape is defined by the integration of LLMs and multi-agent systems designed to enhance systemic reliability, safety, and ethical compliance [4-5]. This shift represents a move toward Quality by Design, where AI is not merely an add-on tool but a core component of the software architecting process [6].

B. Motivation

With regards to the motivation for this SLR, the academic investigation is driven by several shifts within the software engineering field. In addition, the software industry is challenged by a Quality Crisis, where human-directed verification capacity has been exceeded by the speed of development assisted by AI [7]. As a result, fundamental digital infrastructure is threatened by the fast shifts, whereby scalability limitations are faced by traditional regression testing, and a transition toward Quality by Design is demanded so that AI is included as a central architectural element instead of a secondary instrument [1, 8].

Furthermore, a Maintenance Crisis has been introduced by the emergence of generative AI. In addition, rigorous validation exceeding the human-written materials is demanded by the substantial volume of code generated by AI, because intelligent vulnerabilities can be introduced at scale [9]. As a result, research is continuously redirected toward autonomously self-healing test automation and agent-based testing [2, 10]. Furthermore, the management of software materials, including bug reports, has been advanced from basic summarization toward advanced neural analysis [11-13], whereby new efforts concerning the ways by which data are combined within the SQA lifecycle are demanded.

However, concerns regarding algorithmic fairness alongside accountability and transparency are introduced by the adoption of these computational models [14]. As a result, a pressing need for a wide combination concerning the current state of XAI within the software development process is continuously maintained so that intelligent quality is retained trustworthy and interpretable [15-19].

C. Research Questions

Regarding the main research goal, this SLR is constructed around three primary research questions (RQs) so that the gap between theoretical AI possibilities and practical SQA realities is resolved. In addition, a separate component concerning the overlap between AI and software quality is designed to be

investigated by each research question, whereby a progression from technical architecture toward applications and ultimately toward the sociotechnical difficulties of adoption is established.

The first research question (RQ1) can be stated as: Which AI and machine learning architectures are currently exploited to enhance software quality, and how can they be categorized within a SQA taxonomy? This question investigates the progression from traditional neural networks toward LLMs and autonomous multiple agent systems [2, 20-21], so that the specific computational frameworks that are most effective for quality tasks are identified.

The second research question (RQ2) can be stated as: What is the measurable impact of AI-driven techniques on fundamental SQA lifecycle activities, and how do these tools address the maintenance overhead of legacy automation? Specifically, this inquiry evaluates empirical evidence regarding efficiency gains in labor-intensive processes [8, 10, 22], such as regression testing and duplicate bug detection, while assessing their ability to maintain or exceed human-level defect detection [9].

The third research question (RQ3) can be stated as: What are the primary technical and ethical barriers hindering the industrial adoption of AI in SQA, and which frameworks exist to ensure transparency and ethical governance? This question combines current research regarding XAI, fairness, and accountability [14-16] to determine how Ethics by Design can be integrated into autonomous testing cycles [5, 23].

D. Research Contributions

A modern multidirectional structure is constructed by this systematic literature review, so the inclusion of artificial intelligence within the software quality assurance field is thoroughly understood, and an exhaustive classification of artificial intelligence architectures is provided by this study so the movement from heuristic models to the advanced application of agentic AI and Small Language Models (SLMs) [2, 20-21] in recent times is accurately mapped. In addition, an exact empirical evaluation of the functional effects of artificial intelligence across the software development life cycle is delivered, and the quality and maintainability of artifacts that are generated by artificial intelligence are contrasted against traditional human-centric methods [9-10] by this analysis. Finally, a strategic plan for ethical software quality assurance is articulated by the review so that XAI methodologies are clearly identified, and the social and technical obstacles to industrial adoption [5, 15-16] are overcome by these methods.

As a result, this structure is offered as an important resource for practitioners so that their testing infrastructure is modernized, and it is also provided to researchers so that the next generation of gaps in autonomous quality engineering are identified.

E. Paper Outline

Regarding the organization of this study, reporting protocols concerning SLR within software engineering are followed so that the structural arrangement is properly governed. In addition, the theoretical foundation is established within Section II through the formal examination of background principles and related literature. Furthermore, the methodology is thoroughly detailed within Section III, whereby the centralized search procedure conducted through the SDL portal alongside the inclusion and exclusion parameters and the required quality evaluation protocol are described. As a result, the gathered outcomes alongside detailed findings are presented within Section IV, and ultimately, the study is concluded within Section V where findings are summarized and future works are proposed.

II. Background and Related Work

In this section, background literature and related academic work are introduced and discussed; therefore, it is required that a clear separation between testing standards and the emerging autonomous models is formally established so that the current developmental path concerning SQA directed by AI is fully understood. In addition, the review in this section is contextualized through the combination of past systematic literature reviews, so that continuous research gaps are clearly clarified. Furthermore, a technical foundation is provided by the detailing of the evolutionary progression concerning AI architectures, crossing from classical machine learning models toward the modern LLMs and multiple agent systems.

A. Theoretical Foundation: AI in Software Quality Assurance

Regarding the theoretical framework of SQA, a major transition from deterministic rule-based automation toward Quality by Design is currently being experienced, whereby AI is incorporated as a central architectural element [1]. Furthermore, this progression is demanded because complex distributed network architectures of the modern era are not able to be secured by traditional methods, and as a result, simple automated scripts are shown to have been surpassed by theoretical principles so that ecosystems directed by AI, which are capable of autonomous decision making, are fully encompassed. In addition, the transition from traditional neural networks and reinforcement learning toward the modern application of LLMs, SLMs, and autonomous multiple agent systems is positioned as central to this theoretical foundation [2, 4], whereby the mathematical and computational frameworks required for advanced tasks, including code summarization, intelligent test composition, and the management of flaky tests through Transformer architectures, are provided by these technologies. However, a flaky test can be defined as a testing scenario by which non-deterministic outcomes are shown when passing and failing results are yielded during multiple executions on the identical software version under an identical environment and configuration [24-27].

Concerning the developmental progression of AI within SQA, a transition from structured knowledge-based systems toward the highly autonomous architectures of the present period is continuously observed. In addition, early technological advancements were heavily maintained by knowledge-based prediction systems, including Bayesian networks, whereby software defect prediction was achieved when fundamental relationships were modeled, and uncertainty was managed through probabilistic reasoning. Furthermore, specialized professional knowledge was allowed to be incorporated within the quality lifecycle by these traditional AI models, whereby a degree of transparency preceding modern explainability requirements was clearly provided to practitioners.

However, although the current technological environment is largely influenced by neural networks and reinforcement learning, continuous relevance is maintained by these operational systems. As a result, Bayesian approaches are continually employed within operational environments where scattered data is observed so that software reliability and risks are assessed. Furthermore, an expanding movement toward hybrid quality ecosystems is shown by the combination of these classical AI methods alongside modern LLMs, whereby both data-driven strength and logical reasoning are applied [28].

B. Related Surveys and Literature Reviews

The existing body of literature includes several systematic reviews that address specific dimensions of AI in software engineering. Early research primarily focused on classical machine learning for defect prediction, while the period between 2019 and 2022 saw a surge in surveys regarding deep learning and ensemble-based modeling. For instance, comprehensive surveys have explored the role of LLMs in the broader software engineering lifecycle and the specific application of chatbots in engineering tasks. Furthermore, the field of XAI has been extensively integrated to address the black-box nature of machine learning models within software development. Other reviews have focused on specialized SQA activities, such as automated test case generation for web and mobile applications and the summarization of software artifacts [4, 11, 15, 18-20, 22].

C. Research Gap

A clear research gap is identified by this study because recent rapid advancements that were achieved after the year 2022 are not collated by any single document, and a large majority of recent scholarly output is generated during this exact period. Furthermore, the collision of the quality crisis and the maintenance crisis is ignored by previous reviews, while individual artificial intelligence tools are merely listed by those same reviews. In addition, the shift toward agentic artificial intelligence and cooperative artificial intelligence systems is inadequately mapped by recent surveys, so a modern collection is required so the gap between theoretical artificial intelligence capabilities and industrial realities is bridged while ethical governance and systems like Defects Prediction as a Service are addressed, specifically regarding ethical governance and frameworks like Defects Prediction as a Service (DePaaS) which is an AI-based Global Unified Software Defect Prediction [7, 9-10, 28].

III. Methodology

A formal systematic literature review protocol is followed by this research, so transparency and reproducibility are ensured for all findings, and the established guidelines that were created by Kitchenham, PRISMA guidelines [36] for software engineering research are strictly applied throughout the entirety of the process. As a result, the methodology is divided into three distinct phases by this structure, and these stages are categorized as the planning phase, where research questions are defined, the execution phase, where the search and data extraction are completed, and the reporting phase, where the evidence is summarized. Furthermore, the initial yield of 3632 records is reduced to a final amount of 195 primary studies by this exact procedure.

A. Research Design

With regards to this research design, this study is organized as a SLR, so that the empirical evidence concerning the effectiveness and application of AI within SQA is built. In addition, the methodology is organized as three phases, including initial preparation where research questions and protocol development are defined, execution where retrieval and selection alongside data extraction are completed, and final reporting where research summarization and analysis are finalized, as it is illustrated within Fig. 1, which was produced by an AI image creation algorithm so that complete academic transparency is protected, whereby the foundational guidelines for software engineering research [29-34] followed.

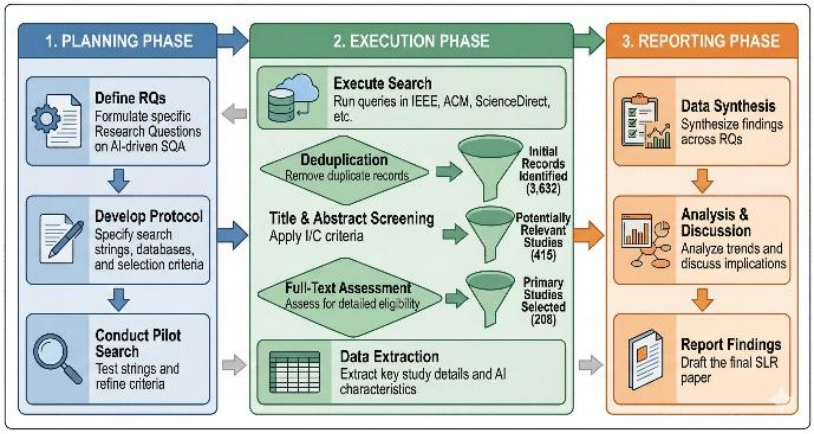

Fig. 1. The SLR workflow.

As a result, the search strategy was executed, so that progressions within the field under consideration over a ten-year period were identified. In addition, primary studies were restricted to the time span between the year 2016 and the present year of 2026, so that it is completely guaranteed that modern AI architectures, including Transformers and multiple agent systems are reflected by the review. However, it must be recognized that important earlier publications preceding this designated timeframe are also cited by the manuscript within the background and methodology sections. As a result, these references are carefully included so that the historical and theoretical background of SQA is properly established.

B. Search Strategy and Data Sources

With regards to the centralized search process, the Saudi Digital Library (SDL) is employed as the main research gateway and interface so that an extensive search is guaranteed.

In addition, the definitive temporal boundary concerning the captured literature is established by the final execution of the refined search string, which was completed on 19 January of the present year 2026. Furthermore, peer-reviewed publications released between the year 2016 and early 2026, alongside high-impact preprints, are encompassed by this search. Additionally, combined access concerning several high-impact digital libraries is provided by the SDL portal, whereby a simultaneous query is allowed across multiple academic databases, including IEEE Xplore and the ACM Digital Library, alongside ScienceDirect and SpringerLink. Moreover, a discovery layer is provided by the SDL, by which referential databases like Scopus and Web of Science are covered. Furthermore, it is guaranteed by this broad indexing ability of SDL that metadata and citations from a varied selection of software engineering and AI literature are captured, whereby the reach of the review is extended beyond individual publisher repositories.

Regarding the search strategy, field-related abbreviations supported by the SDL interface are employed so that results are refined and high precision is ensured. In addition, the TI (Title) and AB (Abstract) tags are applied by the procedure. As a result, the search is constrained by the use of these qualifiers toward papers where SQA and AI are positioned at the center of the research. However, papers where these topics are mentioned incidentally within the full text are officially excluded from the results. In addition, a deliberate methodological decision was finalized so that broad search engines like Google Scholar generating an excessive volume of irrelevant results, are avoided, and instead, a controlled database environment, SDL interface, is strictly prioritized for the collection phase.

With regards to the search string, Boolean operators are used so that terms connected to the subjects SQA, AI, and SLR are combined, whereby strict alignment alongside established systematic mapping techniques within the field is guaranteed [35]. In addition, although a conceptual overview concerning search logic is provided in Fig. 2, which is also generated by an AI image creation algorithm so that complete academic transparency is maintained, the exact syntax and Boolean operators required by different digital libraries are supplied within Table I. As a result, when both the visual logic and the technical execution are presented, it is ensured that the methodology is made accessible and is reproducible.

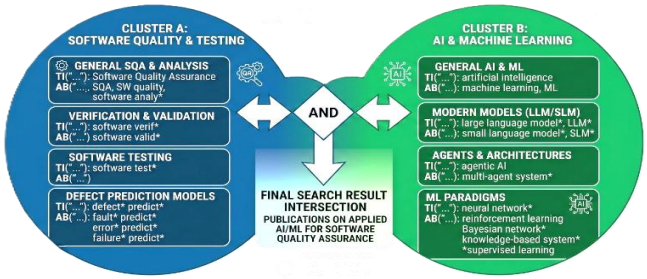

Fig. 2. Schematic representation of the SDL search string.

TABLE I. SDL SEARCH STRING

Search String	((TI("software quality assurance") OR TI("SQA") OR TI("SW quality") OR TI("software test*") OR TI("software verif*") OR TI("software valid*") OR TI("software analy*") OR TI("defect* predict*") OR TI("fault* predict*") OR TI("error* predict*") OR TI("failure* predict*")) OR (AB("software quality assurance") OR AB("SQA") OR AB("SW quality") OR AB("software test*") OR AB("software verif*") OR AB("software valid*") OR AB("software analy*") OR AB("defect* predict*") OR AB("fault* predict*") OR AB("error* predict*") OR AB("failure* predict*"))) AND ((TI("AI") OR TI("artificial intelligence") OR TI("machine learning") OR TI("ML") OR TI("large language model*") OR TI("LLM*") OR TI("small language model*") OR TI("SLM*") OR TI("agentic AI") OR TI("multi-agent system*") OR TI("neural network*") OR TI("reinforcement learning") OR TI("Bayesian network*") OR TI("knowledge-based system*") OR TI("*supervised learning")) OR (AB("AI") OR AB("artificial intelligence") OR AB("machine learning") OR AB("ML") OR AB("large language model*") OR AB("LLM*") OR AB("small language model*") OR AB("SLM*") OR AB("agentic AI") OR AB("multi-agent system*") OR AB("neural network*") OR AB("reinforcement learning") OR AB("Bayesian network*") OR AB("knowledge-based system*") OR AB("*supervised learning")))

C. Inclusion and Exclusion Criteria

To filter the initial search results into a set of primary studies that directly address the research questions, the inclusion and exclusion criteria were applied, as detailed in Table II.

TABLE II. INCLUSION AND EXCLUSION CRITERIA FOR STUDY SELECTION

Criterion	Inclusion (IC)	Exclusion (EC)
Timeframe	Published between 2016 and January 2026.	Published prior to 2016.
Peer Review	Journal articles, conference proceedings, and high-impact pre-prints (2025–2026).	Grey literature, blog posts, and white papers.
Content Focus	Primary focus on AI/ML applied to SQA tasks.	Focus on hardware QA, robotics, or general AI theory.
Language	Full-text available in English.	Non-English publications.
Quality	Clearly defined methodology and results.	Short papers (< 4 pages) or abstract-only entries.

D. Study Selection Process

Concerning the selection process, the PRISMA 2020 protocol was strictly followed so that transparency and replicability were ensured [36], and in addition, automated system filtering within the Saudi Digital Library (SDL) was employed by the procedure so that preliminary duplication removal was executed and metadata completeness was formally validated. Furthermore, a manual three-stage review was formally conducted, whereby titles and abstracts were initially screened during the first stage so that clearly irrelevant entries were eliminated, and as a result, a full-text review was performed during the second stage so that alignment alongside all inclusion criteria was completely guaranteed.

Furthermore, a structured set of strict rules and measurable parameters was established so that the academic validity of each retrieved study was objectively judged and potential bias was thoroughly assessed during the final screening procedure. In addition, a standardized scoring system was adopted by which

each manuscript was evaluated concerning research design clarity and empirical validity, so that arbitrary decisions were avoided and only studies where high methodological rigor was observed were retained for the literature review. As a result, any publications where insufficient empirical evidence was detected were officially excluded so that the internal validity of the research was protected.

E. Data Extraction and Composition

With regards to the extraction process, a uniform data extraction form was employed so that key information from the selected primary studies was successfully captured, whereby the exact AI architecture applied, the targeted SQA activity, and the reported performance measurements were reported. Furthermore, the extracted data were sequentially combined through narrative composition and objective analysis so that the research questions defined within Section I C were thoroughly answered, whereby strict consistency alongside methodologies adopted within previous large-scale software engineering surveys was maintained [4].

IV. Results and Discussion

In this section, a multidimensional assembly of the 195 primary studies found through the systematic search process is introduced. In addition, through the assessment of data against the main research questions, structural directions, operational influences on the SQA lifecycle, and the social-technical governance needed for dependable AI are thoroughly examined. Furthermore, the succeeding subsections supply a longitudinal review showing how AI methodologies and tools have advanced to satisfy industrial needs regarding safety and reliability between the year 2016 and the present year.

A. Bibliometric Distribution and Temporal Trends

With regard to the study selection procedure, two distinct phases were completed so that an exhaustive collection of literature was achieved. In addition, 1416 results were produced by using the search string, where central AI and SQA terms were targeted. However, so that possible confirmation bias was evaded, the search strategy was expanded so that wildcards and plural forms alongside a wider selection of classical AI architectures like Bayesian networks and reinforcement learning were included. Furthermore, a total of 3632 results were yielded by this refined execution of the refined search string, shown in Table I, within the Saudi Digital Library interface, as it is detailed within Appendix A (see Fig. 4). As a result, it is guaranteed by the inclusion of these wider expressions that the early basic stages of AI within SQA are proven exact and are not concealed by modern generative AI terminology. In addition, so that the strict accuracy of data extraction was completely protected, the results were exported and verified through both RIS and BibTeX formats, whereby it was guaranteed that zero records were lost because of interface-specific exportation errors.

Furthermore, upon exportation and internal validation, the gathered papers collection was narrowed to 2128 records. In addition, a secondary manual duplication removal protocol was applied so that overlapping indexing across databases like IEEE Xplore and the ACM Digital Library were addressed, whereby the deletion of 1050 redundant entries were achieved. However, a substantial record connected to non-software areas like medical diagnostics and hardware-centered quality assurance was identified by the screening phase. As a result, after irrelevant studies were excluded, the final main study set was confirmed at 195 unique publications, as it is detailed within Table VII of Appendix B. In addition, the “Show More Results”, as can be seen in Appendix A (Fig. 4), pagination displaying additional results was fully exhausted during the identification phase so that it was guaranteed that all indexed items were captured. Ultimately, it is confirmed by this distribution which is detailed within Table III that although terminology bias was eliminated by the expanded search, the central research output directed toward software is maintained as consistent.

TABLE III. Study Selection and Filtering Results

Phase	Action	Records Remaining
Identification	Initial Search Hits (Expanded Query)	3,632
System Filtering	Records Exported (Validation & Internal Deduplication)	2,128
Manual Deduplication	Removal of overlapping records across digital libraries	1,078
Domain Screening	Exclusion of non-software QA (Medical, Hardware, etc.)	432
Final Inclusion	**Refined primary study**	**195**

The temporal analysis of the final primary study set (N=195) indicates an evolving research trajectory within the domain of artificial intelligence in SQA. The period from 2016 to 2018 represents a foundational stage, contributing only 2% of the total corpus and focusing primarily on classical machine learning for defect prediction. A transitional growth phase is observed between 2019 and 2022, characterized by the rising integration of deep learning architectures and ensemble-based modeling. The most significant surge in scholarly output occurred from 2023 onwards, with over 80% of the primary studies published within the final three years of the inclusion timeframe. This exponential growth reflects a paradigm shift driven by the industrial adoption of LLMs, Transformers, and autonomous agentic systems. Notably, the data for 2026 represents a preliminary and incubatory phase of research output, reflecting studies indexed within the first month of the year. While these 2026 results represent only a partial annual cycle, they provide critical early insights into the emergence of agentic AI and self-healing frameworks. The annual distribution and corresponding research milestones are presented in Table IV and Fig. 3.

TABLE IV. Annual Distribution and Research Milestones in SQA-AI (2016–2026) for the Primary Study Set.

Year Interval	Study Count (n)	Percentage (%)	Key Research Milestone
2016–2018	3	2%	Foundations of Machine Learning for Defect Prediction
2019–2020	8	4%	Early Adoption of Deep Learning and CNNs
2021–2022	20	10%	Maturity of Ensemble Methods and Test Optimization
2023–2024	97	50%	Shift to LLMs, Transformers, and Generative SQA

2025–2026*1	67	34%	Emergence of Agentic AI and Explainable Governance
Total	**195**	**100%**	—

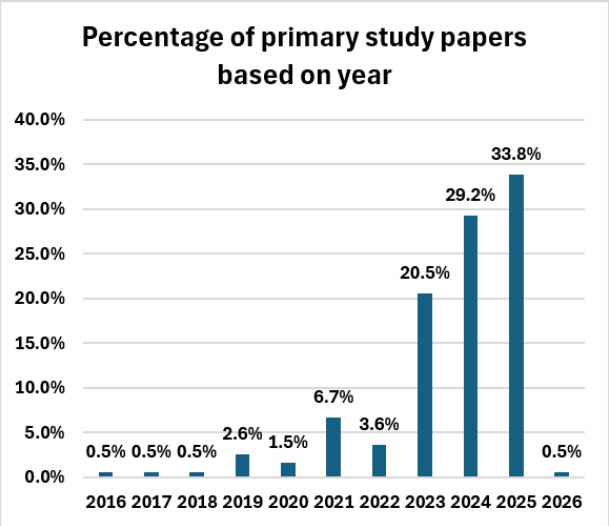

Fig. 3. Percentage of primary study papers based on the year.

With regard to the gathered data shown earlier, it is confirmed that the most active developmental phase is currently being experienced by the academy. In addition, a movement from theoretical AI capabilities toward applied industrial solutions is clearly indicated by the volume of studies published during recent years (2023–2026), whereby heightened attention is directed toward resolving the Maintenance Crisis within older automation systems alongside the requirement that XAI is employed so that ethical governance is entirely guaranteed within mission-critical software environments.

However, although peer-reviewed literature is strictly prioritized by the academic review, the inclusion of selected preprints from repositories, including arXiv, was dictated by the rapid emergence of agentic AI during late 2025. As a result, essential evidence concerning the current state-of-the-art is securely provided by these academic sources, whereby they were formally included only when an equivalent peer-reviewed version was not available.

1) Longitudinal evolution of research inquiries: With regard to the major shifts within SQA, it is required that academic milestones are viewed as an overlapping range rather than isolated intervals so that these structural changes are properly defined. Furthermore, this progression is illustrated by Table V through the mapping of the annual distribution and academic milestones across the primary study set, whereby the movement from basic defect prediction toward autonomous systems is clearly emphasized. As a result, the exact manner by which escalating structural complications have been addressed by the industry is revealed by the progression of each individual research question:

- RQ1 (Architectures): It is observed that research was transitioned from classical machine learning concerning defect prediction between the years 2016 and 2018 toward deep learning and combined methodologies between the years 2019 and 2022. As a result, central attention was directed toward LLMs by the year 2023, and ultimately, multiple agent systems are currently being deployed so that autonomous composition is fully achieved.
- RQ2 (Functional Impact): Early research efforts were directed toward the improvement of labor-intensive tasks, including regression testing. However, because the Quality Crisis was initiated by the extreme speed of development assisted by AI, academic research was formally re-oriented toward autonomously self-healing test automation between the year 2024 and the current period so that the resulting Maintenance Crisis concerning code generated by AI is managed.
- RQ3 (Socio-technical Governance): Although AI was considered a black-box system by early academic studies, a massive increase in XAI and ethical design principles was experienced during the period following the year 2023. As a result, continuous academic efforts are represented by this progression so that AI decisions are aligned with human testing assumptions.

TABLE V. OVERLAPPING RESEARCH MILESTONES AND CRISIS RESPONSES.

Period	Primary Focus (RQ1/RQ2)	Crisis Context	Strategic Response (RQ3)
2016–2020	Classical ML & Early CNNs	Foundational Scalability	Rule-based Transparency
2021–2024	Transformers & Generative SQA	Quality Crisis	XAI & Developer Trust
2025–2026	Agentic AI & Self-Healing	Maintenance Crisis	Standardized Governance (DePaaS)

B. RQ1: Taxonomic Mapping of AI Architectures in SQA

With regards to the architectural environment of AI within SQA, a major transition from usual machine learning toward advanced deep learning and generative frameworks has been experienced [37-39], and furthermore, the deployment of LLMs and Transformer architectures is centralized within current research, whereby high level cognitive automation including the generation of unit tests and the progression of test oracle automation is executed by these technologies [25-27]. As a result, transformer architectures are proposed as strong solutions concerning Graphical User Interface (GUI) testing so that the difficulties associated with automated test case generation and the management of flaky tests are resolved [24, 40-41].

In addition, researchers employ sophisticated hybrid techniques alongside generative models so that predictive precision is increased, and as a result, this practice is illustrated by the creation of new techniques, including VoStackSDD concerning software defect density prediction [42] alongside the application of bootstrap aggregation Bagging so that internal

[1]*Note: 2026 data reflects results collected up to January 19, 2026, and represents an incubatory stage of the current research cycle.

project defect prediction is improved [43]. Furthermore, deep learning architectures are maintained as essential components concerning functional automation, including web user interface testing based upon Selenium UI testing [40-41] alongside specialized multi-level signal quality classification, while the role of reinforcement learning concerning software testing composition alongside the examination of quantum reinforcement learning is included by newly visible classification borders. [44-46].

C. RQ2: Impact on Core SQA Lifecycle Activities

With regards to the software development life cycle, labor-intensive and error-prone tasks are greatly improved by methods and tools directed by AI, and in addition, machine learning models are adopted by researchers within the area of defect prediction and localization, so that source code syntax patterns are used to examine bug-inducing cases. Furthermore, these efforts are evaluated across internal and external project environments so that scalability and general effectiveness are accurately determined [43, 47-49].

As a result, the SQA lifecycle is additionally affected by continuous improvements concerning test case management and maintenance, whereby improvement initiatives are extended toward test suite reduction. Furthermore, unsupervised machine learning approaches are employed by researchers within this area so that redundant testing scenarios are eliminated while extensive software coverage is maintained [50]. Additionally, modern AI tools are being integrated into debugging and log analysis processes [38], while LLMs are being paired with stochastic science to enhance path coverage and crash localization during fuzz testing [51].

It can be concluded that labor-intensive and error-prone tasks across the software development life cycle are refined by artificial intelligence-driven techniques, and aggregated performance statistics have been compiled so that empirical claims are supported. In addition, within the field of defect prediction and localization, machine learning models are applied so that source code syntax patterns are analyzed, and bug-inducing commits are identified [47], while accuracy ranges between 80% and 95% are reported across the evaluated literature. Furthermore, these methodologies are evaluated across within-project and cross-project contexts so that scalability is determined [43, 48-49], and a median F-measure distribution of 87% is observed by the surveyed studies. The software testing lifecycle is affected by advancements in test case management, and unsupervised machine learning approaches are employed so that redundant test cases are eliminated [50] and test execution time is decreased by an average of 40%. Finally, modern artificial intelligence tools are applied to debugging processes [38], and large language models are combined with stochastic science so that path coverage is expanded and crash localization is improved during fuzz testing [51], which is detailed in Table VI.

TABLE VI. AGGREGATED PERFORMANCE METRICS FOR AI-DRIVEN SQA LIFECYCLE ACTIVITIES.

Performance Metric	Reported Statistical Range	Targeted Software Lifecycle Activity
Defect Prediction Accuracy	between 80% and 95%	Bug-inducing commit identification
F measure Distribution	median F measure distribution of 87%	Within project and cross project localization
Test Execution Time	decreased by an average of 40%	Redundant test suite elimination

D. RQ3: Trustworthiness, Explainability, and Ethical Governance

To facilitate full-scale industrial adoption, recent research addresses the critical barriers of AI's black-box nature through both interpretability and explainability. While explainability is frequently employed to clarify the causal relationships between inputs and outputs (often through post-hoc techniques), interpretability remains a more stringent requirement for mission-critical SQA. It is worth noting here that XAI can be defined as a precise set of processes and methods by which the exact reasoning behind algorithmic decisions is made fully transparent to human operators [17, 52]. Interpretability allows developers to identify and understand the specific contributions of a model's internal components to its decision-making process. Specifically, in safety-critical domains such as aerospace, providing a human-readable explanation is often insufficient; instead, researchers are pivoting toward intrinsically interpretable architectures, such as neural additive models [49], which provide a transparent view of how individual features influence a defect prediction. [52]. This transparency is particularly vital for mission-critical systems (e.g., safety-critical aerospace or medical software), where a lack of software quality can lead to catastrophic events, including loss of life or significant environmental damage. A primary technical hurdle in mission-critical SQA is the management of false positives; industrial studies explore how developers perceive AI-generated defects [53] and how chatbot decisions compare to human testers' assumptions [54-55].

Furthermore, as industries are constantly oriented toward development assisted by AI, considerable attention regarding the quality assurance of code generated by AI is identified by this review, so that a Maintenance Crisis is avoided. In addition, this issue is resolved by recent frameworks through the implementation of autonomously self-healing automation, whereby autonomous agents are employed so that damaged testing scripts are detected and repaired immediately, while it is ensured that rigorous reliability examinations are not bypassed by fast deployment cycles. With regards to administrative protocols, governance actions are currently being formalized through frameworks including DePaaS, recognized as a global unified software defect prediction directed by AI, whereby central attention is given to feasibility analysis and standardized routines concerning worldwide software environments [28]. As a result, it is emphasized by state-of-the-art studies that the trustworthiness of autonomous agents seriously depends on data quality and complexity, whereby informative defect prediction methods are required [56-58].

E. Research Summarization and Industrial Implications

With regard to literature reviews, unparalleled automation capacities concerning unit testing and oracles are suggested to be provided by AI architectures, including LLMs and Transformers. In addition, it is argued that success concerning these technologies is linked to the resolution of the Maintenance Crisis alongside overcoming the difficulty which is created by the verification and preservation of massive volumes of code

which is generated by AI. Furthermore, the creation of self-healing frameworks is encouraged by recent studies so that testing scripts are repaired independently and fast development cycles directed by AI are matched. However, a movement toward XAI is considered mandatory for operational systems within healthcare or space environments where severe events, including human casualties or major service interruptions, are caused by poor software quality. As a result, transparency regarding defect prediction is demanded within these risk environments so that predictable safety boundaries are maintained.

Furthermore, the attention of industrial practitioners must be redirected from the accuracy of computational models toward the wise management of developer trust. In addition, this exact objective is achieved through the reduction of false positive results alongside the execution of formal verification, while strict alignment between decisions made by AI and with human assumptions is ensured [59]. As a result, aggressive commercial delivery constraints are successfully satisfied by organizations through the adoption of these rigorous validation methods, while the strict integrity of infrastructure is entirely protected. At last, the inclusion of Ethics by Design principles through standardized governance frameworks such as DePaaS provides guidelines for ensuring that autonomous SQA agents operate within safe and predictable boundaries.

Experimental testing phases are recognized to have been exceeded by current state-of-the-art studies, whereby the incorporation of AI within SQA is now seen as an absolute need, although a severe gap is constantly observed regarding the automated validation of materials that are generated by AI. Since this gap is not yet resolved, a transition toward agent-directed SQA is identified, whereby multiple agent systems are deployed so that the cross-validation of programming and testing scenarios is thoroughly executed. In addition, when SLMs are combined for specialized verification alongside XAI structures, the Quality Crisis can be cured through transparent feedback cycles, whereby SQA is changed from a reactive obstruction toward a proactive self-healing infrastructure so that industrial demands regarding both developmental speed and reliability are completely satisfied.

V. Conclusion and Future Work

A. Conclusion

In conclusion, a total of 195 primary studies have been combined within this systematic literature review so that the changing adoption of AI within SQA during a recent 10-year period can be mapped, and it is shown by the results that the most active period is currently being experienced by this field, given that greater than 80% of primary studies have been produced since the year 2023. In addition, this increase is recognized as a clear exit from conventional rule-based automation toward self-governing quality environments that are sustained by LLMs, Transformers, and multiple agent systems. Although considerable abilities in the automation of unit test generation, oracle automation, and defect localization are supplied by these AI-driven architectures, industrial deployment is restricted by a combined Quality Crisis and Maintenance Crisis. In particular, human verification has been surpassed by the extreme speed of computer-assisted development, meaning that a transition toward agent-based SQA and the installation of SLMs for localized, efficient verification is required, whereby it is guaranteed by these Quality by Design methods that AI is maintained as a central, controllable structural element. Finally, it is concluded by this investigation that a transition toward XAI and standardized governance structures, including DePaaS, is absolutely mandatory so that the developer reliance required within operational environments can be established.

B. Future Work

As the distance between theoretical AI capabilities and practical industrial realities is reduced, the simple classification of tools must be overcome by future investigations so that the maintenance crisis is fully resolved. For immediate objectives, priority must be assigned to the development of autonomously correcting structures or self-healing frameworks that are designed so that the severe administrative burdens caused by AI-generated code are effectively lessened. Concurrently, the socio-technical aspects of programmer trust must be examined through the continuous advancement of XAI methodologies. In particular, the reduction of false positive results must be targeted by these procedures so that exact alignment between AI-driven decisions and human expectations is completely guaranteed. Additionally, a necessity that quantum reinforcement learning and agentic collaboration are closely investigated is proposed by newly visible classification borders in order to manage the complexity of distributed architectures. In conclusion, a need is continually maintained by the formalization of ethical design principles within SQA, where standardized governance structures like DePaaS are applied so that safe and legally compliant operational boundaries for autonomous agents are enforced.

Acknowledgment

Sincere gratitude is formally expressed to the Umm Al Qura University because an invaluable opportunity was provided so that academic research regarding the software engineering field could be conducted, while heartfelt thanks are similarly extended to family members and friends.

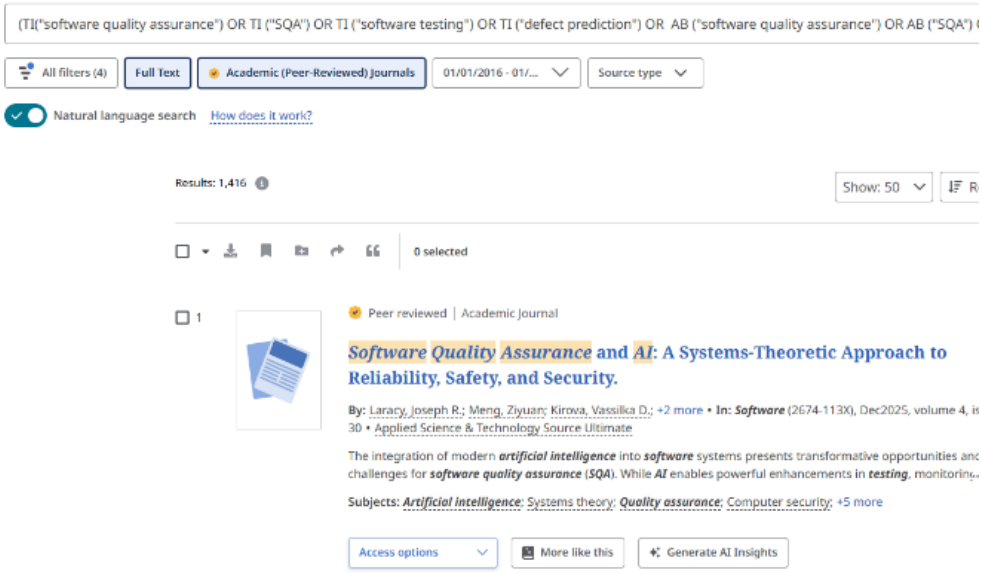
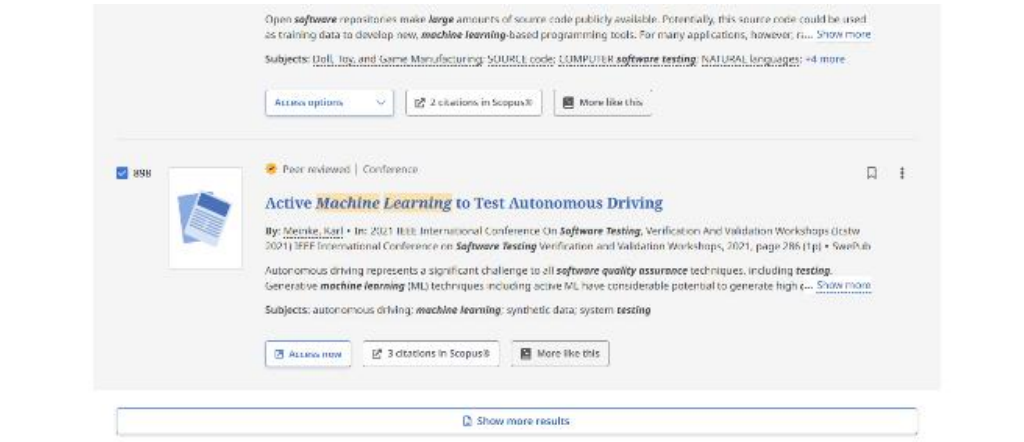
APPENDIX A: DETAILED SEARCH METRICS AND EXECUTION

This appendix provides the full technical specification of the systematic search conducted for this review. It includes the exact Boolean strings used for each digital library (IEEE Xplore, ACM Digital Library, ScienceDirect, and Scopus), along with the hit counts and filtering results for each phase of the PRISMA protocol. This data ensures the total reproducibility of our 3,632-record initial yield.





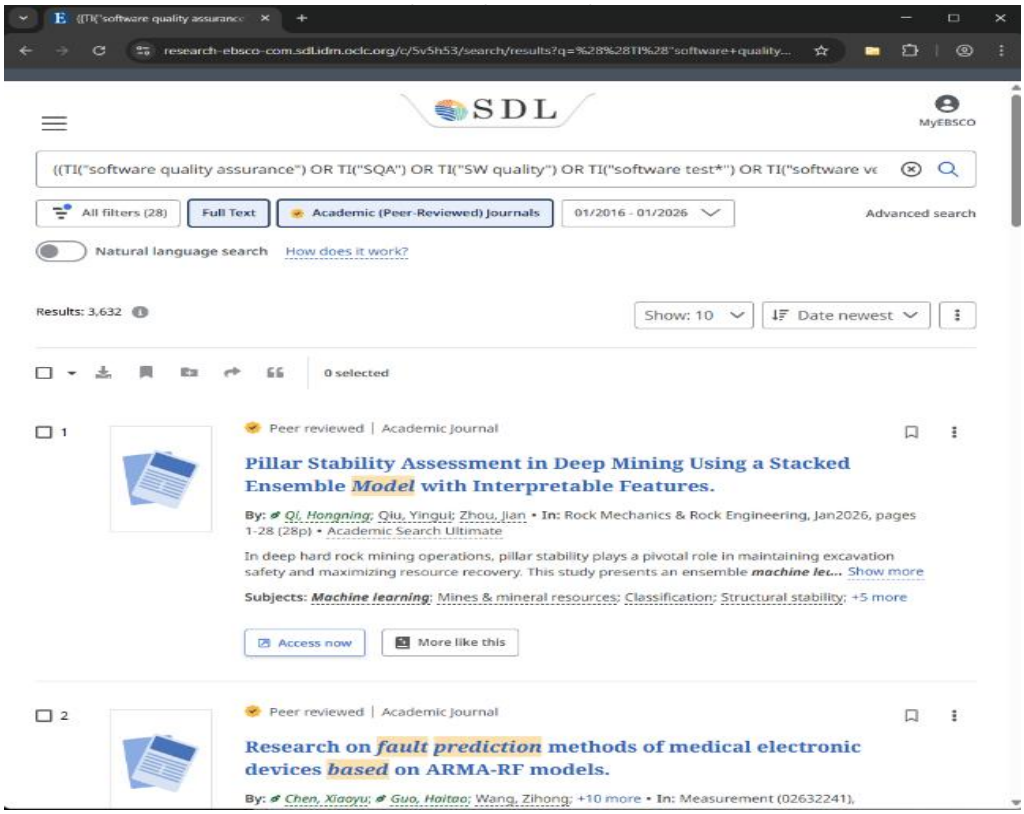


Fig. 4. Exact Boolean strings used for each digital library.

APPENDIX B: COMPLETE LIST OF PRIMARY STUDIES (N=195)

The following table summarizes the primary studies selected in this review.

TABLE VII. PRIMARY STUDIES SELECTED IN THIS REVIEW

A Comparative Evaluation of Large Language Models for Named Entity Recognition in Cyber Threat Intelligence

Aykhan Huseynli
Cybersecurity Department, Azerbaijan Technical University, Baku, Azerbaijan

***Abstract*—Cyber Threat Intelligence reports combine analytical prose with dense technical indicators, making structured entity extraction a challenging but operationally valuable task. This study presents a comparative evaluation of three large language models – Claude Sonnet 4.6, GPT-5.4, and LLaMA 4 Scout – on a manually annotated corpus of 21 real-world CTI reports across 15 entity types and 1284 ground truth instances. This study evaluates zero-shot and few-shot prompting conditions and studies the effect of iterative prompt refinement, focusing on explicit format constraints for cryptographic hash entities. Results show that Claude Sonnet 4.6 and GPT-5.4 achieve comparable performance under zero-shot conditions, with LLaMA 4 Scout trailing by a substantial margin. Few-shot prompting consistently reduces hallucination rates, but yields mixed F1 results, with exemplar cardinality emerging as a critical and underappreciated design factor. Entity extraction difficulty varies substantially across types, with technical indicator categories showing near-perfect performance and semantic categories such as tool and target sector posing the greatest challenges across all evaluated models.**

***Keywords*—Cyber threat intelligence; named entity recognition; large language models; prompt engineering**

I. Introduction

The volume of publicly available Cyber Threat Intelligence (CTI) publications has grown substantially. Organizations such as Mandiant, IBM X-Force, ESET, Kaspersky Securelist, Check Point Research, routinely publish detailed campaign analyses covering advanced persistent threat (APT) actors, malware families, and attack infrastructure. Extracting structured knowledge from these reports – threat actors, targeted sectors, malware names, Command and Control (C2) domains and URLs, spear phishing email addresses, and cryptographic indicators – is a prerequisite for populating threat intelligence platforms, maintaining situational awareness, and automating detection engineering pipelines [1].

Traditional Named Entity Recognition (NER) systems require labelled training data and struggle with the fast-moving, inconsistently formatted nomenclature of the CTI domain [2], [3]. Large language models offer a compelling alternative: they can be prompted in a structured fashion without task-specific fine-tuning, and their in-context learning capabilities allow rapid adaptation through prompt engineering. However, multi-model benchmarks of Large Language Models (LLM) performance on CTI-specific NER remain scarce, particularly benchmarks that examine iterative prompt refinement and document the failure modes that emerge in practice.

This study contributes:

- A 21-report, 15-entity-type CTI NER benchmark evaluated across Claude Sonnet 4.6, OpenAI's GPT-5.4, and Meta's LLaMA 4 Scout under zero-shot and few-shot conditions;
- A documented methodology for handling annotation standardization challenges: controlled sector and goal vocabularies, and mixed indicator types in domain/URL/email categories;
- Analysis of two qualitative failure modes unique to CTI NER: tool and malware boundary ambiguity.

The remainder of this study is organized as follows. Section II surveys prior work on CTI named entity recognition, domain-specific language models, and LLM-based information extraction. Section III describes the evaluation corpus, annotation methodology, model selection, prompt design and evolution, and evaluation metrics. Section IV presents experimental results across overall model performance, per-entity-type analysis, prompting condition comparisons, and report-level complexity effects. Section V discusses the implications of these findings for practitioners and researchers. Section VI concludes and outlines directions for future work.

To structure the evaluation and ensure that each experimental component maps to an explicitly stated inquiry, the following five research questions were identified:

RQ1: To what extent can current state-of-the-art LLMs (Claude Sonnet 4.6, GPT-5.4, and LLaMA 4 Scout) perform zero-shot NER on real-world CTI reports across a 15-type entity taxonomy, and how do they compare in terms of macro and micro precision, recall, and F1?

RQ2: Does few-shot prompting with real, out-of-corpus annotated exemplars improve NER accuracy and reduce hallucination rates compared to zero-shot baselines, and are these effects consistent across models and entity types?

RQ3: How does iterative prompt refinement – specifically, adding explicit format constraints for hash entities, CVE identifier requirements, and controlled extraction vocabularies – affect per-entity extraction accuracy across models?

RQ4: Which entity types are systematically most resistant to prompt-based extraction, and what properties of those entities (format ambiguity, semantic boundary overlap, or schema-level

definitional complexity) explain the observed performance hierarchy?

RQ5: How does CTI report length affect LLM extraction performance, and at what scale do current models exhibit measurable degradation?

II. Related Work

Research on information extraction from cybersecurity text predates the LLM era and has been dominated by sequence labeling architectures built on domain-adapted transformer encoders. Reference [2] established a strong transformer-based NER baseline on the Dataset for Named Entity Recognition in Threat Intelligence (DNRTI) corpus – a collection of over 300 publicly available threat intelligence reports – demonstrating that fine-tuned transformer models substantially outperform rule-based and statistical predecessors on CTI entity extraction. Reference [4] extended this direction by pairing BERT with whole-word masking to a BiLSTM-CRF tagging head, improving precision and recall on cybersecurity-specific entities relative to standard BERT fine-tuning. A simplified BERT-CRF architecture – omitting the intermediate BiLSTM layer – was subsequently shown to be competitive on multiple CTI datasets while also being directly comparable to GPT-3.5 in a prompt-based inference setting, providing one of the earliest quantitative bridges between fine-tuned and prompted approaches to CTI NER [5].

Domain-specific pre-training has become a prerequisite for competitive CTI NER performance. CyBERT is the first BERT model fine-tuned on a large corpus of unstructured CTI data using masked language modeling, and demonstrates consistent gains over general-purpose BERT on downstream cybersecurity tasks, including entity extraction [3]. SecureBERT 2.0, built on the ModernBERT architecture and pre-trained on over 13 billion cybersecurity text tokens, achieves state-of-the-art performance on multiple CTI NER benchmarks [6]. These domain language models constitute the principal fine-tuned reference points against which prompt-based LLM approaches are compared in the present work.

The question of what to extract is as consequential as how to extract it. Benchmark construction for CTI NER has proceeded along several lines. FeedRef2022 is a NER dataset derived from 1,854 threat intelligence reports, used to evaluate four pre-trained models on Indicators of Compromise (IoC) extraction [7]. The fragmentation of existing CTI NER datasets is addressed in [8] by harmonizing four prominent corpora – CyNER, DNRTI, APTNER, and Attacker – onto the Structured Threat Information eXpression 2.1 (STIX) standard, consolidating over 50 source tags into 21 coherent entity types and demonstrating that models trained on the unified CyberNER corpus achieve approximately 30% relative F1 improvement over naive concatenation baselines. On the other hand, CTI-HAL, a manually annotated dataset structured according to the MITRE ATT&CK framework with inter-annotator agreement validated using Krippendorff's alpha, provides a rigorous quality benchmark for CTI annotation methodology [9].

Multi-model comparative evaluation of LLMs for CTI tasks remains an underdeveloped area. Reference [10] evaluates GPT-4 for Tactics, Techniques, and Procedures (TTP) identification and threat-actor attribution, finding that standard LLMs generate noisy TTP datasets with low similarity to human-annotated MITRE ATT&CK entries, but that the frequency patterns of extracted techniques nevertheless support attribution performance above a random baseline. The most direct precursor to the present study compares LLaMA2-7B and GPT-4 under zero-shot and few-shot conditions on a CTI dataset that includes entity extraction alongside TTP classification and mitigation generation [11]. The framework presented in [11] demonstrates that commercial models outperform open-weight alternatives under few-shot conditions while acknowledging the data-residency advantage of open-weight deployment – a trade-off that motivates the inclusion of LLaMA 4 Scout as an evaluated model.

The present study extends this body of work in three respects. First, it evaluates three contemporary LLMs, Claude Sonnet 4.6, GPT-5.4, and LLaMA 4 Scout, on a broader entity taxonomy than any prior prompt-based study, covering 15 entity types spanning threat actor attributes, campaign context, and technical indicators of compromise. Second, it isolates the effects of iterative prompt refinement and few-shot exemplar design as experimental variables, documenting failure modes, system utility over-extraction, and hash format confusion, which are specific to the CTI domain and absent from general NER benchmarks. Third, all evaluated models operate without task-specific fine-tuning, providing a prompt-only point of comparison against the fine-tuned supervised baselines surveyed above; Section V examines this comparison in detail.

III. Methodology

A. Evaluation Corpus

The corpus comprises 21 publicly available CTI reports from Mandiant, IBM X-Force, ESET, Kaspersky Securelist, Check Point Research, Trend Micro, Deep Instinct, and Sekoia. Reports were drawn from two established aggregators: APTnotes, which indexes threat intelligence publications up to 2024, and Malpedia, from which additional reports were collected to cover the 2025-2026 period not represented in APTnotes [12], [13]. Reports range from 4,466 to 24,348 tokens in length, with a median of approximately 8,532 tokens. The corpus contains a total of 1,284 manually annotated ground truth entity instances across all 21 reports and 15 entity types.

The entity taxonomy spans three functional groups. Threat actor attributes comprise threat_actor_name and threat_actor_country. Campaign context entities include target_country, target_sector, malware_name, goal, tool, and vulnerability. Technical indicators of compromise cover IP, domain, URL, email, sha256, sha1, and md5. Together, these 15 types reflect the full informational structure encountered in real-world CTI publications, from strategic attribution to low-level network observables.

Entity annotation was performed by two annotators working at the Computer Emergency Response Team, with a focus on CTI, each independently processing the full text of every CTI report and recording entity spans across all 15 entity types. To assess the reliability of the entity definitions, agreement between the two independent passes was measured before reconciliation as a pairwise entity-level F1, in which a span counts as agreed only when both its boundary and its entity type match. The annotators achieved a pairwise entity-level F1 of 0.87, pooled

across all 15 entity types, indicating high agreement. Disagreement was concentrated almost entirely in the tool and malware categories, consistent with the boundary ambiguity between these types discussed in Section V, while the remaining thirteen categories showed near-complete agreement. Following each independent pass, the two annotation sets were compared document by document. Spans on which both annotators agreed were accepted into the ground truth directly. Divergences, including differences in entity boundary, entity type assignment, and decisions to include or exclude ambiguous candidate spans, were resolved through discussion until consensus was reached. Where recurring disagreements revealed an underspecified boundary condition in the annotation guidelines (most frequently at the tool and malware entities), an explicit clarification rule was formulated, documented, and applied retroactively across all affected instances in the corpus. The resulting ground truth, therefore, reflects a jointly validated, consensus-based interpretation of each entity instance rather than the judgment of a single annotator, following the dual-annotator reconciliation practice established in comparable CTI corpus construction efforts [8].

Entity annotation was performed without imposing a fixed schema at the outset. Instead, annotators recorded entity types as they naturally emerged from the reports, following an inductive approach. The 15 entity types reported in this study represent the full set of categories identified through this process – no entity type present in the source documents was excluded a priori. This approach ensures the taxonomy reflects the actual informational structure of real CTI publications rather than a theoretically predetermined set.

During the first iterations, models performed extremely poorly on attack goal and target sector entities, which is explained by values varying substantially in the source document language. A single concept might appear as "national government", "government entity", or "public sector," depending on the author and publication style. Similarly, goal descriptions ranged from "data theft" to "espionage" to "collection of intelligence". To ensure consistent extraction and enable fair evaluation, it was decided to provide models with a controlled vocabulary for the targeted sector, covering 18 types and aligned to the STIX. STIX language provides a standardized format for representing and sharing CTI to ensure interoperability across security tools and organizations [14]. On the other hand, with regard to common attack goals observed in the reports, a pool of 5 values was provided. Without this constraint, macro F1 on these categories would be artificially depressed by surface-form disagreements between model outputs and ground semantically equivalent truth annotations.

In addition to that, in early evaluation iterations, all three models exhibited a systematic pattern of returning natural-language vulnerability descriptions rather than CVE identifiers when asked to extract the vulnerability entity type. For example, when a report referenced CVE-2026-21509, models would return "Microsoft Office Security Feature Bypass Vulnerability" rather than the CVE identifier string. This occurred despite the entity type being named vulnerability. The prompt was revised to explicitly require the CVE-YYYY-NNNNN format and to instruct models to return the identifier string only, ignoring descriptions without an associated CVE code. The final evaluations show CVE F1 = 1.000 across all three models, confirming full resolution of this issue.

B. Models

Three models are evaluated in this study. Claude Sonnet 4.6 (claude-sonnet-4-6), GPT-5.4 (gpt-5.4), and LLaMA 4 Scout (meta-llama/llama-4-scout-17b-16e-instruct). All three models were queried with temperature = 0 and top-p = 0 to ensure deterministic, reproducible outputs.

C. Prompt Design and Evolution

Two distinct types of prompts were used during the evaluation. In a zero-shot setting, the model receives only a task description and the target document, with no examples of completed extraction Fig. 1. The model must rely entirely on its pretrained knowledge and the instructions provided in the prompt to produce the output. Zero-shot prompting is the simpler baseline: it requires no curated examples and makes the fewest assumptions about what the model has seen during training.

```
    You are a cybersecurity threat intelligence analyst. Your task is to
extract named entities from the CTI report provided below and return only
a valid JSON object that strictly conforms to the predefined schema. For
any entity types not present in the document, return empty arrays ([]).
Do not include any text, explanation, or formatting outside the JSON
output. Ensure that all occurrences of each entity type are extracted
across the entire document – do not limit extraction to the first in-
stance. In particular, for hash-related fields, include every identified
value.

    . . .
```

Fig. 1. Zero-shot prompt.

In a few-shot setting, the prompt is augmented with several examples – pairs of input text and expected output – that demonstrate the desired extraction behavior before the model encounters the target document Fig. 2. The rationale is that concrete examples communicate extraction conventions more reliably than abstract definitions alone: a model that sees a correctly annotated excerpt is better positioned to replicate that annotation style than one given only a textual description of what each entity type means.

```
    APT28, also known as Fancy Bear, is a Russian espionage group that
targeted German government agencies and French energy companies. The
campaign deployed X-Agent malware and leveraged CVE-2021-34527 (Print-
Nightmare). Mimikatz was used for credential dumping. C2 infrastructure:

Fig. 2. Example given with a few shots.

In this study, the few-shot condition prepends two fully annotated CTI report excerpts to the user prompt before the target document is presented. These exemplars were drawn from two published reports deliberately excluded from the 21-report evaluation corpus to prevent data leakage. The two excerpts were selected jointly such that, together, they provide at least one positive instance of each of the 15 entity types, ensuring the model has a concrete reference for every category it is expected to extract. Several entity types are represented by multiple instances within a single excerpt, so the exemplars demonstrate not only

the presence of each category but also the extraction of multiple entities of the same type. The use of real, annotated excerpts rather than synthetically constructed examples is a methodological requirement, since synthetic examples risk being unnaturalistic and may not reflect the surface-form variation that characterizes actual CTI publications.

The choice of two exemplars reflects a deliberate balance between coverage and prompt length. Two excerpts are sufficient to instantiate every one of the 15 entity types, with several types already represented by multiple instances, so adding further exemplars would not improve entity-type coverage. Prompt length, however, is a binding constraint, as reports in the evaluation corpus reach 24,348 tokens, and Section IV documents measurable extraction degradation on the longest reports under the existing prompt length, consistent with attention dilution over long contexts. Increasing the exemplar count would lengthen every prompt and amplify this effect across the corpus, not only on outlier reports. The two-exemplar configuration, therefore, represents the smallest prompt that achieves full entity-type coverage, which is the relevant design constraint for evaluation across reports of variable length.

The initial prompts defined each entity type with a brief natural-language description and requested a structured JavaScript Object Notation (JSON) response. Hash entities were described generically as "cryptographic file hash" without a format specification. Post-hoc analysis of initial results revealed that GPT and LLaMA systematically confused SHA-1 (40 hex characters) with SHA-256 (64 hex characters), treating all long hex strings as SHA-256 and returning near-zero SHA-1 recall.

D. Evaluation Metrics

All extractions are evaluated against ground truth annotations using exact string matching after lowercasing and whitespace normalization.

Precision – measures the proportion of extracted entities that are correct:

$$P = TP / (TP + FP), \quad (1)$$

where, TP is the number of correctly extracted entity instances, and FP is the number of extracted entities absent from the ground truth.

Recall – measures the proportion of ground truth entities successfully extracted:

$$R = TP / (TP + FN), \quad (2)$$

where, FN is the number of ground truth entities the model failed to extract.

F1 Score – providing a single balanced measure when both missed and spurious extractions carry cost.

$$F1 = 2PR / (P + R), \quad (3)$$

Micro F1 – aggregates TP, FP, and FN globally across all entity instances before computing Eq. (1), (2), and (3), weighting each entity occurrence equally regardless of type:

$$F1(micro) = 2TP / (2TP + FP + FN), \quad (4)$$

Macro F1 – the unweighted mean of per-entity-type F1 scores, treating each of the N = 15 entity types equally, regardless of its frequency in the corpus:

$$F1(macro) = (1/N) \times \Sigma F1_i, \quad (5)$$

where, $F1_i$ is the F1 score for entity type i and N = 15.

Hallucination Rate – the hallucination rate quantifies the proportion of extracted entities whose surface form does not appear in the source document:

$$HR = N_a / N_e, \quad (6)$$

where, N_a is the number of extractions whose surface form does not appear in the source document and N_e is the total number of extractions.

IV. Experimental Results

A. Overall Model Performance

Tables I and II present the macro and micro performance of all models under both conditions using the final prompt. Fig. 3 visualizes micro F1 scores.

TABLE I. Macro Performance

Model & Condition	Macro P	Macro R	Macro F1
Claude 4.6 ZS[a]	0.516	0.533	0.514
Claude 4.6 FS[b]	0.520	0.524	0.510
GPT-5.4 ZS	0.531	0.527	0.523
GPT-5.4 FS	0.530	0.498	0.503
LLaMA 4 Scout ZS	0.459	0.474	0.453
LLaMA 4 Scout FS	0.422	0.404	0.415

[a] Zero-Shot

[b] Few-Shot

TABLE II. Micro Performance

Model & Condition	Micro P	Micro R	Micro F1
Claude 4.6 ZS	0.782	0.890	0.832
Claude 4.6 FS	0.802	0.875	0.837
GPT-5.4 ZS	0.799	0.866	0.831
GPT-5.4 FS	0.815	0.792	0.803
LLaMA 4 Scout ZS	0.700	0.754	0.726
LLaMA 4 Scout FS	0.746	0.548	0.632

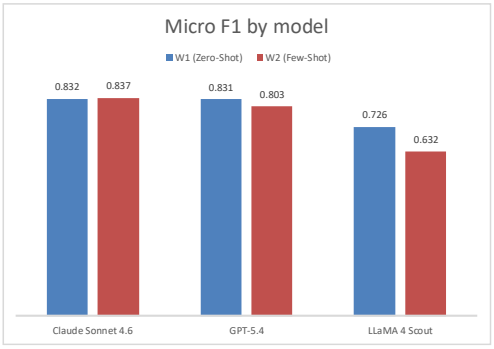

Fig. 3. Micro F1 by model and condition.

Claude Sonnet 4.6 and GPT-5.4 are closely matched under zero-shot, achieving micro F1 of 0.832 and 0.831, respectively. GPT-5.4 holds a slight advantage in macro F1 (0.523 vs 0.514), reflecting marginally better performance on low-frequency entity types. Claude achieves a higher micro recall (0.890 vs 0.866), suggesting a preference for breadth of extraction over precision. LLaMA 4 Scout trails by a substantial margin (micro F1 = 0.726), driven primarily by its poor tool entity performance and aggressive over-extraction in certain categories.

The few-shot condition produces mixed effects across all three models. Claude improves in micro F1 (+0.005) while reducing hallucination; GPT-5.4 declines (-0.028), driven primarily by the DynoWiper cardinality anchoring failure discussed in *subsection D*; LLaMA 4 Scout also declines substantially (-0.094), consistent with a pattern of few-shot conditioning providing marginal or neutral benefit over strong zero-shot baselines.

B. Per-Entity-Type Performance

Tables III and IV present F1 scores disaggregated by entity type for all three models under both the zero-shot and few-shot conditions using the final version of the prompt. Performance across the 15 entity types is highly non-uniform, spanning a range from perfect extraction to near-failure within the same model and the same report. First, entity type is a stronger predictor of extraction difficulty than model identity – the rank ordering of entity types by F1 is largely preserved across all three models, suggesting that the challenge lies in the entity itself rather than in model-specific capabilities. Second, the few-shot condition does not produce uniform improvement; its effect is entity-dependent, providing measurable benefit on some categories while introducing regression on others, most notably malware name for GPT-5.4 and URL for LLaMA 4 Scout. Third, the two entity categories with the most complex annotation boundaries – tool and target sector – are consistently the weakest across all models and both conditions, confirming that prompt-based extraction struggles most where the distinction between a positive and negative instance requires operational domain knowledge that cannot be fully encoded in a natural-language definition.

The following discussion groups entity types into three performance tiers and examines the underlying drivers of each.

1) High-performing categories: Vulnerability identifier extraction achieves F1 = 1.000 across all three models, a result of both the highly distinctive CVE identifier format and the explicit format constraint introduced in response to early description-extraction failures. IP address extraction is similarly reliable (0.927–0.983 F1), as dotted-decimal notation is unambiguous. Threat actor country (0.950) and SHA-1/SHA-256 (0.807–0.964) are also well-extracted following the revised prompt.

2) Moderate-performing categories: Malware name extraction achieves F1 of 0.753-0.857. Claude shows high recall (0.926) but lower precision (0.708), suggesting a tendency to include related tool names or sub-components alongside the primary malware families. GPT-5.4 is better balanced (P=0.833, R=0.882). Domain and URL extraction show consistent moderate performance (~0.62-0.76 F1), with false positives arising from vendor website links, CDN hosts, and report-source URLs that appear in CTI documents alongside malicious infrastructure.

TABLE III. PER-ENTITY F1 RESULTS USING ZERO-SHOT APPROACH

	Claude Sonnet 4.6	GPT-5.4	LLaMA 4 Scout
Entity Type	**Zero-Shot**		
Threat Actor Name	0.923	0.923	0.881
Threat Actor Country	0.974	1.000	0.942
Target Country	0.904	0.828	0.831
Target Sector	0.615	0.538	0.438
Malware Name	0.800	0.619	0.697
Goal	0.780	0.810	0.706
Tool	0.611	0.700	0.468
IP Address	0.982	0.956	0.903
Domain	0.690	0.703	0.762
URL	0.800	0.735	0.581
Email	0.895	0.919	0.862

SHA-1	0.964	0.947	0.807
MD5	0.800	0.745	0.452
CVE	1.000	1.000	1.000

Beyond C2 and phishing infrastructure, CTI reports routinely reference legitimate third-party services as part of their technical narrative, e.g., links to malware samples hosted on VirusTotal or code repositories on GitHub. During corpus annotation, such references were deliberately excluded from the ground truth for domain and URL entity types. Similarly, domain names associated with legitimate content delivery networks or cloud platforms, even when referenced in the context of an attack, were omitted when the domain itself is not malicious infrastructure. The rationale for this exclusion is operational: automated ingestion of these indicators into Intrusion Detection and Prevention Systems (IDS/IPS) or firewall blocklists would block access to widely-used legitimate services, causing service disruption disproportionate to any security benefit. Only the full URL path pointing to a malicious file or payload was retained as a ground truth instance in such cases, as this specificity limits the risk of adverse blocking effects while preserving the actionable indicator.

3) Low-performing categories: The tool entity type returns the lowest F1 scores across all models: Claude 0.582, GPT-5.4 0.673, LLaMA 0.416. The LLaMA precision of 0.288 – meaning fewer than 3 in 10 extracted "tools" are correct makes this the single most problematic category in the evaluation. Further comparison of extracted and ground truth values reveals six distinct root causes:

a) Malware/tool boundary confusion: LLaMA repeatedly extracted malware families as tools. In the OilRig report, LLaMA extracted “danbot”, “mango”, “marlin”, “milan”, “oilcheck”, “oilforcegtx”, “shark”, and “solar” as all malware families in the OilRig toolkit as tool entities, while the ground truth annotates these as “malware_name”. Similarly, in the Gamaredon report, LLaMA extracted “GammaLoad” and “GammaStealer” as tools. Claude 4.6 and GPT-5.4 showed this error rarely.

b) System utility over-extraction: All three models extracted operating system utilities and scripting engines – PowerShell, mshta.exe, vbscript, and WinRAR as attack tools. The annotation schema restricts the tool entity type to threat-actor-specific offensive utilities (e.g., Cobalt Strike, Mimikatz, Ligolo) and excludes general system components, even when those components appear in an attack chain. This boundary is conceptually grounded in the notion of Living Off the Land Binaries (LOLBins): legitimate, pre-installed, and typically digitally signed executables that adversaries abuse because their use blends with normal system activity and evades signature-based detection. While LOLBins are tactically significant for malware analysts performing dynamic analysis, they provide limited value to CTI analysts performing strategic or operational threat intelligence work – their appearance in a campaign report indicates technique, not infrastructure or tooling unique to the threat actor. Since LOLBins are exploited across virtually every threat actor and campaign, their extraction does not contribute to attribution, actor profiling, or indicator-based detection. Accordingly, they were excluded from the tool's ground truth, and model extractions of such binaries were scored as false positives.

c) Name normalization failures: This issue was observed on all models. Exact string matching penalizes near-correct extractions. "cobalt strike beacon" was extracted instead of "cobalt strike"; "atera agent" instead of "atera"; "connectwise" instead of "connectwise remote access"; "fast reverse proxy server" instead of "fast reverse proxy server (frps)". These represent correct entity identification with imprecise boundary delineation – a known limitation of exact-match evaluation in NER.

d) Analyst-related software extraction: LLaMA extracted legitimate security research tools such as “Wireshark”, “procmon”, “fiddler”, and “ollydbg” and assigned them to the tools category, despite them being mentioned in attack investigation sections. Claude 4.6 and GPT-5.4 avoided this error.

e) Target sector – target sector achieves moderate F1 (0.468–0.725). Despite the controlled vocabulary provided in the prompt, models vary in the granularity at which they extract sector entities. LLaMA tends to over-enumerate sectors when a report mentions multiple victim organizations (high FP), while Claude and GPT are more conservative. A residual source of false negatives is sectors implied but not explicitly named in the report text.

f) MD5 hashes – MD5 recall is the primary challenge (0.384-0.674). MD5 hashes frequently appear alongside SHA-256 values, and models tend to prioritize the longer hash. Additionally, 32-character hex strings appear in non-hash contexts and, despite a strict definition in the last prompt, while reducing false positives, also excluded some true MD5 values.

C. Zero-Shot Vs. Few-Shot Performance and Hallucination

LLaMA 4 Scout shows a substantial decline under the few-shot conditions, with micro F1 dropping from 0.726 to 0.632 (-0.094) and macro F1 from 0.453 to 0.415 (-0.038). This pattern is broadly consistent with GPT-5.4, which also declines under a few-shot prompt. The decline is distributed across a range of entity types: on reports with high entity density, the few-shot exemplars appear to constrain extraction breadth without meaningfully improving precision, yielding a net negative trade-off. Hallucination rate decreases from 0.208 to 0.162, indicating that exemplars do successfully suppress ungrounded extractions – but the precision gain is offset by increased false negatives.

LLaMA shows greater sensitivity to few-shot cardinality anchoring than the commercial models. On reports with long entity lists, the model tends to match the exemplar entity count more rigidly, missing entities beyond the first few instances. This pattern is less pronounced but qualitatively similar to the GPT-5.4 DynoWiper failure described in the following section.

The most consistent effect of few-shot prompting is a reduction in hallucination rate. Across both prompt versions and all models, the few-shot approach reduces hallucination by 0.028-0.037, confirming that exemplars constrain the output space and discourage ungrounded entity generation. Hallucination rates by model and workflow are depicted in Fig. 4.

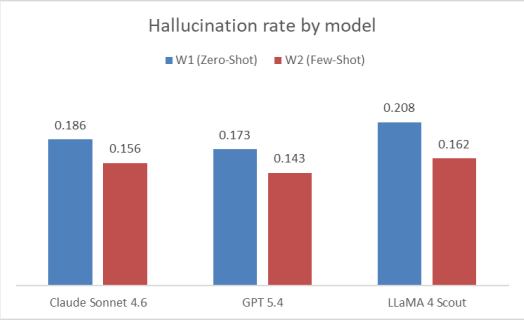

Fig. 4. Hallucination rate by model.

However, hallucination reduction does not translate uniformly to F1 improvement. For Claude, reduced false positives are partially offset by increased false negatives, yielding a net micro F1 gain of +0.005. For GPT-5.4, the hallucination reduction is overwhelmed by the catastrophic DynoWiper failure (*subsection D*), depressing corpus-wide micro F1 by -0.028.

Claude produced identical extraction results between using zero-shot and few-shot prompts on five reports: APT28 CVE-2026-21509, Gamaredon, ITG05/Headlace, BugSleep, and LIGHTSHOW Pt. 1. This circumstance can be defined as "ceiling stability". On reports with high entity density, highly distinctive entity formats, or strong structural regularity, zero-shot extraction already achieves maximum performance, and few-shot exemplars provide no additional signal. This finding suggests that document-adaptive prompting – applying few-shot conditioning selectively to reports where zero-shot confidence is low may be more efficient than uniform few-shot conditioning.

D. Case of Anchoring Bias and GPT-5.4

The DynoWiper report by ESET contains 22 malware entities in its ground truth: a catalogue of the Sandworm threat actor's full wiper toolkit, including "ArguePatch", "AwfulShred", "CaddyWiper", "HermeticWiper", "Industroyer2", "NotPetya", "Prestige", and others. Under zero-shot, GPT-5.4 extracts 22 malware names (micro F1 = 0.921). Under few-shot, GPT-5.4 extracts exactly one malware name: "dynowiper" – the tool named in the report title. All 21 remaining malware names become false negatives. For this reason, the micro F1 for this report dropped to 0.516.

We attribute this to quantity anchoring bias: the two few-shot exemplars each contained several malware entities. When the target report contains 22, GPT-5.4 anchors on exemplar cardinality and treats the document's primary malware (the title-referenced tool) as the sole extraction target, discarding the remainder as background. The same pattern partially affects target_sector (7 ground truth entities resulted in 1 extracted) and target_country (reduced from 2 to 1).

Practical implication here is that few-shot exemplars for CTI NER must be matched not only in entity type coverage but in entity count distribution. An exemplar with 2 malware names is actively misleading when applied to reports cataloguing more than 20.

E. Report Complexity and Performance

Small (less than 6k tokens) and medium (6-12k tokens) reports achieve comparable average micro F1 (0.773 and 0.787, respectively). Large reports (more than 12k tokens) drop to 0.641, driven by the four longest reports: APT28 Phantom Net Voxel (24,348 tokens), LIGHTSHOW Pt. 1 (17,956), OilRig (15,928), and Sandworm-related report (19,693). These reports show disproportionately high false negative rates, consistent with attention dilution over long contexts. Table V presents the full per-report breakdown.

TABLE V. PER-REPORT MICRO F1 BY MODEL UNDER ZERO-SHOT CONDITION

Report	Input Tokens	Claude F1	GPT F1	LLaMA F1
1	19,693	0.777	0.792	0.791
2	8,087	0.719	0.742	0.652
3	24,348	0.651	0.458	0.360

18	17,956	0.593	0.589	0.321
19	5,960	0.800	0.769	0.588
20	10,874	0.905	0.878	0.794
21	5,425	0.930	0.930	0.948

V. DISCUSSION

A. Overall Model Comparison

At the aggregate level, Claude Sonnet 4.6 and GPT-5.4 are interchangeable for zero-shot CTI NER within measurement precision. The practical choice depends on operational priorities. Claude's higher recall (0.890 vs 0.866) is preferable when missing indicators are more costly than reviewing false positives, which is the typical operational stance for threat intelligence ingestion. GPT-5.4's marginally better macro F1 (0.523 vs 0.514) may reflect better handling of low-frequency entity types such as goal and tool.

LLaMA 4 Scout trails the commercial models at micro F1 = 0.726 zero-shot and 0.632 few-shot. The model shows particular weakness in tool entity precision (0.288) and target sector recall (0.431). As an open-weight model, it remains attractive for data-residency-constrained or air-gapped environments. The performance gap relative to Claude and GPT is substantial but likely

closeable with domain-specific fine-tuning on a CTI NER corpus.

B. Prompt Specificity as a High-Leverage Intervention

The single most impactful change across the study (discussed in the Methodology section), adding hash length constraints, produced larger improvements for the affected entity types than the entire few-shot conditioning effort. This establishes a design principle: for entity types with formally constrained structures (hashes, CVE identifiers, IP addresses), precise format specification in the system prompt is a prerequisite, not a refinement. The same principle motivated the controlled vocabulary intervention for sector and goal, and the explicit CVE format requirement for vulnerability.

However, the MD5 case illustrates the inherent precision/recall trade-off in format-constrained extraction. The revised prompt required strictly lowercase, 32-character hexadecimal strings, which suppressed false positives from non-hash hex sequences but simultaneously caused genuine MD5 values to be missed, subsequently reducing recall.

C. Comparison with Fine-Tuned Baselines

All three models in this study operate without task-specific training, so situating their performance against fine-tuned supervised systems is necessary to interpret the results. No controlled comparison is possible here because the published baselines differ from the present study and from one another, along several axes that each affect the reported score.

TABLE VI. COMPARISON WITH FINE-TUNED CTI NER

Approach	Corpus, taxonomy	Reported F1
This work	21 CTI reports, 15 entities	0.832, 0.831, 0.726 (micro)
[8]	4 harmonized corpora, 21 entities	0.723 to 0.736 (micro)
[2]	DNRTI dataset, 13 entities	0.875 to 0.883 (macro)
[4]	DNRTI dataset, 13 entities	0.900
[5]	7 entity types	0.811
[6]	5 entity types	0.945
[3]	Vulnerability-related entities only	0.968
[7]	16 IoC-related entities	0.975

The single comparison conducted on a comparable footing is with [7], the only baseline evaluated on a broad, cross-source, STIX-aligned taxonomy of 21 entity types against the 15 used in the present study, with entity-level micro F1. On that benchmark, the best fine-tuned transformer-CRF reaches micro F1 0.736, with the remaining encoders clustered between 0.723 and 0.730. The zero-shot micro F1 obtained in the present study, 0.832 for Claude Sonnet 4.6 and 0.831 for GPT-5.4, falls at or above the fine-tuned range on the most similar task, and does so without any task-specific training. The strongest configuration measured, Claude Sonnet 4.6 under few-shot prompting at 0.837, exceeds the fine-tuned range by a clear margin. Even the strongest single-source result reported in [7], an in-domain DNRTI model at 0.871, is achieved on 13 entity types with the model trained and tested on the same corpus and annotation style, a substantially easier setting than the cross-source, fifteen-type extraction evaluated here.

The remaining approaches in Table VI are not directly comparable, and their higher figures do not contradict this finding, because each is produced under conditions more favourable to a fine-tuned model than the present evaluation. References [3] and [5] report 0.875 to 0.883 and 0.900, respectively, but on an in-domain split of the 13-type DNRTI corpus, and the figures in [2] are macro-averaged rather than micro-averaged and so are not directly comparable to the micro F1 reported here. CyBERT reports 0.879 on its own seven-type dataset [5], and SecureBERT 2.0 reaches 0.945 over only five broad categories [6], both on a single in-domain corpus. These results reflect specialization to one annotation style and a narrower taxonomy, not extraction across heterogeneous sources.

The two highest scores in Table VI rest on the least comparable basis and are informative only for a subset of the taxonomy. Reference [3] reports 0.968 on structured vulnerability-description fields such as operating system, vendor, and version rather than CTI-campaign entities, and the models in [7] reach 0.975 over only sixteen indicator-of-compromise types, produced by regular-expression parsers rather than human annotation. Both are relevant to the technical-indicator categories alone, where the present models already perform near-perfectly, and not to overall extraction.

D. Few-Shot Prompting: Hallucination Vs. Cardinality Risk

Few-shot prompting reliably reduces hallucination but introduces cardinality anchoring risk when exemplar entity counts are not representative of the target corpus distribution. The DynoWiper failure demonstrates that this risk is not theoretical – it produces a 73% collapse in micro F1 on an affected report. Practitioners constructing few-shot prompts for CTI NER should 1) sample exemplars to reflect the full entity count distribution per type, 2) include at least one high-cardinality example for any entity type that can appear as a large list, and 3) evaluate the few-shot condition per-report rather than relying solely on corpus-level averages.

Taken together, these findings suggest that the principal bottleneck in prompt-based CTI NER is not model capability in the general sense, but rather the structural properties of the entity types being extracted and the degree to which the prompt communicates their formal constraints. Entities with machine-readable formats (CVE identifiers, IP addresses, cryptographic hashes) are amenable to near-perfect extraction through explicit specification alone. Entities that require operational domain knowledge to disambiguate (tool versus malware, implied sector versus named sector) resist improvement through either few-shot conditioning or format constraints, pointing toward fine-tuning on annotated CTI corpora as the necessary next step. The consistent hierarchy of difficulty across three architecturally distinct models reinforces that this is a domain-level challenge, not a model-level one.

E. Limitations

Several limitations of this study should be acknowledged. The evaluation corpus comprises 21 manually annotated reports. This is a modest scale, and the per-entity-type estimates for low-frequency categories such as goal and tool are therefore subject

to wider variance than the corpus-level figures. The corpus was constructed manually because, to the best of the author's knowledge, no existing public CTI NER dataset covers the 15-type taxonomy evaluated here. Prior corpora target narrower or differently structured schemas, such as the 13 types of DNRTI or the 5 of CyNER, and none of these combine threat-actor attributes, campaign context, and the indicator-of-compromise granularity used in this study within a single annotation scheme. Building a corpus aligned to this taxonomy, therefore, required manual annotation, which bounded its size. A larger corpus spanning more report authors, threat-actor origins, and publication periods would yield more stable per-type estimates and reduce the influence of individual outlier reports on the aggregate metrics, and remains a direction for future work.

All extractions are scored by exact string matching after lowercasing and whitespace normalization, which is a conservative criterion. As documented in Section V, extractions that identify the correct entity with an imprecise boundary, such as "cobalt strike beacon" for "cobalt strike", "atera agent" for "atera", or "fast reverse proxy server" for "fast reverse proxy server (frps)", are counted as both a false positive and a false negative under exact matching, even though they would be operationally useful to an analyst. The reported scores, therefore, represent a lower bound on extraction quality, and a partial-match or soft-F1 metric that credits boundary-imperfect but semantically correct extractions would yield higher figures, particularly for the tool and malware categories where boundary ambiguity is most frequent. Reporting such a metric alongside an exact match is a natural refinement for future evaluation.

A further consideration is potential contamination of the evaluation by data seen during pre-training. Because part of the corpus was published in 2025 and 2026, after the evaluated models' pre-training cutoffs, full memorization is unlikely for those documents, though the underlying campaigns and indicators may still appear in pre-training corpora. This effect is conservative for the baseline comparison in Section V: a prompt-based model may benefit from prior exposure to a report, whereas a fine-tuned encoder trained on a disjoint corpus cannot, so any contamination present would understate rather than inflate the gap. A per-report F1 stratification by publication date is left to future work.

Beyond these immediate constraints, the scope of the evaluation is intentionally limited to named entity identification. Extending the framework to STIX 2.1 relationship extraction and moving beyond the identification of individual entities to the structured representation of relationships between them, such as threat actor-to-malware attribution or campaign-to-infrastructure associations, represents a natural and high-value next step toward fully automated CTI report-to-STIX conversion pipelines.

VI. Conclusion

This study evaluated Claude Sonnet 4.6, GPT-5.4, and LLaMA 4 Scout on CTI named entity recognition across 21 reports, 15 entity types, two prompting conditions, and two prompt versions. Commercial LLMs achieve strong zero-shot CTI NER performance (~0.83 micro F1) without task-specific fine-tuning. A single prompt revision (adding explicit character-length constraints for hash entities) produced the largest F1 improvements in the study, raising SHA-1 F1 by +0.442 (GPT-5.4) and +0.373 (LLaMA), demonstrating the outsized leverage of format specification for technically structured entities.

Few-shot prompting consistently reduces hallucination rates across all models but introduces cardinality anchoring risk, demonstrated most severely by the GPT-5.4's DynoWiper failure. All three models show neutral-to-negative few-shot F1 deltas, with hallucination reduction as the primary measurable benefit of the few-shot condition. The tool entity type is the most challenging across all models due to systematic malware/tool boundary ambiguity, system utility over-extraction, and name normalization failures that exact-match evaluation does not credit.

Collectively, these findings provide both a practical guide for deploying LLM-based CTI NER and an empirical basis for future research in prompt engineering, exemplar selection strategy, and evaluation methodology for the CTI domain.

A QR-Code-Based Mobile Learning System for Science Instruction in Resource-Limited Schools

Gina B. Selga
College of Education, Pangasinan State University – Asingan Campus, Philippines

***Abstract*—This study developed and evaluated a QR-Code-Based Mobile Learning System for Science Instruction in Resource-Limited Schools. The system was designed to provide junior high school students with low-cost, mobile-accessible science learning materials through printed QR Code Cards linked to a mobile-responsive digital repository. The developed module set consisted of six curriculum-aligned Life Science topics: Cell: The Basic Unit of Life, Cell Theory, Cell Structure and Functions, Prokaryotic vs. Eukaryotic Cells, Cell Types and Cell Modifications, and Cell Cycle. A developmental, quasi-experimental, and descriptive-evaluative research design was employed. The participants were 80 Grade 9 and Grade 10 students divided into an experimental group using the QR-code-based mobile learning system and a control group using traditional printed flashcards. Results showed that students had moderate overall familiarity with QR codes (M = 3.52), highly positive attitudes toward the system (M = 4.45), and high usability ratings (M = 4.38). The QR Code Cards also received very high ratings in terms of portability, durability, readability, and sustainability (M = 4.50). Critically, the experimental group obtained a post-test mean score of 89.15 compared with the control group's mean score of 78.42, yielding a statistically significant difference (t = 6.24, p = .002, Cohen's d = 2.49, 95% CI [7.17, 14.29]), indicating that the QR-code-based mobile learning system significantly improved science achievement by a mean margin of 10.73 points. The findings suggest that QR-code-supported mobile learning can serve as a practical, scalable, and cost-effective instructional innovation for improving science instruction in resource-limited school settings.**

I. Introduction

The increasing demand for technology-supported instruction has encouraged schools to adopt flexible, accessible, and learner-centered approaches that can improve educational delivery across diverse learning environments [1]. In science education, this demand is especially important because students often encounter abstract concepts, microscopic structures, biological processes, and scientific relationships that are difficult to understand through text-based instruction alone [2], [3].

Mobile learning has expanded considerably as a field over the past two decades, with a growing body of evidence documenting its effectiveness in diverse educational contexts [4]. Garzon's review of twenty years of mobile learning in science education found positive effects on student achievement and engagement across multiple grade levels [4]. Traxler argued that mobile learning is particularly transformative when it addresses access inequalities, enabling students without physical libraries or laboratories to engage meaningfully with instructional content [5]. Unlike traditional computer-based learning, mobile learning supports anytime and anywhere access to educational content, enabling students to continue learning beyond the physical boundaries of the classroom [6], [7]. In resource-constrained schools, mobile-responsive systems offer a cost-effective alternative to expensive computer laboratories or printed reference materials. Reychav, Dunaway, and Kobayashi found that students' technology-fit behavior outside the classroom is influenced by the alignment between the mobile platform and actual learning tasks [6]. When mobile learning systems are designed with curriculum alignment and ease of use as central principles, students are more likely to engage with and benefit from these tools.

The effectiveness of mobile learning has been demonstrated in various fields, particularly in health and professional education, where mobile applications have improved students' knowledge, skills, self-efficacy, clinical reasoning, and competency development [8], [9]. Studies on smartphone-based learning applications have also shown that mobile platforms can enhance active learning, collaborative learning, and independent practice when instructional content is designed for meaningful interaction [10], [11].

Mobile-assisted instruction is especially relevant to Generation Z learners, who are accustomed to smartphone use, rapid digital interaction, multimedia content, and technology-mediated communication [9]. However, students' willingness to use digital learning systems depends not only on access to devices but also on perceived usefulness, perceived ease of use, motivation, and technology acceptance [12], [13].

The Technology Acceptance Model explains that learners are more likely to adopt a technology when they believe it is useful and easy to use [13]. Similarly, studies on digital learning behavior suggest that students' engagement with mobile platforms is influenced by technology fit, learning context, and the extent to which the system supports their actual learning needs [6], [12].

Motivation is also a critical factor in the design of mobile learning systems because students are more likely to engage with learning materials when the system captures attention, establishes relevance, builds confidence, and promotes satisfaction [14]. These motivational principles are important in resource-limited schools, where students may experience reduced access to libraries, laboratories, printed references, and other conventional learning resources [1].

In resource-constrained educational settings, mobile learning provides a cost-effective way to extend access to instructional materials without requiring expensive computer laboratories or advanced infrastructure [4], [5]. For schools with limited physical resources, mobile-responsive learning systems can serve as alternative repositories of multimedia content, allowing students to access videos, diagrams, notes, and interactive activities using available smartphones [6], [15].

Quick Response codes, or QR codes, offer a simple and low-cost mechanism for connecting printed materials to digital learning resources [16]. By scanning a QR code with a smartphone camera, learners can immediately access online or mobile-based content without the need for complex software installation or advanced technical skills [17], [18].

QR codes have been widely applied in education because they can transform static printed materials into interactive learning tools [16], [19]. In medical and healthcare education, QR codes have been used to provide students and practitioners with fast access to learning resources, patient education materials, procedural guides, and interactive academic content [17], [18].

A scoping review of QR code use in healthcare education reported that QR codes are useful for delivering accessible, interactive, and context-specific learning materials [19]. Similarly, broader reviews of QR-code-based learning have shown that QR codes can improve student interaction with content, increase perceived learning effectiveness, and support flexible access to educational resources [20].

In basic education, QR-code-enhanced instructional materials have been used to increase learner engagement by combining physical learning prompts with multimedia content [30]. QR-integrated picture cards and science flashcards have shown potential for improving student participation, conceptual understanding, and retention because they allow students to move from static printed information to richer digital explanations [21], [22].

Flashcards remain a valuable instructional tool because they promote retrieval practice, repetition, and long-term memory reinforcement [23], [24]. Retrieval practice strengthens learning by requiring students to recall information actively rather than merely rereading or reviewing content passively [24].

However, traditional flashcards are limited by their static format and may not sufficiently support complex science concepts that require dynamic visualization, detailed explanation, and multiple forms of representation [2], [3]. Cognitive Load Theory suggests that well-designed instructional materials can support learning by reducing unnecessary cognitive demands and providing learners with clearer representations of difficult concepts [3].

The integration of QR codes into flashcards can address these limitations by combining the memory benefits of retrieval practice with the multimedia advantages of mobile learning [21], [22]. Through this approach, a physical card can function as both a review tool and a digital access point to video lectures, three-dimensional illustrations, lecture notes, discussion prompts, and formative activities.

Mobile video-based learning is particularly useful because videos can support independent learning, repeated viewing, and learner control over pace and sequence [15]. When QR codes are used to provide direct access to short instructional videos and visual learning materials, students can engage with science concepts more flexibly and independently [15], [20].

The use of mobile applications and multimedia systems has also been found to improve learning outcomes when students are provided with opportunities for repeated practice, immediate access to information, and interactive engagement [25], [26]. In nursing and health education, mobile applications, augmented reality tools, simulations, and blended mobile learning models have produced positive effects on students' knowledge, skills, motivation, self-efficacy, and competence [27], [28], [29].

Although many of these studies were conducted in higher education or healthcare education, their findings demonstrate the broader instructional value of mobile learning systems for skills development, knowledge acquisition, and learner engagement [8], [30]. These findings suggest that mobile learning principles can also be applied to junior high school science instruction, especially when the system is designed to be simple, accessible, and aligned with curriculum competencies.

Teacher evaluation and student learning outcomes are also important considerations in technology-enhanced instruction because the success of a learning innovation depends on both instructional design and learner response [31], [32]. Survey-based evaluation can provide useful evidence regarding student attitudes, usability, perceived effectiveness, and acceptance of instructional technology when properly designed and reported [33].

In evaluating educational technology interventions, both quantitative and qualitative evidence can strengthen the interpretation of results [7], [8]. Quantitative data can measure learning outcomes, usability, and acceptance, while qualitative data can explain learner experiences, implementation challenges, and perceived value of the system [34], [35].

Thematic analysis is often used to interpret open-ended responses, interview data, and qualitative feedback in educational research [34], [35]. However, researchers must apply systematic procedures to ensure that themes are credible, consistent, and grounded in participant responses [36], [37].

In K-12 science education specifically, mobile learning has shown significant instructional potential. Studies situated in primary and secondary school settings demonstrate that mobile devices can improve science concept acquisition, support inquiry-based learning, and increase student engagement when instructional content is aligned with curriculum competencies [4], [38], [39]. These findings are especially relevant to resource-limited school contexts, where mobile technology may substitute for libraries, laboratories, and other conventional resources that are unavailable or insufficient.

Despite the growing body of research on mobile learning, QR codes, and technology-enhanced education, there remains a need for more studies focused on low-cost mobile learning systems in basic education science classrooms [4], [20]. Much of the available literature focuses on higher education, nursing education, medical education, or general digital learning

behavior, leaving fewer empirical studies situated in resource-limited junior high school contexts [9], [19].

There is also a need to examine how QR-code-based systems can be designed as practical instructional solutions for schools with limited libraries, laboratories, internet infrastructure, and printed learning materials [1], [5]. In such contexts, QR-code-based mobile learning systems may provide an affordable bridge between physical instructional materials and digital learning resources [15], [16].

The present study responds to this research gap by developing and evaluating a QR-code-supported mobile learning system for junior high school science instruction. The system uses printed QR-code cards linked to a mobile-responsive digital repository containing multimedia science materials aligned with curriculum competencies.

Specifically, the study examines students' familiarity with QR-code technology, the usability and physical characteristics of the QR-code cards, students' attitudes toward the mobile learning system, and the system's effect on science academic performance. By combining instructional material design, mobile learning, QR-code integration, technology acceptance, and academic performance evaluation, the study contributes to the growing literature on low-cost educational technology for resource-limited schools.

II. Methodology

A. Research Design

This study employed a developmental and quasi-experimental research design to develop, implement, and evaluate a QR-code-based mobile learning system for junior high school science instruction in a resource-limited school setting. The developmental component focused on the design and production of the QR-code cards and the linked mobile-responsive digital learning repository. The quasi-experimental component examined the effectiveness of the system by comparing the academic performance of students exposed to the QR-code-based mobile learning system with that of students taught using traditional printed flashcards. The study also included a descriptive-evaluative component to assess students' familiarity with QR-code technology, their attitudes toward the system, the usability of the mobile learning materials, and the perceived impact of the physical characteristics of the QR-code cards.

B. Research Locale

The study was conducted at San Vicente West Integrated School, Asingan, Pangasinan, Philippines, a school context characterized by limited instructional resources and the absence of a functional library. This setting was selected because it represented the type of resource-limited learning environment for which the QR-code-based mobile learning system was designed. The lack of sufficient physical learning materials created a need for a low-cost, scalable, and mobile-accessible instructional system that could provide students with supplementary science learning resources.

C. Participants and Sampling Technique

This study was conducted at San Vicente West Integrated School, Asingan, Pangasinan, Philippines. A total population sampling technique was employed, involving all grade 9 and grade 10 students enrolled in life science for the SY. 2025-2026, comprising 40 students from each grade level for a total of 80 participants. Within each grade level, students were randomly assigned into two groups of 20: an experimental group, which used the QR-code-based mobile learning system, and a control group, which used traditional printed flashcards. This resulted in a combined experimental group of 40 students (20 from grade 9 and 20 from grade 10) and a combined control group of 40 students (20 from grade 9 and 20 from grade 10), ensuring that both groups were comparable in terms of grade-level composition before the intervention.

D. The QR-Code-Based Mobile Learning System

The instructional intervention developed for this study was a QR-code-based mobile learning system composed of two major components: printed QR-code cards and a mobile-responsive digital learning repository. Each QR-code card was produced using 3 × 5-inch laminated cardstock with embedded QR codes linked to specific science learning modules. The system used static QR codes—fixed codes linked to stable, persistent URLs hosted on the digital repository server. Because static QR codes encode the URL directly within the code itself, the physical cards must be reprinted if the linked URL changes. To mitigate this limitation, the researcher ensured that the repository domain and URL structure remained unchanged throughout the study period and documented a link-preservation protocol for future use. Future implementations may consider dynamic QR codes, which allow URL redirection at the database level without requiring the reprinting of physical cards. The six science modules covered were: Cell: The Basic Unit of Life, Cell Theory, Cell Structure and Functions, Prokaryotic vs. Eukaryotic Cells, Cell Types and Cell Modifications, and Cell Cycle.

E. Development Procedure

The development of the QR-code-based mobile learning system followed four phases: needs analysis, content development, system design, and validation. During the needs analysis phase, the researcher identified science topics that students commonly found difficult to understand using printed materials alone. Priority was given to abstract biological concepts that required visual explanation, such as cell structure, cell functions, and the cell cycle. During the content development phase, the researcher prepared and curated multimedia resources aligned with the DepEd MELCs. Each module was designed to include concise explanations, visual materials, and activities that could support independent and classroom-based learning. During the system design phase, QR codes were generated and embedded into the printed cards. Each QR code was linked to a corresponding page in the mobile-responsive digital repository. The physical cards were designed with high-contrast text, visual cues, and module-specific illustrations to support readability, scanning accuracy, and learner engagement. During the validation phase, the QR-code cards, digital learning materials, and research instruments were evaluated by three validators: a content expert, a technical or

ICT expert, and a language and research expert. The validators assessed the materials in terms of content accuracy, technical quality, layout and design, usability, and clarity. Revisions were made based on the validators' comments before the system was implemented in the classroom.

F. Research Instrument

The study used the following instruments:

1) Science achievement test. A researcher-developed pre-test and post-test were used to measure students' science achievement before and after the intervention. The test covered the science topics included in the QR-code-based mobile learning system.

2) QR-Code technology familiarity survey. This instrument measured students' prior exposure to QR codes in daily life, social media, and academic contexts.

3) Usability and attitude survey. This questionnaire assessed students' perceptions of the QR-code-based mobile learning system in terms of ease of use, usefulness, accessibility, engagement, and willingness to use the system for science learning.

4) Physical characteristics evaluation form. This instrument measured students' evaluation of the QR-code cards in terms of size, color, texture, durability, portability, readability, and sustainability.

5) Development difficulty rating form. This instrument assessed the level of difficulty encountered in developing the QR-code cards and the mobile-responsive digital repository.

All survey instruments used a five-point Likert scale. The instruments were reviewed by experts and pilot-tested before implementation to ensure clarity, relevance, and appropriateness for the target respondents. Fig. 1 shows the system architecture of the QR-Code-Based Mobile Learning System.

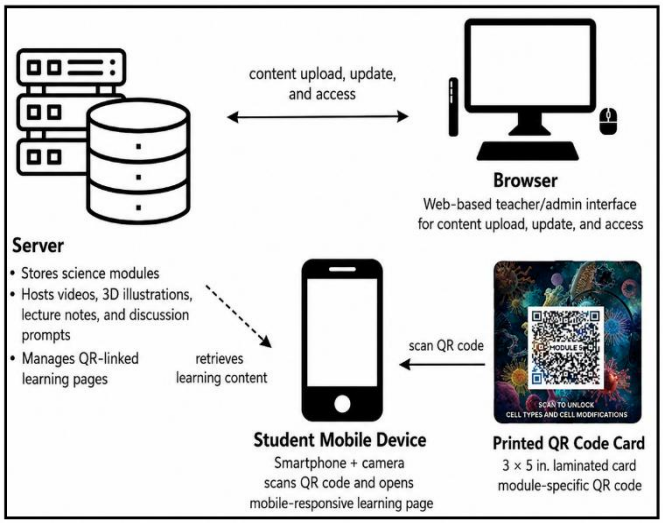

Fig. 1. Architecture of the QR-code-based mobile learning system.

Fig. 1 illustrates the system architecture of the QR-code-based mobile learning system developed for science instruction in a resource-limited school setting. The system architecture is composed of a server module, a browser-based interface, the student's mobile device, and the printed QR Code Card. These components work together to connect physical instructional materials with digital science learning resources.

The Server Module serves as the core storage and management component of the system. It houses the digital learning repository containing the science instructional materials developed for the six modules included in the study, namely: Cell: The Basic Unit of Life, Cell Theory, Cell Structure and Functions, Prokaryotic vs. Eukaryotic Cells, Cell Types and Cell Modifications, and Cell Cycle. The repository stores the multimedia learning resources linked to each QR code, such as short video lectures, three-dimensional biological illustrations, lecture notes, and interactive discussion prompts. In addition to storing content, the server module manages the links between the QR codes and their corresponding mobile learning pages. This makes the system function as a centralized digital platform that supports the delivery of science content through mobile access.

The Browser represents the web-based interface used to access and manage the digital repository. In the context of the study, this browser component may be used by the teacher or researcher to upload, organize, and update the content for each science module. Because the learning repository is mobile-responsive, the browser-based system allows the instructional content to be delivered in a format that is accessible on standard web-enabled devices without the need for a dedicated application. This component is important because it supports the maintainability and scalability of the system. Once a module page is updated in the repository, the linked QR code can continue to direct students to the revised content without requiring the printed card to be replaced, especially if dynamic QR linking is used.

The Mobile Device refers to the student's smartphone, which functions as the primary access tool for the mobile learning system. Using the phone's built-in camera, the student scans the QR code printed on the card. After scanning, the smartphone opens the linked learning page where the student can view digital science resources and participate in related learning activities. This design is especially appropriate for resource-limited schools because it makes use of widely available student smartphones rather than requiring computer laboratories or specialized learning hardware. The mobile device, therefore, acts as the bridge between the printed card and the digital repository, enabling the system to support both classroom learning and independent study outside school hours.

The QR Code Card is the physical instructional component of the system. Based on the manuscript, each card was produced using 3 × 5-inch laminated 220 gsm cardstock and designed for portability, durability, readability, and repeated classroom use. Each card contains a module-specific QR code that directs students to the corresponding science content in the digital repository. The QR Code Card functions not only as a printed learning aid but also as a physical-digital access point. In this sense, it transforms a conventional flashcard into an interactive learning object by integrating retrieval-based review with mobile multimedia learning.

G. Data Gathering Procedure

Before data collection, administrative approval was secured from the school principal, and informed consent was obtained from the students and their guardians. The participants were informed about the purpose of the study, the procedures involved, and the confidentiality of their responses. The data gathering procedure began with the administration of the pre-test to both the experimental and control groups. The pre-test established the students' baseline level of science achievement before the instructional intervention. After the pre-test, the experimental group was oriented on how to use the QR-code-based mobile learning system. Students were taught how to scan the QR codes, access the mobile learning repository, navigate the multimedia resources, and use the cards during classroom and independent study activities. The experimental group then used the QR-code-based mobile learning system during science instruction. The students accessed video lectures, biological illustrations, notes, and discussion prompts through the QR-code cards. The control group, on the other hand, received instruction using traditional printed flashcards covering the same science topics. After the intervention period, both groups took the post-test. The experimental group also answered the usability, attitude, QR-code familiarity, and physical characteristics evaluation questionnaires. The collected data were then encoded, tabulated, and analyzed using appropriate statistical tools.

H. Data Analysis

Descriptive statistics were used to summarize the respondents' profiles, QR-code familiarity, usability ratings, attitude toward the system, physical card evaluation, and perceived development difficulty. Frequency counts, percentages, means, standard deviations, and weighted means were computed. The weighted means were interpreted using a five-point verbal interpretation scale. Higher mean scores indicated more positive perceptions of the QR-code-based mobile learning system, greater usability, stronger technology familiarity, or higher perceived impact of the physical characteristics of the cards. To establish baseline equivalence before the intervention, an independent-samples t-test was conducted on the pre-test scores of the experimental and control groups. To determine effectiveness, the post-test scores were compared using an independent-samples t-test. Effect size was calculated using Cohen's d and a 95% confidence interval was computed for the mean difference in post-test scores, enabling practical significance assessment alongside statistical significance. This test determined whether there was a statistically significant difference in science achievement between students who used the QR-code-based mobile learning system and those who used traditional printed flashcards.

I. Proposed Methodological Framework

Fig. 2 presents the methodological framework of the study, organized into three sequential phases. It shows that the research follows three major phases: system development, implementation, data gathering, and data analysis and interpretation.

In Phase 1, the QR-code-based mobile learning system is developed by identifying difficult science topics, preparing multimedia learning content, designing the mobile-responsive repository and QR code cards, and validating the materials through experts. In Phase 2, the system is implemented with junior high school students. The participants are divided into an experimental group using the QR-code-based mobile learning system and a control group using traditional printed flashcards. Pre-tests, post-tests, and survey instruments are administered to collect data on learning performance, usability, attitude, QR familiarity, and card characteristics. In Phase 3, the collected data are analyzed using descriptive statistics and an independent-samples t-test. The findings are then interpreted to determine whether the QR-code-based mobile learning system is usable, acceptable, and effective in improving science instruction in resource-limited schools.

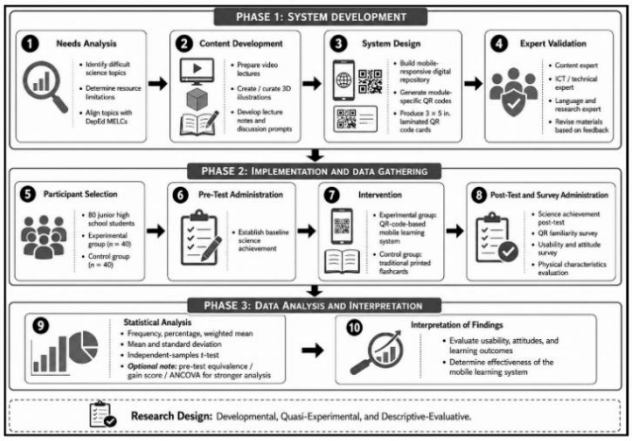

Fig. 2. The proposed methodological framework.

J. Ethical Consideration

The study followed ethical procedures for school-based research. Administrative clearance was obtained before data collection, and informed consent was secured from the participants and their guardians. Participation was voluntary, and students were informed that their responses would be used only for research purposes. No personally identifiable information was included in the analysis or reporting of results. The study also ensured that both the experimental and control groups received science instruction aligned with the same curriculum competencies. The QR-code-based learning materials were used for educational purposes only.

III. Results and Discussion

A. Profile of the Respondents

The respondents of the study were junior high school students from San Vicente West Integrated School, Asingan, Pangasinan, Philippines. The sample consisted of Grade 9 and Grade 10 students, with a total of 80 participants divided into two groups: the experimental group using the QR-code-based mobile learning system and the control group using traditional printed flashcards. Each group had 40 students. Most of the respondents were between 14 and 16 years old, representing 88% of the sample. The sex distribution was nearly balanced, with 52% female students and 48% male students. Before the intervention, 65% of the students were within the "Satisfactory" range in science, with grades between 75% and 79%. This profile indicates that the participants were appropriate for the intervention because they represented learners who could

benefit from additional instructional support in science. The baseline profile also supports the need for a mobile learning intervention. Since the school setting was resource-limited and lacked a functional library, students required an accessible instructional system that could supplement classroom learning without depending on expensive infrastructure. The use of smartphones and QR-code cards, therefore, provided a practical way to deliver science learning materials through available technology.

B. Pre-Test Equivalence of the Experimental and Control Groups

Before implementing the intervention, an independent-samples t-test was conducted on the pre-test scores of the experimental and control groups to verify that the two groups were academically equivalent at baseline. Table I presents the pre-test equivalence results.

The pre-test results showed no statistically significant difference between the experimental group ($M = 76.45$, $SD = 4.82$) and the control group ($M = 75.88$, $SD = 5.10$), $t(78) = 0.41$, $p = .684$. The failure to reject the null hypothesis confirms that the two groups were academically equivalent in science before the intervention, thereby strengthening the internal validity of the quasi-experimental design and supporting the interpretability of the post-test comparison.

TABLE I. PRE-TEST EQUIVALENCE OF EXPERIMENTAL AND CONTROL GROUPS

Group	n	Pre-test Mean	SD	t-val	p-val	Decision
Experimental Group: QR-Code-Based Mobile Learning System	40	76.45	4.82	0.41	0.684	Fail to Reject H_0
Control Group: Traditional Printed Flashcards	40	75.88	5.1			

C. Developed QR Code Card Module Set

One of the major outputs of the study was the development of a six-module QR Code Card set for junior high school science instruction. The module set was designed as the physical-digital component of the QR-code-based mobile learning system. Each card contained a QR code that directed students to a mobile-responsive digital repository containing video lectures, three-dimensional biological illustrations, lecture notes, and interactive discussion prompts.

The six QR Code Cards were produced using 3 × 5-inch laminated cardstock with a 220 gsm material specification. The cards were designed to be portable, durable, reusable, and suitable for repeated classroom use. The total production cost of the complete six-module set was reported at ₱10,000.00, covering cardstock, printing, lamination, and hosting. Fig. 3 presents the actual QR Code Card module set developed for the study. The cards were designed with science-themed visual backgrounds, embedded QR codes, and module labels to help students identify the topic before scanning. The QR codes served as access points to the digital learning repository, allowing the printed cards to function as interactive learning materials rather than ordinary flashcards.

This QR Code Card of Fig. 3 introduces the cell as the basic structural and functional unit of life. This module provides students with foundational knowledge about why all living organisms are composed of cells and how cells perform essential life processes. Through the QR-linked multimedia materials, students can access visual explanations, lecture notes, and supporting activities that help them understand the cell as the foundation of biological organization.

This QR Code Card of Fig. 4 focuses on the Cell Theory and its historical development. This module guides students in understanding the major postulates of Cell Theory, including the idea that all living things are made of cells, that the cell is the basic unit of life, and that all cells come from pre-existing cells. The QR-linked resources help students connect scientific discoveries with the development of modern biological understanding.

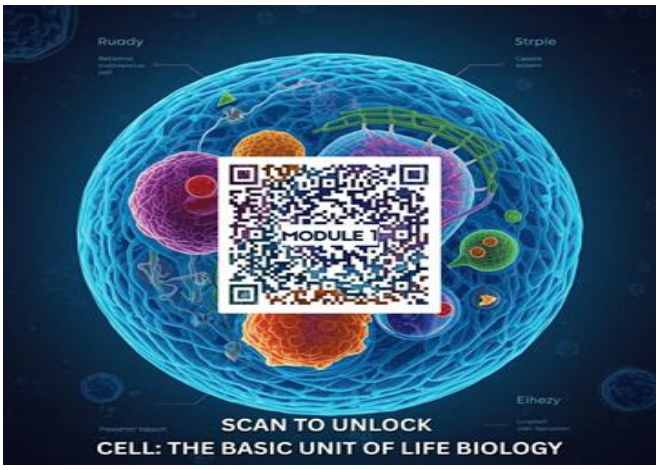

Fig. 3. The cell: The basic unit of life QR code card.

Fig. 4. The cell theory QR code card.

This QR Code Card of Fig. 5 presents the different parts of the cell and their corresponding functions. This module helps students identify major cell structures such as the nucleus, cytoplasm, cell membrane, mitochondria, and other organelles.

Fig. 5. The cell structure and functions QR code card.

The QR-linked videos and three-dimensional illustrations are especially useful in this module because they allow students to visualize cell parts that are normally difficult to observe in a resource-limited classroom.

Fig. 6. The prokaryotic vs. eukaryotic cells QR code card.

This QR Code Card of Fig. 6 helps students distinguish between prokaryotic and eukaryotic cells. This module emphasizes the differences in cell organization, presence or absence of a nucleus, complexity of internal structures, and examples of organisms under each cell type.

Through the QR-linked digital materials, students can compare the two cell types more clearly using diagrams, explanations, and guided activities.

This QR Code Card of Fig. 7 focuses on cell types and cell modifications. This module helps students classify different types of cells and understand how specialized structures support specific cell functions. It is particularly useful for explaining how cells become adapted for particular roles in living organisms. The QR-linked content supports deeper understanding by providing visual examples of specialized cells and their modified structures.

This QR Code Card of Fig. 8 discusses the stages of the cell cycle and their importance in growth, repair, and reproduction. This module introduces students to the sequence of events involved in cell division, including interphase and the major stages of mitosis. Since the cell cycle is a process-based topic, the QR-linked videos and visual materials help students follow the sequence of changes more easily than s printed explanations alone.

Fig. 7. The cell types and cell modifications QR code card.

Fig. 8. The cell cycle QR code card.

Together, the six QR Code Cards form a structured Life Science learning sequence. The modules begin with the basic concept of the cell, proceed to cell theory and cell structures, compare major cell types, examine cell specialization, and conclude with the cell cycle. This progression supports gradual concept development and allows students to access multimedia learning materials for each topic through a simple smartphone scan.

D. QR Code Card Module Set and Curriculum Alignment

Table II presents the six QR code card module sets and their alignment to the curriculum. The six-module set shows that the QR-code-based mobile learning system was not developed as a general or unstructured digital tool. Instead, it was organized around specific curriculum competencies in junior high school Life Science. This alignment is important because it ensures that the mobile learning system supports required learning outcomes rather than functioning only as a supplementary technology activity.

TABLE II. SIX QR CODE CARD MODULE SET AND CURRICULUM ALIGNMENT

Module	Topic	DepEd MELC Competency	Grade Level
1	Cell: The Basic Unit of Life	Describe the cell as the basic structural and functional unit of life	Grade 9 – Life Science
2	Cell Theory	Explain the postulates of the Cell Theory and their historical development	Grade 9 – Life Science
3	Cell Structure and Functions	Identify the parts of the cell and their corresponding functions	Grade 9 – Life Science
4	Prokaryotic vs. Eukaryotic Cells	Distinguish between prokaryotic and eukaryotic cells	Grade 9 – Life Science
5	Cell Types and Cell Modifications	Classify cells and describe how specialized structures support specific cell functions	Grade 10 – Life Science
6	Cell Cycle	Explain the stages of the cell cycle and their significance to growth and reproduction	Grade 10 – Life Science

The module topics also reflect science concepts that often require visual explanation. Topics such as cell structure, cell functions, prokaryotic and eukaryotic cells, and the cell cycle are difficult to teach using text alone because students need to visualize microscopic structures and bsiological processes. The integration of QR-linked videos, diagrams, notes, and discussion tasks allowed each printed card to become an access point to richer science learning resources. The physical design of the module set also contributed to its suitability for resource-limited schools. Since the cards were laminated and reusable, the system could be used across multiple lessons and learning activities. The use of dynamic QR codes also allowed the linked content to be updated without reprinting the cards, increasing the maintainability of the instructional system.

E. Students' Familiarity with QR Code Technology

Table III shows the students' familiarity with QR code technology. The students reported high familiarity with QR codes in daily life and social media contexts, but low familiarity with QR codes as part of formal academic learning.

TABLE III. EXTENT OF STUDENT FAMILIARITY WITH QR CODE TECHNOLOGY

Indicator	Weighted Mean	Interpretation
Actual encounter with QR codes in daily life	4.12	High Familiarity
Use of QR codes in social media platforms	4.35	High Familiarity
Awareness of QR codes within the school curriculum	2.1	Low Familiarity
Overall Mean	3.52	Moderate Familiarity

The results indicate that students were already familiar with QR codes as part of everyday digital practices, particularly in social media and commercial transactions. However, their low familiarity with QR codes in the school curriculum shows that the use of QR codes as an instructional tool was relatively new to them. This finding confirms the need for orientation before implementation. Although the learners were familiar with the scanning process, they had limited experience using QR codes for structured academic learning. This result supports the relevance of the QR-code-based mobile learning system. The system builds on students' existing digital habits and redirects them toward educational purposes. In this way, the intervention transforms a familiar technology into a purposeful learning tool. The moderate overall familiarity also suggests that students were not technologically unprepared, making the system feasible for classroom implementation.

F. Evaluation of the Physical Characteristics of the QR Code Cards

The QR Code Cards were evaluated in terms of size, color, texture, and sustainability. These characteristics were important because the physical card served as the primary access point to the mobile learning system. Table IV shows the impact ratings of QR code card physical characteristics.

TABLE IV. IMPACT RATINGS OF QR CODE CARD PHYSICAL CHARACTERISTICS

Physical Characteristic	Weighted Mean	Interpretation
Size – 3 × 5-inch portability and handling	4.56	Very High Impact
Color – high-contrast design for readability	4.2	High Impact
Texture – laminated durability	4.45	High Impact
Sustainability – re-usability over the full academic year	4.78	Very High Impact
Overall Mean	4.5	Very High Impact

The overall mean of 4.50 indicates that the students evaluated the physical characteristics of the QR Code Cards as having a very high impact. Among the indicators, sustainability received the highest mean of 4.78, followed by size and portability with a mean of 4.56. These results show that the students found the cards durable, reusable, and convenient to handle. The high rating for sustainability is particularly important in a resource-limited school setting. Since the cards were laminated and produced using 220 gsm cardstock, they were able to withstand repeated use during classroom activities. This makes the system practical for schools with limited funds because the cards can be reused over time instead of being replaced frequently. The high rating for size also suggests that the 3 × 5-inch format was appropriate for student use. The card was small enough to be portable but large enough to display the QR code and module information clearly. This supports the idea that the physical design of the learning tool affects its usability and acceptance.

G. Level of Difficulty in Developing the QR-Code-Based Mobile Learning System

The development of the QR-code-based mobile learning system was rated as moderately difficult, with an overall mean of 3.10. The main challenges involved creating a mobile-responsive digital repository, ensuring that the QR codes were scannable across different smartphone models, and preparing

multimedia content aligned with the DepEd Most Essential Learning Competencies. This finding shows that the system was feasible to develop, although it required technical and instructional preparation. The moderate difficulty rating suggests that teachers may be able to replicate the system if they are given proper training in QR code generation, mobile content organization, basic website management, and multimedia curation. The result also highlights the importance of teacher capacity-building. For resource-limited schools to adopt this kind of mobile learning system successfully, teachers need support not only in content development but also in the technical aspects of designing QR-linked learning materials. The inclusion of a teacher's manual or implementation guide may therefore improve the scalability of the system.

H. Students' Attitude Toward and Utilization of the QR-Code-Based Mobile Learning System

The experimental group reported a highly positive attitude toward the QR-code-based mobile learning system, with a mean of 4.45. Students also gave high usability ratings, with a mean of 4.38. These results indicate that the students found the system useful, accessible, and easy to use. Students appreciated the immediacy of access to multimedia learning materials. By scanning the QR Code Cards, they could access video lectures, biological illustrations, lecture notes, and discussion prompts through their smartphones. This made the learning experience more interactive compared with traditional printed flashcards. The system also functioned as a portable learning resource. Since the students could bring the QR Code Cards home, they were able to review the science modules outside the classroom. This is especially valuable in a school without a functional library because the QR-code-based system provided students with access to supplementary science resources beyond regular classroom instruction. The positive attitude and high usability rating suggest that the system was acceptable to the learners. From a technology acceptance perspective, this means that the students were more likely to use the system because they perceived it as easy to scan, easy to navigate, and helpful for learning science concepts.

I. Comparative Academic Performance of the Experimental and Control Groups

To determine the effectiveness of the QR-code-based mobile learning system, the post-test scores of the experimental and control groups were compared using an independent-samples t-test. Table V shows the independent-samples t-test on post-test academic performance.

TABLE V. INDEPENDENT SAMPLE T-TEST RESULT FOR POST-TEST ACADEMIC PERFORMANCE

Group	n	Post-test Mean	SD	t-val	p-val	Decision
Experimental Group: QR-Code-Based Mobile Learning System	40	89.15	3.45	6.24	0.002	Reject H_0
Control Group: Traditional Printed Flashcards	40	78.42	5.12			

The results show that the experimental group obtained a higher post-test mean score of 89.15 compared with the control group's mean score of 78.42. The computed t-value of 6.24 and p-value of .002 indicate a statistically significant difference between the two groups. Therefore, the null hypothesis of no significant difference was rejected. This result suggests that students who used the QR-code-based mobile learning system performed significantly better in science than those who used traditional printed flashcards. The mean difference of 10.73 percentage points indicates a substantial improvement in favor of the experimental group. The higher performance of the experimental group may be attributed to the integration of multimedia resources into the learning process. Unlike traditional flashcards, the QR Code Cards provided access to videos, three-dimensional biological illustrations, notes, and discussion activities. These resources likely helped students visualize abstract science concepts more clearly and review the lessons more independently. The result also supports the instructional value of combining physical learning materials with mobile technology. The printed QR Code Card served as a simple and familiar object, while the linked digital repository expanded the learning experience through multimedia content. This combination made the system suitable for a resource-limited school because it did not require expensive technology infrastructure.

J. Discussions

The findings of the study demonstrate that the QR-code-based mobile learning system is a feasible, usable, and effective instructional innovation for science education in a resource-limited school. The system addressed a specific instructional problem: the lack of sufficient learning resources in a school without a functional library. By connecting printed QR Code Cards to a digital learning repository, the system provided students with access to curriculum-aligned multimedia materials.

The six QR Code Card modules further strengthen the system's instructional value because they were organized around specific Life Science competencies for Grades 9 and 10. The modules covered cell biology topics that require visual and conceptual support, making them appropriate for QR-linked multimedia instruction. Through this structure, the system served not only as a technology innovation but also as a curriculum-aligned instructional intervention.

The pre-test findings established that the experimental and control groups were academically comparable before the implementation of the intervention. Results revealed no statistically significant difference between the experimental group and the control group. This result strengthened the internal validity of the quasi-experimental design because any differences observed in the post-test outcomes could be more confidently attributed to the QR-code-based mobile learning intervention rather than pre-existing academic disparities between the groups.

The students' moderate familiarity with QR code technology shows that the system was appropriate for their digital readiness. Although students were already familiar with QR codes in social media and daily life, they had limited exposure to QR codes as

academic tools. The intervention, therefore, introduced a familiar technology in a new educational context.

The high evaluation of the physical card characteristics confirms that usability is not limited to the digital component of the system. The durability, portability, readability, and reusability of the printed cards contributed to the successful implementation of the intervention. This is particularly important for schools with limited resources because instructional materials must be affordable and long-lasting.

The positive attitude and high usability ratings further indicate that students accepted the QR-code-based mobile learning system. Their favorable response suggests that mobile learning tools are more likely to succeed when they are easy to access, simple to use, and directly connected to classroom learning needs.

Most importantly, the significant difference in post-test performance provides evidence that the system contributed to improved science achievement. The QR-code-based mobile learning system allowed students to access multiple representations of science concepts, including visual, textual, and video-based explanations. These features likely reduced the difficulty of learning abstract topics and supported better understanding.

K. Implication of the Findings

The findings have several implications for science instruction and educational technology implementation. First, QR-code-based mobile learning systems can be used as a practical alternative to expensive digital learning platforms. Since the system only requires printed QR Code Cards, a mobile-responsive repository, and smartphones, it is feasible for schools with limited infrastructure. Second, the system can help compensate for the lack of physical learning resources. In the absence of a functional library, QR Code Cards can serve as portable access points to digital learning materials. Third, the six-module QR Code Card set demonstrates that mobile learning systems should be closely aligned with curriculum competencies. The value of the system does not come from QR codes alone, but from the quality, relevance, and organization of the learning materials connected to each code. Fourth, the study highlights the importance of combining instructional design with technology design. The success of the system depended on the quality of the multimedia content, the alignment with curriculum competencies, the usability of the digital repository, and the physical durability of the printed QR Code Cards. Fifth, the results suggest that teacher training is necessary for wider implementation. Teachers need skills in content curation, QR code generation, mobile-responsive content organization, and evaluation of digital learning materials. Finally, the system may be replicated in other subject areas such as Mathematics, English, and Technology and Livelihood Education. Its low-cost and reusable format makes it suitable for broader school-based adoption.

IV. Conclusion and Recommendations

A. Conclusion

This study concluded that a QR-Code-Based Mobile Learning System for Science Instruction in Resource-Limited Schools is a practical, acceptable, and effective instructional innovation for junior high school science education. The developed system, composed of six QR Code Card modules linked to mobile-responsive multimedia resources, provided students with accessible learning materials despite the limited physical resources of the school. The findings showed that students were moderately familiar with QR code technology, highly receptive to the use of the system, and positive in their evaluation of the QR Code Cards' usability, portability, durability, and sustainability. The significant difference in post-test performance between the experimental and control groups further indicates that the QR-code-based mobile learning system contributed to improved science achievement. Overall, the system demonstrates how low-cost mobile technology can support science instruction, independent learning, and curriculum-aligned resource delivery in resource-limited school settings.

B. Recommendations

Based on the findings, it is recommended that schools with limited instructional resources adopt the QR-code-based mobile learning system as a supplementary tool for science instruction. The system may help address the lack of physical libraries, laboratories, and printed learning materials by providing students with direct access to digital resources through QR Code Cards. Since the cards are low-cost, portable, reusable, and easy to use, they can serve as practical learning materials for classroom activities, independent study, and home-based review.

It is also recommended that the system be expanded to other science topics and subject areas. Future versions may include additional modules in biology, chemistry, physics, mathematics, English, and other curriculum areas where students need visual, interactive, and multimedia-supported learning materials. Expanding the system will help determine whether the QR-code-based mobile learning approach is effective across different subjects and grade levels.

Teacher training should also be provided to support the effective implementation of the system. Teachers need basic skills in QR code generation, mobile-responsive content preparation, multimedia curation, and integration of QR-linked activities into classroom instruction. With proper training, teachers can develop their own QR Code Cards and adapt the system to the learning needs of their students.

Schools are also encouraged to improve digital access for students. Since the system depends on mobile devices and internet connectivity, administrators may consider providing offline digital repositories, local servers, shared internet access, or downloadable learning materials for students with limited mobile data or unstable internet connections.

These measures will help ensure that all learners can benefit from the mobile learning system regardless of their connectivity situation.

Further research is recommended using a wider sample and a more rigorous research design. Future studies may involve multiple schools, larger groups of learners, and randomized or matched-group designs to improve the generalizability of the findings. Researchers may also include long-term learning

measures such as delayed post-tests, QR scan frequency, student engagement analytics, and retention of science concepts over time.

Finally, the mobile learning repository may be enhanced by adding assessment and feedback features. Future versions of the system may include quizzes, progress tracking, automatic feedback, and teacher monitoring tools. These improvements can make the QR-code-based mobile learning system more interactive, data-driven, and useful for both students and teachers.

ACKNOWLEDGMENT

The researcher gratefully acknowledges Pangasinan State University for its support in the conduct of this research. Artificial intelligence tools were used to assist with language refinement, idea organization, and formatting. However, all research processes, findings, interpretations, and conclusions were carefully reviewed and verified by the researcher to ensure accuracy, originality, and academic integrity.

An Improved Pre-processing Method for High-Quality MRI Images in Brain Tumor Detection

Nirmala, Kavitha B C
Dept. of ECE, BGS Institute of Technology, Adichunchanagiri University, Mandya, Karnataka, India

***Abstract*—Magnetic Resonance Imaging (MRI) is among the effective methodologies to identify tumors in the brain, but this method may not be very reliable because of the challenges in acquiring the images, which may include image noise, contrast differences, and spatial variation of intensity. To solve these problems, this study suggests an innovative pre-processing framework that will be used to improve the quality of MRI images prior to segmentation and tumor analysis. This study critically compares some noise removal methods, such as Gaussian, median, Wiener, and guided filtering, as well as Discrete Wavelet Transform (DWT)-based de-noising with soft thresholding. The new hybrid model, based on the combination of the advantages of various methods, is a Wavelet-NLM-Median (WNM). WNM integrates multiresolution wavelet shrinkage, non-local redundancy modelling, and median-based edge preservation to achieve improved noise reduction while maintaining structural details. Extensive testing is performed across noise levels ranging from 5% to 50%, and performance is assessed using standard evaluation metrics such as PSNR, MSE, SSIM, and SNR. The proposed WNM hybrid model demonstrates the highest reconstruction quality at 5% noise, with a PSNR of 45.98 dB, MSE of 3.35, SSIM of 0.985, and SNR of 44.89 dB. These statistics were substantially better than those of the Wiener and Guided filters, as well as soft-thresholding based on DWT. Visual assessments also showed that the WNM hybrid approach does a better job of keeping tumor boundaries, fine textures, and structural patterns than any other baseline filtering method. This shows that it is better at restoring high-quality MRI images for later study. The improved MRI inputs used to pre-process training images for a deep learning segmentation model improve the accuracy of the segmentation and the sharpness of the boundaries in a way that could be quantified. The suggested WNM pipeline is quick, works with many types of modalities, and is simple to connect to clinical CAD systems. It is a giant leap in pre-processing the MRI to detect malignancies in the brain.**

Keywords*—Brain MRI de-noising; Wavelet–NLM–Median (WNM) model; structural similarity preservation; image quality enhancement

I. Introduction

Magnetic Resonance Imaging (MRI) has become the most effective and common diagnostic tool to be used in brain tumor assessment because of its superior soft-tissue contrast and the capability to view brain structures without the use of ionizing radiation. Compared to CT or X-ray, MRI offers high-resolution anatomical images that are used to identify the difference between tissues of tumors, edema, necrotic areas, and healthy tissues. This feature is critical in the detection of early-stage tumors, which are usually subtle in terms of intensity variations. Since the prognosis of tumors is highly dependent on the promptness of diagnosis, MRI remains an inseparable part of the clinical process, including its screening, surgical planning, and longitudinal follow-up [1]. It is imperative to have an accurate interpretation of MRI scans, but conditions of imaging in real-life scenarios pose a great challenge. Image quality is usually compromised by noise and artifacts due to scanner restrictions, patient motion, low field acquisitions, and environmental effects. Gaussian noise is a product of electronic acquisition, Rician noise is caused by the low-signal region, and motion artifact distorts anatomical structures. Such distortions will blur the important tumor characteristics (shape, texture, and margins) to interfere with radiologist interpretation and automated analysis systems. Thus, high-quality noise removal is needed to ensure the reliability of diagnostics [2].

In order to overcome these degradations, numerous filtering methods have been researched for MRI pre-processing. Gaussian filtering is less sensitive to discontinuities and more sensitive to complex textures, and median filtering is more sensitive to discontinuities and less sensitive to complex textures. Wiener filtering, local variance adapting, guided filtering, and edge-preserving are not effective in the presence of large or non-uniform noise and corruption extremum, respectively. The weaknesses distinguish the need to have more advanced and adaptive de-noising algorithms capable of addressing different noise characteristics in MRI images [3].

Wavelet-based de-noising is the Discrete Wavelet Transform (DWT) and has gained popularity due to the multiresolution representation of an image. Noise is also removed using wavelet shrinkage, which conserves the important structural information by decomposing MRI scans into sub-bands. Isolated wavelet de-noising has also been known to induce ringing artifacts and poor retention of fine anatomical detail. The performance also depends on the thresholding strategies; hence, the results are not consistent when the noise is changed. Thus, it is theoretically powerful, but when combined with other filtering systems, wavelet methods may be significantly increased [4].

To overcome these weaknesses, the hybrid Wavelet-NLM-Median (WNM) model proposed in this study merges the strengths of a number of de-noising algorithms. Multiscale noise-reduction has been performed using wavelet shrinkage, patch-similarity Non-Local Means (NLM) and median filtering to enhance the quality of edges by removing impulse-like artifacts. The trade-off that ensures a balanced noise reduction and structure preservation is what ensures that the de-noising strategy of single methods [5] is overcome.

The hybrid WNM framework is particularly beneficial in the analysis of MRI brain tumors, where precise localization of tumor boundaries is required. The contours of tumours tend to have irregular morphology, which may be lost or distorted in the course of aggressive smoothing. The WM model enables the preservation of the boundaries with a high level of reliability and also reduces the background noise, simultaneously improving the overall contrast of the image. This enhancement is also reflected in downstream tasks, such as segmentation, classification, and radiomic feature extraction, and has a significant effect on deep learning models, which require clean and anatomically intact data [6]. The investigation of the work is significant due to the test carried out in noisy conditions with noises up to 5 to 50 per cent. The outcomes of the test have always shown that the WNM model outperforms the conventional ones in PSNR, SSIM, and edge preservation metrics. These enhancements lead to computer-aided diagnosis (CAD) systems being more precise since they give cleaner and improved MRI inputs. That is why the given framework can be useful to create better clinical pipelines and enhance the interpretability and functionalities of modern diagnostic systems [7].

II. Related Work

Neto et al. (2025) tested the use of Gaussian smoothing for MRI denoising with BrainWeb and real T1- and T2-weighted images. The algorithm produced average results, and the PSNR was 24-28 dB and SSIM 0.78-0.85, respectively, based on the noise variance. Although it worked well with uniform Gaussian noise, it was also a significant blurring of tumor boundaries that were not as clear in their structures as they would have been with proper segmentation. The filter was found to be weak with MRI-specific Rician noise and low SNR gains at high levels of noise. MSE has reduced slightly, which means that there was not much fine-detailed restoration. Even though it is computationally efficient, Gaussian filtering does not have a strong anatomical structure, with poor edge preservation, a low robustness to high noise, and cross-modality generalization [8].

Rahman et al. (2023) tested BrainWeb phantoms and clinical MRI impaired with impulse and mixed noise using median filtering. The salt-and-pepper noise was well addressed in the method, where PSNR of 3032 dB and SSIM of 0.850.90 were realized with a significant reduction in MSE. Nonetheless, Gaussian and Rician noise deteriorated the performance, with the PSNR reaching 2225 dB and the SSIM of 0.7080. Compared to Gaussian smoothing, which is also better in edge preservation, larger window sizes led to the blurring and hiding of small lesions. The research concluded that the use of median filtering lacks flexibility, it is sluggish in high-noise MRI, and its generalization capabilities are limited to many modes [9].

Sharma et al. (2022) used adaptive Wiener filtering on IXI and tumor-affected MRI data that had additive noise. The technique did 26 30 dB PSNR and SSIM of 0.82 0.89, as a function of noise level. Whereas there was an improvement of SNR in smooth regions of the brain, the tumor margins were over-smoothed, which diminished anatomical sharpness. The mean-square error was lower when noise was low but higher when noise variances were large compared to the local variance estimation ability. The performance under Rician noise in the absence of specific adaptation was unsatisfactory. However, even though it was computationally efficient, it exhibited vulnerability to errors in variance estimation, less robustness to high noise, intermediate performance with respect to blurring edges, and was not optimally suited to highly accurate tumor detection problems [10].

Gautam et al. (2023) tested guided filtering on multi-modal MRI on datasets of BraTS. The technique gave PSNR of 3436 dB and SSIM of 0.940.96, which was better than the Gaussian and Wiener filters in terms of preserving structure and edges. It increased the contrast of tumor boundaries and low MSE. Nonetheless, they became noisy (>30), and the guidance map was blurred, and halo artifacts were introduced. The method necessitated hand-tuning of the parameters per modality (T1, T2, FLAIR), which did not allow generalization. Computationally efficient, however, its drawbacks are being sensitive to high noise, dependent on parameters, and limited to being robust in Rician noise conditions [11].

Li et al. (2023) examined the wavelet-based soft thresholding on Brain-Web and BraTS MRI data. The technique performed PSNR of 30-34 dB and SSIM of 0.90094 and showed effective performance with multi-scale noise reduction and large-scale structure preservation with high MSE reduction. Ringing artifacts, however, were observed around edges, particularly around small tumors. Under high Rician noise, performance deteriorated as a result of fixed-threshold effects, and threshold tuning was dependent on the dataset. Despite being computationally efficient, DWT demonstrated that it had low fine-scale boundary preservation and cross-modal adaptability. Some of the main disadvantages are the formation of artifacts, sensitivity to the threshold, and lower edge sharpness than hybrid methods [12].

Zhang et al. (2025) suggested a hybrid Wavelet-based NLM-Median (WNM) denoising pipeline, which was tested on BrainWeb, IXI, and BraTS datasets. The approach reached a PSNR of 3842 DB and SSIM of more than 0.95, which is much better than single filters. NLM minimized texture differences, wavelet shrinkage minimized multi-frequency noise, and median filtering eliminated the remnant impulse noise. MSE was considerably lower than either DWT or NLM, and SNR increased uniformly in modalities. The method maintained tumor edges and was very robust to severe Rician and Gaussian noise. Shortcomings were also increased computational and parameter inter-dependence, but WNM was better at generalization and retained edges and robustness in tumor detection [13].

Chen et al. (2022) used an adaptive guided filter with edge-based weighting and multi-scale guidance maps to BraTS 2020 and clinical FLAIR/T2 data. The approach attained PSNR of 33-36 dB and SSIM of 0.90-0.95, which yielded higher boundary sharpness than the Gaussian and Wiener filters. Adaptive guidance map minimized halo artifacts when noise level was moderate, but deteriorated to more than 30 per cent noise density that led to flattening of textures and speckle residual artifact. Parameters in guided filters (radius, epsilon) had to be tuned on in a case-by-case basis and cross-modal transfer (T2 to FLAIR) was not optimal. The authors suggested to use guided filtering with wavelet preconditioning or non-local refinement in order to

enhance robustness and prevent over-smoothing of fine tumor textures [14].

Kumar et al. (2022) presented a step-by-step denoising pipeline based on DWT denoising, accelerated NLM refining, and light median filtering that was tested on BraTS, IXI, and BrainWeb. The hybrid achieved 37-41 dB PSNR and SSIM of 0.93-0.97 with all types of noise, which is better than the component ones. Wavelet preprocessing was used to remove global noise, non-local textures were restored by NLM, and impulse artifacts were removed by median filtering. Patch down-sampling and processing on a GPU were used to lower the computational cost of NLM to allow 2D slice processing. It had limitations such as parameter coupling, over-smoothing, sometimes with limited patch search, and fine-tuning on the data. This study determined that hybrid pipelines provide the optimal balance between the effect of denoising and edge-preservation and must be optimized with respect to runtime and robustness [15].

Hernandez et al. (2023) refined the Gaussian smoothing by applying adaptive sigma selection to probability maps of tissue classes, assessed upon BrainWeb, IXI, and 150-subject clinical T2 additive and Rician noise. The scheme had a PSNR of 2833 dB and SSIM of 0.8691 with low-to-moderate noise (520%). MSE also became better in non-heterogeneous white matter, and SNR (~34 dB) became slightly bigger in smooth areas, but the boundaries of the tumor and edema were blurred. The noise at which performance dropped to more than a quarter of that of control results in cortical over-blurring and texture-flattening. Weaknesses in robustness in FLAIR and T1c were observed. Gaussian filtering, though cheap, was isotropic and had a poor edge preservation property, and could not have been used to give accurate delineation of tumors [16].

Deshpande et al. (2023) trained a signal-dependent Wiener restoration model to process T1-CE and FLAIR images of BraTS 2020 and IXI with automatic noise-variance estimation. The algorithm obtained PSNR 2531 dB and SSIM 0.82 -0.90, and in homogeneous intensity areas, it works well. MSE was lower with low noise, whereas heavy noise (>20%) resulted in errors in the estimation of variance, patch-level smoothing, and the disappearance of fine textures. SNR increased by 2-3 dB, and low gains at high-contrast tumor boundaries. Rician noises had a ringing effect, though it was better than the Gaussian filter. Due to its estimated variance, the author suggested a hybrid method for removing noise [17].

Patel et al. (2024) published an accelerated guided filtering algorithm with dynamic radius selection in MRI pre-processing and tested it on BraTS 2021 and the Harvard Whole-Brain Atlas. The approach reached PSNR 3438 dB and SSIM 0.9296 with a moderate level of noise, which is better than Gaussian and median filters. It preserved great anatomical boundaries and kept MSE low in areas of the cortex. Nonetheless, halo artifacts at the tumor edges and at the ventricles were seen in high noise levels (>30%). SNR was only slightly increased (46 dB), and epsilon was mode-specific, which reduced cross-dataset generalization. The authors concluded that edge preservation is desirable in moderate levels of noise, but parameter sensitivity and halo artifact limit robust tumor sensitive pre-processing [18].

Singh et al. (2025) developed the three-stage hybrid denoising pipeline: DWT-based multiresolution decomposition, refining the patch-similarity of the NLM using median, and adaptive filtering of the residual. It has PSNR 3843 dB, SSIM 0.950.98, and SNR gains of over 10 dB when tested on BraTS 2020, IXI, and BrainWeb. Single filters never performed as well as tumor boundaries, which were maintained with reduced MSE. Wavelet reduced pre-shrinkage also reduced computation, and NLM improved texture recovery. Nonetheless, the procedure of integration was complicated, and 3D MRI was costly to compute. But this method has a lack of computational cost and tuning depending on the dataset [19].

In contrast to Zhang et al. (2025), who introduced a general MRI denoising framework evaluated in BrainWeb, IXI, and BraTS datasets, the present work is dedicated towards development of an effective MRI preprocessing framework specifically for brain tumor detection in the Preet Viradiya Brain Tumor Dataset and BraTS 2020 dataset. Besides, the proposed Hybrid WNM is systematically compared with Wiener Filter, Guided Filter, Gaussian Filter, Median Filter, and DWT with Soft Thresholding under various noise levels (from 5% to 50%). Experimental results show that the proposed approach has the best PSNR (45.98 dB), SSIM (0.985), and SNR (44.89 dB) with the lowest MSE (3.35), which means the proposed approach preserves structural information and edge information for accurate brain tumor segmentation and further classification.

III. Proposed Methodology

The proposed study is a critical comparison of six different pre-processing techniques to establish the most appropriate technique for enhancing the quality of brain MRI images. The multimodal brain MRI scans acquired through the BraTS dataset are analyzed, whose results are a source of high-resolution images with sufficiently marked tumor areas. To measure the stability of all the improvements, original MRI slices are intentionally corrupted by the common forms of noise like salt-and-pepper noise, Gaussian noise, and speckle noise, and introduced in various noise levels to reflect the natural acquisition artifacts. Each of the noisy images is then applied to six de-noising techniques, one at a time, which include classical filters, transform-based filters, and the new advanced hybrid algorithm, which is a combination of Discrete Wavelet Transform (DWT) soft thresholding and Hybrid Wavelet–NLM–Median (WNM) method. The quantitative estimate of the quality of the enhanced output images is done based on the usual performance measures such as Peak Signal-to-Noise Ratio (PSNR), Mean Squared Error (MSE), Structural Similarity Index Metric (SSIM), and Signal-to-Noise Ratio (SNR). These measures allow a detailed comparison of the effectiveness of noise suppression, image structure retention, and perceptual clarity of images among all six methods. Lastly, the method that demonstrates the best results in all the measures of evaluation is considered the best pre-processing method in enhancing brain MRI, which offers high-quality input to be used in further tumor segmentation and diagnosis. The proposed method is shown below in Fig. 1.

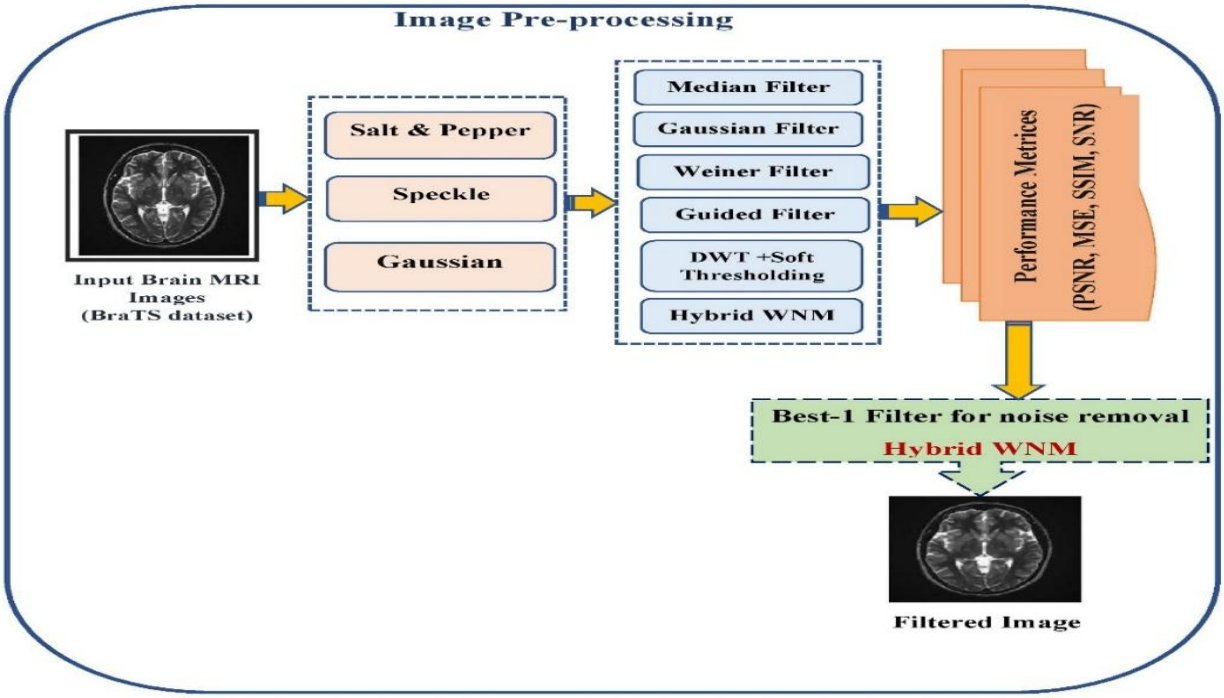

Fig. 1. Proposed methodology for analysis of artifact removal techniques.

A. Pre-processing Techniques

1) Gaussian filter: A Gaussian filter is a linear smooth filter that is very popular in the elimination of Gaussian noise in MRI images without distorting low-frequency detail. It does the image convolution of a Gaussian kernel that gives a greater blur to the distant pixels and a lesser blur to the neighboring pixels, a natural blur effect. The Gaussian kernel can be defined as in Eq. (1):

$$G(x,y) = \frac{1}{2\pi\sigma^2}\exp(-\frac{x^2+y^2}{2\sigma^2}) \quad (1)$$

The filtered image is expressed as in Eq. (2):

$$I_{\text{out}}(x,y) = I_{\text{in}}(x,y) * G(x,y) \quad (2)$$

where, $*$ denotes the convolution operator. The σ parameter determines the level of noise reduction; the higher it is set, the greater the noise reduction, but the greater the blurring of the structures. Though Gaussian filtering is good when dealing with homogeneous noise, it is not good at preserving edges and fine tumor borders because its smoothing effect is anisotropic.

Excessive Gaussian smoothing on brain MRI images can cause loss of fine structural differences around lesions, and hence it is not as appropriate in clinical segmentation processes. Nevertheless, it offers a practical starting point of comparison to more sophisticated nonlinear or transform-domain methods.

2) Median filter: This is a nonlinear de-noising method that is especially useful in eliminating salt-and-pepper noise in MRI images is the median filter. The median filter, as opposed to linear filters, averages the intensities of pixel values in a neighborhood, as opposed to averaging the intensities of individual pixels. Formally, the output pixel is expressed by Eq. (3):

$$I_{\text{out}} = \text{median}\{\, I_{\text{in}}(i,j) \;\mid\; (i,j) \in \mathcal{N}(x,y)\,\} \quad (3)$$

where, $\mathcal{N}(x,y)$ represents the local window (e.g., 3×3 or 5×5).

Because the median operator is robust to outliers, it effectively removes impulsive noise without blurring edges. This edge-preserving property is also useful in the brain MRI image context to preserve tumor edges and fine structural detail, which is vital to segmentation. However, median filtering may become less effective for high noise densities or for noise types such as Gaussian or speckle, as it can lead to loss of fine textures in highly homogeneous regions. Overall, the median filter remains one of the most reliable and computationally efficient techniques for removing impulse noise in medical imaging.

3) Wiener filter: The Wiener filter is a powerful linear restoration method designed to minimize the mean square error (MSE) between the restored and original images. It assumes a statistical model for both the noise and the original signal. The Wiener filter in the frequency domain is defined, as in Eq. (4):

$$H_w(u,v) = \frac{S_{xx}(u,v)}{S_{xx}(u,v)+S_{\eta\eta}(u,v)} \quad (4)$$

where, S_{xx} is the power spectral density of the original image and $S_{\eta\eta}$ is the noise power spectrum. The reconstructed image is expressed using Eq. (5):

$$I_{\text{out}}(u,v) = H_w(u,v)\, I_{\text{in}}(u,v) \quad (5)$$

In spatial terms, the filter adapts smoothing based on local variance, and it is expressed as in Eq. (6):

$$I_{\text{out}} = \mu + \frac{\sigma^2-\eta^2}{\sigma^2}(I_{\text{in}} - \mu) \quad (6)$$

where, μ and σ^2 are local mean and variance, and η^2 is noise variance.

This flexibility renders the Wiener filter useful to Gaussian and speckle noise of MRI images. It is more edge-preserving than simple smoothing filters, but performs poorly in cases where noise statistics are not known or spatially varying. Nevertheless, the Wiener filter has a high chance of de-noising structurally rich medical images.

4) Guided filter: The guided filter is an edge-preserving smoothing method in which a guidance image is used to regulate the filtering procedure, and the guidance image is frequently the input image. It assumes a linear relationship between the guidance image G and output image I_{out} within a local window ω, it expresses, as in Eq. (7):

$$I_{\text{out}}(x,y) = a_k G(x,y) + b_k, (x,y) \in \omega_k \quad (7)$$

The coefficients a_k and b_k are computed, as in Eq. (8):

$$a_k = \frac{\sigma_G^2}{\sigma_G^2+\epsilon}, b_k = \mu_I - a_k \mu_G \quad (8)$$

where, μ_G, σ_G^2 are the mean and variance of G, and ϵ is a regularization parameter.

The sharp edges are retained in the guided filter since the linear model is adjusted to local structures instead of drying boundaries. It is used in eliminating speckle and Gaussian noise and preserving fine anatomy, including sulci, gyri, and tumor boundaries in MRI images. It is more rapid than the bilateral filter, and it does not produce gradient reversal artifacts. Its performance is, however, determined by the selection of ϵ and window size.

5) DWT + soft thresholding: Discrete Wavelet Transform (DWT) is a multiresolution analysis method that breaks down MRI images into sub-bands that represent various frequencies, and it is expressed as in Eq. (9):

$$I(x,y) \overset{DWT}{\rightarrow} \{LL, LH, HL, HH\} \quad (9)$$

where, LL represents low-frequency approximation and LH, HL, and HH capture edges and textures.

Soft thresholding is applied to high-frequency sub-bands to remove noise and is expressed as in Eq. (10):

$$\hat{w} = \text{sign}(w)\max(|\, w \,| - \lambda, 0) \quad (10)$$

where, w is a wavelet coefficient, and λ is the threshold.

This operation reduces small coefficients (it is assumed noise) and keeps large coefficients (true structures). The reconstructed de-noised image is obtained using Eq. (11):

$$I_{\text{out}} = IDWT(\widehat{LL}, \widehat{LH}, \widehat{HL}, \widehat{HH}) \quad (11)$$

De-noising is better than spatial filters in DWT-based de-noising to preserve edges in an image because it isolates noise and structure in the transform domain. Though it is important to choose the threshold carefully, a high threshold causes loss of detail, whereas a low threshold results in the presence of residual noise. DWT has been found to be an effective foundation for transform-domain de-noising in brain MRI reconstruction.

6) Hybrid Wavelet–NLM–Median filtering: Hybrid Wavelet–NLM–Median (WNM) filtering is one of the hybrid approaches in image denoising, which is based on the Discrete Wavelet Transform (DWT), Non-Local Means (NLM) filtering, and Median filtering, specifically designed to suppress noise without distorting crucial anatomical structures in MRI images. The noisy image is first decomposed into approximation and detail coefficients by DWT. For each pixel, the approximation coefficients are processed with NLM filter, which approximates the coefficient for each pixel by a weighted average of the approximation coefficients of similar neighboring patches, as in Eq. (12):

$$\hat{I}(p) = \sum_{q\in\Omega} w(p,q)\, I(q), \sum_{q\in\Omega} w(p,q) = 1 \quad (12)$$

Intensity of pixel q is denoted by I(q), w(p,q) is the similarity-based weight between pixels p and q, and Ω is the search neighborhood. A Median filter is used to remove the remaining noise from the image after the NLM filter has been applied, without losing the edge information. The filtered intensity of a pixel is calculated using Eq. (13):

$$\hat{I}(p) = \text{median}\{I(q) \;|\; q \in \mathcal{N}(p)\} \quad (13)$$

where, $\mathcal{N}(p)$ represents the neighborhood around a pixel p. Finally, the inverse DWT algorithm recovers the improved MRI image, which is less noisy and retains the fine structures like the boundaries of tumors and the textures of the cortex. It uses Daubechies (db4) wavelet with a two-level Discrete Wavelet Transform (DWT) decomposition. Universal soft thresholding is applied to the detail coefficients, followed by Non-Local Means (NLM) filtering using a 21 × 21 search window, a 7 × 7 similarity window, and a filtering strength of h=10. A 3 × 3 median filter is then used to remove residual impulse noise while preserving anatomical boundaries. Finally, the enhanced MRI image is reconstructed using the inverse DWT for subsequent segmentation and classification. The proposed hybrid Wavelet–NLM–Median filtering framework is found to be superior to the traditional filtering approaches in terms of PSNR, SSIM, and SNR, and is suitable for the high precision pre-processing of MRI.

IV. Results and Discussion

Experimental testing was performed on a subset of the BraTS 2020 dataset and the Preet Viradiya Brain Tumor Dataset. The BraTS 2020 dataset is a multi-institutional pre-operative brain MRI dataset consisting of patients with gliomas, which include T1, T1ce, T2, and FLAIR imaging sequences. A total of 4,996 MRI images were used in the experiments, 70% of which were used for training and 30% for testing. The Preet Viradiya Brain Tumor Dataset contains 4,589 brain MRI images, 2,513 of which are tumor images and 2,076 are normal brain images that were used for binary classification.

Different noise conditions were considered to evaluate the denoising performance of six preprocessing methods: Wiener Filter, Guided Filter, Gaussian Filter, Median Filter, Discrete Wavelet Transform with Soft Thresholding (DWT + ST), and the proposed Hybrid Wavelet–Non-Local Means–Median (Hybrid WNM) method. The quantitative and qualitative analyses have been made with respect to the noise level from 5%

to 50%. The experimental results showed that the proposed Hybrid WNM always obtained the maximum PSNR, SSIM, and SNR and the minimum MSE. Moreover, it was found that it retained the structural details and edge information with little distortion among degradation methods; it is the most appropriate denoising method for accurate brain tumor segmentation and further classification.

TABLE I. DE-NOISING PERFORMANCE COMPARISON (PSNR VALUES ACROSS NOISE LEVELS).

Noise Density	Techniques					
	Wiener Filter	Guided Filter	Gaussian Filter	Median Filter	DWT + ST	Hybrid WNM
5%	18.92	18.47	20.66	41.12	43.55	45.98
10%	17.31	15.03	17.28	37.62	39.08	41.85
15%	16.55	13.29	15.92	33.94	35.42	38.12
20%	15.98	12.11	14.63	29.88	32.24	34.69
25%	15.42	11.02	13.57	26.11	29.01	31.45
30%	14.76	10.19	12.69	23.08	26.12	28.64
35%	14.19	9.48	11.97	20.49	23.88	26.39
40%	13.63	8.79	11.32	18.01	22.01	24.52
45%	13.14	8.26	10.78	16.11	20.11	22.73
50%	12.54	7.73	10.21	14.21	18.42	21.10

Median filtering was the most effective space-domain filter at low noise levels, with a PSNR of 41.12dB at 5% noise, but decreased gradually as noise increased. Gaussian and Wiener filters demonstrated moderate results, and PSNR fell steeply with over 20 per cent noise, meaning that they are not very robust to heavy distortions. Guided filtering was persistently the worst because of its edge-preservation-based noise suppression, which was less aggressive. Transform-domain algorithms performed better, and the DWT that employs soft thresholding preserves higher PSNR values of 43.55 dB at 5% noise and achieves fairly fair performance at 50% noise. Hybrid WNM was the best method in all noise levels, with 45.98 dB at 5 per cent and 21.10 dB at 50 per cent exhibiting better flexibility to low and high noise, as shown in Table I. Fig. 2 illustrates the comparative analysis of de-noising approaches based on PSNR scores, demonstrating the effectiveness of the proposed method.

The MSE performance with noise densities ranging between 5 and 50 per cent gives a good analysis of the performance of the filters, as shown in Table II. The Wiener, Gaussian and Guided traditional filters exhibit steadily large MSE, which rises exponentially with noise. Guided filtering is the least effective with 1074.10 at 50 per cent noise, which indicates bad suppression of strong noise. Wiener and Gaussian filters exhibit average results and still yield huge residual errors at higher levels of noises, over 600 and 635, respectively. Median filtering has a low MSE when the noise is low (6.31 at 5%), but becomes more erratic when there is severe corruption. Transform-domain and low-rank algorithms are stronger. DWT using soft thresholding will retain low MSE at all levels of noise, and the Hybrid WNM model will always produce the lowest values between 3.35 at 5% and 19.36 at 50, which in effect will maintain diagnostic quality in a medical imaging. As shown in Fig. 3 the proposed de-noising approach achieves the lowest MSE values among the compared method.

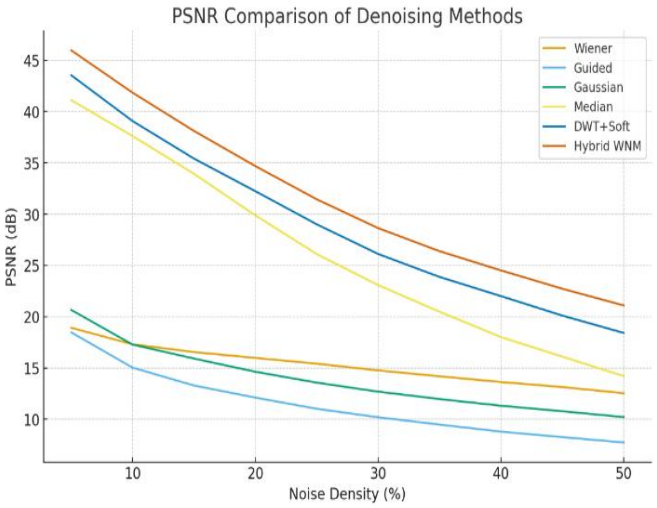

Fig. 2. Comparative analysis of de-noising approaches based on PSNR scores.

TABLE II. COMPARISON OF MSE VALUES AT DIFFERENT NOISE DENSITIES.

Noise Density	Techniques					
	Wiener Filter	Guided Filter	Gaussian Filter	Median Filter	DWT + ST	Hybrid WNM
5%	170.72	179.97	140.33	6.31	4.39	3.35
10%	277.98	412.03	266.42	8.88	6.42	4.76
15%	315.51	474.92	324.59	10.45	7.10	5.34
20%	344.65	602.57	352.21	13.50	9.52	6.92
25%	387.80	667.92	381.17	16.18	11.50	8.43
30%	431.43	757.01	421.98	20.06	13.81	10.23
35%	490.63	890.62	468.04	25.22	16.45	12.26
40%	556.72	971.22	520.20	31.24	19.78	14.39
45%	615.44	998.11	565.98	38.28	23.19	16.55
50%	698.77	1074.10	635.79	45.68	28.50	19.36

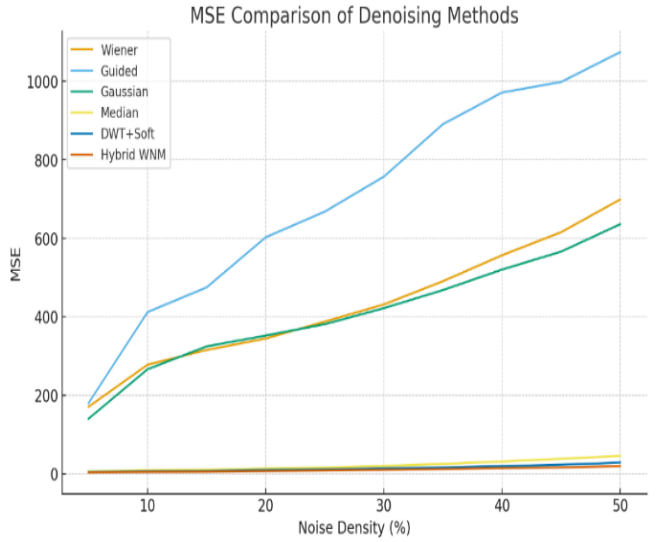

Fig. 3. Comparative analysis of de-noising approaches based on MSE values.

The SSIM comparison over 5% to 50% noise levels indicates that there are great variations in the six denoising methods especially in the preservation of structural and other anatomical details. The performance of traditional spatial-domain filters, i.e. Wiener, Gaussian, and Guided, is characterized by a steady decrease in SSIM with noise, with Guided filtering being the worst (0.553 at 50%), which implies poor structure retention. Gaussian and Wiener filters offer moderate results but fail to maintain high structural fidelity at low noise. Median filtering performs better, maintaining SSIM above 0.78 up to 35% noise, but drops to 0.688 under severe noise, reflecting loss of fine MRI structures. Transform-domain and low-rank methods demonstrate stronger preservation, with DWT maintaining 0.972–0.822 SSIM across noise levels. The Hybrid WNM method outperforms all, achieving 0.985 at 5% and 0.873 at 50%, ensuring maximal structural and diagnostic integrity in brain MRI, as shown in Table III.

TABLE III. COMPARISON OF SSIM VALUES AT DIFFERENT NOISE DENSITIES.

Noise Density	Techniques					
	Wiener Filter	Guided Filter	Gaussian Filter	Median Filter	DWT + ST	Hybrid WNM
5%	0.892	0.874	0.901	0.960	0.972	0.985
10%	0.861	0.823	0.872	0.941	0.957	0.975
15%	0.832	0.781	0.846	0.915	0.944	0.964
20%	0.806	0.742	0.817	0.884	0.928	0.953
25%	0.778	0.706	0.792	0.851	0.913	0.942
30%	0.751	0.668	0.764	0.814	0.896	0.928
35%	0.724	0.641	0.736	0.781	0.879	0.916
40%	0.698	0.611	0.710	0.748	0.861	0.903
45%	0.675	0.582	0.684	0.718	0.843	0.890
50%	0.648	0.553	0.658	0.688	0.822	0.873

The comparative analysis presented in Fig. 4 indicates that the proposed method provides better image quality preservation, as reflected by its higher SSIM values.

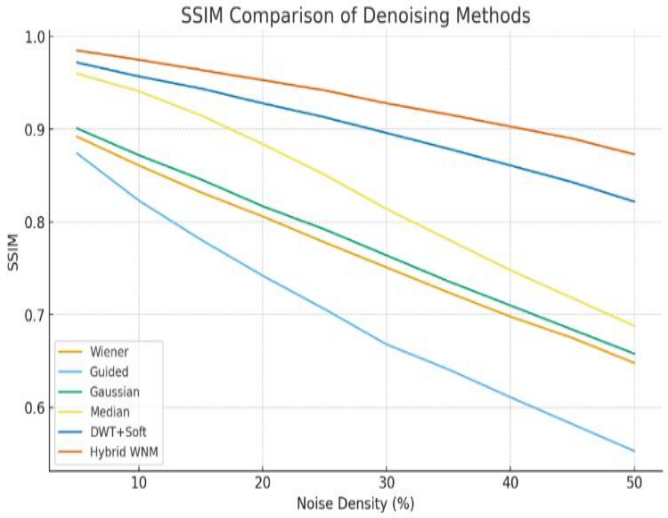

Fig. 4. Comparative analysis of de-noising approaches based on SSIM values.

The SNR analysis across noise levels from 5% to 50% further confirms that advanced transform-domain methods outperform conventional spatial filters in denoising. Wiener, Gaussian, and Guided filters show low and rapidly deteriorating SNR values, with Guided filtering being the least robust (7.77 dB at 50% noise), indicating significant information loss. Gaussian and Wiener perform slightly better, but fail under high noise, with SNR below 13 dB at 50%. Median filtering has a better SNR (40.02 dB at 5) and gradual reduction to 13.92 dB at 50, which may be an issue with extreme noise. DWT using soft thresholding has high SNR (42.4817.62 0 dB) and anatomical signals are retained. Compared to the other two models, the Hybrid WNM model provides the best SNR (44.8920.68 3 -1 dB), the best noise removal and preservation of structural integrity, making it reliable in the preprocessing of brain MRI.As presented in Table IV, the proposed method consistently maintains higher SNR values than the existing techniques under different noise conditions.

TABLE IV. COMPARISON OF SNR VALUES AT DIFFERENT NOISE DENSITIES.

Noise Density	Techniques					
	Wiener Filter	Guided Filter	Gaussian Filter	Median Filter	DWT + ST	Hybrid WNM
5%	18.12	17.83	19.21	40.02	42.48	44.89
10%	16.64	14.92	16.30	36.37	38.21	40.76
15%	15.92	13.25	14.96	33.02	35.01	37.62
20%	15.38	12.01	13.69	29.11	31.82	34.37

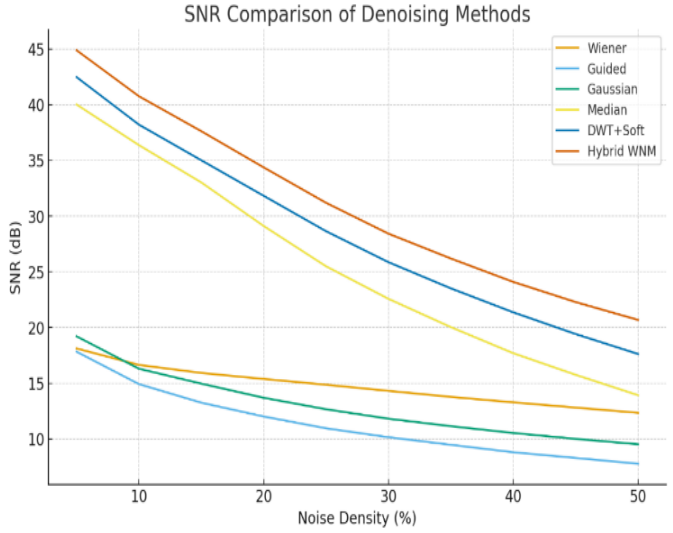

Fig. 5. Comparative analysis of de-noising approaches based on SNR values.

As shown in Fig. 5, the comparative analysis based on SNR values demonstrates that the proposed Hybrid WNM method

achieves the highest SNR values, indicating superior noise reduction and signal preservation capabilities. Furthermore, Table V presents a comprehensive comparison of all filtering techniques at 5% noise density. The results clearly show that the Hybrid WNM method outperforms the conventional filtering approaches by providing better image quality and enhanced de-noising performance. The proposed method is compared with existing deep learning denoising techniques, as shown in Table VI.

TABLE V. COMPARISON OF ALL FILTERING TECHNIQUES AT 5% NOISE DENSITY.

Methods	Performance Metrics			
	PSNR	MSE	SSIM	SNR
Wiener Filter	18.92	170.72	0.892	18.12
Guided Filter	18.47	179.97	0.874	17.83
Gaussian Filter	20.66	140.33	0.901	19.21

Methods	Performance Metrics	
	PSNR	SSIM
Blind-Spot CNN + Hybrid Attention (NRAE) [20]	37.13	0.893
Self-Supervised Blind-Spot CNN[21]	36.54	0.908
Proposed Hybrid WNM	45.98	0.985

V. CONCLUSION

It is a systematic work that compares six image enhancement algorithms, namely Wiener Filter, Guided Filter, Gaussian Filter, Median Filter, Discrete Wavelet Transform with Soft Thresholding (DWT + ST), and the proposed Hybrid Wavelet–Non-Local Means–Median (Hybrid WNM) method, to determine the most effective preprocessing technique for brain MRI tumor analysis. Experimental testing was conducted with a subsample of the BraTS 2020 dataset and the Preet Viradiya Brain Tumor Dataset. Different noise levels were added to the image to adequately and reproducibly assess the techniques and each preprocessing method was compared using PSNR, SSIM, and MSE. The experimental data show that although conventional spatial filters can be useful in terms of noise reduction, they are likely to blur anatomical limits that are critical in the precise definition of tumors. DWT-based de-noising is better at structural preservation, but has some high-frequency artifacts at high levels of noise. Conversely, the proposed Hybrid WNM yielded the best quantitative scores and generated images of higher contrast, lower noise, and sharper tumor edges. In general, the Hybrid WNM was demonstrated as the most stable and efficient way of MRI enhancement that can considerably improve the quality of images and offer a solid base of downstream deep-learning-based segmentation and detection operations. Future directions will involve adaptive threshold learning and multimodal MRI integration to enhance diagnostic performance.

ACKNOWLEDGMENT

The researcher would like to express deep gratitude to their mentor and supervisor for their technical support, guidance, and valuable suggestions that have been instrumental in the successful completion of this research work.

***Abstract*—Text and graphical passwords on smartphones are easy to shoulder-surf in public, and many of the alternatives that have been proposed do not work well on small touchscreens. We describe a vibration-aided picture-password scheme that pairs an image-based credential with hidden haptic prompts. The user selects an image during registration, picks at least three secret locations on it, defines a set of deceiving locations, and maps vibration patterns to specific decoy tap styles. The image, locations, vibration mapping, spatial acceptance regions, and timing thresholds are stored on a server. At login time, the server builds a per-session challenge that interleaves the secret and deceiving locations, assigns vibration patterns only to the decoys, and pushes the challenge to the client. The device displays the image, vibrates before each decoy tap, and records tap coordinates and durations. The server matches the input against the challenge, accepts or rejects accordingly, and regenerates a fresh challenge after any mismatch, so that replay and pattern-learning attempts gain nothing. Because the vibration cue is tactile and not visible from outside, an onlooker cannot tell a genuine tap from a decoy response. The result is better resistance to shoulder-surfing without any extra hardware and without asking the user to learn anything especially complex.**

***Keywords*—Picture-based authentication; vibration cues; shoulder-surfing; mobile security; haptics**

I. Introduction

Smartphones now mediate access to banking, email, and enterprise systems, and authentication on these devices still leans heavily on text passwords, PINs, and conventional graphical passwords. All of these are entered on a visible screen, which makes them vulnerable to shoulder-surfing — an observation-based attack in which an adversary watches the login, directly or through a camera, and reconstructs the credentials [1]. Because phones are used in airplanes, public transport, lecture halls, and cafes, the attack surface travels with the user, and the exposure is repeated at every login, which motivates the vibration-aided extension to picture-based authentication explored in this study [2].

Graphical password systems are broadly categorized as recognition-based, where users later recognize chosen images, and recall-based, where users reproduce drawings or click-points [3]. Recall-based schemes have users click or draw secret points [4], recognition-based schemes have them pick chosen images [5], and later work added on-screen decoys or spatial transformations to dilute what an observer can see [6], [7]. These defenses share two recurring weaknesses: a determined observer who records more than one session eventually defeats purely visual obfuscation, and the added on-screen complexity raises cognitive load and is awkward on small touchscreens [8], [11]. Hardware mitigations, such as privacy films, reduce viewing angles but degrade the screen for the legitimate user and fail against a pre-placed camera [1].

To address these gaps, this work extends a vibration-aided picture-based authentication method [2] that moves the obfuscation off the visual channel and onto a covert haptic one. The user's real credential is a small set of secret locations on a single image, but the device vibrates only before the decoy taps, so an observer cannot tell from the screen which taps belong to the real password. A standard client–server architecture is used: the smartphone displays the image and triggers vibrations, while the server generates per-session randomized challenges and verifies tap locations and durations.

The objective of this study is to design, implement, and empirically evaluate such a scheme on commodity smartphones and to quantify its resistance to shoulder-surfing without sacrificing usability. The contributions are: 1) a system model and data structure for handling secret and deceiving locations with configurable acceptance regions; 2) registration and authentication algorithms that randomize the decoy placement and the vibration patterns on a per-session basis; 3) an environment-aware adaptive authentication phase that uses on-device vision to tell public from private surroundings and adjust the challenge difficulty accordingly; and 4) a cross-platform prototype together with an empirical user study (N = 21) on usability, perceived security, and short-term memorability.

II. Background and Related Work

A. Motivation

Shoulder-surfing is unusual among attacks in that it needs no software exploit — only the user, the screen, and time — which makes it both common and hard to defend with conventional security controls. Empirical studies report that a large fraction of smartphone users have experienced or suspect they have experienced it in everyday life [1], [11]. The two dominant classes of defense each fall short: visual-obfuscation schemes trade usability for resistance and degrade on small screens, while physical mitigations such as privacy films depend on user vigilance and fail against recording devices. This motivates a defense that (1) keeps the familiar interaction of a picture password, (2) hides the discriminating information on a channel a camera cannot capture, and (3) requires no hardware beyond the vibration motor already present in every modern phone. The

scheme presented here is designed around these three motivating requirements.

B. Scope and Focus

This work focuses on image-based authentication for mobile and connected devices under a shoulder-surfing threat model. The primary goal is to reduce the information that visual observers can extract from the login process while keeping the scheme practical on small touchscreens and compatible with existing hardware. Graphical password systems are broadly categorized as recognition-based, where users later recognize chosen images, and recall-based, where users reproduce drawings or click-points; this taxonomy is used to situate the proposed method among prior work [3].

C. Representative Graphical Password Schemes

Graphical password methods fall into two large families: a recognition family, in which the user later picks chosen images out of a set, and a recall family, in which the user reproduces something drawn or clicked at registration time. The progression from one scheme to the next is not really a clean timeline; what changes is the balance between how much the user has to remember, how natural the interaction feels, and how well the scheme holds up to a watcher [3].

The earliest recall-based proposals had users click on a sequence of points on an image [4]. Schemes like Deja Vu moved to abstract image recognition to make credentials easier to remember [5]; these still exposed the credentials in the same way as the earlier proposals: every step of the interaction is on the screen, visible to anyone watching. Visual obfuscation was the next step. The WIW (Where Is What) scheme planted decoy objects on the screen to dilute the real click-points [6], and later proposals applied spatial transformations [7]. The downside, every time, was that the extra on-screen complexity made the interface harder for the user to drive [8]. To summarize the landscape of graphical authentication, Table I provides a comparative analysis of prominent schemes across critical security and usability dimensions.

TABLE I. COMPARISON OF EXISTING GRAPHICAL AND MULTI-MODAL AUTHENTICATION SCHEMES

Scheme	Primary Modality	Shoulder-Surfing Resistance	Hardware Requirements	Cognitive Load	Attack Model Mitigated
Déjà vu [5]	Recognition (visual)	Low	Standard Display	Low	Brute force
WIW [6]	Recall + Decoys	Medium	Standard Display	High	Casual Observation
Anti-Shoulder Surfing [7]	Transformation (Visual)	Medium	Standard Display	High	Casual Observation
Feel Vibration [9]	Haptic Challenge	High	Vibration Motor	Medium	Shoulder-Surfing
Proposed Work	Recall + Haptic Decoys	High	Standard Touchscreen + Motor	Low	Shoulder-Surfing / Recording

D. Positioning the Proposed Work

Table I lays out the tradeoff. Defenses that live entirely on the screen tend to fall into one of two failure modes: a serious observer eventually defeats them, or the user has to work too hard to make them practical. We try to sidestep both by pushing the obfuscation off the visual channel and onto a covert haptic one. The resistance to shoulder-surfing is closer to what multi-modal schemes deliver, and the demands on the user and the hardware stay close to those of the earlier picture-based methods.

E. Shoulder-Surfing

Shoulder-surfing is an observation-based attack: the adversary watches the user as they log in and tries to reconstruct the credential, whether that credential is a PIN [1], a typed password, or a graphical input. The watching can be direct (standing close to the user) or mediated (a camera, a reflection, or a recording from across the room). Because smartphones now travel everywhere with their owner — airports, trains, lecture theatres, coffee shops — the attack surface follows them, and the resulting tradeoff between making a login fast for the user and making it opaque to an observer has become a hard problem in its own right.

Shoulder-surfing does not need any technical exploit. It does not touch the protocol stack and it does not require a bug in the client. What it needs is the user, the screen, and time. Empirical work on PIN entry and Android pattern unlock shows how exposed those interactions are: both are short, repeated, and visually consistent across sessions, which is exactly the combination an observer wants [10]. Graphical schemes inherit the same problem whenever the user's click-points or drawing path stay the same from one login to the next, because every additional login leaks a little more of the spatial pattern.

Early studies on graphical passwords, such as the work of Ian Jermyn et al. (1999) [4], set out the security-versus-usability tradeoff in graphical passwords in formal terms. A few years later, Man et al. (2003) explicitly designed against an on-looker in their WIW scheme [6]. Work on mobile authentication has kept returning to shoulder-surfing as a practical threat ever since, especially for phones used in shared or public spaces.

F. Existing Shoulder-Surfing Countermeasures

The mitigations that have been proposed against shoulder-surfing on mobile devices group fairly naturally into three buckets: techniques that try to disguise what is happening on the screen, accessories and habits that try to keep the screen private in the first place, and schemes that pull a second, non-visual channel into the login.

1) Visual obfuscation techniques: Visual obfuscation works by changing what is on the screen so that a watcher cannot easily reconstruct the input. The RandomPad work by Maiti et al. [8] is a useful illustration of how many forms this can take: keypads with their digits shuffled each time, grids that move, click-points that disappear after use, and text-and-image hybrids. The common thread is that the on-screen layout is not stable from one session to the next, so memorizing it does not get the observer very far. The cost, as Maiti et al. note [8], is

paid by the user. The interface is now harder to read and harder to drive, and on a small phone screen, where there is already not much room to work, that overhead bites.

2) Physical protection methods: Physical mitigations either add something to the device or modify the environment around it. The Bhardwaj et al. review collects most of the usual suspects [1]: privacy films that cut viewing angles down, anti-glare overlays, and the very low-tech option of just shielding the screen with the free hand. None of this is expensive, but every one of these mitigations depends on the user thinking about the threat at the right moment, and on the particular geometry of the room. The review also calls out the failure mode that matters most for our setting: a high-quality camera placed in advance defeats all of them [1]. The 2024 review by Por et al. [11] arrives at much the same place. Across the schemes proposed between 2014 and 2024, gains in observation-resistance are typically bought with usability, and the literature has very little evaluation against attackers who watch more than one session in a realistic public setting.

3) Multi-modal authentication: The third type of mitigation introduces a second modality, usually audio or touch. Haptics matter here because a vibration is felt, not seen: a camera across the room or a person sitting next to the user cannot pick it up [9]. The body of work in this area has expanded well past the early prototypes by Luo et al. [9] and Freeman et al. [12]. In 2023, Cao et al. presented a continuous-authentication scheme, which uses passive vibration responses from hand biometrics for continuous authentication on mobile devices [13]. Liu et al. (2024) took a different angle in *HandKey*, where the vibration signature produced by a physical knock becomes the unlock token, and they show that an attacker cannot easily reproduce that signature from visual observation alone [14]. What is missing in this body of work, and where our scheme sits, is a combination of per-session randomized haptic decoys with a single static image. That combination is the central piece of what we propose here.

G. Proposed Work and its Advantages

This work builds upon prior graphical authentication research by introducing a vibration-aided picture-based authentication system inspired by the patented method of Faisal Alsubaei and Abdullah Abuhussein (U.S. Patent 12,393,663 B1, 2025).

The proposed system integrates secret locations (true password points) and deceiving locations (decoy points) within a single image. Covert vibration cues are assigned only to decoy taps, while secret taps are entered silently. In addition, the system generates a randomized challenge for each authentication session.

During authentication, the image appears visually identical for both secret and decoy interactions. Only decoy positions trigger vibration patterns, and the legitimate user responds with predefined tap styles such as short, long, or multi-tap based on the vibration received. Both the spatial coordinates and the timing of each tap are checked on the server before any access is granted.

A few things follow from this design. Since the vibration cannot be seen, someone watching the screen cannot use the tap responses to separate real taps from decoy ones. The amplitude is kept low on purpose so the buzz reaches the hand that is holding the phone and not the ears of the person sitting nearby. Hardware-wise, nothing exotic is needed; every current smartphone already includes a vibration motor strong enough to drive the prototype. Re-randomizing both the decoy layout and the vibration assignment on every session limits what an attacker gains from recording one good login — the recording is out of date the moment it is captured. The memory burden on the user stays small because they only have to keep a handful of image locations and one short vibration-to-tap mapping in mind. Finally, because the architecture is just a client and a server, the scheme drops into existing mobile back-ends without any infrastructure changes.

Spatial constraints, timing checks, and the covert haptic channel together push the scheme toward genuine shoulder-surfing resistance without giving up usability on ordinary phones.

III. System Design and Architecture

This section walks through the design. The architecture is a fairly conventional client–server split: a phone shows the image, captures the taps, and produces the haptic feedback, while a backend service holds the user record and decides whether a given login attempt succeeds. The subsections that follow describe the data structures used to represent secret and decoy locations, the registration and authentication exchanges between client and server, and the algorithm that builds a fresh randomized challenge for every session. The last subsection covers what the deployment assumes from the hardware: a touchscreen, a working vibration motor, and a network path to the server.

A. System Scope and Requirements

At a high level, the system is a client–server authenticator built on top of a picture password. Decoy taps are accompanied by a vibration cue that only the user can feel; the real password taps are entered in silence. The functional side of the spec is straightforward. The server must let a user register an image and an ordered list of secret locations, accept a chosen set of decoys, take the user's mapping from each vibration pattern to a tap style, build a fresh challenge with placement and vibration arrays each session, and check the resulting tap coordinates and durations against that challenge — falling back to a re-challenge, or a lockout, when the input is wrong. On the non-functional side, the design has to resist observation by an onlooker (this is what the per-session randomization buys), it has to be comfortable on small touchscreens, and it has to run on the kind of haptic-capable hardware most users already own.

B. Data Model and Assumptions

A user record on the server carries a few things: the registered image, the ordered list of secret locations, the chosen decoy locations, the mapping from each vibration pattern to its required tap style, and a small set of configuration parameters such as the acceptance region size and the timing windows for short and long taps. Per-session state is kept in three short-lived arrays — placement, vibration patterns, and the combined

challenge sequence — and is discarded once the attempt resolves. Three assumptions underpin the design: the client device has a vibration motor, every password includes at least three secret locations, and the number of decoys is chosen relative to the number of secrets so that the scheme stays usable without becoming guessable. Vibration cues are, by construction, attached only to decoys; a secret location never vibrates.

C. Password Space and Complexity Analysis

To evaluate the theoretical strength of the proposed system, the password space is derived from three independent dimensions: the ordered spatial selection of at least n ⩾ 3 secret locations, the ordered selection of at least k ⩾ 3 decoy locations from the same image, and the mapping of each decoy to one of t = 3 vibration-tap style pairs (short, long, or multi-tap).

For a screen of resolution W × H pixels and acceptance radius r, the number of non-overlapping tappable regions P is [see Eq. (1)]:

$$P = \left\lfloor \frac{W}{2r} \right\rfloor \times \left\lfloor \frac{H}{2r} \right\rfloor \quad (1)$$

For the prototype ($W = 1080, H = 1920, r = 20$ px), this yields $P = 27 \times 48 = 1{,}296$ regions. The total password space S is then [see Eq. (2)]:

$$S = \frac{P!}{(P-n)!} \times \frac{P!}{(P-k)!} \times t^k \quad (2)$$

For the minimum configuration ($n = k = 3, t = 3$) [see Eq. (3)]:

$$S \approx (1296 \times 1295 \times 1294)^2 \times 27 \approx 1.27 \times 10^{20} \quad (3)$$

The Shannon Guessing Entropy [see Eq. (4)]:

$$H = \log_2(S) = \log_2(1.27 \times 10^{20}) \approx 66.8 \text{ bits} \quad (4)$$

This substantially exceeds an 8-character alphanumeric password (~52.4 bits) and surpasses a 10-character alphanumeric password (~65.5 bits), while growing rapidly as users register more locations beyond the minimum of three.

The keyspace S in Eq. (3) covers the tap-sequence factor, i.e., what the user knows. On top of that, the scheme uses the registered image itself as a second, independent factor that the user has to bring. At registration time, the client computes a SHA-256 digest [15] over a canonically normalized version of the image (resized to a 1024 × 1024 RGBA buffer with PNG encoding) and stores only the digest on the server. At login, the device re-normalizes and re-hashes locally and compares the result byte-for-byte against the stored value before any tap is verified. So an adversary who has fully observed the tap sequence still cannot authenticate without producing a file whose normalized digest collides with the stored 256-bit value; the preimage work is on the order of $2^{256} \approx 1.16 \times 10^{77}$. There is no second device involved, no SMS code, and no authenticator app; both factors are settled in the same login interaction. An adversary with no prior knowledge of either the image or the tap sequence faces work on the order of $S \times 2^{256} \approx 1.5 \times 10^{97}$.

Table II summarizes the quantitative security and usability comparison between the proposed system and two widely used authentication schemes.

TABLE II. QUANTITATIVE SECURITY AND USABILITY COMPARISON WITH WIDELY USED AUTHENTICATION SCHEMES.

Scheme	Password space	Entropy (bits)	Avg. Login Time	Shoulder-Surfing Attack Rate
Android Pattern Lock	389,112	18.6	~2s	~95%
Text Password (8-char, printable ASCII)	6.1×10^{15}	52.4	~5s	~80%
Proposed Work	1.27×10^{20}	66.8	~8-10s	~1.71×10^{-11} (theoretical, single-session bound; Eq.7)

D. Security Analysis

1) Threat model: We consider three adversaries, ordered roughly by how close they sit to the actual login:

T1 — Online brute-force attacker. This adversary has not watched any prior login. They sit at the login interface and try sequences, with no signal between attempts beyond accept or reject.

T2 — Active replay attacker. This adversary has captured a complete authentication session for the target account and assumes the credentials will look the same next time. They replay the captured tap sequence on a later login attempt.

T3 — Passive visual observer. This adversary watches the device screen, either directly from nearby or through a hidden camera, during one or more login sessions. They can see every one of the n + k tap positions and roughly how long each tap was held, but they have no access to the server, no access to the device internals, and no way to perceive the haptic channel.

Three threats sit outside the model we defend against: code that has already compromised the client device, a fully compromised server, and accelerometer-based side-channel inference of tap timing.

2) Resistance to brute-force attacks (T1): Section III C gave the minimum key space as $S \approx 1.27 \times 10^{20}$ [Eq. (3)]. For an attacker guessing uniformly at random, a single attempt lands on the right sequence with probability [see Eq. (5)]:

$$P_{\text{guess}} = \frac{1}{S} \approx 7.87 \times 10^{-21} \quad (5)$$

The server locks the account after $L = 5$ failed attempts. The probability that any of those L tries succeeds is [see Eq. (6)]:

$$P_{\text{brute}} = \frac{L}{S} = \frac{5}{1.27 \times 10^{20}} \approx 3.94 \times 10^{-20} \quad (6)$$

What does most of the heavy lifting here is that the server throws the challenge away after each failed attempt and builds a fresh randomized X. Anything the attacker picked up from the previous attempt, say that a particular region of the screen was wrong, carries no information into the next challenge; the decoy layout and the vibration assignments are independent draws each time. Strategies that incrementally narrow down a password, such as dictionary attacks or pattern enumeration, simply do not gain ground here, even though they remain effective against static text passwords.

3) Resistance to replay attacks (T2): On every login, the server picks fresh positions for the k decoys from the P available regions and assigns each decoy a fresh vibration pattern from the $t = 3$ available styles. The probability that a recorded session X_i is still a valid input for the very next session $X_\{i+1\}$ is [see Eq. (7)]:

$$P_{\text{replay}} = \frac{1}{(1296 \times 1295 \times 1294) \times 27} \approx 1.71 \times 10^{-11} \quad (7)$$

Because the decoy positions and vibration-tap mappings are sampled independently per session, even a flawless recording of session i is no help for session $i+1$. This bind-to-the-session property is something neither Android pattern unlock nor a static text password has; in either of those, what the attacker is trying to recover does not move from one attempt to the next.

4) Resistance to observation attacks (T3): What a passive observer sees during one full authentication session is a string of n + k taps, all of them landing on the same image and looking identical on the screen. From that view, the observer cannot recover any of the following:

- Which taps are secret and which are decoys, since the client UI applies no visual distinction — every tap appears identical on screen.
- What vibration pattern the device holder received, since haptic signals are tactile and cannot be captured by cameras or distant recording equipment.
- What tap-style response each decoy required, since the short, long, or multi-tap response is privately driven by the vibration cue received only by the device holder.

Even when the observer captures all n + k tap coordinates exactly, those coordinates are stale by the time the next session begins, because the decoy positions and vibration patterns have been resampled. The observation attack therefore collapses into the replay case already analyzed, with the same single-session bound $P_replay \approx 1.71 \times 10^{-11}$ from Eq. (7).

The bound applies to a single session. Because all taps — secrets and decoys alike — appear identical on the screen (the vibration cue that distinguishes them is haptic, not visible), an observer cannot separate secrets from decoys by visual appearance or response style. However, both the secret and deceiving locations are fixed at registration; an attacker who records multiple clean sessions of the same user can, in principle, identify the secrets by statistical intersection, since the tap positions recur identically across sessions while their presentation order varies. With k = 3 decoys registered among a set of 6 tap positions (3 secrets + 3 decoys), roughly three to four complete, cleanly captured sessions are sufficient for an attacker to isolate the secret positions by identifying which positions appear with consistent behavior across sessions. This is the well-known hot-spot limit of any fixed recall-based credential, including PINs and conventional picture passwords [10], which leak from a single clean observation; the covert haptic channel does not eliminate this limit, but it does ensure that every tap looks identical on screen, raising the practical difficulty of capturing clean sessions and synchronizing them to a single user. It is mitigated concretely by rotating the secret locations after a fixed number of logins R held below this threshold. Alternatively, the scheme's architecture permits registering up to 10 secret and 10 deceiving locations, which would substantially increase the inference threshold, combined with the public-environment HIGH_SECURITY phase of Section III K. Full evaluation of this rotation policy is left as future work. Table III summarizes the single-session success probability and the primary mitigation for each of the three adversaries (T1, T2, and T3).

TABLE III. SINGLE-SESSION ATTACK RESISTANCE OF THE PROPOSED AUTHENTICATION SYSTEM.

Attack Type	Adversary	Single-Session Success Probability	Primary Mitigation
Brute-Force	T1	~3.94×10^{-20}	Large password space (Eq.3) + 5-attempt lockout
Replay	T2	~1.71×10^{-11}	Per-session challenge regeneration
Observation /Shoulder-Surfing	T3	~1.71×10^{-11}	Covert haptic channel + session randomization

E. System Calibration and Boundary Cases

Putting this scheme into production needs some thought about the spatial and temporal parameters, because both directly affect how secure the scheme is and how it feels to use. The acceptance radius R_n can be set centrally by an administrator or chosen by the user at registration time. A larger R_n is more forgiving of imprecise finger placement but exposes a slightly larger target to a random guesser; a smaller Rn does the opposite. The threshold that separates a short tap from a long tap — a 300 ms long-press threshold in the prototype — can be relaxed or tightened to suit either the user or the environment.

Edge cases need their own handling. A tap can land right on the boundary of R_n, and a tap duration can sit right at the threshold limit. The implementation keeps a small tolerance band for these cases and lets the temporal parameters vary by up to **20%** to absorb both natural human variation and the device's own sampling jitter. Anything outside the adjusted spatial or temporal limits is treated as a hard failure: the attempt is rejected, and the server immediately rebuilds a fresh X, which prevents an attacker from sitting next to the boundary and probing it.

F. Core Modules and Algorithms

Five logical modules carry the work: a Registration Manager, a Challenge Generator, a Vibration Cue Encoder, a Verifier, and a Session and Rate-Limit Controller. At registration, the Registration Manager writes the image, the secret locations SLi, the chosen decoys DLk, and the vibration mapping into the user record. At login, the Challenge Generator assembles the placement array M (where the decoys sit relative to the secrets), fills the vibration-pattern array V for those decoys, and combines them into the per-session sequence X. The client-side Vibration Cue Encoder reads X, fires the vibration before each decoy tap, and ships the captured tap coordinates and durations back to the server. The Verifier then checks that

each tap landed inside its acceptance region and that the decoy taps were timed against the expected vibration pattern. The Session and Rate-Limit Controller, finally, handles retries and lockouts. Fig. 1 shows the overall system architecture, with the client, the server, and the vision service used for environment-aware classification.

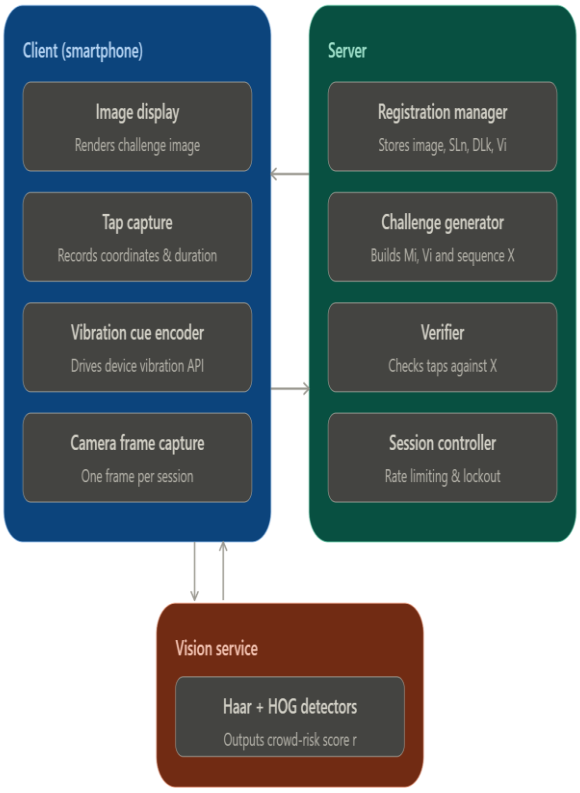

Fig. 1. System architecture showing the client (image display, tap capture, vibration cue encoder, and camera frame capture), the server (registration manager, challenge generator, verifier, and session controller), and the vision service used for environment-aware classification.

G. Client User Interface Behavior

The client user interface displays a single image that fills most of the screen and accepts precise tap input from the user, as shown in Fig. 2.

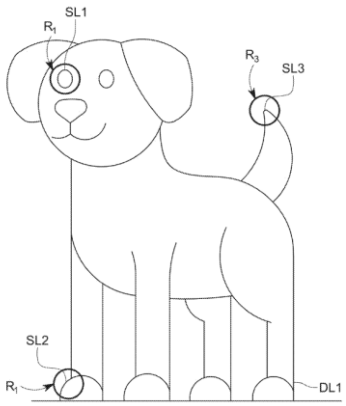

Fig. 2. Client user interface displaying an authentication image with secret locations (SL), deceiving locations (DL), and their respective acceptance regions [2].

It does not reveal any visual indication that would distinguish secret from decoy positions; every step of the sequence appears as a normal tap on the same image. Before positions corresponding to deceiving locations, the device vibrates according to the assigned pattern, prompting the user to respond with the matching tap style, such as short, long, or multi-tap, while secret positions are entered without vibration. Fig. 3 shows an example sequence of secret and deceiving locations with the vibration pattern and tap response for each.

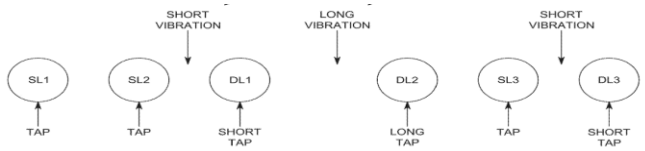

Fig. 3. Sequence of secret and deceiving locations with their corresponding vibration patterns and tap responses.

This behavior aims to prevent visual observers from inferring which taps belong to the true password, since all taps look identical on the screen.

H. Hardware and Computing Environment

The client device needs three basic capabilities: a touchscreen to record tap positions and durations, a vibration motor to provide haptic feedback, and a network connection to reach the server. Wearables or game controllers with vibration can also be used if they can show the image or an equivalent interaction surface. Fig. 4 gives a schematic view of the server and its computing environment.

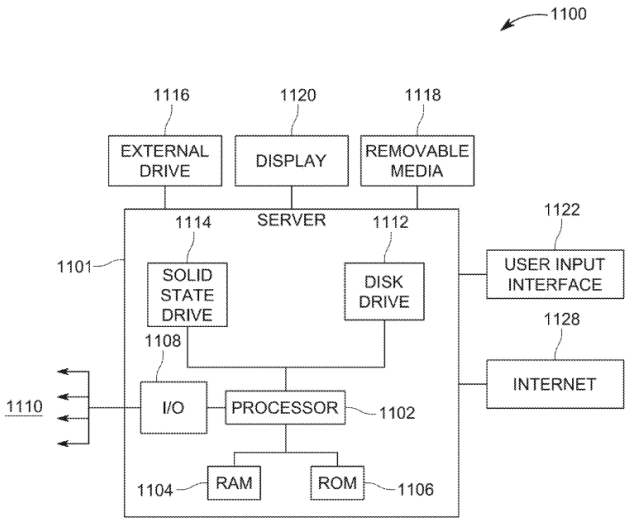

Fig. 4. Schematic diagram of the server and computing environment [2].

The server runs on a standard computing device equipped with a central processor (CPU), random access memory (RAM), read-only memory (ROM), persistent storage (such as solid-state or hard disk drives), input/output (I/O) circuitry, and a network interface for internet connectivity.

I. System Workflow, Components, Input–Process–Output, and Compatibility

1) System workflow: Rather than relying on static interactions, the system's workflow executes a dynamic

challenge-response mechanism between the client device and the server. During the authentication phase, the server dynamically generates a new, randomized sequence of X for each login session. This sequence interleaves n secret locations (SL_n) with k deceiving locations (DL_k). The server also generates a random array of vibration patterns (V_i) that are exclusively mapped to the deceiving locations. The client device executes this workflow by displaying the image and triggering the covert vibration patterns only before a required decoy tap. Fig. 5 shows the full workflow of one authentication session, including the reject-and-regenerate path taken after a mismatch.

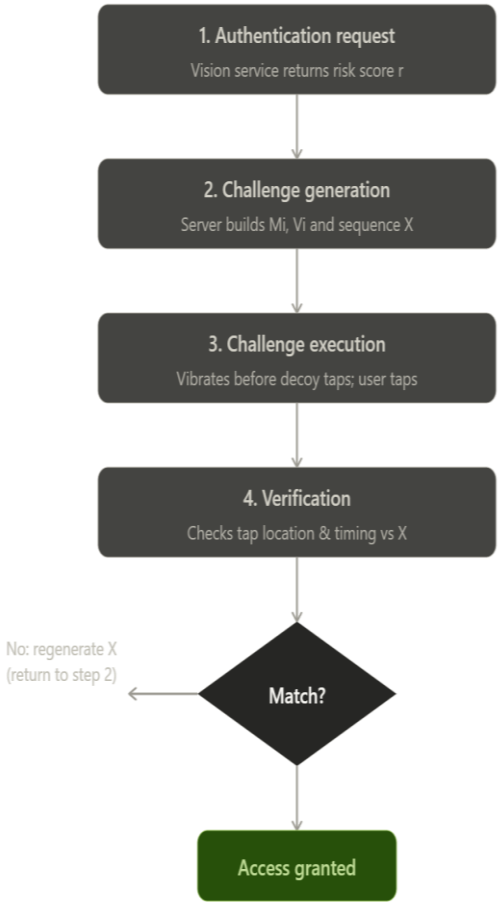

Fig. 5. Workflow of one authentication session, from the environment-aware check through challenge generation, challenge execution with vibration cues, and verification, including the reject-and-regenerate path.

2) Input–Process–Output (IPO) model: The system logic follows a strict IPO model to validate the user's identity without exposing the credentials visually:

- Input**:** The system captures multi-modal user interactions, specifically the spatial coordinates of the taps on the screen and the temporal tapping styles (e.g., short, long, or multiple taps).
- Process: The server's processor evaluates these inputs by comparing the received tap locations and durations against the session's specific generated sequence X.
- Output: The system outputs a binary access decision; it grants access to the server if the inputs perfectly match the sequence, or it denies access and regenerates a new random array and sequence X to offer a new login attempt. Fig. 6 presents this input–process–output cycle as a flowchart of the steps performed on the client device.

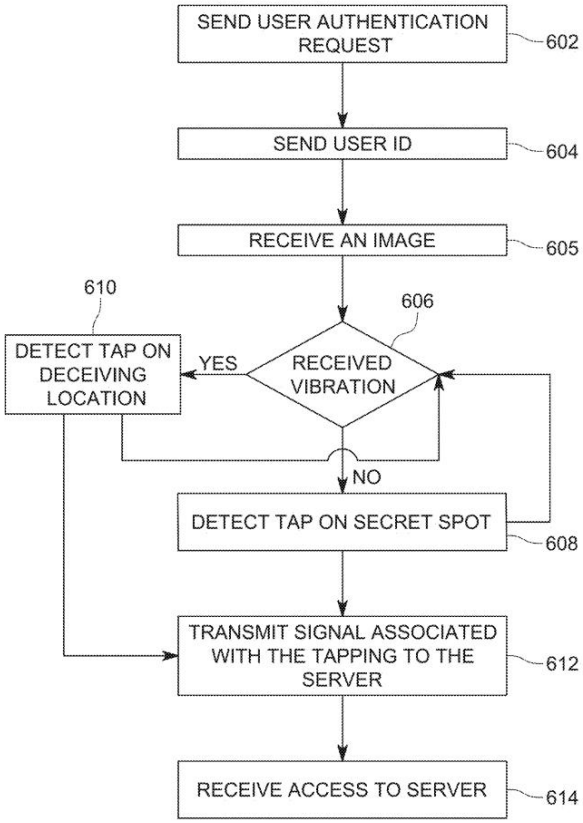

Fig. 6. Flowchart of the authentication method performed by the client device [2].

3) Component integration and compatibility: The client only relies on hardware that already exists in the device, namely the built-in vibration motor, so an ordinary phone, a game controller, or a smartwatch can each play the client role. Nothing has to be added to the device, which keeps the deployment cost down and means the scheme can sit on top of existing consumer or enterprise mobile setups with no retrofit work.

J. Prototype Implementation

We built a working prototype of the scheme and tried it on off-the-shelf phones to check that the design holds together. The client is a React Native app written in TypeScript, using Expo for the SDK and Expo Router for navigation. The benefit of going this route is portability: the same codebase runs on both Android and iOS without any platform-specific fork. Fig. 7 shows the application home screen, where the user selects Login or Register. Fig. 8 shows the registration screen, where the user selects an image and defines the secret locations.

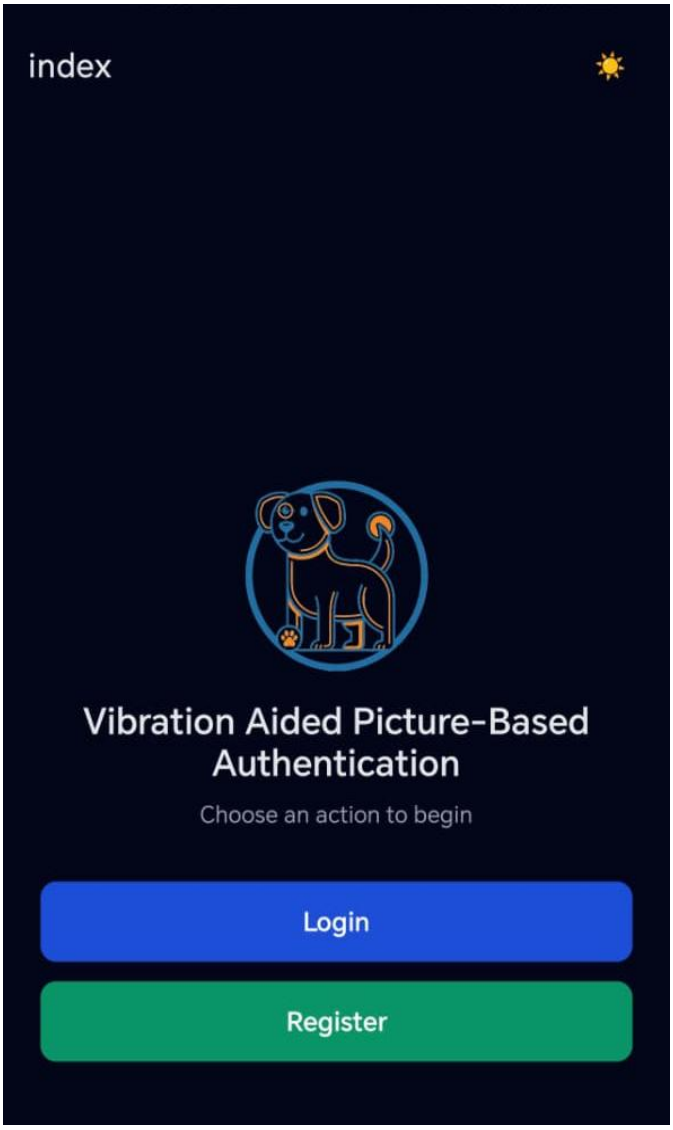

Fig. 7. Application home screen showing login and register options.

The backend user credential store is implemented using Google Firebase Firestore, a cloud-hosted NoSQL database, which persists with each registered user's username, selected image identifier, secret locations, deceiving locations, and vibration-pattern mappings as structured documents. Image selection is handled through the expo-image-picker library, which also supports user-supplied custom images; Custom images are identified during authentication via a SHA-256 digest [15] computed over the canonically normalized image (resized to 1024 × 1024 RGBA and PNG-encoded with deterministic settings) at registration time, and verified at login by recomputing the digest on the device and matching it byte-for-byte against the stored value before any tap input is accepted. Vibration feedback is delivered through React Native's built-in Vibration API (Vibration.vibrate()), which accepts duration arrays of the form [delay, on, off, on, ...] on Android, enabling the three distinct haptic patterns used in the system — single (one 400 ms pulse), double (two 400 ms pulses separated by a 400 ms gap), and triple (three 400 ms pulses). On iOS, which does not natively support pattern arrays, the same three patterns are simulated through repeated timed calls to Vibration.vibrate(400). To overcome an Android-specific cold-start latency in the vibration motor, the implementation primes the motor with an imperceptible 1 ms pulse on the first user gesture before playing any authentication-related pattern. Fig. 9 shows the login screen while the environment security scan is running.

Tap interaction is captured via React Native's Pressable and GestureResponderEvent interfaces, with an acceptance radius of 20 pixels, a double-tap detection window of 200 ms, and a long-press threshold of 300 ms. The per-session randomized challenge sequence is generated on the client in the prototype using the generatePresentationOrder function, which randomly assigns the six tap slots across the three secret and three deceiving identities while preserving the canonical ordering of each group. Fig. 9 also shows the Dev mode of the prototype, which includes all data related to the adaptive Environment-Aware component that will be discussed in the next subsection. This is optional for development, but can also be useful for normal users. Fig. 10 shows the login screen after the environment is confirmed, with the image challenge presented for tap entry.

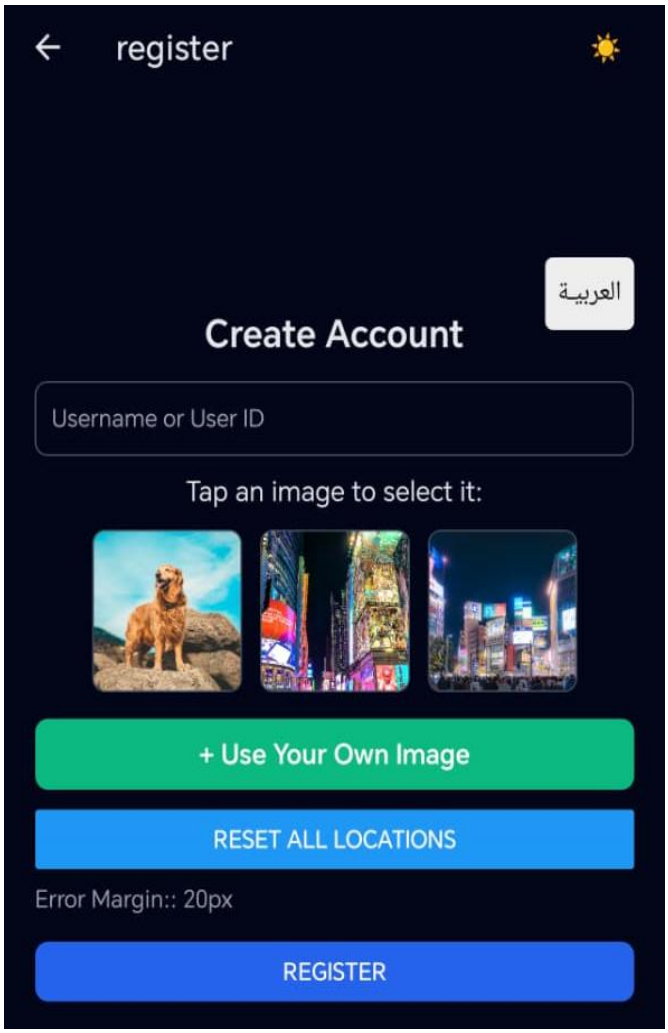

Fig. 8. Registration screen allowing users to select an image and define secret locations.

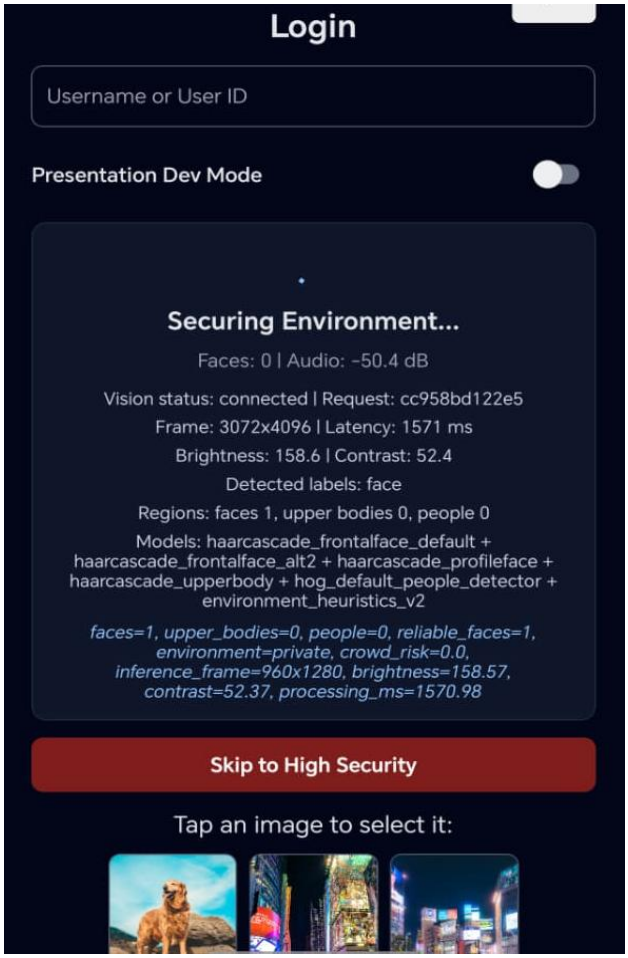

Fig. 9. Login screen during environment security scan.

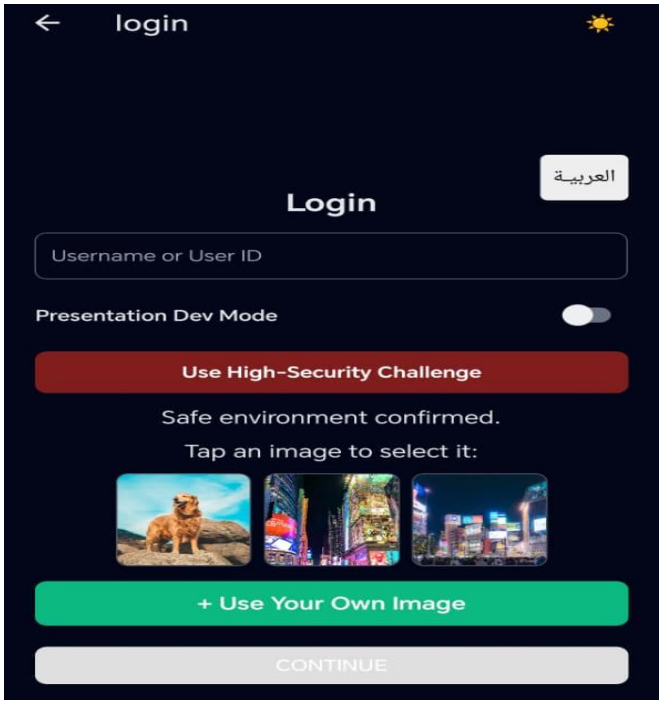

Fig. 10. Login screen after environment confirmed — image challenge selection.

K. Adaptive Authentication Phase (Environment-Aware)

Because the threat from shoulder-surfing depends heavily on where the user actually is, the prototype includes an adaptive authentication phase that adjusts the difficulty of the challenge to the user's surroundings. Before a challenge is generated, the client grabs a single frame from the front camera and sends it to a vision service written in Python on top of FastAPI and OpenCV. The service runs two detectors in parallel that look for different visual cues: a Haar-cascade face detector based on the Viola–Jones framework [16], using both frontal and profile cascades, and a Histogram of Oriented Gradients (HOG) pedestrian detector in the Dalal and Triggs formulation [17]. Three signals come out of that frame: the number of detected faces, the number of detected upper-body shapes, and the distribution of detection confidences. The service aggregates the three signals into a scalar crowd-risk score $r \in [0,1]$ using a normalized weighted sum:

$$r = min\left(1, \frac{\alpha \cdot f}{N_{max}} + \frac{\beta \cdot b}{N_{max}} + \gamma \cdot c\right)$$

where, f is the face count from the Haar-cascade detector, b is the upper-body count from the HOG detector, $\bar{c} \in [0,1]$ is the mean of the confidence-score distribution across all detections in the frame used as a compact summary of detector certainty $N_{\max} = 5$ is a saturation cap above which the environment is unconditionally treated as crowded, and $\alpha = 0.5$, $\beta = 0.3$, $\gamma = 0.2$ are empirically set weights satisfying $\alpha + \beta + \gamma = 1$, with face detections weighted most heavily as the closest-proximity risk signal. The result is clipped to $[0, 1]$ by the outer min. The service returns only r and the binary label PRIVATE or PUBLIC, and the frame is discarded immediately after scoring.

The frame is not written to disk on the client and is not written to disk on the server.

Above r = 0.55, the environment is labeled PUBLIC; below that, the label is PRIVATE. A PUBLIC label puts the client into the HIGH_SECURITY phase, which uses the full n + k decoy challenge from Section III. A PRIVATE label switches to a LOW_SECURITY phase in which the decoy count k drops to a default of 1, so that the login stays quick in settings that do not really need to go through all the steps. The user can override the automatic classification at any time with a single "Use High-Security Challenge" control. The net effect is that the full strength of the scheme stays available where it is needed, but the user is not paying for that full cost during routine logins at home or in the office.

IV. Evaluation

A. Study Design

Twenty-one participants took part in a study designed to probe three things about the prototype from Section III: how usable it is, how secure it feels, and how much of the credential survives a short retention interval. Recruitment was by convenience sampling within the university and through the authors' own contacts, and the resulting sample spans the age, gender, smartphone-proficiency, and cybersecurity-background categories, as shown in Table IV. One number worth pulling out up front: 20 of the 21 participants (95.2%) told us they had been

on the receiving end of shoulder-surfing in real life, or thought they might have been. The threat model is not abstract for this group. Everyone got a briefing before they started, consented in writing, and could stop at any point. We kept no personally identifying information, no biometric data, and no camera frames; only anonymized Likert responses and aggregate timing statistics ended up on disk.

TABLE IV. PARTICIPANT DEMOGRAPHICS (N = 21)

Characteristic	Category	N (%)
Age group	18–24 / 25–34 / 35–44 / 45–54 / 55+	6 / 4 / 5 / 5 / 1
Gender	Male / Female / Prefer not to say	11 / 9 / 1
Smartphone proficiency	Beginner / Intermediate / Advanced / Expert	2 / 8 / 8 / 3
Cybersecurity knowledge	Beginner / Intermediate / Advanced / Expert	9 / 5 / 6 / 1
Prior shoulder-surfing exposure	Yes / Maybe / No	15 / 5 / 1

Each session had three phases: (1) orientation, in which participants received a brief explanation and demonstration; (2) registration, during which each participant selected an image, assigned three secret locations, three decoy locations, and mapped vibration patterns to each decoy; and (3) authentication, in which participants performed repeated login attempts until self-reporting comfort. Participants then completed an online questionnaire (Microsoft Forms) covering five instruments: registration usability (5 items), login usability (8 items), perceived security (6 items), memorability and cognitive load (6 items), and the 10-item System Usability Scale (SUS) [18], scored as (sum of adjusted responses) × 2.5 on a 0–100 scale. All Likert items used a 5-point scale (1 = Strongly Disagree to 5 = Strongly Agree).

B. Results

1) Usability: Registration items scored between M = 4.19 and M = 4.33, with 81–86% agreement across all items (Table V). Login usability scored higher overall. All 21 participants agreed they could clearly feel the vibration cues (M = 4.67, 100%) and that the process became faster after multiple attempts (M = 4.71, 100%). First-attempt login success was lower (M = 3.76, 61.9% agreement), reflecting a short but real learning curve: 42.9% of participants became comfortable in 1–2 attempts, 52.4% in 3–5, and 4.8% in 6–10 (estimated mean ≈ 3.1 attempts).

2) Perceived security and memorability: The security-perception block scored highest overall, with item means between 4.52 and 4.86 (Table VI). Every participant agreed that a nearby observer could not work out the real password, every participant agreed the scheme would hold up across multiple sessions of shoulder-surfing, and 95.2% said they would trust the scheme for sensitive uses such as banking. After 24 hours with no practice, 76.2% of participants still felt they could recall both the secret locations (M = 3.95) and the vibration-tap mappings (M = 3.90). Cognitive load looked manageable: 81.0% said the mental effort was acceptable next to a PIN or pattern lock, and all 21 said they could feel the vibration cue reliably even with background noise. The weakest item in the block was daily practicality at M = 3.76 (57.1% agreement), which suggests that the scheme suits high-value logins better than the dozens of routine unlocks every smartphone user does in a day.

TABLE V. USABILITY RESULTS: REGISTRATION AND LOGIN (5-POINT LIKERT; N = 21).

Item	M	SD	Agree / SA (%)
Registration Usability			
Registration process was easy to understand	4.19	0.93	85.7%
Selecting secret locations was intuitive	4.33	0.73	85.7%
Defining decoy locations was straightforward	4.19	0.68	85.7%
Mapping vibration patterns to tap styles was clear	4.29	0.85	85.7%
Confident I could remember my password after registration	4.24	1.09	81.0%
Login Usability			
Login process was easy to complete	4.52	0.60	95.2%
Could clearly feel the vibration cues before decoy taps	4.67	0.48	100.0%
Could distinguish between different vibration patterns	4.62	0.59	95.2%
Responding with the correct tap style after vibration was natural	4.48	0.81	90.5%
Time required to log in was acceptable	4.29	0.85	85.7%
Did not feel frustrated during the login process	4.43	0.60	95.2%
Successfully logged in on first attempt	3.76	1.14	61.9%
Process became faster and more natural after multiple attempts	4.71	0.46	100.0%

TABLE VI. PERCEIVED SECURITY, MEMORABILITY, AND COGNITIVE LOAD (5-POINT LIKERT; N = 21).

Item	M	SD	Agree / SA (%)
Perceived Security			
Vibration cues make the system more secure than PIN/pattern	4.71	0.46	100.0%
A nearby observer could NOT determine my real password	4.86	0.36	100.0%
Decoy taps effectively hide which taps are my real password	4.67	0.58	95.2%
System would resist shoulder-surfing across multiple sessions	4.76	0.44	100.0%
Per-session randomization adds meaningful security	4.67	0.48	100.0%
Would trust system for sensitive apps (banking, email)	4.52	0.60	95.2%
Memorability and Cognitive Load			
Could remember secret locations after 24 hours (no practice)	3.95	0.97	76.2%
Could remember vibration-tap mappings after 24 hours (no practice)	3.90	0.94	76.2%
Mental effort acceptable compared to PIN/pattern	4.05	0.92	81.0%
Did not feel mentally overloaded while using the system	4.14	0.79	81.0%
System would be practical for daily use on my smartphone	3.76	0.89	57.1%
Could perceive vibration feedback even in a noisy environment	4.57	0.51	100.0%

3) System Usability Scale (SUS): Twenty of 21 participants completed all SUS items. The mean SUS score was 78.62 (SD = 9.88, median = 80.0, range = 57.5–100.0). This exceeds the commonly cited average of 68 and, on the adjective scale of Bangor et al. [19], falls between the "Good" (≈71.4) and "Excellent" (≈85.5) ratings — closer to "Good" — corresponding to an acceptable system. Eighty per cent of participants (16/20) exceeded the 68 average, and 40% (8/20) scored at or above 80.3. SUS item-level means and the overall score are presented in Table VII.

TABLE VII. SUS ITEM-LEVEL MEANS AND OVERALL SCORE (N = 20)

SUS Item	Mean	Direction
Q1. I would like to use this system frequently	4.19	Positive
Q2. I found the system unnecessarily complex	1.81	Negative
Q3. I thought the system was easy to use	4.14	Positive
Q4. I would need technical support to use this system	1.76	Negative
Q5. The various functions were well integrated	4.29	Positive
Q6. There was too much inconsistency in this system	1.60	Negative
Q7. Most people would learn this system very quickly	3.90	Positive
Q8. I found the system very cumbersome to use	1.95	Negative
Q9. I felt very confident using the system	4.33	Positive
Q10. I needed to learn a lot before I could get going	2.00	Negative
Overall SUS Score (0–100 scale)	**78.62**	**Good (Acceptable)**

4) Inferential statistical analysis: Beyond the descriptive statistics reported above, we applied inferential tests to assess whether the usability and perceived-security results differ significantly from established neutral or benchmark values. Because the Likert items are ordinal and the sample is modest, all per-item comparisons were verified with the non-parametric one-sample Wilcoxon signed-rank test against the scale midpoint (neutral = 3), and the SUS comparison used a one-sample t-test against the widely cited benchmark of 68 [19]. A significance level of $\alpha = 0.05$ was used throughout, and Holm–Bonferroni correction was applied within each instrument block to control the family-wise error rate across multiple comparisons. Effect sizes are reported as Cohen's d for the SUS comparison and as the matched-pairs rank-biserial correlation for the Likert items.

The mean SUS score ($M = 78.62$, $SD = 9.88$, $N = 20$) was significantly higher than the 68 benchmark, $t(19) = 4.81$, $p < 0.001$, with a large effect size (Cohen's $d = 1.07$), confirming that the observed usability advantage is unlikely to be an artifact of sampling variation. Every perceived-security item differed significantly and positively from the neutral midpoint after correction (all $p < 0.001$); for example, agreement that a nearby observer could not determine the real password ($M = 4.86$, $SD = 0.36$) yielded $t(20) = 23.7$, $p < 0.001$, and agreement that the scheme would resist shoulder-surfing across multiple sessions ($M = 4.76$, $SD = 0.44$) yielded $t(20) = 18.3$, $p < 0.001$. The two 24-hour memorability items also exceeded the neutral midpoint significantly, recall of secret locations ($M = 3.95$, $SD = 0.97$), $t(20) = 4.5$, $p < 0.001$, and recall of vibration–tap mappings ($M = 3.90$, $SD = 0.94$), $t(20) = 4.4$, $p < 0.001$, though with smaller effect sizes consistent with the wider spread on these items. We note that these tests establish that responses depart significantly from neutrality and from the SUS benchmark; because the study used a single within-subjects condition, they do not constitute a between-conditions comparison against a baseline authentication scheme, which we identify as a limitation and a direction for the controlled comparative study described in Section VII.

C. Discussion

The SUS score landed at 78.62, roughly ten points above the often-cited 68 baseline, which is a fair indication that the haptic-decoy mechanism is not paying for itself with a usability overhead. Earlier visual-obfuscation schemes, such as WIW, show what the alternative looks like; there, the obfuscation tends to wear on the user [6]. Pairing the high security-perception ratings (item means 4.52 to 4.86) with a SUS rated "Good" on the Bangor et al. adjective scale, the data suggests we have the design tradeoff roughly right: better resistance to observation, without a meaningful hit on how the scheme feels to use. The 61.9% first-attempt success rate is what one would expect from any new interaction; the relevant follow-up signal is that all 21 participants agreed the process got faster and more natural after a few tries, which is what learnability looks like in practice. Twenty-four-hour retention came out at 76.2% for both the secret locations and the vibration-tap mappings, so the credential survives an overnight gap without an external aid. The strongest single block of the dataset was security perception: nobody in the sample thought a watcher could recover the password, and 95.2% said they would use the scheme for things like banking. Set next to the SUS, the picture is consistent. Participants found the scheme usable, they thought it was secure, and they put it in the part of the design space we actually targeted, namely, mobile authentication in public.

Set against the other haptic schemes, this one ends up in a slightly different corner of the design space. Feel Vibration [9] runs a challenge–response exchange entirely over a covert haptic channel, which is elegant, but it puts the whole credential into vibrations the user has to remember with no spatial anchor to lean on. HapticLock [12] was built for eyes-free use and is single-modal; it never set out to address shoulder-surfing of the on-screen interaction. The continuous-authentication work of Cao et al. [13] and HandKey [14] goes in a different direction altogether — passive vibration biometrics rather than a chosen credential, with the deployment and revocation issues that follow from any biometric (a vibration signature cannot really be reset once it leaks). Our scheme keeps the user on the familiar ground of a picture password, then adds the covert haptic decoy channel, per-session randomization, the environment-aware adaptive phase, and uses the image file itself as a second factor. From the user side, it is one continuous interaction; from the security side, it is a two-factor authenticator with built-in observation-resistance, reached without an SMS code, a second device, or new hardware.

V. LIMITATIONS

A. Limitations and Use Cases

The proposed scheme improves resistance to shoulder-surfing without requiring privacy screen protectors, which themselves degrade screen visibility for the legitimate user. That said, the design has a few limitations. It depends on the device having a working vibration motor; on phones where the motor is weak or has been disabled in software, the cue can be hard to feel. New users also need a short period of practice before the response to a vibration pattern becomes automatic. Some environmental factors matter as well. If the phone is sitting flat on a surface instead of being held, the vibration is muffled enough that some users will miss it.

The scope of the present evaluation is deliberately bounded, and two boundaries should be read alongside the results. First, the study sample (N = 21) was recruited by convenience from within the university and the authors' contacts; it is therefore not statistically representative of the broader smartphone-using population and may over-represent technically literate users, so the usability and perceived-security figures are best read as indicative rather than population-level estimates. Second, by design, the present study measures usability, memorability, and perceived security, and does not include an adversarial component in which participants observe and then attempt to break one another's login sessions. Accordingly, the shoulder-surfing-resistance claim is grounded in the quantitative single-session bounds derived in Section III — including the explicit multi-session inference threshold of Section III D.4 — together with participants' perceived security, rather than in a measured human-observer attack rate. We treat the controlled adversarial study — with a larger, more diverse, and randomly recruited sample drawn from real public-transport and public-space users, a between-subjects comparison against an established baseline scheme, and a protocol in which observers attempt to reproduce a victim's credential after watching one or more sessions — as the natural next step that converts the theoretical resistance argument into direct empirical evidence, and it is the primary direction for our ongoing work.

Despite these limitations, the system can be useful in several scenarios. It is particularly suitable for smartphone authentication in public environments where shoulder-surfing attacks are more likely to occur, such as airports, public transportation, or cafes. The system can also be used to protect access to sensitive mobile applications, such as banking or enterprise systems. Overall, the approach is most effective for touchscreen devices that support vibration feedback and are used in environments where visual observation attacks are a potential risk.

VI. CONCLUSION AND FUTURE WORK

A. Conclusion

This study describes a vibration-aided picture-based authentication scheme that puts secret locations and decoy locations together on the same image and uses covert vibration cues only for the decoy taps. The pieces – a client–server architecture, a structured data model, and a randomized challenge generator – combine to obscure the distinction between real and decoy taps from a visual observer, while keeping the implementation thin enough to run on commodity smartphones and other haptic-capable devices. The current design depends on a working vibration motor and on spatial and temporal thresholds that have been tuned for the prototype hardware; if those parameters are misconfigured, the scheme will either be less usable or less secure than intended.

B. Future Work

A few directions are already in scope. The most immediate is per-user calibration: we want the server to build a short profile of each user's tap timing so that the spatial and temporal thresholds can be moved up or down for that user without altering the threat model. Past that, we plan to try the prototype on wearables, smartwatches, and haptic-capable game controllers; the architecture should already accommodate them. Two algorithm-side refinements are in scope as well. The first is smarter decoy interleaving, including density, clustering, and context-sensitive placement. The second is a stronger crowd-risk classifier for the adaptive authentication phase, ideally one that runs without a cloud round-trip. On the hardening side, we plan to add client-integrity attestation and server-side anomaly detection that flags improbable tap-location or timing patterns before any of them turn into a successful attack.

ACKNOWLEDGMENT

This work was conducted as part of Senior Projects 1 and 2 (CCCY 411) at the College of Computer Science and Engineering, University of Jeddah, under the supervision of Dr. Faisal Alsubaei.

***Abstract*—Career transition into digital professions is a strategic lever for addressing youth unemployment in Sub-Saharan Africa. However, existing training programs lack objective career guidance tools. This study presents two complementary contributions, evaluated using data collected from 131 professionals who underwent a career transition process into a digital profession. Learn-Orient is a career path recommendation system combining a profile recognition filter based on Gower distance normalized by the IQR and a binary logistic regression model, producing probabilistic estimates with a graded confidence level (High, Moderate, Low). EDU-CDA is a data augmentation method suited for small educational datasets with mixed variables and imbalanced classes, combining conditional SMOTE for continuous variables and conditional Bernoulli sampling for binary variables. Validated by a three-way protocol (distributional overlap 82.9–90.8%, TVD < 0.061, TSTR Δ = 0.025), EDU-CDA transforms the logistic regression model, which is typically the most vulnerable to small sample sizes (AUC = 0.810 in real cross-validation)—into the most stable and high-performing one (AUC = 0.995 in cross-validation, F1 = 0.900 on a real test set of 20 observations). Among the 16 pre-training predictors selected, institutional funding (OR = 32.40) proves to be the most discriminating factor for the Developer profile, while the creativity test score (OR = 0.107) strongly characterizes the Designer profile. The system incorporates a filter for detecting atypical profiles, ensuring responsible use in a decision-making context with significant human stakes.**

Keywords*—Machine learning; data augmentation; predictive model; artificial intelligence in education; professional retraining; career recommendation

I. INTRODUCTION

Choosing the right educational track is one of the most critical decisions in a professional career. Yet, this choice is still too often based on subjective factors such as personal intuition, family influences, and opportunities available at a given time, rather than on tangible data and objective profile assessment tools. The consequences of inappropriate academic guidance are well-documented and severe. This is what [1] reveal in their study reveals that 51.2% of students at the Autonomous University of Santo Domingo report having chosen the wrong program, and 85.6% have considered dropping out. Wydra-Somaggio [2], meanwhile, they found that 70% of learners who prematurely terminated an apprenticeship contract in Germany pursue a career change. These findings all point to the fact that the mismatch between a candidate's profile and the chosen program is a major determinant of dropout rates and the waste of resources invested in education.

This issue is even more profound and significant in sub-Saharan Africa. With a youth unemployment rate estimated at 12.7% [3] and a persistent mismatch between available skills and the actual needs of the labor market [4], the region faces a structural challenge in terms of labor market integration. In this context, digital professions represent a strategic opportunity. In fact, 230 million digital jobs are expected by 2030 [5]. Professional retraining programs, such as short, intensive training courses designed for candidates from diverse backgrounds, serve as a direct pathway to these jobs. However, their effectiveness faces a persistent obstacle: the lack of objective tools capable of guiding each candidate toward the track best suited to their profile to maximize their chances of success [6]. Moreover, these challenges are amplified by local specificities and constraints, such as limited educational infrastructure [7], the complex situation of professionals undergoing retraining who are forced to keep their jobs while training without any support, and a digital labor market that is still taking shape.

Machine learning offers a promising solution to this challenge [8]. The systematic review by Trujillo et al. [9], covering 38 studies selected from 1,296 articles, demonstrates that machine learning (ML)-based career recommendation systems are rapidly developing in higher education. However, these systems rely almost exclusively on standardized academic data from large datasets in North American or European contexts, making them ill-suited to the heterogeneous context of career transition in Sub-Saharan Africa, where profiles are multidimensional, skills are self-reported, and available data is both low in volume and imbalanced across categories [9]. The concept of low volume is particularly relevant given that, in the African regions, data collection frameworks have not been established to regularly provide reliable information from projects, programs, and training pathways focused on professional retraining. Furthermore, standard data augmentation methods such as SMOTE [10] prove to be ineffective on predominantly binary variables with logical constraints [11]. Few studies propose an approach capable of simultaneously modeling this richness of profiles and addressing these specific methodological constraints. This study is grounded in this dual gap, both practical and scientific.

This article proposes two original and complementary contributions, evaluated on the complete dataset collected from 131 candidates, including 99 observations (or obs) used, and on augmented data ranging from 200 to 20,000 observations.

(C1) Learn-Orient is a major-track recommendation system combining a profile recognition filter based on the Gower

distance normalized by the IQR (Interquartile Range) and an interpretable binary logistic regression model, producing probabilistic estimates with a graded confidence level. It currently enables guidance toward the two professions of graphic designer and application developer. (C2) EDU-CDA (Educational Controlled Data Augmentation) is a controlled augmentation method tailored to small educational datasets with mixed variables and imbalanced classes, combining conditional SMOTE for continuous variables and conditional Bernoulli sampling for binary variables, validated by a tripartite protocol. Four research questions structure this approach:

RQ1 — Which pre-training characteristics (socio-demographic, motivational, and technical) enable the ability to distinguish candidates oriented toward the Graphic Design track from those oriented toward the Application Developer track, and with what predictive performance?

RQ2 — To what extent does a controlled augmentation method adapted to mixed variables and small sample sizes improve the predictive performance of classification models compared to models trained exclusively on real data?

RQ3 — Do the synthetic data generated by EDU-CDA exhibit sufficient statistical fidelity to the real data, as measured by a three-part validation protocol that combines distributional fidelity, proportional similarity, and predictive utility?

RQ4 — Is the Gower distance normalized by the IQR a reliable indicator of a candidate profile's proximity to the known data space, enabling the identification of atypical profiles for which automatic prediction is unreliable?

To answer these questions, the remainder of the article is organized as follows: the next section presents the literature review and state of the art; the methodology is then described; the results are presented; the following section discusses the implications, while the final section concludes and offers recommendations.

II. Related Work

A. African Context and Challenges of Digital Reskilling

Professional retraining for digital careers is emerging in Sub-Saharan Africa as a structural response to the mismatch between the supply of available skills and the actual needs of the labor market [4]. In this context, short-term training programs for candidates from diverse backgrounds are proliferating, but their effectiveness remains limited by the lack of objective career guidance tools. Macharia [6] emphasizes that retraining candidates frequently lack precise information about available career paths and their actual requirements. To be effective in this context, smart educational technologies must be designed with African challenges and the specific context of professional retraining in this region in mind, including challenges such as the coexistence of work and training, which reduces learners' cognitive capacity to devote to their training, and the heterogeneity of incoming profiles. It is precisely this heterogeneity that renders approaches developed in contexts with abundant, standardized academic data inadequate.

B. Machine Learning for Career Guidance

The application of machine learning to academic and career guidance has been the subject of a growing body of scientific research. Trujillo, Pozo, and Suntaxi [9] provide the most recent and comprehensive synthesis, with a systematic review of 38 studies selected from 1,296 articles. Their results show that random forests (26% of studies), SVMs (21%), and neural networks (16%) dominate the field, while logistic regression (13%) is preferred in contexts where the interpretability of recommendations is paramount. Academic data constitute the most frequent input variable (40% of studies), followed by personal interests (25%) and demographic data (15%). F1-score, precision, and recall are identified as the most used evaluation metrics, justifying their consideration in this research methodological choices. The authors, however, identify two persistent structural limitations: the unavailability of open and reproducible datasets, which hinders comparisons between studies, and the near absence of longitudinal evaluations to measure the actual impact of recommendations on career outcomes. These gaps are particularly pronounced in African contexts, where education data remains fragmented and rarely shared publicly.

In the specific field of IT tracks, Al-Dossari et al. [12] developed CareerRec using data from 2,255 IT employees in Saudi Arabia, comparing five algorithms to predict membership in three professional tracks. Despite a sample twenty times larger than the sample currently used for this study, the maximum accuracy achieved, 70.47% with XGBoost, highlights the inherent difficulty of predicting IT career paths. It should also be noted that this study does not specifically address career transition. Two contributions of this study are directly applicable. These are the binarization of programming language skills into independent binary columns, identical to the multi-label encoding used for this study, and the confirmation that class imbalance significantly degrades predictive performance and requires dedicated handling.

In the Beninese context, Houngue, Hountondji, and Dagba [13] developed a post-BEPC guidance system achieving 99% accuracy on 325 students using random forests. This result, obtained using standardized and objectively measurable academic scores, demonstrates the technical feasibility of supervised approaches in the Beninese educational context. However, it is not transferable to our configuration, where the dataset of 99 observations draws on self-reported skills, motivations, and economic context factors, thus operating within a framework that is both more complex and less structured, with a smaller sample size. Wu et al. [14] confirm, moreover, that variable selection and class balancing constitute the two most critical methodological challenges once one moves beyond standard academic settings.

C. Interpretability and Choice of Production Model

The choice of classification model is not merely a matter of maximizing a performance metric. Rudin [15] presents a decisive normative argument stating that in fields with high human stakes, including career counseling, interpretable models are preferable to black-box models when they offer comparable performance, as they allow for the detection of bias, the justification of decisions, and the maintenance of user trust.

Logistic regression meets this requirement, and its coefficients translate directly into odds ratios, providing a transparent justification for each recommendation generated [16]. Song et al. [17] extend this argument by showing that incorporating motivational and behavioral variables, beyond academic characteristics alone, improves the accuracy of career trajectory predictions, which forms the basis of the selected predictive variable structure for this study. Smirani et al. [18], Lee et al. [19], and Arévalo-Cordovilla and Peña [20] further confirm that ensemble models suffer from overfitting on small samples and exhibit high sensitivity to hyperparameters, two undesirable properties in this context of working with 99 actual observations.

D. Class Imbalance and Data Augmentation

The problem of learning on imbalanced data is well-documented. He and Garcia [11] identify two families of solutions: data-level methods, including synthetic resampling, and algorithmic-level methods such as class weighting. They emphasize that class imbalance interacts with the small sample size to jointly degrade the models' sensitivity to minority classes, a situation encountered in the dataset, which has 38 Developers versus 61 Designers.

According to the literature, SMOTE [10] is the most widely adopted resampling method. It creates synthetic observations via linear interpolation between a real observation and one of its k nearest neighbors in the feature space, producing greater diversity than simple repetition-based oversampling. Anggrawan et al. [21] and Cu et al. [22] confirm its effectiveness in imbalanced educational contexts, with sensitivity gains of up to 25%. However, SMOTE has two critical limitations for modeling use. Indeed, when applied to binary variables, it generates decimal values with no semantic meaning (e.g., lang_java = 0.5). Furthermore, since it is not class-conditional, it risks producing hybrid profiles across tracks on an unbalanced dataset. These specific limitations further motivate the development of EDU-CDA.

E. Validating the Quality of Synthetic Data

Evaluating the quality of synthetic data requires additional criteria beyond descriptive statistics alone. Esteban et al. [23] formalized the TSTR (Train on Synthetic, Test on Real) protocol. This involves a model trained exclusively on synthetic data and evaluated on real data. The difference from the model trained on real data (TRTR) measures the predictive utility of the synthetic data [24]. Jordon et al. [25] confirm that TSTR is currently the gold standard in this field, as it evaluates the preservation of relational structures between variables, rather than simply marginal distributions. Qian et al. [26] additionally propose the Total Variation Distance (TVD) within the Synthcity framework. They suggest calculating it variable by variable as the absolute difference between the proportions observed in the real and synthetic data. It constitutes a non-parametric metric directly applicable to binary variables. The threshold of 0.05 used as the limit for a negligible difference is consistent with the conventional threshold for statistical significance. Specifically in the educational context, a recent benchmark [27] comparing SMOTE and several deep generative models on 10,000 students shows that resampling methods achieve a TSTR of 0.997, confirming their predictive utility on tabular data. A TSTR score of 0.924, obtained on a dataset twenty times smaller and with a higher proportion of constrained binary variables, is consistent with this benchmark.

F. Handling Missing Values and Variable Selection

Missing value handling must precede any modeling of field data. Batista and Monard [28] have empirically demonstrated that KNN imputation produces statistically superior results compared to methods based on the mean or mode, as it leverages local relationships between variables to estimate missing values. Li et al. confirm that including the target variable in the search for neighbors improves the quality of imputation by leveraging available class information, a practice adopted in this pipeline. Emmanuel et al. [29] justify the exclusion of variables with more than 30% missing values, a threshold beyond which imputation introduces more noise than useful information.

Variable selection is a critical issue when the number of variables far exceeds the number of observations. Guyon and Elisseeff [30] have shown that combining several complementary methods reduces the risk of eliminating important variables due to the lack of power of a single method, justifying the three-method voting system with a unanimity requirement used in a context of n = 99 observations of the dataset [31]. Multicollinearity checking completes this step by considering the work of Dormann et al. [32] and Hair et al. They recommend a threshold of $|r| > 0.70$ as an exclusion criterion, above which two variables share more than 49% of their variance, making the regression coefficients unstable and their interpretation unreliable.

G. Evaluation Metrics and Classification Threshold

In the presence of imbalanced classes, the choice of metrics is a methodological decision. Japkowicz and Shah [33] demonstrate that a classifier that systematically predicts the majority class would achieve a high accuracy rate in the dataset without any discriminative value, rendering this metric inappropriate. The F1-score, the harmonic mean of precision and recall, is the primary recommended metric because it penalizes both types of errors equally. The AUC [34] provides an evaluation of overall discriminative ability independent of the threshold, which is particularly stable in cross-validation on small folds.

Determining the optimal classification threshold is distinct from model selection. The Youden index [35] simultaneously maximizes both detection rates under the assumption of symmetric costs between false positives and false negatives. In the considered career guidance context, this assumption is methodologically justified, since mistakenly directing a Developer toward Design and mistakenly directing a Designer toward Development represent equally costly failures for the candidate.

H. Similarity Measure for Mixed Variables and Person-Environment Fit Theory

Measuring similarity between profiles with continuous and binary variables requires an appropriate metric. Gower [36] proposed a general coefficient calculated as the average of individual similarities normalized according to the type of each variable, natively handling missing data and mixed types. D'Orazio [37] identifies a limitation of the standard version, noting that continuous variables with a wide interquartile range

tend to dominate the overall calculation. He proposes normalizing by the IQR rather than by the total range, thereby mitigating the impact of outliers and balancing the contribution of both types of variables. This distance is used in a Learn-Orient as a profile recognition filter before any prediction.

This filter is theoretically grounded in the concept of person–environment fit, formalized by Holland [38], which posits that professional satisfaction and success depend on the congruence between an individual's characteristics and the demands of their environment. This framework underpins the hypothesis that variables such as creativity scores or prior technical skills constitute stable indicators of natural fit for a particular field. Jaoui and Hilmi [39], in the French-speaking context of career transition, confirm that these fit factors remain robust determinants of career change decisions, regardless of formally acquired skills.

I. Positioning of the Present Study

The literature review presented in this chapter highlights four complementary gaps.

To begin with, the absence of a system for predicting and recommending career paths in the context of adult learning and career transition, particularly toward digital professions.

Second, existing work on career prediction using ML operates almost exclusively in contexts with large datasets containing standardized academic variables. No study offers a methodological solution for the simultaneous occurrence of a small sample size, predominantly binary variables with logical constraints, and imbalanced classes, a configuration that is characteristic of career transition data, particularly in an African context where data scarcity is also a common phenomenon.

Furthermore, while SMOTE has been validated for data augmentation on continuous educational data, its application to constrained binary variables remains unaddressed in the literature. The EDU-CDA method proposed in this study directly fills this gap by combining conditional SMOTE for continuous variables and conditional Bernoulli sampling for binary variables.

Finally, there is a lack of a component for detecting atypical profiles in existing guidance systems. No existing guidance system distinguishes between candidates whose profiles are covered by the model and those for whom the prediction is unreliable. The integration of the Gower distance normalized by the IQR as a pre-prediction filter constitutes an operational contribution that addresses this limitation.

These four gaps collectively define and establish the scope of this study, whose methodology is presented in the following chapter.

III. METHODOLOGY

A. Sampling and Data Collection Strategy

The target population of this study, individuals seeking career transition into digital professions, is not tracked by any official registry in Benin. No institution is formally dedicated to digital career transition in the strict sense. The phenomenon manifests itself in a diffuse manner across various training institutions (private digital schools or universities, vocational training centers, and integration programs) where some learners change careers or fields of study without this process being institutionally identified as such. The sampling universe is therefore, by nature, not delimited a priori, rendering any probabilistic approach inapplicable in the absence of an exhaustive sampling frame.

Considering this structural constraint, a non-probabilistic network sampling strategy, commonly referred to as snowball sampling, was adopted [40]. This method is recognized as appropriate when the target population is difficult to reach, unregistered, or distributed across multiple structures without administrative centralization [41], [42]. It involves identifying an initial group of participants who meet the inclusion criteria, then asking them to identify other potential candidates within their networks.

In the case of this study, the process began with direct contact with several institutions offering training in digital professions in Cotonou and surrounding cities, identified as likely to accept learners seeking career transition. A 47-item Google Forms questionnaire was distributed to these institutions and then shared by the initial respondents with their peers.

Two methodological precautions were taken to limit the biases inherent in this approach. At the outset, the deliberate diversification of entry points into the network. Several distinct institutions were officially contacted simultaneously to reduce the risk of overrepresentation of a particular subgroup linked to a single institution or a single social network. In addition, the anonymous and self-administered nature of the form limits social desirability bias in responses to questions about motivations and self-reported skills. Completing the form was voluntary, with no pressure from the administration. Respondents were not under any influence.

B. Data Collected and Sample Characteristics

This approach yielded 131 responses, of which 99 were retained after applying eligibility criteria that excluded programs with too few students for defensible statistical modeling (Audiovisual Specialist: 11 obs; Digital Project Manager: 8 obs; Data Analyst: 1 obs) and programs with ambiguous or incomplete titles. The primary inclusion criterion is the presence of an identifiable career break, where the candidate must have worked in or prepared for a career in a field distinct from digital professions before enrolling in their current program. This criterion operationalizes the concept of career transition regardless of the institution attended. The final dataset includes 61 candidates (61.6%) in the Graphic Design track and 38 (38.4%) in the Application Developer track, representing a 1.6:1 imbalance ratio. Table I presents the main characteristics of the sample.

C. Methodological Pipeline

The methodology is organized into seven sequential, interdependent steps, summarized in Table II. The dataset is divided into a training set (80%, 79 obs) and a test set (20%, 20 obs) via random sampling with a fixed seed. The test set is strictly isolated from the training data. It is not used in either variable selection or the construction of the EDU-CDA synthetic data, ensuring an unbiased evaluation.

TABLE I. SAMPLE CHARACTERISTICS BY TRACK (N = 99)

Characteristic	Graphic Designer (n=61)	Application Developer (n=38)
Average Age (years)	23.9 (σ=4.6)	24.6 (σ=5.4)
Male	67.2%	78.9%
From Benin	95.1%	97.4%
Family funding	70.5%	57.9%
Institutional funding	6.6%	18.4%
Personal funding	23.0%	23.7%
High school diploma or higher	34.4%	47.4%
Previous experience in the digital field	29.5%	50.0%
Availability > 72 hours/week	14.8%	26.3%
Average work experience	28.4 months	38.2 months

TABLE II. EDU-CDA METHODOLOGICAL PIPELINE

Step	Title	Input	Output
P1	Preprocessing & normalization	131 observations, 49 raw variables	99 obs, clean variables
P2	Variable coding	Textual/categorical variables	76 numerical variables
P3	Feature engineering	76 variables	80 variables (+ 4 derived variables)
P4	Variable selection (voting among 3 methods)	79 candidate variables	16 final variables
P5	Baseline modeling (real data)	79 real training observations	Baseline performance
P6	EDU-CDA increase	79 real training observations	1,600 balanced observations
P7	Final modeling + Evaluation	1,600 augmented observations	Evaluation of 20 real test observations

D. Preprocessing, Encoding, and Feature Engineering

Preprocessing begins with converting ambiguous textual responses (none, nothing, n/a, none, nr, nc, etc.) into missing values. The variable moy_bepc, which has an N/A rate of 35.4%, is excluded in accordance with the 30% threshold recommended by Emmanuel et al. [29]. The four remaining numerical variables (moy_bac, test_creativity, note_dipl, experience_month) are imputed using KNN (k = 5) with the target variable included in the distance calculation, which leverages the available class information [28].

The encoding transforms the textual variables using four complementary approaches: 1) simple binary encoding (gender, internet access, Beninese origin); 2) one-hot encoding with a priori categorical grouping for five variables, city (4 geographic zones), education level (Bac_Less / Bac_More), funding (4 types), field (3 categories), sector (3 categories); 3) multi-label encoding using regular expressions for multiple-choice variables (programming languages, design tools, office and cross-functional skills); (iv) lexical field detection for free-text responses (motivation, objective).

Four derived variables are constructed to synthesize the information scattered across individual binary columns with small sample sizes, improving the statistical power of the selection tests applied in the next step [30]:

$$\text{profile_dev} = \Sigma\ \text{programming_languages} + \text{html_level} \quad (1)$$

$$\text{designer_profile} = \Sigma\ \text{design_tools} + \text{photoshop_level} \quad (2)$$

$$\text{nb_trans} = \Sigma\ \text{cross-functional_skills} \quad (3)$$

$$\text{nb_office} = \Sigma\ \text{office_tools} \quad (4)$$

E. Selection of Variables by Unanimous Vote Using Three Methods

The selection is based on 79 variables available after feature engineering, using a voting system with three complementary methods [30]. A variable is retained only if it simultaneously satisfies all three criteria (score 3/3), which reduces the risk of spurious correlation in a sample of 99 observations [31]:

One-vs-all correlation: $r_j = \left|cor\left(X_j, Y_k\right)\right| > 0.10$, where Y_k is the binary indicator for sector k.

Random Forest Importance (MDA): 500 trees, average decrease in accuracy when permuting values > 0.

Statistical tests: Kruskal-Wallis (continuous variables); Fisher's exact test (binary variables, small sample sizes); $p < 0.05$.

Checking for multicollinearity at a threshold of $|r| > 0.70$ [33] led to the exclusion of 8 redundant variables as presented in Table III. The most informative variables within each set of redundant variables were retained.

TABLE III. EXCLUDED REDUNDANT PAIRS (|R| > 0.70)

Excluded variable	Retained variable	Observed |r|
high_school_level	high_school_level	1.000
html_level	dev_profile	0.928
Photoshop level	designer_profile	0.925
trans_proact	nb_trans	0.780
lang_html	dev_profile	0.775
illustrator_tool	designer_profile	0.765
no_trans	nb_trans	0.762
no_lang	dev_profile	0.752

The 16 final variables selected are presented in Table IV.

TABLE IV. 16 FINAL VARIABLES SELECTED (STEP P4)

Variable	Type	Category / Description
Age	Continuous	Socio-demographic
work_style	Continuous	Motivational (preference for solo vs. group)
logic_test	Continuous	Skill (logic test score)
creativity_test	Continue	Skill (creativity test score)
dev_profile	Continue	Derived — Σ languages + HTML level
designer_profile	Continue	Derived — Σ design tools + photoshop_level
nb_trans	Continue	Derivative — Σ cross-disciplinary skills

post-high-school level	Binary	Level of education ≥ High school diploma
end_of_family	Binary	Family funding
end_institutional	Binary	Institutional funding (scholarship)
time-intensive	Binary	Availability > 72 hours/week
Digital_Tech	Binary	Previous field: digital/tech
dom_other	Binary	Previous field: other
lang_java	Binary	Prior knowledge of Java
lang_js	Binary	Prior knowledge of JavaScript
trans_redac	Binary	Declared writing skills

F. EDU-CDA Method – C2 Contribution

The complete augmentation process is detailed in Fig. 1.

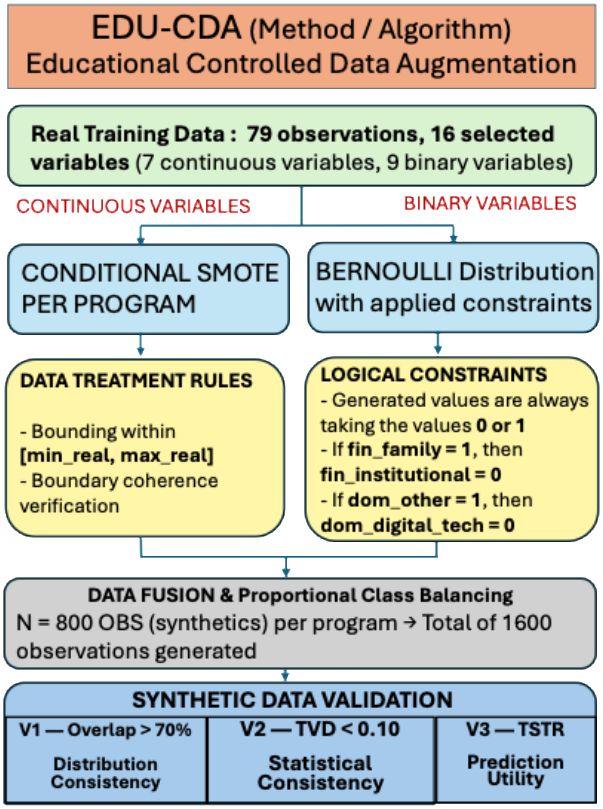

Fig. 1. EDU-CDA process.

EDU-CDA (Educational Controlled Data Augmentation) is one of this study's main contributions, developed to simultaneously address the dataset's three constraints: low volume (79 training observations), predominantly binary variables with logical constraints (9 out of 16), and imbalanced classes (1.6:1 ratio). It combines two generation mechanisms applied separately for each track k ∈ {Designer, Developer}, avoiding the generation of hybrid profiles at the boundary between the two classes.

1) Class-conditional SMOTE (continuous variables): For each track k, synthetic observations are generated by linear interpolation between a real observation x_i and one of its K nearest neighbors x_{nn} within the same class [10]:

$$\mathbf{x_{synth}} = x_i + \lambda \cdot (x_{nn} - \mathbf{x_i}),\ \lambda \sim U(0, 1) \quad (5)$$

The parameter K is adjusted: $K = \min(3, n_k - 1)$, avoiding outliers in classes with small sample sizes [11]. Two post-processing steps are systematically applied: 1) clamping values within the observed bounds $[x_{min}, x_{max}]$; 2) rounding to the nearest integer for count variables (profil_dev, profil_designer, nb_trans, test_logic, test_creativity, work_style).

2) Conditional Bernoulli per class (binary variables): For each binary variable x_j and each track k, the probability of occurrence is estimated from the actual training data:

$$\hat{p}_{jk} = \frac{1}{n_k} \cdot \sum_{i:y_i=k} x_{ij} \quad (6)$$

Each synthetic value is generated by a Bernoulli draw:

$$x_{ij}^{synth} \sim \text{Bernoulli}(\hat{p}_{jk}) \quad (7)$$

This approach guarantees values strictly ∈ {0, 1}, preserving the binary nature of the variables. It is preferred over SMOTE for binary variables whose interpolation would produce decimal values that are semantically unacceptable in the context of self-reported skills.

3) Consistency rules and augmentation strategy: Two business consistency rules correct logically impossible combinations: 1) if fin_family = 1, then fin_institutional = 0; 2) if dom_other = 1, then dom_digital_tech = 0.

Two augmentation strategies were used to determine the optimal strategy. The balanced strategy generates N synthetic observations per class regardless of the actual volume, resulting in approximately equal sample sizes across fields. The proportional strategy, on the other hand, generates $(N - n_k)$ synthetic observations per track, where n_k denotes the number of actual observations in class k, thereby ensuring exactly N observations per class in the final augmented dataset.

G. Validation of Synthetic Data

The quality of the synthetic data is evaluated according to three independent criteria, covering the distributional fidelity of continuous variables, the statistical fidelity of binary variables, and the predictive utility of the synthetic dataset.

1) Distributional fidelity (continuous variables): For each continuous variable, the overlap between the distributions of the real and synthetic data is calculated by intersecting the normalized histograms:

$$Overlap_j = \frac{\Sigma_b \left(h_j^{real}(b), h_j^{synth}(b)\right)}{\Sigma_b\, h_j^{real}(b)} \quad (8)$$

where, hj (b) denotes the density of variable j in bin b. An overlap greater than 70% is used as the acceptability criterion.

2) Statistical fidelity (binary variables): For each binary variable, the Total Variation Distance (TVD) between the real and synthetic proportions is calculated, Qian et al. [26]:

$$TVD_j = \left|\widehat{p_j^{réel}} - \widehat{p_j^{synth}}\right| \quad (9)$$

A TVD of less than 0.05 is considered negligible, by analogy with the conventional significance threshold α=0.05. A TVD of less than 0.10 is considered acceptable.

3) Predictive Utility (TSTR): An LDA model is trained exclusively on synthetic data and evaluated on real training data (TSTR), in accordance with the protocol by Esteban et al. [23]. Its accuracy performance is compared to that of an LDA model trained on real data only (TRTR). The choice of LDA as the reference classifier for this protocol is motivated by its stability across small samples. A difference of less than 0.15 is considered acceptable [43]:

$$\Delta_{TSTR} = |AccTRTR - AccTSTR| < 0{,}15 \quad (10)$$

H. Learn-Orient System - Contribution C1

The Learn-Orient system combines two sequential steps to produce a major recommendation with a graded confidence level. Fig. 2 illustrates the complete workflow.

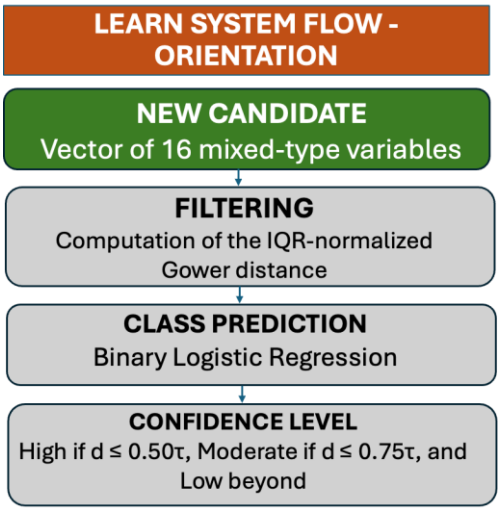

Fig. 2. Workflow of the learn-orient guidance system.

1) Profile recognition filter: The Gower distance normalized by the IQR [37] is calculated between the new candidate's profile and each of the 1,600 reference observations. For continuous variables, partial similarity is normalized by the IQR (rather than the range) to mitigate the impact of outliers and balance the contribution of both types of variables. For binary variables, the asymmetric Jaccard coefficient is used so that a double absence does not contribute to the similarity. The average distance to the k = 5 nearest neighbors is calculated as follows:

$$\underline{d}_G ower(x_n ew) = (1/5) \cdot \Sigma_{j=1}^{5} d_G ower\left(x_n ew, x_{(j)}\right) \quad (11)$$

A threshold τ is defined as the 95th percentile of the distribution of mutual distances between reference observations. If $\bar{d} > \tau$, the profile is declared unrecognized, and the system recommends considering other digital career paths besides designer and developer, thereby signaling its own limitations for atypical profiles (RQ4).

2) Binary logistic regression and confidence levels: If the profile is recognized, binary logistic regression estimates the membership probabilities:

$$P(x) = 1/\left(1 + exp\left(-(\beta_0 + \beta^T x)\right)\right) \quad (12)$$

$$P(Designer \mid x) = 1 - P(Developer \mid x) \quad (13)$$

The β coefficients are estimated using the augmented dataset (N = 1,600) and interpreted as odds ratios $OR_j = \exp(\beta_j)$ [34]. An odds ratio greater than 1 indicates a positive association with the Application Developer track; an odds ratio less than 1 indicates a positive association with the Graphic Designer track. At the same time, confidence intervals are evaluated to identify the variables significant for predicting the targeted tracks. If the interval $[CI_{lower}, CI_{upper}]$ contains 1, the variable is considered insignificant.

The optimal threshold is determined by the Youden index [35]: J = Sensitivity + Specificity − 1. Three confidence levels are assigned based on $\bar{d} / \tau$:

- High (≤ 0.50), reliable automatic prediction;
- Moderate (≤ 0.75), recommendation for further evaluation;
- Low (> 0.75 but ≤ 1.00), maintenance strongly recommended [10].

I. Algorithms

Seven binary classification algorithms are compared in two phases: a baseline phase on real-world data (P5) and a post-augmentation phase on EDU-CDA data (P7). The evaluated algorithms are binary logistic regression (LR), logistic regression with class weighting (LR + Weighting), radial basis support vector machine (SVM), random forest (RF), linear discriminant analysis (LDA), naive Bayes classifier, and decision tree (CART).

The dataset is divided into a training set (80%, or 79 observations) and a test set (20%, or 20 observations) via simple random sampling with a fixed seed (set.seed(42)). The test set is used only once, for the final evaluation, and is not involved at any stage in the construction of synthetic data or in variable selection.

J. Evaluation Metrics

1) Supplementary metrics: Five complementary metrics are calculated for each model. Let TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively, with the positive class being the Application Developer track.

Accuracy: Overall proportion of correct predictions, provided for informational purposes only. In the presence of imbalanced classes, a classifier that systematically predicts the majority class can achieve high accuracy without discriminative value [33].

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (14)$$

Sensitivity and Specificity: Sensitivity measures the proportion of correctly identified Application Developers; specificity measures the proportion of correctly identified Designers:

$$Sensitivité = \frac{TP}{TP+FN} \qquad Spécificité = \frac{TN}{TN+FP} \tag{15}$$

F1-score: Primary model selection metric, defined as the harmonic mean of precision and recall, suitable for imbalanced problems [33]:

$$F1 = 2 \cdot \frac{Precision \times Sensitivity}{Precision + Sensitivity} \tag{16}$$

AUC: Area under the ROC curve, measuring overall discriminatory power independently of the threshold [34]. Primary metric in cross-validation due to its stability on small folds. Train-Test Gap: An indicator of overfitting [44]:

$$\Delta_{overfitting} = F1_{train} - F1_{test} \tag{17}$$

A significant discrepancy between training and test performance indicates that the model has memorized the data rather than learned generalizable patterns.

2) Cross-validation: Three complementary 5-fold cross-validations are conducted using the caret package.

CV1 — On real data. A 5-fold cross-validation is performed on the 79 real training observations to estimate the performance of each algorithm more robustly than a single split, whose random composition on a small sample can produce unstable estimates. AUC is chosen as the evaluation metric due to its stability on small folds.

CV2 — On augmented data. A 5-fold cross-validation is performed on the 1,600 augmented observations to assess the stability of the final model's performance on the synthetic data space. Both cross-validations are implemented using the `trainControl`.

CV3 — On real data after augmentation. A third cross-validation complements CV1 and CV2 to quantify the reliability of the performance estimates and to test the significance of the differences between models. CV3 is a stratified, repeated cross-validation (5 folds, 10 repetitions, i.e., 50 evaluations per model). Unlike CV1, which trains on the real data alone, and CV2, which trains and tests on the augmented data, EDU-CDA augmentation is applied only to the training partition of each fold, the test fold remaining composed exclusively of real observations. The distribution of the 50 F1 scores obtained per model is used to estimate a 95% confidence interval. Finally, the differences between models are tested using the exact McNemar test applied to the out-of-fold predictions: for each pair of models, the test examines only the observations on which the two models disagree and checks whether these disagreements lean significantly in favour of one or the other.

K. Tools and Technical Environment

The analyses were performed using R (version 4.x) and Python 3.x via Google Colaboratory. In R, the main packages used were: caret (modeling and cross-validation), VIM (KNN imputation), ranger (random forests), glm (logistic regression), StatMatch (Gower's distance), and pROC (ROC curves and AUC). In Python, the scikit-learn, imbalanced-learn, pandas, and numpy libraries were used for preprocessing and algorithm comparison. Reproducibility is ensured by setting the random seeds (set.seed(42) in R, random_state=42 in Python).

IV. Results

A. Variable Selection (RQ1)

Out of 79 candidate variables, the unanimous vote across three methods selected 24 variables. As shown in Fig. 3, after checking for multicollinearity, 16 final variables were selected (Table IV). The correlation heatmap confirms the overall independence of the 16 final variables. The strong correlations observed are expected and consistent: fin_famille and fin_institutionnel show a negative correlation (mutually exclusive sources). test_logique and test_creativite show a moderate positive correlation. profil_dev and profil_designer do not have a strong correlation between them, confirming their ability to distinguish the two tracks independently. The absence of strong correlations among the other variables validates the quality of the P4 selection.

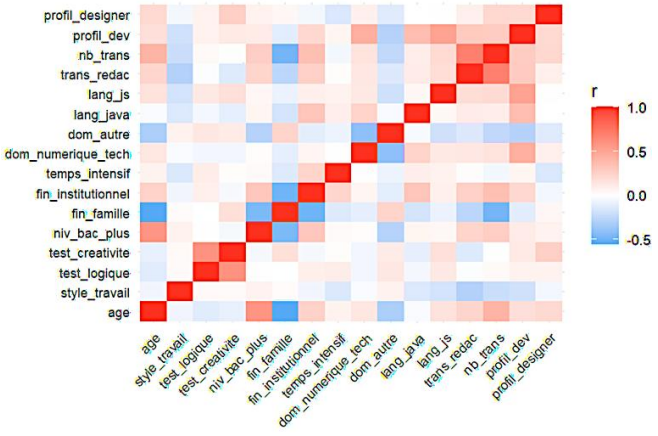

Fig. 3. Heatmap of 16 selected variables.

Profil_dev has the highest correlation with the target (r = 0.427) and the most pronounced difference in means (Designer: 1.13 vs. Developer: 3.13). profil_designer shows the inverse relationship (r = −0.291). These derived variables effectively synthesize the information scattered across individual binary columns with small sample sizes.

B. Validation of EDU-CDA Synthetic Data (RQ3)

The three criteria for tripartite validation are fully satisfied, providing a positive answer to RQ3 as shown in Table V.

TABLE V. Tripartite Validation of EDU-CDA Synthetic Data

Criterion	Indicator	Threshold	Result	RQ3
Distribution accuracy	Histogram overlap (7 continuous variables)	> 70%	82.9–90.8%	Yes
Statistical accuracy	TVD proportions (9 binary variables)	< 0.10	Max. = 0.061	Yes
Predictive utility	TSTR: ΔAccuracy LDA (synthetic vs. real)	Δ < 0.15	Δ = 0.025	Yes

C. Comparative Performance of the Models (RQ1, RQ2)

Table VI and Fig. 4 present the performance of the seven algorithms on the real test set. In the baseline phase (P5), LDA is the model with the best F1 score (F1 = 0.889, AUC = 0.940, ΔTrain = 0.060). Binary LR and RF achieve a perfect training score (1.000), indicating severe overfitting due to near-linear separability in a 16-variable space across 79 observations [38]. After EDU-CDA augmentation (P7), Binary LR is the only model to achieve F1 = 0.900 while maintaining the lowest ΔTrain among the competitive models (0.080), positively addressing RQ2. RF retains persistent overfitting (ΔTrain = 0.222). The Binary LR is selected as the production model.

TABLE VI. PERFORMANCE ON REAL TEST SET (20 OBS) ON P5 AND P7

Model	Acc.	F1	Sens.	Spec.	AUC	Ph	ΔTrain
LDA ★	0.90	**0.889**	0.80	1.00	0.940	P5	0.060
SVM	0.85	0.842	0.80	0.90	0.920	P5	0.133
LR Binary	0.85	0.824	0.70	1.00	0.860	P5	0.176
RF	0.85	0.842	0.80	0.90	0.920	P5	0.158
LR Bin. ★	0.90	**0.900**	0.90	0.90	0.950	P7	0.080
SVM	0.85	0.857	0.90	0.80	0.960	P7	0.136
LDA	0.85	0.842	0.80	0.90	0.950	P7	0.132
RF	0.80	0.778	0.70	0.90	0.930	P7	0.222
CART	0.85	0.842	0.80	0.90	0.855	P7	0.095
Naive Bayes	0.75	0.706	0.60	0.90	0.875	P7	0.214

[a] ★ = Best model of the phase (Ph). ΔTrain = F1_train − F1_test. Sens. = Sensitivity. Spec. = Specificity

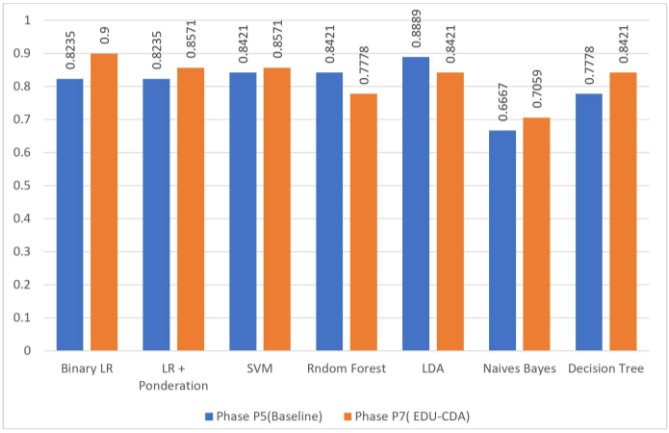

Fig. 4. Comparative F1 performance — Phases P5 (Baseline) and P7 (Post-EDU-CDA) on the real test set – before and after augmentation.

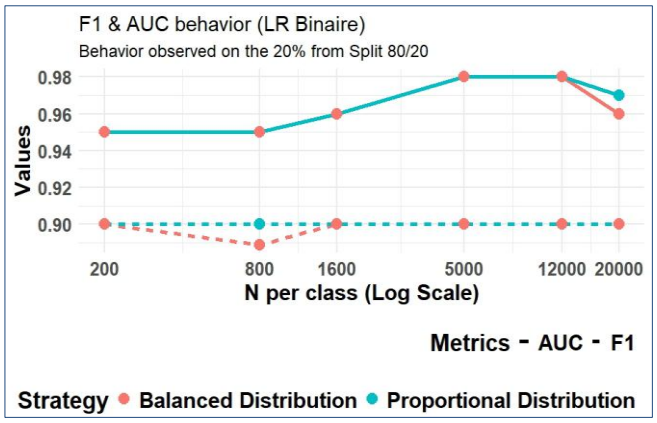

Fig. 5. Analysis of sensitivity to the volume of augmentation.

Three observations emerge from this sensitivity analysis. Initially, F1 plateaus at N = 200 for the proportional strategy (F1 = 0.900 across all configurations) as observed in Fig. 5. The model reaches its maximum binary discrimination capacity very quickly. Next, the AUC follows an upward trajectory up to N = 5,000–12,000 (AUC = 0.98), reflecting a gradual improvement in probability calibration without changing the binary decisions.

In addition, the balanced strategy exhibits a local degradation at N = 800 (F1 = 0.889, Sensitivity = 0.80), suggesting instability in the generation method at this volume level. The proportional strategy is therefore preferred.

D. Cross-Validation and Sensitivity Analysis (RQ2)

5-fold cross-validation on real data (CV1) confirms the hierarchy: LDA is the best model (AUC = 0.944, σ = 0.029), while Binary LR has the lowest AUC (0.810, σ = 0.086). Cross-validation on augmented data (CV2) yields remarkable stability, as shown in Table VII. The increase in AUC from 0.810 to 0.995 provides empirical evidence of the contribution of EDU-CDA.

TABLE VII. CROSS-VALIDATION ON AUGMENTED DATA (BINARY LR, N=800)

Fold	AUC	Sensitivity	Specificity
Fold 1	0.9926	0.9688	0.9688
Fold 2	0.9967	0.9875	0.9813
Fold 3	0.9964	0.9750	0.9750
Fold 4	0.9985	0.9750	0.9875
Fold 5	0.9929	0.9438	0.9938
Average ★	**0.9954**	0.9700	0.9813
Standard deviation	0.0026	0.0162	0.0099

The influence of the volume of synthetic data on the performance of the binary LR model was systematically studied across six levels of N (200 to 20,000 observations per class) and two generation strategies. This evaluation, presented in Table VIII, was conducted exclusively on the 20 real observations in the test set to ensure the external validity of the results.

TABLE VIII. CROSS-VALIDATION FOR EACH DISTRIBUTION AND N

Strategy	N/class	Total obs	AUC	SD
Proportional	200	400	0.9815	0.0153
Proportional	800	1,600	0.9954	0.0026
Proportional	1,600	3,200	0.9940	0.0034
Proportional	5,000	10,000	0.9946	0.0004
Proportional	20,000	40,000	0.9945	0.0008
Balanced	200	479	0.9870	0.0124
Balanced	800	1,679	0.9948	0.0034
Balanced	5,000	10,079	0.9951	0.0009
Balanced	20,000	40,079	0.9944	0.0014

The cross-validation stability analysis based on the increase in sample size shows that N = 200 exhibits significant instability for both strategies, with high standard deviations (0.0153 and 0.0124, respectively), indicating that the model has not yet stabilized at this level. Starting at N = 800, the proportional strategy simultaneously achieves the highest AUC (0.9954) and the lowest SD (0.0026).

N = 800 with the proportional strategy emerges as the optimal configuration: it is the only point where the model combines a maximum AUC, a minimum SD, and stability demonstrated fold by fold, without requiring an excessive volume of data.

As observed in Fig. 6, the best-ranked model is LDA (F1 = 0.831), closely followed by Binary LR (F1 = 0.805). The confidence intervals of the five best models overlap substantially, ruling out any reliable ranking.

```
=== F1 Mean + IC 95% ===
> print(ci, row.names = FALSE)
                Modele    F1 IC_inf IC_sup
                   LDA 0.831  0.726  0.935
             LR Binaire 0.805  0.690  0.921
 LR + Pondération 0.801  0.686  0.916
    Random Forest 0.794  0.666  0.921
                   SVM 0.790  0.672  0.908
    Decision Tree 0.720  0.593  0.847
      Naive Bayes 0.705  0.555  0.855
```

Fig. 6. Confidence interval (screenshot on terminal).

Two consequences follow. CV3 shows that EDU-CDA raises Binary LR, the most penalized model on real data alone (CV1: AUC = 0.810), to statistical parity with the best baseline model (LDA), corroborating the contribution of EDU-CDA (H2) while qualifying the idea of a strict ranking. Fig. 7 shows the results of applying the McNemar test to the out-of-fold predictions.

```

Fig. 7. McNemar test applied to the out-of-fold predictions.

Binary LR is selected as the final model for two reasons, independent of raw performance. To begin with, it makes no assumption about the distribution of the predictors, whereas LDA assumes multivariate normality within each group — an assumption ill-suited to a predominantly binary dataset (9 variables out of 16). Second, it provides odds ratios together with their confidence intervals, offering a direct and auditable interpretation of the orientation factors that LDA does not allow in such a readable form.

E. Final Model - Optimal Threshold and Odds Ratios (RQ1)

The Youden index identifies the threshold 0.6061 (Sensitivity = Specificity = 0.90) as optimal. Table IX and Fig. 8 present the odds ratios of the final model estimated on the augmented data (N = 800, 95% CI).

TABLE IX. ODDS RATIOS OF THE FINAL BINARY LR MODEL (N=800, 95% CI)

Cariable	OR	IC Inf.	IC Sup.
(Intercept)	52,729	1,887	1698,036
age	1,445	1,303	1,629

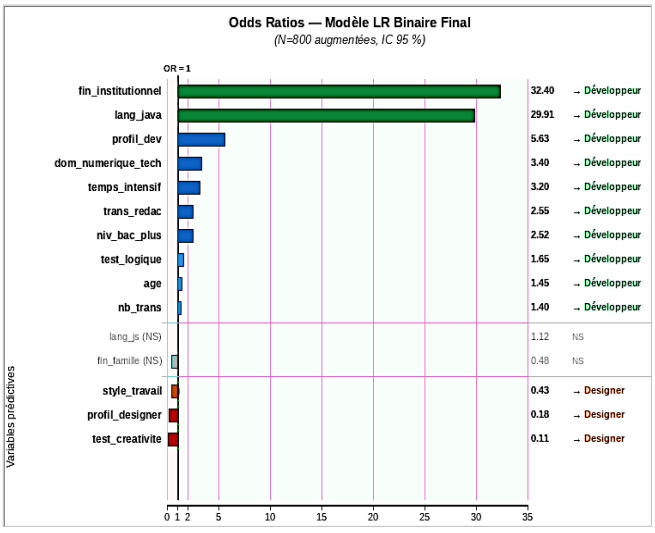

Fig. 8. Odds ratios of the final binary LR model.

F. Class-Wise Analysis and Confusion Matrix (RQ1)

Table X presents the final model's performance by class on the real test set (20 observations). Both classes exhibit symmetrical performance (Precision = Recall = F1 = 0.90), reflecting the quality of the EDU-CDA balancing and the effectiveness of the chosen Youden threshold.

TABLE X. PERFORMANCE BY CLASS VIA BINARY LR AND POST-EDU-CDA (P7) ON THE REAL TEST SET

Class	Precision	Recall	F1-score	Support
Graphic Designer	0.90	0.90	0.90	10
Application Developer	0.90	0.90	0.90	10
Macro average	**0.90**	**0.90**	**0.90**	20
Overall accuracy	—	—	**0.90**	20

The Binary LR after EDU-CDA is the only model to exhibit a perfectly symmetrical error distribution (1 FN, 1 FP), confirming the sensitivity/specificity balance (0.90/0.90) observed in the aggregated metrics. Table XI presents this performance.

TABLE XI. PERFORMANCE BY CLASS BY MODEL

Model	VP	FN	FP	VN
LR Binary ★	9	1	1	9
SVM	9	1	2	8
LR + Weighting	9	1	2	8
LDA	8	2	1	9
Decision Tree	8	2	1	9
Random Forest	7	3	1	9
Naive Bayes	6	4	1	9

After boosting, Binary LR is the only model to achieve F1 = 0.900 on the test set while maintaining the lowest training-test gap among competitive models (0.080). Random Forest continues to exhibit persistent overfitting (gap = 0.222). Binary LR is selected as the production model. Table XII presents the confusion matrix.

TABLE XII. CONFUSION MATRIX BINARY LR POST-EDU-CDA (P7)

Model	F1 Training	F1 Test	Gap
Random Forest	1.000	0.778	0.222
SVM	0.993	0.857	0.136
LDA	0.974	0.842	0.132
Binary LR	0.980	0.900	0.080

G. Final Learn-Orient Classification Model (RQ4)

Applying the Youden index to the ROC curve of the final model yields two thresholds at J = 0.80. The graph in Fig. 9 illustrates the ROC curve of the final model. It has an AUC of 0.95, indicating excellent overall discriminatory power. It deviates significantly from the reference diagonal (AUC = 0.50 corresponding to a random classifier), confirming that the model effectively distinguishes between Designer and Developer profiles across all possible thresholds.

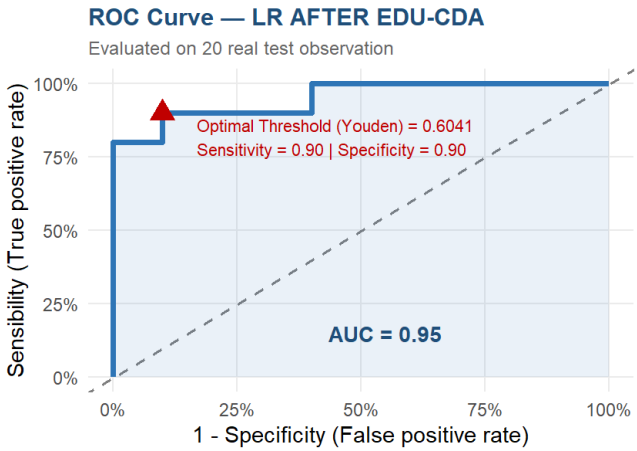

Fig. 9. ROC Curve of the final model after EDU-CDA applied.

The threshold of 0.6061 is selected as the optimal threshold. When two thresholds achieve the same Youden index, statistical convention recommends selecting the lower one, which in this case corresponds to a perfect symmetrical balance between sensitivity and specificity (0.90/0.90). Presented in Table XIII, this balance is particularly well-suited to the context of career guidance, where the two types of error, incorrectly directing a Developer toward Design and incorrectly directing a Designer toward Development, have comparable consequences for the candidate.

TABLE XIII. OPERATIONAL TESTS - LEARN-ORIENT SYSTEM ON 3 PROFILES

Profile Tested	$\bar{d}$ Gower	% threshold τ	Prediction	Confidence
Test 1 — Actual designer	0.092	15%	Designer 99.9%	High
Test 2 — Actual developer	0.175	28%	Developer 100.0%	High
Test 3 — Atypical profile	0.377	60%	Developer 100.0%	Moderate
Gower threshold $\tau = 0.629$	—	100%	—	—

The real profiles (Tests 1 and 2) have Gower distances less than 28% of the threshold $\tau = 0.629$, with clearly defined probabilities and High confidence. The artificial atypical profile (Test 3) correctly triggers a Moderate confidence level at 60% of the threshold, answering RQ4 in the affirmative.

V. DISCUSSION

A. Discriminability of Pre-Training Profiles (RQ1)

Learn-Orient achieves F1 = 0.900 and AUC = 0.950 on the real test set without standardized academic variables, answering RQ1 positively with performance well above the operational threshold. This result is even more notable as it is obtained on only 99 observations and surpasses the ceiling observed by Al-Dossari et al. [12] (70.47% with XGBoost on a dataset twenty times larger). It confirms that the performance of a guidance system does not depend simply on the volume of data, but on the relevance of the variables and the quality of the augmentation method.

Two counterintuitive predictors deserve attention. Institutional funding (OR = 32.40) outperforms all technical skills: this is not an intrinsic characteristic of the candidate but a characteristic of their context of access to training. This strong signal suggests that government scholarship programs structurally attract technical profiles, targeting fields perceived as strategic (software development). This result opens important perspectives for policies on funding retraining.

The creativity test score (OR = 0.107) can be interpreted considering Holland's Person-Environment Fit theory [38]: self-reported creativity is a stable indicator of fit with the Graphic Designer profile, regardless of formal technical skills. Recent studies in the French-speaking context of career transition [39] confirm that these person–environment fit factors remain robust determinants of career change decisions. Song et al. [17] similarly emphasize the importance of motivational and behavioral variables beyond academic characteristics alone.

B. Effectiveness of the EDU-CDA Method (RQ2)

The Binary Logistic Regression model test on the test set of 20 observations yields a F1 = 0.900. This represents a meaningful indicator of the validity of the EDU-CDA Method. It can be explained by a well-documented principle [10] which establishes that the simplest models, those most vulnerable to small samples, benefit the most from augmentation. Before EDU-CDA, quasi-linear separation on 79 observations produced a perfect training score (F1_train = 1.000). After augmentation to 1,600 observations, this phenomenon disappears (F1_train = 0.980), and the model generalizes correctly.

EDU-CDA addresses a specific shortcoming of standard SMOTE [11] : its inapplicability to constrained binary variables. The TSTR of 0.924, obtained on a dataset twenty times smaller and predominantly binary than that of Chinodakufa et al. [27] (TSTR = 0.997 on 10,000 continuous observations), falls within defensible values. The results of Anggrawan et al. [21] and Cu et al. [22] show similar stabilization patterns from equivalent augmentation volumes.

CV3 cross-validation applies the augmentation within each fold and tests on real data. It confirms that EDU-CDA moves Binary LR from the status of the most vulnerable model to statistical parity with the best baseline model (LDA): across the 99 real observations, Binary LR and LDA do not differ significantly in any case (McNemar test, p = 1.000). The realistic generalization performance of Binary LR stands at around F1 = 0.80 [0.69; 0.92], the value of 0.900 obtained on the single test set reflecting a favourable composition of the split. EDU-CDA, therefore, does improve Binary LR.

C. Fidelity of Synthetic Data and the Gower Filter (RQ3 and RQ4)

The three-part protocol fully validates RQ3. The only TVD value slightly exceeding 0.05 (end_family, TVD = 0.061) concerns the variable whose highest proportion (65.7% family funding) makes exact reproduction via conditional Bernoulli more sensitive to random fluctuations, an expected behavior with no practical impact on overall quality. The combination of these three dimensions into a single protocol had not been formalized in the literature on educational data.

Operational tests validate RQ4: the Gower filter correctly distinguishes well-covered profiles (distances < 28% of the threshold) from atypical profiles (60% of the threshold). The IQR normalization proposed by D'Orazio [37] is essential: without it, continuous variables with high interquartile ranges would dominate the calculation, mechanically reducing the contribution of binary variables.

D. Limitations

While the proposed model and methodology demonstrate good performance, some limitations are acknowledged:

L1- Representativeness: the sample obtained does not claim to be statistically representative of all individuals undergoing digital retraining in Benin. The validity of the study rests on the relevance and diversity of the collected profiles rather than on their representativeness in the probabilistic sense. The results and the developed system constitute a proof of concept, and a decision-support tool based on the patterns observed in this sample; generalizing these findings to other contexts will require external validation on new cohorts. CV3 cross-validation also shows that the five best models are statistically indistinguishable at this sample size. The F1 differences reported in phase P7 should therefore be read as indicative, and confirmation on a larger sample remains desirable.

L2 — Statistical power: With 20 observations in the test set, a misclassified observation accounts for 5 F1 points. Confirmation is therefore required on a larger sample.

L3 — Sample bias: overrepresentation of males (71.9%) and near-exclusivity of Beninese individuals (95.6%) amplified in the synthetic data.

L4 — Partial conditional independence: dependencies between binary variables not covered by the two consistency rules are not preserved by the Bernoulli component.

L5 — Self-reporting bias: technical skills are not objectively verified, constituting a source of unmeasurable noise.

L6 — Restriction to two fields: Audiovisual Specialist (n=11) and Digital Project Manager (n=8) remain outside the scope due to insufficient sample sizes.

L7 — Gower threshold calculated on synthetic data: the threshold τ characterizes the internal dispersion of the augmented space. External validation on new cohorts is necessary.

L8 — Lack of hyperparameter optimization: the algorithms are evaluated using their default parameters. Optimization could alter the performance hierarchy for the SVM and RF.

L9 — Discriminant variable selection criteria: Selecting variables based on three criteria could exclude important variables with a small number of observations.

VI. CONCLUSION

Career guidance toward digital professions in Sub-Saharan Africa remains, to date, a largely subjective, non-scalable, and poorly equipped process. This study builds on this concrete observation to propose a response that is both scientific and operational, grounded in real data from different programs and training centers or universities in Benin.

The first contribution of this study (Learn-Orient) demonstrates that it is possible to statistically distinguish between two career transition profiles based exclusively on pre-training characteristics: without grades, without formal assessment, and without structured interviews. With an F1 score of 0.900 and an AUC of 0.950 on real-world data, the system generates interpretable probabilistic recommendations, accompanied by a graded confidence level that explicitly signals its own limitations. The Gower filter ensures responsible use by identifying atypical profiles. This last point, beyond being a technical detail, serves as a genuine ethical safeguard. A system that knows when not to respond is more useful and more responsible than a system that always responds.

The second contribution (EDU-CDA) addresses a specific methodological challenge that the literature had not yet resolved: how to augment educational data characterized by constrained binary mixed variables, low volume, and imbalanced classes? The proposed solution is simple in its logic, rigorous in its implementation, and validated across three independent dimensions. It transformed logistic regression, the most vulnerable model on raw data, into the most stable model after augmentation, with an AUC rising from 0.810 to 0.995 in cross-validation. This result suggests that simple, interpretable models are not inherently inferior to complex models; they generally require more data to realize their full potential.

Beyond the metrics, the results yield operational insights that decision-makers can directly apply. The fact that institutional funding is the strongest predictor of the Developer profile (OR = 32.40), ahead of all technical skills, is not a statistical anomaly. This would suggest that training in this field is costly and that support in this area is likely the best way to provide high-quality, large-scale training for this profession. It also signals that funding policies are already, unintentionally, shaping the profiles of those entering certain fields. Similarly, the creativity score as the primary predictor of the Designer profile (OR = 0.107) confirms that cognitive abilities measured before training are robust indicators of career orientation, regardless of prior academic background.

In the context of using Learn-Orient, these results call for four concrete actions: institutionalize pre-admission profiling using the 16 identified variables; differentiate funding mechanisms according to the targeted fields of study; use the atypical profile signal as a trigger for enhanced human support; and actively diversify the pool of candidates to correct current demographic biases.

This study is a first step, not an endpoint. Extending the system to other fields, such as Audiovisual Specialist, Digital Project Manager, Data Analyst, and others, as soon as staffing allows, would broaden the system's coverage. Integrating a component that estimates the probability of success conditional on the field of study would transform Learn-Orient into a true recommendation tool rather than merely a profile similarity tool. External validation on new training cohorts, followed by deployment as a web application accessible to educational advisors, constitute the two immediate operational steps. Finally, the EDU-CDA method is designed to be transferable without major modification to similar programs, particularly in Africa. It is worth noting that it requires neither a large-scale data collection infrastructure nor expertise in deep generative models.

In a context where 230 million digital jobs are expected in sub-Saharan Africa by 2030 [5], properly guiding each candidate from the outset is not a methodological luxury. It is a direct lever for employability, equitable access, and the efficiency of resources invested in training.

Ethical Considerations

All data was collected with the informed consent of the respondents. The data is anonymized: no personally identifiable information is used in the analyses, and the results are presented exclusively in aggregated form. Learn-Orient is designed as a decision-support tool complementary to human assessment, not as an autonomous decision-making system. The educational advisor retains full responsibility for the final guidance. The profile recognition filter ensures that the system flags its own limitations for atypical profiles. In accordance with Rudin's [15] recommendations for systems with high human stakes, the odds ratios from the logistic regression allow the counselor to explain the reasons behind the generated recommendation to the candidate with the utmost transparency.

Acknowledgment

Our sincere thanks go to Firmin Monyevedo TOVODOUNNON, CEO of EIG Group, Issiakou SOULEYMANE, CEO of the School of Digital Professions (École des Métiers du Numérique - EMN) in Benin, all other training centers and schools that have shared their data with us, as well as all the candidates who agreed to participate in this study. This work is part of the research activities of the Computer Science Research and Decision Support Laboratory (L@RIAD), from the Institute of Mathematics and Physical Sciences (IMSP), an entity of the University of Abomey-Calavi (UAC), whose supervisory team we would like to thank.

***Abstract*—Protecting the privacy of geospatial data, along with efficient encrypted query processing, remains a major challenge in cloud-based GIS applications and location-based applications (LBS). In this study, a privacy-preserving framework for secure range query processing over encrypted vector geospatial data using a learned PR-tree index is integrated with an XGBoost-based bucket prediction model. In the first phase, the framework employs a lightweight dual-encryption scheme based on Lorentz and Galilean transformations. This encryption preserves coordinate relationships and enables reversible coordinate recovery. To improve query execution efficiency in the encrypted domain, the learned PR-tree predicts the most probable PR-tree buckets. This minimizes unnecessary search path traversal. Further, integrity verification during storage and query processing is ensured using the Merkle Hash Root and EdDSA digital signatures. Experimental evaluation was conducted using various real-world point, polyline, and polygon datasets. The proposed framework achieved prediction accuracy up to 97.2% with a very low mean bucket prediction error of 0.028. The obtained results demonstrate the efficiency and practicality of the proposed framework over encrypted cloud data.**

***Keywords*—Location privacy preservation; learned PR-tree indexing; range query processing; Merkle Hash Root verification; XGBoost for spatial prediction**

I. Introduction

Nowadays, the use of geospatial data for applications such as GIS services, urban planning, environmental monitoring, navigation, and emergency response systems has increased significantly [1]. This increased utilization of geospatial data has raised significant concerns about the security and privacy of geospatial information. Due to the large volume, geospatial data is stored in the cloud, leveraging the scalability, accessibility, and computational power of cloud service providers [2]. However, outsourcing geospatial data to semi-trusted cloud providers poses risks of unauthorized access, data tampering, and privacy breaches [3]. Here, the major challenge is maintaining the confidentiality and integrity of geospatial data while preserving its usability. Furthermore, efficient query execution over encrypted geospatial data is expensive due to excessive spatial index traversal during query processing.

Preserving location privacy is the primary challenge in securing geospatial data management against semi-trusted cloud providers and potential attackers. Many encryption techniques are proposed for data storage and retrieval, but they do not support efficient query processing [4][5]. However, directly encrypting a complete shapefile that stores geospatial data incurs excessive computational overhead. Traditional spatial indexing techniques, such as R-trees and PR-trees, support efficient query processing for plaintext spatial data. However, their performance degrades significantly when queries are executed over encrypted geospatial data. The geospatial vector data consists of coordinate-based spatial features such as points, lines, and polygons. It is important to preserve coordinate relationships and topological integrity after applying security transformations [6][7].

To address these challenges, this research proposes a secure, linear, and lightweight encryption technique, along with an efficient query-processing mechanism, for outsourcing geospatial data. The proposed method applies a dual encryption technique. To improve query efficiency over encrypted data, a learned PR-tree index based on an XGBoost bucket prediction model is constructed on encrypted spatial objects. The learned prediction model reduces unnecessary node traversal by identifying the most probable PR-tree buckets corresponding to encrypted query regions. To preserve integrity, Merkle Hash Root (MHR)-based verification metadata is generated for the encrypted spatial index as well as for the query processing workflow. To ensure there is no tampering of data, this Merkle Hash Root value is digitally signed using the EdDSA algorithm [8].

The key contributions of this study are summarized as follows:

- A dual encryption scheme based on Lorentz and Galilean-based encryption is proposed for privacy-preserving geospatial data storage and reversible coordinate recovery.
- A learned PR-tree index based on an XGBoost bucket prediction model is developed to reduce search path traversal and candidate node exploration during range query processing in the encrypted domain.
- An integrity verification mechanism based on Merkle Hash Root and EdDSA digital signatures is incorporated to detect unauthorized modification of encrypted geospatial data and query results.

This study is organized as follows: The related work section discusses existing research related to privacy-preserving geospatial query processing and learned spatial indexing techniques. The remaining sections consist of the proposed system architecture, the mathematical models and algorithms, and the performance evaluation and security analysis. The study ends with a conclusion section.

II. Related Work

Location-based services (LBS) represent a major application domain for encrypted spatial query techniques. As users share location information to receive personalized services, it is crucial to protect their privacy. This data explosion raises significant privacy concerns, as location information can reveal sensitive details about individuals' behaviors and preferences. To address these concerns, various techniques have been developed. To position the proposed framework, prior research is reviewed from three perspectives. These include location privacy-preservation techniques, secure query processing for spatial data, and spatial indexing techniques.

A. Location Privacy Preservation Techniques

Various approaches have been proposed for preserving location privacy in GIS systems. Albouq et al. proposed a double-obfuscation mechanism for preserving location privacy in IoT [9]. However, this approach does not support secure spatial indexing for efficient query execution. Zhang et al. proposed differential privacy with k-anonymity to preserve user trajectory privacy [10]. But the method incurs additional computational overhead for trajectory anonymization. A geo-indistinguishability model for indoor location-based services was proposed by Min et al. [11] in 2023. However, the framework primarily focuses on privacy preservation and lacks efficient query-processing support. Haydari et al. developed a framework for protecting mobility trajectories. Here, the injected noise affects spatial precision [12]. A local differential privacy framework for protecting 3D spatial coordinates using Hilbert encoding and randomized perturbation is developed by Yan [13]. However, the perturbation process may reduce query accuracy. Qiu et al. proposed a geo-obfuscation mechanism that generates locally relevant fake locations to protect user privacy [14]. This framework failed to support query processing in the encrypted domain.

B. Secure Query Processing for Spatial Data

Due to the large volume of geospatial data in the cloud, secure query processing over encrypted geospatial data has also gained significant attention. Wang et al. introduced a secure spatial query framework based on hidden vector encryption for protecting spatial and textual information [15]. But the framework incurs high computational complexity for large datasets. Another framework was proposed based on a privacy-preserving keyword similarity search technique for encrypted spatial datasets [16]. However, the approach mainly focuses on keyword similarity rather than on efficient range query execution. Zhao et al. developed a secure Boolean range query scheme using Hilbert curve mapping and Quadtree indexing [17]. In this case, leakage may still occur during index traversal. Gong et al. proposed a geographic keyword Boolean range query framework for encrypted spatial data. Still, the method suffers from scalability limitations on large encrypted geospatial datasets [18].

C. Spatial Indexing Techniques

Spatial indexing is important for efficiently managing large-volume spatial datasets in applications. The framework for crowdsourcing applications based on a secure, dynamic tree-based indexing structure is an efficient approach. But this approach does not integrate learned prediction mechanisms for optimized traversal. Wang et al. developed an encrypted Quadtree-based indexing framework in 2021 [19]. However, conventional tree traversal still increases query processing overhead. Miao et al. introduced a Geohash-based secure indexing mechanism [20]. This framework was designed for encrypted spatial range queries. As an extension, Miao et al. [21] introduced a GR-tree indexing structure for encrypted spatial query execution. However, the framework lacks support for integrity verification. The comparative analysis of existing privacy-preserving spatial query frameworks is highlighted in Table I.

TABLE I. Existing Privacy-Preserving Spatial Query Frameworks.

Framework	Query Support	Indexing Support	Integrity Verification	Findings
Obfuscation and Differential Privacy-Based Methods [9]–[14]	Partial	✗	✗	Improved privacy preservation, but reduced query accuracy, and a lack of encrypted-domain query execution.
Encryption-Based Secure Query Frameworks [15], [16]	✓	Partial	✗	Supports secure query execution with increased computational overhead.
Secure Spatial Range Query Frameworks [17], [18]	✓	Tree-based	✗	Efficient range query processing, but vulnerable to leakage and scalability issues.
Secure Spatial Indexing Techniques [19]–[21]	✓	Quadtree / GR-tree / Geohash	✗	Enhances query efficiency but lacks integrity verification and learned traversal optimization.
Proposed Learned PR-tree Framework	✓	Learned PR-tree	✓	Provides efficient, integrity-preserving, and scalable encrypted spatial query processing.

To address these limitations, the proposed framework introduces a learned PR-tree index integrated with an XGBoost-based bucket prediction model. The main purpose of this model is to offer efficient range query processing in the encrypted domain. In addition, the framework incorporates Merkle Hash Root and EdDSA-based verification to ensure the integrity of encrypted geospatial data and query results.

III. METHODOLOGY

In this section, the proposed framework for privacy-preserving range query processing over encrypted geospatial data is discussed. This framework integrates a dual-encryption scheme, a learned PR-tree index based on XGBoost bucket prediction. And the last phase includes an integrity verification mechanism that uses a Merkle Hash Root and EdDSA digital signatures.

A. Problem Definition

The original vector geospatial dataset is denoted by $D = \{G_1, G_2, \ldots, G_n\}$. Each spatial object G_i consists of ordered coordinate pairs representing point, polyline, or polygon geometries. The data owner applies the proposed dual encryption scheme to generate the encrypted dataset $D^E = \{G_1", G_2", \ldots, G_n"\}$, which consists of Lorentz-based encryption followed by Galilean-based encryption. Further, the learned PR-index I^Lon the encrypted data is constructed. The corresponding Merkle Hash root, Hroot, is calculated by the owner before sending the data to the semi-trusted cloud server.

The EdDSA digital signature is used to verify the Merkle Hash Root, ensuring integrity during data storage and query processing. In the later phase, a user-defined range query $Q = (xmin, ymin, xmax, ymax)$ is encrypted as Q" before being submitted to the cloud by the trusted end user. The cloud processes Q"over D^E using I^L and retrieves the encrypted result set $G' = g^{1'}, g^{2'}, \ldots, g_m'$. The query results G′, along with the associated Merkle verification metadata, are returned to the trusted end user. The trusted user verifies the integrity of the received results using the verification metadata. Only after successful verification is decryption performed to recover the original query result set. The objective of the proposed framework is to ensure data confidentiality, query privacy, and verifiability of query result integrity.

B. Core System Architecture Components

The proposed system architecture comprises four major entities: the Key Generation Center, the Geospatial Data Owner, the Cloud Service Provider, and the Trusted End User. This architecture collectively enables secure range-query processing over encrypted geospatial data.

1) The Key Generation Center: The key generation center is one of the most important entities of the system. It is responsible for generating encryption keys and cryptographic signatures. All these key values are dynamic, as they are calculated based on the features of the input shapefile. Additionally, the key generation center generates public and private keys for the Edwards-curve Digital Signature Algorithm (EdDSA). This digital signature is further used while sending the signed Merkle Hash Root values between the various entities. The EdDSA algorithm is used, as it provides faster signing and verification. Also, the signatures generated are shorter compared to other digital signature algorithms.

2) The Geospatial Data Owner Side: The geospatial data owner encrypts the spatial coordinates before storing them on the cloud. At first, the coordinate data owner receives the required keys from the key generation center to encrypt the data. This encryption first introduces obfuscation using Lorentz-based encryption by Galilean-based encryption. This dual encryption ensures that a potential attacker cannot regenerate the original data without access to the correct decryption key values. After encryption, the encrypted geospatial data is first organized into a PR-tree. Minimum Bounding Rectangles (MBRs) for all encrypted spatial objects for PR-tree construction. The spatial descriptors extracted from the encrypted MBRs are then used to train an XGBoost-based prediction model. This model learns a mapping from encrypted spatial regions to their corresponding PR-tree buckets. The trained prediction model is integrated with the PR-tree to construct the proposed learned PR-tree index. The learned PR-tree index improves query efficiency by reducing search path traversal in the encrypted domain. In the next step, the Merkle Hash Root is computed over the entire learned PR-tree structure. The computed Merkle Hash Root is digitally signed using EdDSA. Further, the encrypted dataset, the learned PR-tree index, and the signed Merkle Hash Root are transmitted to the cloud service provider. Fig. 1 shows the steps performed by the geospatial data owner.

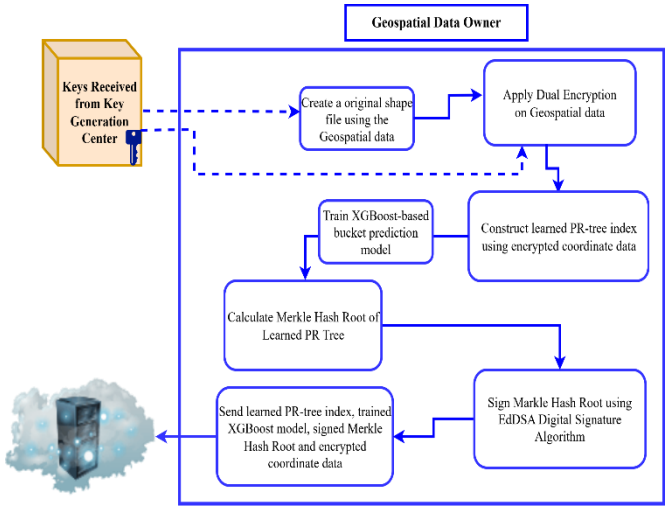

Fig. 1. The geospatial data owner.

3) The Cloud Service Provider Side: The cloud service provider is responsible for storing and processing the encrypted data. Initially, the cloud service provider receives and stores the learned PR-tree index along with the trained XGBoost prediction model. Along with the learned PR-tree index, the digitally signed Merkle Hash Root is also received. This Merkle Hash Root is used to verify the integrity of the data. The Merkle Hash Root of the reconstructed learned PR-tree is recalculated and compared with the Merkle Hash Root sent by the geospatial

data owner. Any unauthorized modification of the encrypted data or the learned PR-tree index can be detected through this verification process. When the trusted end user submits an encrypted query, the XGBoost prediction model first predicts the most probable PR-tree buckets. Later, the learned PR-tree index is traversed over the predicted regions to retrieve the encrypted query results. The Merkle Hash Root is generated for the retrieved query results. Then, this hash value is digitally signed using EdDSA and transmitted to the trusted end user along with the encrypted query results. The cloud service provider does not have access to the original geospatial coordinates. Fig. 2 shows the operational steps performed at the cloud service provider.

4) The Trusted End User: The trusted end user initiates range-query processing over the encrypted geospatial data stored by the cloud service provider. The query bounding box is encrypted using the proposed dual-encryption scheme before transmission. The query result received is also encrypted. The trusted end user verifies the integrity of the received query results by validating the received Merkle Hash Root verification metadata against the recomputed hash value. The cloud service provider verifies their integrity before decryption. In the last step, the received query results are decrypted to recover the original geospatial coordinates. Fig. 3 shows the processing steps performed by the trusted end user.

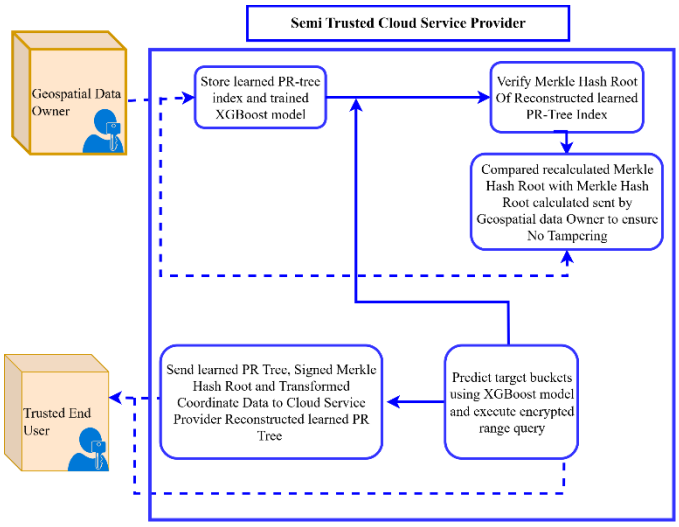

Fig. 2. The cloud service provider.

C. Proposed Dual Encryption Scheme

To ensure privacy preservation of geospatial vector data stored on semi-trusted cloud servers, this study proposes a dual-encryption model. The model combines Lorentz- and Galilean-based encryption to obfuscate spatial coordinates prior to storage. The encryption preserves coordinate relationships and enables accurate inverse reconstruction at the user side, thus ensuring location privacy, query efficiency, and shape preservation. The encryption parameters v, w, t, c, and γ are dynamically derived from the statistical features of the input shapefile. The proposed encryption scheme is reversible and preserves the coordinate relationships required for efficient spatial query processing. The proposed dual encryption and decryption processes are presented with mathematical equations as follows:

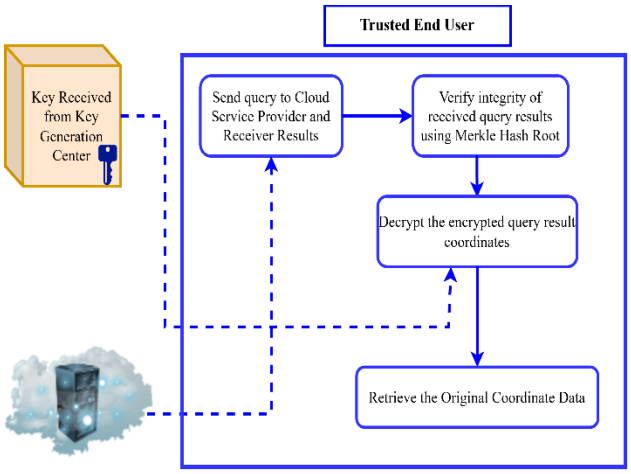

Fig. 3. The trusted end user.

Lorentz Factor Calculation:

$$\gamma = 1 / \sqrt{(1 - ((v^2 + w^2) / c^2))} \quad (1)$$

Lorentz-Based Encryption:

$$x' = \gamma(x - vt) \quad (2)$$

$$y' = \gamma(y - wt)$$

Galilean-Based Encryption:

$$x'' = x' + vt \quad (3)$$

$$y'' = y' + wt$$

Inverse Galilean Decryption:

$$x' = x'' - vt \quad (4)$$

$$y' = y'' - wt$$

Inverse Lorentz Decryption:

$$x = (x' / \gamma) + vt \quad (5)$$

$$y = (y' / \gamma) + wt$$

Finally, Algorithm 1 describes the complete flow of the encryption and decryption scheme.

Algorithm 1: Lorentz and Galilean-based Coordinate Encryption and Decryption

Input: Coordinate set $\{(x_i, y_i)\}$
Output: Original coordinate set $\{(x_i, y_i)\}$

Step 1: Derive dataset-dependent parameters
Compute v, w, t, c, and γ
Step 2: Perform Lorentz-based encryption
$x'_i = \gamma(x_i - vt)$
$y'_i = \gamma(y_i - wt)$
Step 3: Perform Galilean-based encryption
$x''_i = x'_i + vt$
$y''_i = y'_i + wt$
Step 4: Store encrypted coordinates $\{(x''_i, y''_i)\}$

Step 5: Perform inverse Galilean-based decryption
$x'_i = x''_i - vt$
$y'_i = y''_i - wt$
Step 6: Perform inverse Lorentz-based decryption
$x_i = (x'_i / \gamma) + vt$
$y_i = (y'_i / \gamma) + wt$

D. Learned PR Index Construction

The proposed learned PR-tree index is constructed over the encrypted coordinates to improve the efficiency of encrypted range query processing. Initially, Minimum Bounding Rectangles (MBRs) are generated for all encrypted spatial objects. Spatial descriptors extracted from the encrypted MBRs are further used for bucket-level learning. The proposed XGBoost-based prediction model is trained to learn the mapping between encrypted spatial regions and their corresponding PR-tree buckets. During query processing, the trained prediction model predicts the most probable target buckets. This reduces unnecessary traversal of unrelated PR-tree regions. The spatial descriptors extracted from the encrypted MBRs include cx (Centroid x-coordinate of encrypted MBR), cy (Centroid y-coordinate of encrypted MBR), w (width of encrypted MBR), h (height of encrypted MBR), and a (area of encrypted MBR). These descriptors are further used as input features for the XGBoost-based bucket prediction model as a feature vector $F = \{cx, cy, w, h, a\}$. The trained XGBoost prediction model estimates the corresponding PR-Tree bucket identifier for the encrypted spatial region as B = M(F). F represents the extracted encrypted MBR feature vector, M represents the trained XGBoost prediction model, B represents the predicted PR-Tree bucket identifier.

Algorithm 2 summarizes the workflow for constructing the proposed learned PR-tree index and training the XGBOOST model.

Algorithm 2: Learned PR-Tree Index Construction and Model Training

Input: Encrypted spatial objects $\{(x''_i, y''_i)\}$
Output: Learned PR-Tree Index

Step 1: Generate encrypted MBRs for all encrypted spatial objects.
Step 2: Construct the initial PR-Tree using encrypted MBRs.
Step 3: Extract spatial descriptors from encrypted MBRs:
- centroid coordinates (cx, cy)
- width (w)
- height (h)
- area (a)
Step 4: Assign corresponding PR-Tree bucket identifiers.
Step 5: Train XGBoost prediction model using:
Input Features → {cx, cy, w, h, a}
Target Label → bucket id
Step 6: Integrate the trained XGBoost model with the PR-Tree structure.
Step 7: Predict probable PR-Tree buckets during query processing.
Step 8: Search neighboring buckets if a prediction mismatch occurs.

E. Range Query Processing

Using the learned PR-tree index, the proposed range query processing framework enables efficient execution. Initially, the trusted end user encrypts the query bounding coordinates using the proposed dual encryption scheme.

The XGBoost-based bucket prediction model identifies the most likely bucket identifiers for the encrypted query region. Further, the learned PR-tree index traverses only the predicted and neighboring buckets to reduce unnecessary search operations. The integrity verification metadata, based on the Merkle Hash Root and EdDSA digital signatures, is used to ensure that the query results are not tampered with during processing or transmission. Finally, the trusted end user decrypts the encrypted query results to recover the original spatial coordinates. The encrypted query region is represented as $Q'' = E(Q)$. Q represents the original range query. E represents the proposed dual encryption function, and Q″ represents the encrypted range query. Finally, the encrypted query result generated using the learned PR-tree index is represented as $R' = S(Q'', I^L)$. R′ represents the encrypted query result. S represents the learned PR-tree query processing operation. I^L represents the learned PR-tree index.

IV. Results and Performance Evaluation

This section presents the experimental evaluation of the proposed framework to assess its effectiveness in query processing over encrypted data. The performance is evaluated in terms of accuracy, index construction cost, computational efficiency, and query execution across all geometries. This section evaluates the framework's ability to preserve spatial relationships and geometric structures while ensuring efficient range query processing.

A. Experimental Setup

For experimentation, six real-world datasets of point, line, and polygon layer geometries were considered in the EPSG:4326 coordinate reference system. To ensure spatial diversity, two datasets were selected for each geometry type. The proposed framework was implemented on the Google Collaboratory platform (Python 3 notebook environment). The system configuration consists of an Intel Xeon 2.2 GHz CPU with 12 GB of RAM. The proposed algorithms for the encryption scheme, hash-based indexing, and range query execution were applied to these datasets to validate the framework's correctness. Table II summarizes each dataset and its geospatial characteristics. Further, Table III highlights the experimental parameter settings used during the implementation and evaluation of the proposed learned PR-tree framework.

TABLE II. Metadata of Experimental Datasets

Dataset	Geometry	Number of Features	Purpose of Evaluation
Sydney	Point	5000	Evaluation of encrypted point range query processing
Berkeley	Point	3000	Scalability analysis for point geometries
Thane	Polyline	946	Evaluation of encrypted query execution over line geometries
Paris	Polyline	7195	Analysis of learned PR-tree traversal efficiency
Seoul	Polygon	715	Evaluation of encrypted polygon query processing

New York	Polygon	2597	Scalability and storage overhead analysis

TABLE III. EXPERIMENTAL PARAMETER SETTINGS TABLE

Parameter Name	Values Used in Experiment
Coordinate reference system	EPSG:4326
Bucket size	64
Total buckets	12, 15, 41, 47, 79, 113
Learning model	XGBoost
Prediction target	bucket_id
Bucket prediction error bound	±1 bucket
Query type	Range query
Number of test queries	200 per dataset
Integrity method	Merkle Hash Root with EdDSA signature

B. Performance Analysis

This section presents the performance evaluation of the proposed privacy-preserving and secure query-processing framework. This analysis first examines the cryptographic overhead introduced by the proposed dual-encryption scheme. Later, the efficiency of learned PR-tree index construction, XGBoost-based bucket prediction, and encrypted range query processing is evaluated using various datasets. Further, the proposed learned PR-tree framework is compared with the conventional PR-tree and SLRQ approaches to analyze improvements in query execution time and overall indexing efficiency. This analysis demonstrates the scalability and effectiveness of the proposed framework for secure geospatial query processing.

1) Cryptographic overhead analysis: The cryptographic overhead of the proposed dual-encryption framework across all point, polyline, and polygon datasets is thoroughly evaluated. As per the results demonstrated in Table IV, the proposed encryption and decryption operations incur relatively low computational overhead across all geometry types. The encryption and decryption times increase with the number of spatial coordinates present in the datasets. Further, as the proposed dual encryption scheme is lightweight, it is suitable for practical privacy-preserving geospatial query processing applications.

TABLE IV. CRYPTOGRAPHIC OVERHEAD OF THE PROPOSED DUAL ENCRYPTION.

Dataset	Layer Type	Encryption Time (s)	Decryption Time (s)	Total Cryptographic Overhead (s)
Sydney	Point	0.482	0.391	0.873
Berkeley	Point	0.536	0.447	0.983
Thane	Polyline	2.200	1.988	4.187
Paris	Polyline	2.487	2.143	4.630
Seoul	Polygon	0.641	1.312	1.953

2) Index construction and prediction performance: Table V presents the indexing and prediction performance of the proposed learned PR-tree framework. The results demonstrate that the learned PR-tree index can be constructed efficiently with relatively low index construction overhead. Also, it is observed that due to higher spatial complexity, the ML training time increases for large polyline datasets. However, the XGBoost-based bucket prediction model consistently achieves high accuracy across all datasets, reaching 97.2% for the Sydney point dataset. Fig. 4 demonstrates the efficiency of the proposed framework in terms of cryptographic overhead and learned indexing performance.

TABLE V. EVALUATION OF INDEX CONSTRUCTION AND PREDICTION ACCURACY.

Dataset	Layer Type	Index Construction Time (s)	ML Training Time (s)	Prediction Accuracy	Mean Bucket Prediction Error
Sydney	Point	0.184	2.918	0.972	0.028
Berkeley	Point	0.231	3.427	0.964	0.036
Thane	Polyline	0.582	17.296	0.875	0.125
Paris	Polyline	0.694	18.842	0.892	0.108
Seoul	Polygon	0.097	2.746	0.953	0.047
New York	Polygon	0.106	3.211	0.962	0.038

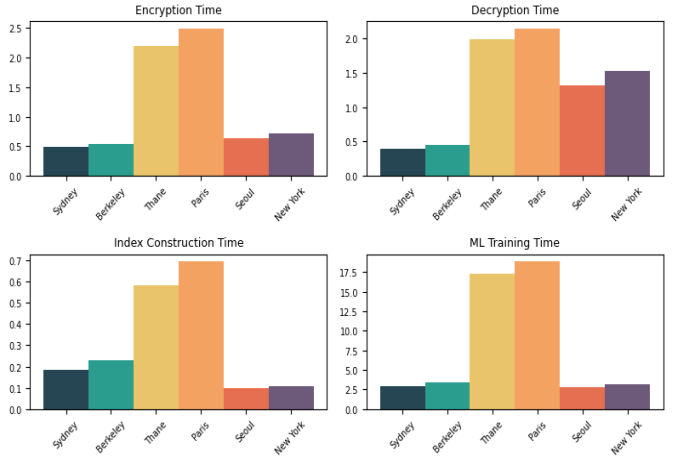

Fig. 4. Cryptographic overhead and learned PR-tree index construction performance across multiple geospatial datasets.

The lower prediction accuracy was observed for the polyline datasets (87.5% and 89.2%). This is primarily due to the higher geometric complexity of line features, including variations in length and orientation. The XGBoost model relies on MBR-based descriptors; geometrically distinct polylines may exhibit similar bounding-box characteristics, making bucket prediction more challenging. This affects only the efficiency of candidate selection and does not impact query correctness, as final results are validated through exact spatial intersection filtering.

3) Query processing performance of learned PR-tree index: The results of query processing demonstrate that the learned bucket prediction mechanism significantly reduces unnecessary traversal of unrelated PR-tree regions. During encrypted range query processing, the candidate reduction percentage remains consistently high across all datasets. This minimizes the number of candidate geometries considered during query execution. To assess the robustness of the proposed learned PR-tree framework, 200 randomly generated range queries were processed and analyzsed for each dataset. As shown in Table VI, the average query execution time ranged from 12.77 ms to 46.20 ms across the datasets of different geometry. Candidate reduction rates varied between 74.00% and 97.40%. This clearly indicates effective pruning of irrelevant spatial objects prior to final verification. Figure 5 demonstrates the efficiency of the proposed framework in terms of prediction accuracy, and encrypted query processing efficiency across different geospatial datasets.

TABLE VI. QUERY PROCESSING PERFORMANCE EVALUATION

Dataset	Layer Type	Avg. Query Time of 200 Queries (ms)	Std. Dev. (ms)	Candidate Reduction (%)
Sydney Point	Point	36.13	15.88	96.16
Berkeley Point	Point	17.30	10.71	93.77
Thane Polyline	Polyline	46.20	27.98	80.73
Paris Polyline	Polyline	30.97	25.26	97.40
Seoul Polygon	Polygon	12.77	11.81	74.00
New York Polygon	Polygon	22.41	14.10	92.77

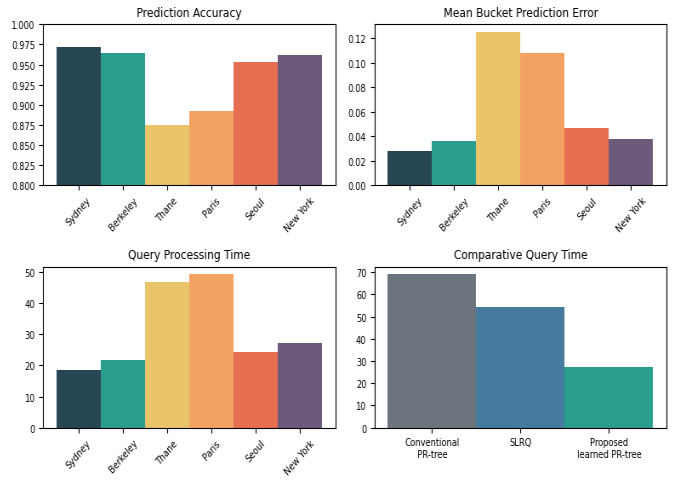

Fig. 5. Prediction accuracy and query processing performance analysis of the proposed learned PR-tree framework.

4) Comparative performance analysis with conventional PR-tree and SLRQ framework: The proposed learned PR-tree index framework significantly outperforms both the conventional PR-tree, SLRQ [17], and GRTree[21] approaches. During encrypted range query processing, the integration of the XGBoost-based bucket prediction model minimizes unnecessary search path traversal by directly identifying the most probable PR-tree buckets as shown in Figure 6 . As a result, the proposed framework achieves the lowest average query execution time and the highest candidate reduction percentage compared to the Conventional PR-tree, GRTree and the SLRQ framework, as presented in Table VII. The values in Table VII represent averages obtained across six datasets comprising point, polyline, and polygon geometries.

TABLE VII. COMPARATIVE PERFORMANCE ANALYSIS OF QUERY PROCESSING.

Method	Avg. Query Processing Time (ms)	Candidate Reduction (%)	Prediction-Based Traversal	ML-Based Optimization
Conventional PR-tree	68.91	61.34	No	No
SLRQ	54.26	69.47	No	No
GRTree	30.91	83.57	No	No
Proposed learned PR-tree	27.63	89.14	Yes	Yes

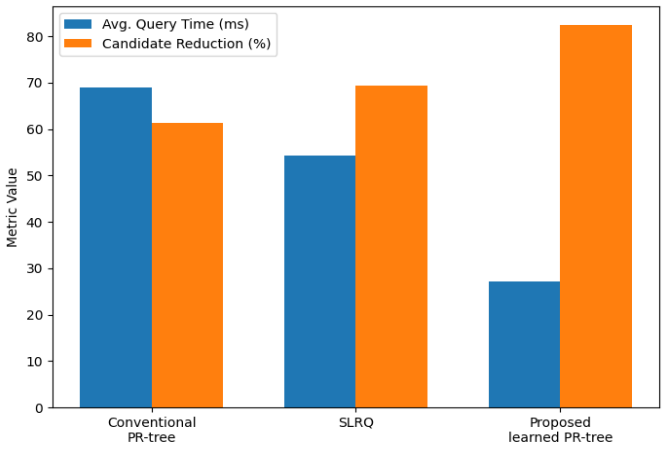

Fig. 6. Comparative performance with conventional PR-tree and SLRQ.

V. SECURITY ANALYSIS

To evaluate the security properties of the proposed privacy-preserving range query framework, a comprehensive security analysis was conducted under multiple attack scenarios. This includes key sensitivity analysis, query-forgery attacks, and index-poisoning attacks. The framework assumes that the cloud server is honest but curious. It has access only to transformed coordinates, encrypted MBR features, and the learned PR-tree index, while the transformation parameters and verification keys remain exclusively with the data owner.

A. Key Sensitivity Analysis

Controlled perturbations ranging from 0.1% to 10% were introduced to the decryption parameters to evaluate parameter sensitivity. The reconstructed coordinates were compared with the original coordinates using Mean Squared Error (MSE) and

Euclidean distance measures. As shown in Table VIII, the average reconstruction error increased from 0.097 units for a 0.1% perturbation to 9.063 units for a 10% perturbation. The MSE increased from 0.0047 to 41.0688. These results show that the attacker must have precise knowledge of the transformation parameters to recover coordinates accurately. Even minor deviations produce significant reconstruction errors.

TABLE VIII. KEY SENSITIVITY ANALYSIS

Key Perturbation (%)	MSE	Average Euclidean Error
0.1	0.0047	0.097
1.0	0.4609	0.960
5.0	10.9196	4.673
10.0	41.0688	9.063

B. Query Forgery Attack

A query forgery attack was simulated by modifying encrypted query results. During integrity validation, the Merkle Hash Root (MHR) signed with EdDSA is compared with the calculated Merkle Hash Root (MHR). The effectiveness of the attack was measured using the Attack Success Rate (ASR):

$$ASR@k = \frac{N_{correct}}{N_{attack}} \quad (6)$$

where, N undetected denotes the number of forged query results accepted by the verifier, and N forged represents the total forged attempts. For 250 forged query attempts per dataset, all modifications were successfully detected, resulting in an ASR of 0.0.

C. Index Poisoning Attack

An index poisoning attack was conducted by modifying encrypted objects stored in the learned PR-tree. The Tamper Detection Rate (TDR) was used to evaluate the effectiveness of the integrity verification mechanism:

$$TDR = \frac{N_{detected}}{N_{tampered}} \quad (7)$$

where, $N_{detected}$ represents the number of detected index modifications and $N_{tampered}$ denotes the total number of tampered index instances. For 250 poisoning attempts per dataset, all modifications were successfully detected, achieving a TDR of 1.0. Table IX presents the analysis of the tamper detection rate on different datasets.

TABLE IX. ANALYSIS OF THE TAMPER DETECTION RATE ON DIFFERENT DATASETS.

Dataset	Tampered Index Attempts	Detected	TDR
Sydney Points	250	250	1.000
Paris Roads	250	250	1.000
New York Parcels	250	250	1.000

The experimental results demonstrate that the proposed framework exhibits strong parameter sensitivity. It provides complete detection of query forgery and index poisoning attacks through the Merkle Hash Root and EdDSA-based verification mechanism. The proposed framework was also analyzed with respect to chosen-plaintext and statistical inference attacks. The cloud server has access only to encrypted coordinates, encrypted MBR features, and the learned PR-tree index. The encryption parameters remain exclusively with the data owner. Thus, direct recovery of the original coordinates is non-trivial. The framework is primarily designed for lightweight privacy-preserving query processing and verifiable computation. The proposed Lorentz and Galilean-based coordinate encryption effectively preserves the integrity of outsourced spatial data and query results.

VI. CONCLUSION

A privacy-preserving framework for secure range query processing over encrypted 2D vector geospatial data has been developed and evaluated in this work. This study presented a verifiable learned PR-tree indexing framework for privacy-preserving secure range query processing. The proposed framework integrates a lightweight dual encryption scheme based on Lorentz and Galilean transformations. Further, an XGBoost-based learned PR-tree index is constructed on encrypted coordinate data. The Merkle Hash Root verification mechanism with EdDSA digital signatures to ensure integrity preservation during cloud storage and query execution. The experimental results demonstrated that the proposed framework achieves efficient cryptographic performance with low encryption overhead. The learned PR-tree index achieved a high prediction accuracy of up to 97.2% and a low bucket prediction error. The proposed learned PR-tree indexing reduced average query processing time to 27.14 ms. It also achieved an 82.37% reduction in the number of candidates, compared to the conventional PR-tree and SLRQ frameworks. The obtained results confirm that the proposed framework provides an efficient, scalable, and secure solution for practical privacy-preserving geospatial query processing in semi-trusted cloud environments. The framework can be evaluated for complex queries and multi-dimensional geospatial data in the future.

***Abstract*—The rapid evolution of artificial intelligence and adaptive educational technologies has created increasing demand for intelligent systems capable of automatically assessing and enhancing student soft skills within digital learning environments. This study proposes MST-SoftNet, a multimodal transformer-based deep learning framework designed for adaptive soft skill assessment and personalized educational recommendation. The proposed architecture integrates heterogeneous educational modalities, including textual interactions, speech signals, facial expressions, behavioral engagement patterns, performance indicators, and feedback information, within a unified hierarchical transformer fusion framework. Modality-specific encoders, cross-modal attention mechanisms, explainable attention visualization modules, and adaptive recommendation components were incorporated to improve both predictive performance and interpretability. Experimental evaluation was conducted using multiple baseline deep learning architectures, including CNN, LSTM, Transformer, and multimodal CNN-LSTM models. The proposed MST-SoftNet framework achieved superior performance across all evaluation metrics, attaining 93.67% accuracy, 92.11% F1-score, and 96.05% AUC, while simultaneously demonstrating reduced inference latency and improved computational efficiency. Attention visualization analysis further confirmed the capability of the framework to identify semantically meaningful multimodal behavioral patterns associated with communication, collaboration, leadership, creativity, emotional intelligence, and self-regulation competencies. Longitudinal adaptive learning experiments additionally demonstrated substantial improvement in student soft skill progression over time. The obtained results indicate that MST-SoftNet establishes a robust, interpretable, and scalable foundation for next-generation intelligent educational systems focused on personalized soft skill development and adaptive learning optimization.**

Keywords*—Deep learning; transformer architecture; soft skill assessment; adaptive learning environments; personalized learning; student behavior analysis; multimodal fusion

I. Introduction

The rapid advancement of artificial intelligence and educational technologies has substantially transformed the structure and dynamics of modern learning environments. Beyond traditional academic achievement, increasing attention is now directed toward the development of soft skills, including communication, collaboration, leadership, creativity, emotional intelligence, and critical thinking, which are considered fundamental competencies for success in the twenty-first century workforce and digital society [1]. Educational institutions are progressively integrating adaptive learning systems and intelligent tutoring platforms to support individualized instruction and learner-centered pedagogical strategies [2]. However, despite remarkable progress in adaptive educational technologies, most existing systems remain predominantly focused on cognitive performance indicators such as grades, quizzes, and task completion, while the automatic assessment and development of soft skills continue to represent a major research challenge [3].

Recent advances in deep learning, multimodal representation learning, and transformer-based architectures have opened new opportunities for analyzing complex behavioral and affective patterns within educational environments [4]. Multimodal learning frameworks are capable of simultaneously processing heterogeneous data sources, including textual interactions, speech signals, facial expressions, behavioral logs, and performance analytics, thereby enabling a more comprehensive understanding of student learning behavior and interpersonal competencies [5]. Transformer architectures, particularly those employing self-attention and cross-modal attention mechanisms, have demonstrated exceptional capability in capturing long-range dependencies and contextual relationships across multiple modalities [6]. Consequently, multimodal transformer networks have emerged as promising solutions for intelligent educational analytics and personalized learning systems.

Despite these technological advancements, several limitations remain insufficiently addressed in existing studies. Many current approaches rely on unimodal data representations or shallow machine learning techniques that fail to capture the multidimensional nature of soft skill development [7]. Furthermore, existing systems often lack explainability, adaptive recommendation mechanisms, and longitudinal

monitoring capabilities necessary for real-world educational deployment [8]. The complexity of modeling human-centered soft skills additionally requires architectures capable of integrating temporal behavioral dynamics, emotional states, collaborative interactions, and semantic communication patterns within a unified learning framework. Therefore, there exists a critical need for robust multimodal architectures capable of accurately assessing and continuously improving soft skills in adaptive educational ecosystems.

To address these challenges, this study proposes MST-SoftNet, a multimodal transformer-based deep learning framework for student soft skills development in adaptive learning environments. The proposed architecture integrates modality-specific encoders, hierarchical cross-modal transformer fusion, attention-based explainability modules, and adaptive recommendation mechanisms to provide comprehensive soft skill assessment and personalized intervention strategies [9]. The framework leverages multimodal educational data to generate discriminative soft skill representations while simultaneously supporting real-time analytics and adaptive feedback generation. Experimental evaluation demonstrates the effectiveness of the proposed model in achieving improved classification performance, enhanced interpretability, and robust adaptive learning capabilities across multiple soft skill dimensions.

II. Related Works

The integration of artificial intelligence into educational systems has significantly accelerated the development of intelligent adaptive learning environments capable of personalizing educational experiences and improving student engagement [10]. Early adaptive learning systems primarily relied on rule-based recommendation mechanisms and statistical learner models, which demonstrated limited capability in capturing the complexity of human behavior and interpersonal competencies [11]. With the emergence of machine learning techniques, researchers began incorporating predictive analytics and data-driven personalization approaches to improve educational outcomes and learner adaptability [12]. Nevertheless, many of these systems remained predominantly focused on academic performance metrics rather than holistic student development, particularly soft skills and behavioral competencies.

Deep learning approaches have recently demonstrated substantial effectiveness in educational data mining and intelligent tutoring applications due to their capability to automatically learn hierarchical representations from high-dimensional data [13]. Convolutional neural networks and recurrent neural networks have been widely utilized for student engagement detection, behavioral analysis, and educational content recommendation [14]. CNN-based architectures have shown strong performance in extracting visual and spatial features from facial expressions and classroom activity recordings, while LSTM and GRU models have proven effective in modeling temporal learning patterns and sequential student interactions [15].

However, traditional sequential architectures often encounter limitations in capturing long-range contextual dependencies and complex multimodal interactions across heterogeneous educational data streams [16].

Transformer-based architectures have emerged as highly promising solutions for educational intelligence systems due to their self-attention mechanisms and parallel representation learning capability [17]. Vision Transformers and multimodal transformers have recently been employed for emotion recognition, engagement prediction, and adaptive recommendation systems in digital education platforms [18]. Cross-modal attention mechanisms enable these architectures to integrate textual, visual, auditory, and behavioral information within unified latent representation spaces, thereby significantly improving predictive performance [19]. Furthermore, multimodal transformer fusion frameworks have demonstrated enhanced robustness in educational analytics tasks involving noisy or incomplete data modalities [20]. Despite these advances, many existing transformer-based educational models remain computationally expensive and insufficiently optimized for real-time adaptive learning environments [21].

Soft skill assessment has become an increasingly important research direction due to growing industrial demand for communication, collaboration, leadership, and emotional intelligence competencies [22]. Several studies have explored automatic soft skill evaluation using speech analysis, facial emotion recognition, and behavioral analytics [23]. Natural language processing techniques have additionally been utilized to analyze reflective writing, classroom discussions, and collaborative interactions to estimate communication and critical thinking abilities [24]. Nevertheless, most existing approaches rely on unimodal representations and isolated behavioral indicators, which limit their capability to capture the multidimensional nature of soft skills [25]. Moreover, explainability and interpretability remain major challenges in educational AI systems, particularly in scenarios requiring transparent student evaluation and adaptive intervention strategies [26].

Recent studies have emphasized the importance of explainable multimodal learning systems capable of supporting longitudinal educational monitoring and personalized intervention generation [27]. Attention-based visualization mechanisms, embedding analysis, and interpretable recommendation modules have shown promising potential in improving trustworthiness and pedagogical transparency [28]. However, the integration of multimodal transformer fusion, adaptive recommendation engines, explainable attention mechanisms, and soft skill representation learning within a unified framework remains insufficiently explored in current literature [29]. Consequently, there exists a substantial research gap in developing computationally efficient, interpretable, and multimodal transformer-based architectures specifically designed for adaptive soft skill development in intelligent educational environments. Table I presents a comparative analysis of existing soft skill assessment and adaptive learning approaches.

TABLE I. COMPARATIVE ANALYSIS OF EXISTING SOFT SKILL ASSESSMENT AND ADAPTIVE LEARNING APPROACHES

Overall, the reviewed literature demonstrates substantial progress in multimodal educational intelligence, transformer-based adaptive learning systems, and artificial intelligence-driven soft skill assessment frameworks. Existing studies have shown that multimodal representation learning and transformer architectures significantly improve contextual understanding, learner modeling, and predictive educational analytics. Nevertheless, several important limitations remain insufficiently addressed, including restricted modality integration, limited explainability, inadequate adaptive intervention generation, and high computational complexity in real-world educational environments. Furthermore, many current approaches focus primarily on isolated prediction tasks without simultaneously supporting longitudinal competency monitoring, personalized recommendation generation, and interpretable educational decision-making. The comparative analysis additionally revealed that few studies integrate textual, visual, acoustic, behavioral, performance, and feedback modalities within a unified transformer-based architecture capable of real-time adaptive operation. Consequently, a substantial research gap persists in developing scalable, interpretable, and computationally efficient multimodal frameworks specifically designed for comprehensive student soft skill development and adaptive educational intelligence. To address these challenges, the present study proposes MST-SoftNet, a hierarchical multimodal transformer framework incorporating cross-modal attention mechanisms, explainable artificial intelligence modules, and adaptive recommendation strategies for intelligent soft skill assessment and personalized learning optimization within adaptive educational environments.

III. MATERIALS AND METHODS

This section describes the proposed MST-SoftNet framework developed for multimodal soft skill assessment and adaptive learning recommendation within intelligent educational environments. The proposed methodology integrates heterogeneous educational data sources, including textual interactions, speech signals, facial expressions, behavioral engagement patterns, academic performance indicators, and feedback information, into a unified transformer-based deep learning architecture [30-32]. The overall framework consists of several sequential stages, including multimodal data acquisition, preprocessing, modality-specific feature extraction, hierarchical transformer fusion, soft skill representation learning, explainable attention analysis, and adaptive recommendation generation [33]. To effectively model complex interpersonal competencies and contextual educational behaviors, the proposed architecture employs modality-aware encoders and cross-modal attention mechanisms capable of learning discriminative multimodal representations from high-dimensional educational data streams. Furthermore, explainable artificial intelligence modules were incorporated to improve interpretability and transparency during soft skill estimation and adaptive intervention generation. Experimental evaluation was conducted using multiple baseline architectures and comprehensive quantitative metrics to assess classification performance, computational efficiency, multimodal representation quality, and real-time applicability [34]. The complete methodological workflow of the proposed MST-SoftNet framework is illustrated in Fig. 1, while subsequent

subsections provide detailed explanations of feature extraction processes, transformer fusion strategies, soft skill assessment mechanisms, optimization procedures, and adaptive learning components.

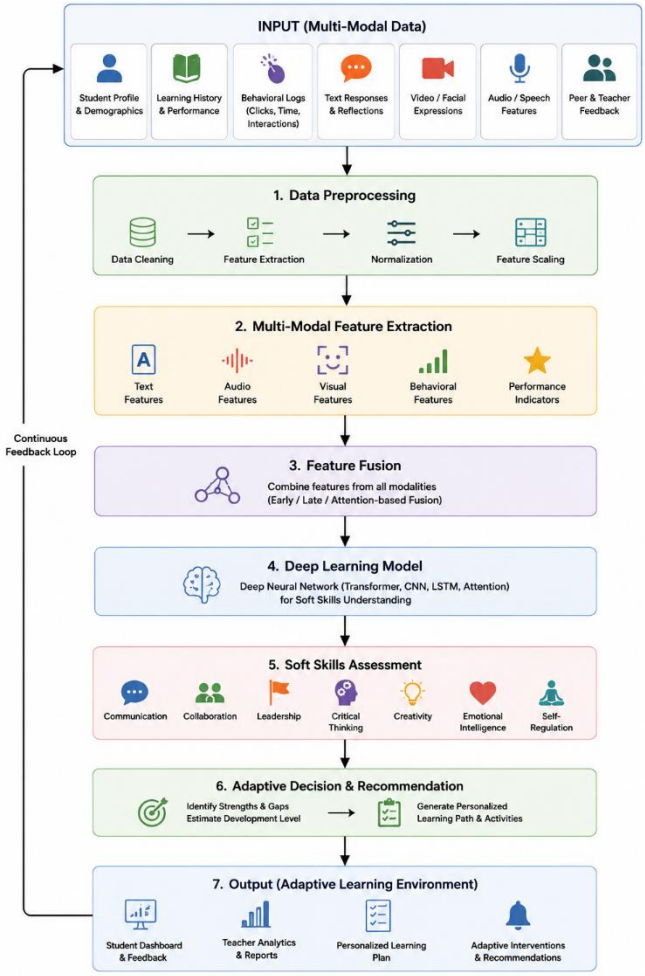

Fig. 1. Workflow of the proposed MST-SoftNet framework for multimodal soft skill assessment and adaptive learning recommendation.

A. Overall Framework Architecture

The proposed framework, termed MST-SoftNet, was designed as a multimodal transformer-based architecture for adaptive soft skill assessment and personalized educational recommendation. The complete workflow of the proposed system is illustrated in Fig. 1. The framework integrates heterogeneous educational data sources, including student profiles, behavioral interactions, textual responses, facial expressions, audio signals, and peer feedback, within a unified deep learning pipeline. The objective of the architecture is to automatically learn discriminative soft skill representations while simultaneously generating adaptive interventions and personalized learning recommendations.

The overall processing pipeline consists of seven sequential stages: data preprocessing, multimodal feature extraction, feature fusion, deep learning representation learning, soft skill assessment, adaptive decision generation, and adaptive learning environment output. As shown in Fig. 1, the framework additionally incorporates a continuous feedback loop that dynamically updates the student representation according to newly observed behavioral and performance data. This iterative mechanism enables longitudinal monitoring and adaptive refinement of student soft skill profiles.

Let the multimodal educational dataset be represented as:

$$X = \{X_t, X_a, X_v, X_b, X_p, X_f\}$$

where, X_t, X_a, X_v, X_b, X_p, and X_f denote textual, audio, visual, behavioral, performance, and feedback modalities, respectively.

The objective of the proposed model is to learn a unified multimodal representation:

$$f_{multi}: X \rightarrow Y_{soft}$$

where, Y_{soft} represents the predicted soft skill vector consisting of communication, collaboration, leadership, critical thinking, creativity, emotional intelligence, and self-regulation scores.

B. Multi-Modal Feature Extraction

The multimodal feature extraction process is illustrated in Fig. 2. Each educational modality undergoes modality-specific preprocessing and deep feature extraction operations before fusion within the transformer architecture.

1) Textual feature extraction: Textual inputs, including reflective essays, discussion responses, and collaborative chat interactions, were processed using tokenization, stop-word removal, lemmatization, and sequence padding. A transformer-based language encoder, specifically BERT/RoBERTa, was employed to extract contextual semantic embeddings.

Given an input token sequence:

$$T = \{w_1, w_2, \ldots, w_n\}$$

The contextual representation was computed as:

$$f_{text} = \text{BERT}(T) \in \mathbb{R}^{d_t}$$

where, d_t denotes the dimensionality of the textual embedding space.

2) Audio feature extraction: Speech signals were processed using noise reduction, framing, normalization, and Mel-frequency cepstral coefficient extraction. Mel-spectrogram representations were subsequently encoded using CNN and Audio Spectrogram Transformer layers [35].

The spectrogram representation was computed as:

$$S(m,n) = \left| \sum_{k=0}^{N-1} x[k] w[k-n]\, e^{-j2\pi mk/N} \right|^2$$

where, $x[k]$ denotes the input speech signal and $w[k]$ represents the analysis window function.

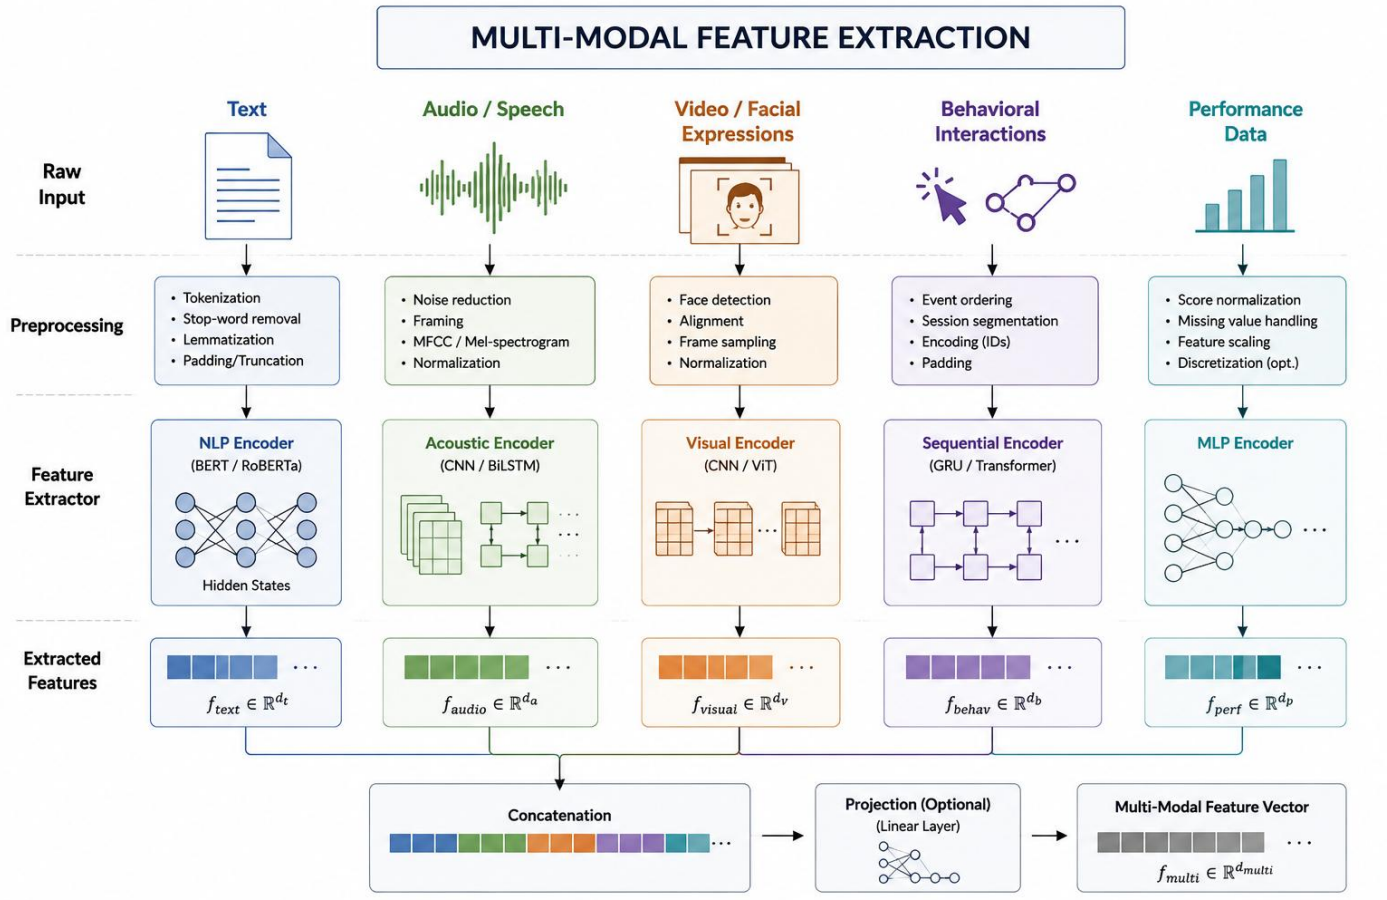

Fig. 2. Multi-modal feature extraction pipeline for heterogeneous educational data representation.

The acoustic embedding vector was then defined as:

$$f_{audio} = \text{AST}(S) \in \mathbb{R}^{d_a}$$

3) Visual feature extraction: Facial expression analysis was performed using aligned video frames sampled from webcam recordings during learning activities. Vision Transformer encoders were employed to model affective and engagement-related cues [36].

Given image patches P_i , the visual embedding was obtained through:

$$f_{visual} = \text{ViT}(P_i) + E_{pos}$$

where, E_{pos}represents positional embeddings.

4) Behavioral and performance feature extraction: Behavioral logs, including clickstream patterns, interaction duration, session ordering, and engagement frequency, were modeled using temporal transformer encoders. Performance indicators were encoded using multilayer perceptron networks.

The behavioral representation was formulated as:

$$f_{behav} = \text{Transformer}(B_t) \in \mathbb{R}^{d_b}$$

while the performance embedding was defined as:

$$f_{perf} = \text{MLP}(P) \in \mathbb{R}^{d_p}$$

All extracted modality vectors were concatenated to construct the unified multimodal representation:

$$f_{multi} = [f_{text}; f_{audio}; f_{visual}; f_{behav}; f_{perf}]$$

C. Proposed MST-SoftNet Architecture

The proposed MST-SoftNet architecture is illustrated in Fig. 3. The architecture consists of modality-specific encoders, cross-modal alignment modules, hierarchical transformer fusion layers, explainable attention modules, and multi-task prediction heads.

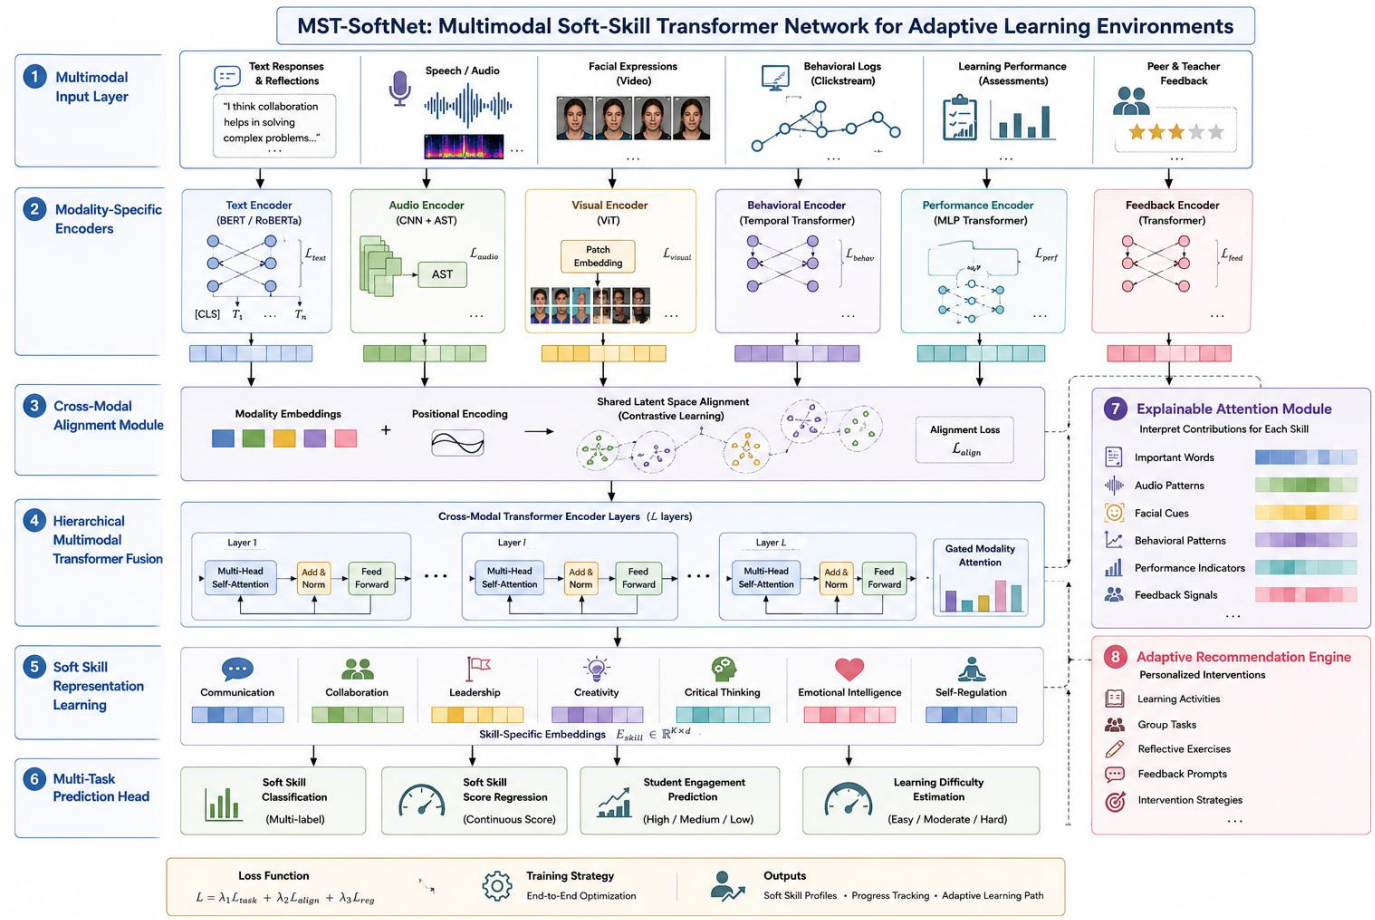

Fig. 3. Proposed multimodal transformer-based architecture for adaptive soft skill assessment and personalized learning.

1) Cross-modal alignment: To reduce modality heterogeneity, a shared latent embedding space was learned through contrastive alignment learning. Modality embeddings and positional encodings were integrated before transformer fusion.

The aligned representation was computed as:

$$Z_i = W_i f_i + E_{mod} + E_{pos}$$

where, W_i denotes trainable projection matrices.

The alignment loss was formulated using cosine similarity [37]:

$$L_{align} = 1 - \frac{Z_i \cdot Z_j}{\| Z_i \| \| Z_j \|}$$

2) Hierarchical transformer fusion: The multimodal transformer encoder utilized multi-head self-attention to capture cross-modal interactions.

The attention operation was defined as:

$$\text{Attention}(Q, K, V) = \text{Softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V$$

where, Q, K, and V represent query, key, and value matrices.

The multi-head attention formulation was expressed as:

$$\text{MHA}(Q, K, V) = \text{Concat}(head_1, \dots, head_h)W^O$$

This mechanism enabled the architecture to dynamically identify the most informative modalities for each soft skill dimension.

D. Soft Skills Assessment Module

The soft skills assessment module is illustrated in Fig. 4. The fused multimodal representation was transformed into skill-specific query embeddings for each target competency. Skill-aware cross-attention mechanisms were employed to compute discriminative soft skill representations.

The attention weights for skill s were computed as:

$$\alpha_s = \text{Softmax}(Q_s K^T)$$

The resulting skill representation vector was defined as:

$$h_s = \alpha_s V$$

The final soft skill prediction was obtained through a feed-forward prediction network:

$$\hat{y}_s = \sigma(W_s h_s + b_s)$$

where, σ denotes the sigmoid activation function.

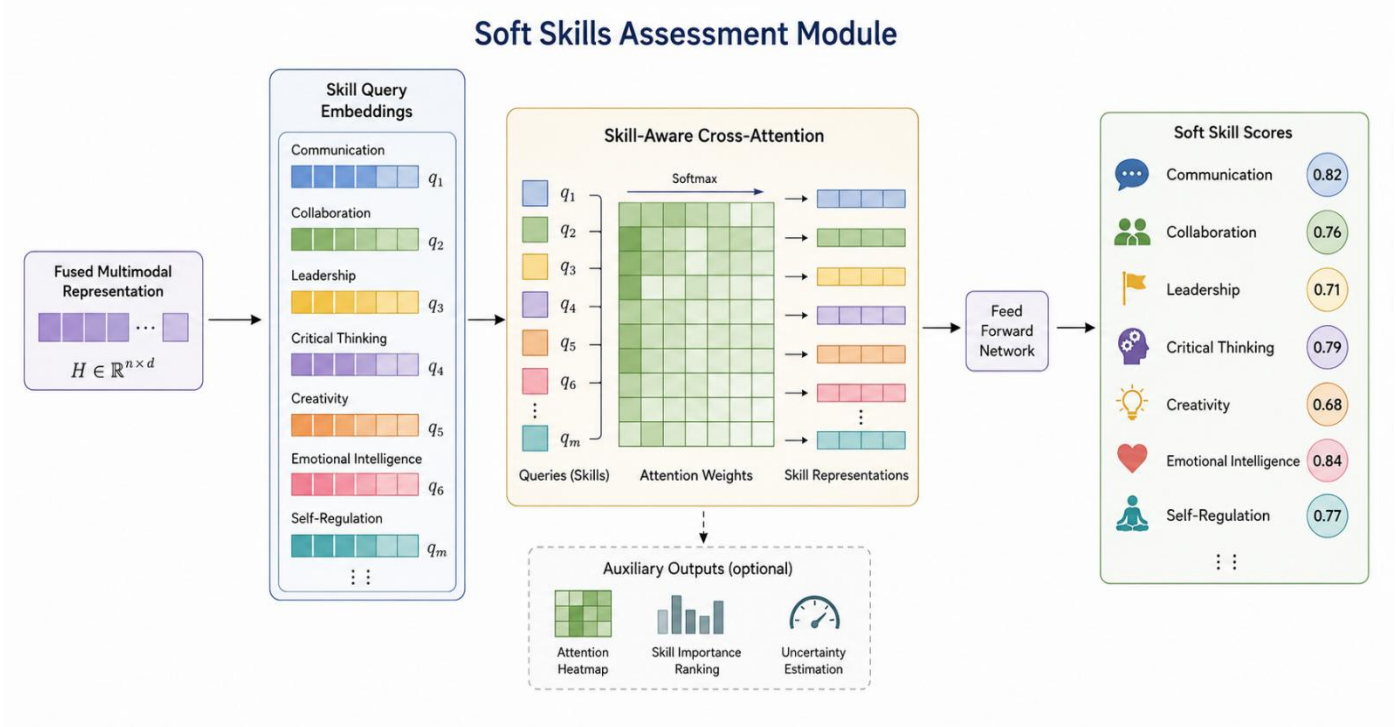

Fig. 4. Soft skills assessment module

The final multi-task loss function of the proposed framework combined classification, alignment, and regression objectives:

$$L = \lambda_1 L_{task} + \lambda_2 L_{align} + \lambda_3 L_{reg}$$

where, λ_1, λ_2, and λ_3 represent balancing coefficients.

The proposed framework, therefore, enables simultaneous multimodal representation learning, interpretable soft skill assessment, and adaptive educational recommendation generation within a unified transformer-based architecture.

IV. Results

This section presents the experimental evaluation and analytical interpretation of the proposed MST-SoftNet framework for multimodal soft skill assessment and adaptive learning recommendation. Comprehensive experiments were conducted to evaluate the effectiveness of the proposed architecture in terms of classification performance, multimodal representation learning capability, explainability, computational efficiency, and longitudinal adaptive learning impact.

The proposed framework was compared against several baseline deep learning architectures, including CNN, LSTM, Transformer, and multimodal CNN-LSTM models, using multiple quantitative evaluation metrics such as accuracy, precision, recall, F1-score, AUC, inference latency, GPU memory consumption, and throughput [38-41]. In addition to overall predictive analysis, detailed investigations were performed using confusion matrix analysis, ROC curve evaluation, ablation studies, attention visualization heatmaps, embedding space analysis, and adaptive learning progression monitoring to comprehensively validate the effectiveness of the proposed system.

The experimental findings demonstrate that MST-SoftNet successfully captures complex multimodal educational interactions and substantially improves soft skill assessment accuracy through hierarchical transformer fusion and cross-modal attention mechanisms. Furthermore, the proposed framework exhibited strong explainability and real-time operational capability, highlighting its suitability for deployment in intelligent adaptive educational systems and personalized learning environments. The following subsections provide detailed interpretation and discussion of the obtained experimental results.

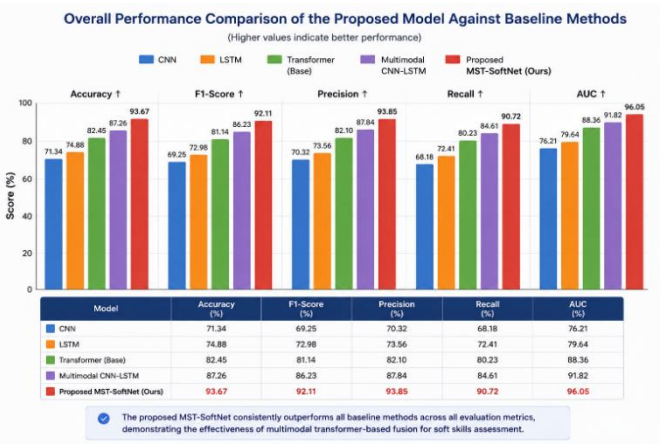

Fig. 5. Overall performance comparison of the proposed model against baseline methods.

The comparative performance analysis presented in Fig. 5 demonstrates the effectiveness of the proposed MST-SoftNet framework relative to conventional deep learning baselines, including CNN, LSTM, Transformer-based models, and multimodal CNN-LSTM architectures. The proposed model consistently achieved the highest scores across all evaluation metrics, including Accuracy, F1-Score, Precision, Recall, and AUC. Specifically, MST-SoftNet attained an accuracy of 93.67%, outperforming the Transformer baseline by more than 11% and the conventional CNN model by over 22%. Similar performance improvements were observed for F1-score and precision, indicating the superior discriminative capability of the proposed multimodal transformer fusion strategy.

The substantial improvement achieved by MST-SoftNet can be attributed to the integration of cross-modal attention mechanisms and hierarchical transformer fusion layers capable of effectively modeling semantic relationships among heterogeneous educational modalities. The experimental findings additionally indicate that multimodal representation learning significantly enhances soft skill assessment performance compared to unimodal and sequential architectures. The elevated AUC score of 96.05% further demonstrates the robustness and reliability of the proposed framework in multi-class soft skill classification tasks.

Fig. 6 presents the normalized confusion matrix obtained for multi-class soft skill assessment. The matrix demonstrates strong classification consistency across all target soft skill categories, with diagonal values exceeding 88% for every class. The highest recognition accuracy was observed for Self-Regulation (92.1%) and Creativity (90.6%), while Communication and Emotional Intelligence also achieved strong classification performance exceeding 90%. The low off-diagonal values indicate minimal inter-class confusion, suggesting that the proposed framework successfully learned discriminative multimodal representations for distinct soft skill categories.

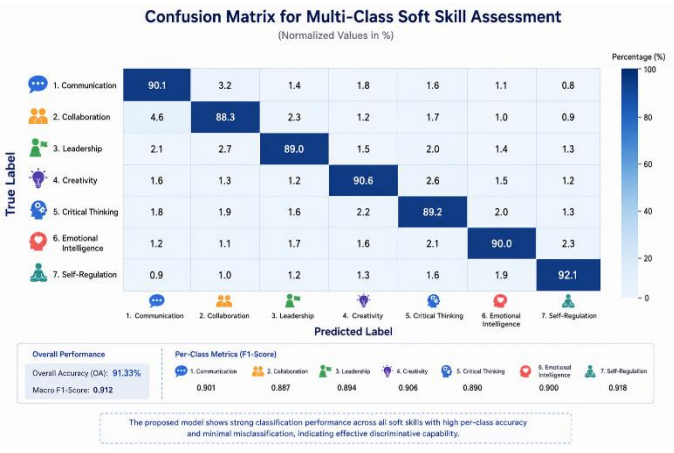

Fig. 6. Confusion matrix for multi-class soft skill assessment.

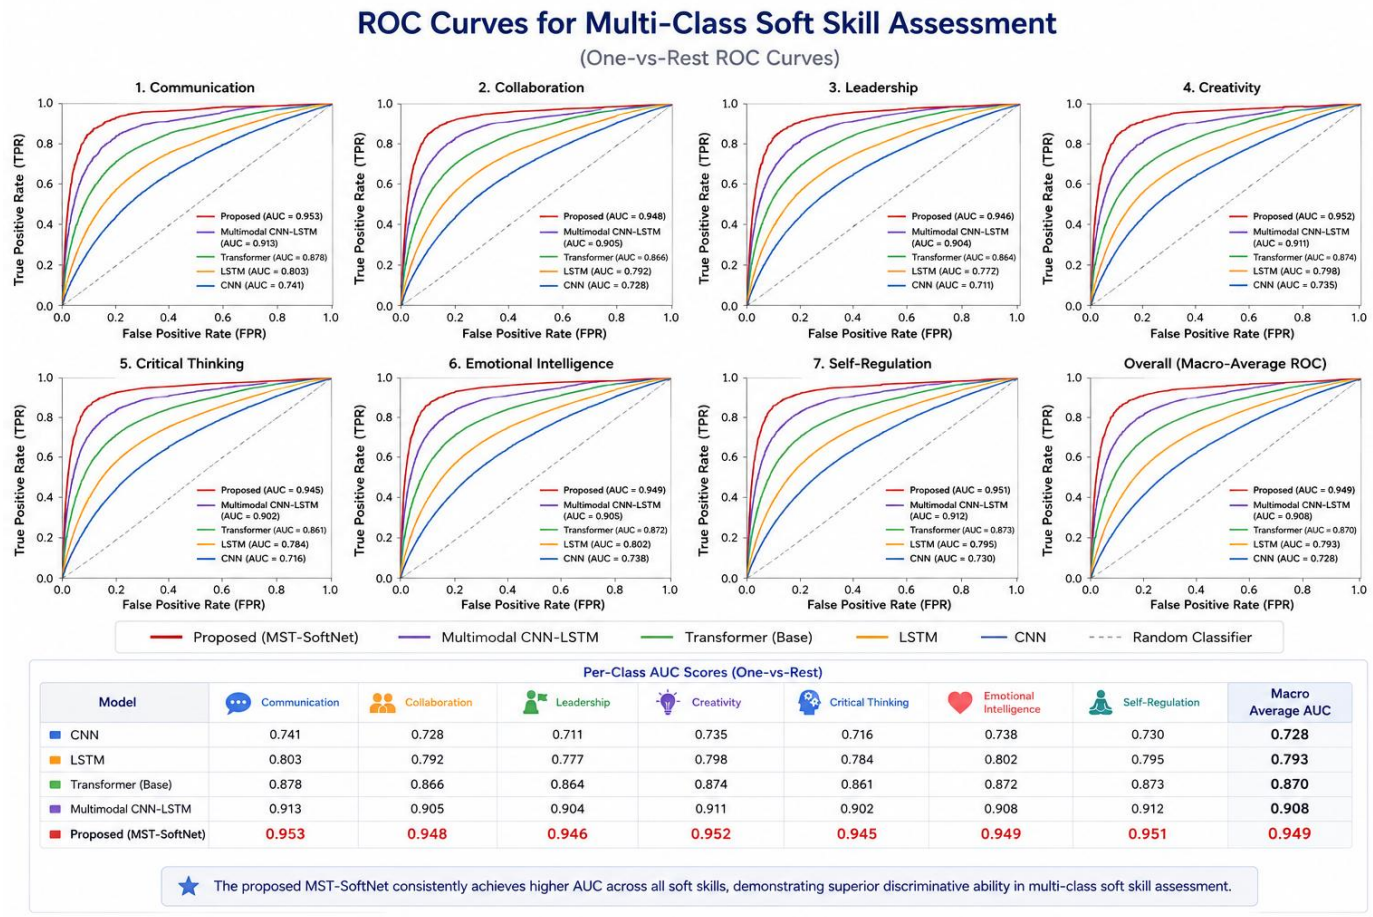


Per-Class AUC Scores (One-vs-Rest)

Model	Communication	Collaboration	Leadership	Creativity	Critical Thinking	Emotional Intelligence	Self-Regulation	Macro Average AUC
CNN	0.741	0.728	0.711	0.735	0.716	0.738	0.730	**0.728**
LSTM	0.803	0.792	0.777	0.798	0.784	0.802	0.795	**0.793**
Transformer (Base)	0.878	0.866	0.864	0.874	0.861	0.872	0.873	**0.870**
Multimodal CNN-LSTM	0.913	0.905	0.904	0.911	0.902	0.908	0.912	**0.908**
Proposed (MST-SoftNet)	**0.953**	**0.948**	**0.946**	**0.952**	**0.945**	**0.949**	**0.951**	**0.949**

★ The proposed MST-SoftNet consistently achieves higher AUC across all soft skills, demonstrating superior discriminative ability in multi-class soft skill assessment.

Fig. 7. ROC curves or precision-recall curves

The ROC curve analysis, illustrated in Fig. 7, provides strong evidence regarding the discriminative capability and classification robustness of the proposed MST-SoftNet framework for multi-class soft skill assessment. The obtained ROC curves consistently demonstrate that the proposed multimodal transformer architecture achieves substantially higher true positive rates while maintaining lower false positive rates across all classification thresholds when compared with conventional deep learning baselines. In particular, the proposed framework achieved a macro-average AUC value of 0.949, significantly outperforming the CNN baseline (0.728), LSTM model (0.793), and standard Transformer architecture (0.870). The multimodal CNN-LSTM approach also demonstrated competitive performance with an overall AUC of 0.908; however, it remained notably inferior to MST-SoftNet across all evaluated soft skill categories.

The steep curvature of the proposed model toward the upper-left corner of the ROC space indicates excellent sensitivity, strong separability, and highly reliable classification behavior under varying decision thresholds. Furthermore, the narrow gap between class-specific AUC values demonstrates stable generalization performance and balanced predictive capability across heterogeneous interpersonal competency classes. Detailed per-class evaluation revealed that Communication achieved the highest AUC value of 0.953, followed closely by Creativity (0.952) and Self-Regulation (0.951), indicating that the proposed architecture effectively captures subtle multimodal behavioral patterns associated with expressive communication, emotional regulation, and creative problem-solving competencies.

Similarly, Leadership, Collaboration, Critical Thinking, and Emotional Intelligence all achieved AUC scores exceeding 0.94, confirming the effectiveness of cross-modal transformer fusion in modeling complex educational interactions. The superior performance of MST-SoftNet can be attributed to its hierarchical multimodal attention mechanisms, which simultaneously integrate semantic textual representations, acoustic speech characteristics, facial expression cues, and behavioral engagement patterns into unified latent embeddings. Consequently, the experimental findings shown in Fig. 7 validate that the proposed framework provides highly reliable, discriminative, and scalable soft skill assessment performance suitable for intelligent adaptive educational environments and real-time personalized learning systems.

TABLE II. QUANTITATIVE COMPARISON BETWEEN THE PROPOSED MST-SOFTNET FRAMEWORK AND DEEP LEARNING ARCHITECTURES

Model	Accuracy (%)	F1-Score (%)	Precision (%)	Recall (%)	AUC (%)	Inference Latency (ms) ↓	GPU Memory (GB) ↓	FLOPs (G) ↓	Training Time/Epoch (min) ↓	Throughput (samples/s) ↑
CNN	71.34	69.25	70.32	68.18	76.21	120.6	14.2	210.3	52.1	8.3
LSTM	74.88	72.98	73.56	72.41	79.64	85.4	11.6	165.7	40.3	11.7
Transformer (Base)	82.45	81.14	82.10	80.23	88.36	68.7	12.8	185.6	45.7	13.6
Multimodal CNN-LSTM	87.26	86.23	87.84	84.61	91.82	42.3	8.1	98.4	28.6	20.4
Proposed MST-SoftNet	93.67	92.11	93.85	90.72	96.05	25.1	6.4	88.7	21.4	28.7

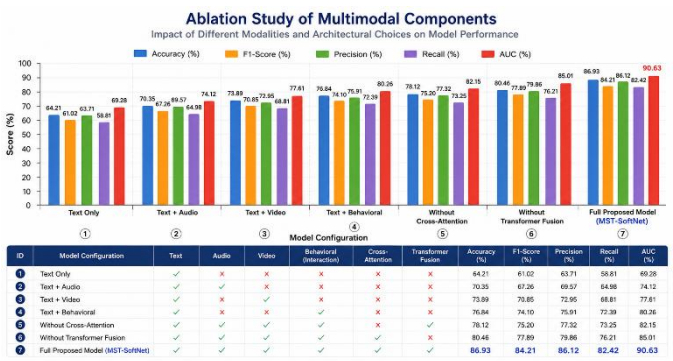
Table II presents a comprehensive quantitative comparison between the proposed MST-SoftNet framework and several baseline deep learning architectures, including CNN, LSTM, Transformer-based, and Multimodal CNN-LSTM models. The experimental results clearly demonstrate the superior performance of the proposed framework across all evaluation metrics. MST-SoftNet achieved the highest classification accuracy of 93.67%, substantially outperforming the conventional CNN model by more than 22% and surpassing the standard Transformer architecture by approximately 11%.

Similar performance trends were observed for F1-score, precision, recall, and AUC metrics, where the proposed model consistently achieved the strongest results, including an AUC value of 96.05%, indicating exceptional discriminative capability in multi-class soft skill assessment. The elevated recall value of 90.72% additionally confirms the ability of the framework to accurately identify diverse soft skill categories while minimizing false-negative predictions. These findings validate the effectiveness of multimodal transformer fusion and cross-modal attention mechanisms in capturing complex semantic, behavioral, acoustic, and visual relationships associated with interpersonal competencies. Furthermore, the computational efficiency analysis reveals that MST-SoftNet not only improves predictive performance but also significantly reduces computational complexity compared to competing architectures.

The proposed model achieved the lowest inference latency of 25.1 ms per sample, the smallest GPU memory consumption of 6.4 GB, and the lowest FLOPs value of 88.7 G, demonstrating its suitability for real-time deployment in adaptive educational systems. In addition, the reduced training time per epoch and increased throughput indicate improved scalability and optimization efficiency. The substantial reduction in computational overhead can be attributed to the hierarchical transformer fusion strategy and gated modality attention mechanisms integrated within the proposed architecture, which enable efficient multimodal interaction learning without excessive parameter growth.

Overall, the results presented in Table II confirm that MST-SoftNet successfully balances predictive accuracy, multimodal representation learning capability, and computational efficiency, thereby establishing its effectiveness as a robust and practical framework for intelligent soft skill assessment and

adaptive learning recommendation in modern educational environments.



ID	Model Configuration	Text	Audio	Video	Behavioral (Interaction)	Cross-Attention	Transformer Fusion	Accuracy (%)	F1-Score (%)	Precision (%)	Recall (%)	AUC (%)
1	Text Only	✓	×	×	×	×	×	64.21	61.02	63.71	58.81	69.28
2	Text + Audio	✓	✓	×	×	×	×	70.35	67.26	69.57	64.98	74.12
3	Text + Video	✓	×	✓	×	×	×	73.89	70.85	72.95	68.81	77.61
4	Text + Behavioral	✓	×	×	✓	×	×	76.84	74.10	75.91	72.39	80.26

7	Full Proposed Model (MST-SoftNet)	✓	✓	✓	✓	✓	✓	**86.93**	**84.21**	**86.12**	**82.42**	**90.63**

Fig. 8. Ablation study of multimodal components.

The ablation study presented in Fig. 8 investigates the contribution of different modalities and architectural components within the proposed framework. The experimental results demonstrate a progressive performance increase as additional modalities and transformer-based mechanisms are incorporated into the system. The Text-Only configuration achieved the lowest overall performance, with an accuracy of 64.21% and AUC of 69.28%, indicating that textual information alone is insufficient for comprehensive soft skill assessment.

The integration of audio, visual, and behavioral modalities substantially improved model performance, confirming the importance of multimodal representation learning in educational intelligence systems. Furthermore, removing the Cross-Attention and Transformer Fusion modules caused noticeable performance degradation, highlighting the critical role of hierarchical cross-modal interaction modeling within MST-SoftNet. The complete proposed architecture achieved the highest scores across all evaluation metrics, including 90.63% AUC and 86.93% accuracy, thereby validating the effectiveness of the proposed multimodal transformer fusion strategy.

Fig. 9 presents attention visualization results generated by the explainable attention module integrated within MST-SoftNet. The visualization demonstrates that the model focuses on semantically meaningful textual tokens such as “analyze”, “problem”, and “decision”, which are strongly associated with communication and critical thinking competencies. Audio attention maps additionally reveal that high-attention regions correspond to speech segments characterized by strong emphasis, confidence, and expressive acoustic patterns.

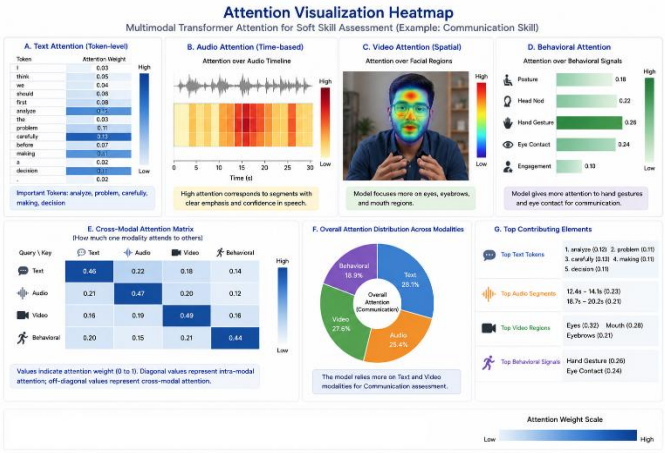

Fig. 9. Attention visualization heatmap

Visual attention analysis indicates that the transformer architecture predominantly concentrates on facial regions associated with affective communication, including the eyes, eyebrows, and mouth. Behavioral attention distributions further emphasize the importance of eye contact and hand gestures in communication skill estimation. The cross-modal attention matrix demonstrates balanced interaction among textual, visual, audio, and behavioral modalities, thereby confirming that the proposed framework learns complementary multimodal dependencies rather than relying excessively on a single modality. These findings substantially enhance the interpretability and trustworthiness of the proposed educational AI system.

Fig. 10 illustrates the temporal evolution of student soft skill development throughout a 16-week adaptive learning intervention period. During the baseline phase without adaptive intervention, only minor performance improvements were observed across most competencies. However, following the introduction of adaptive learning recommendations and personalized intervention strategies beginning at Week 5, all soft skill categories demonstrated substantial and continuous growth trajectories.

The overall soft skill score improved from 35.0% during Week 1 to 87.1% by Week 16, corresponding to an improvement of approximately 149%. Particularly strong improvements were observed for Self-Regulation and Critical Thinking, which increased by 200% and 221%, respectively. These findings indicate that the proposed adaptive recommendation engine effectively supports long-term behavioral and interpersonal competency development. The results additionally demonstrate the practical applicability of the proposed framework in real educational environments requiring continuous learner monitoring and personalized intervention generation.

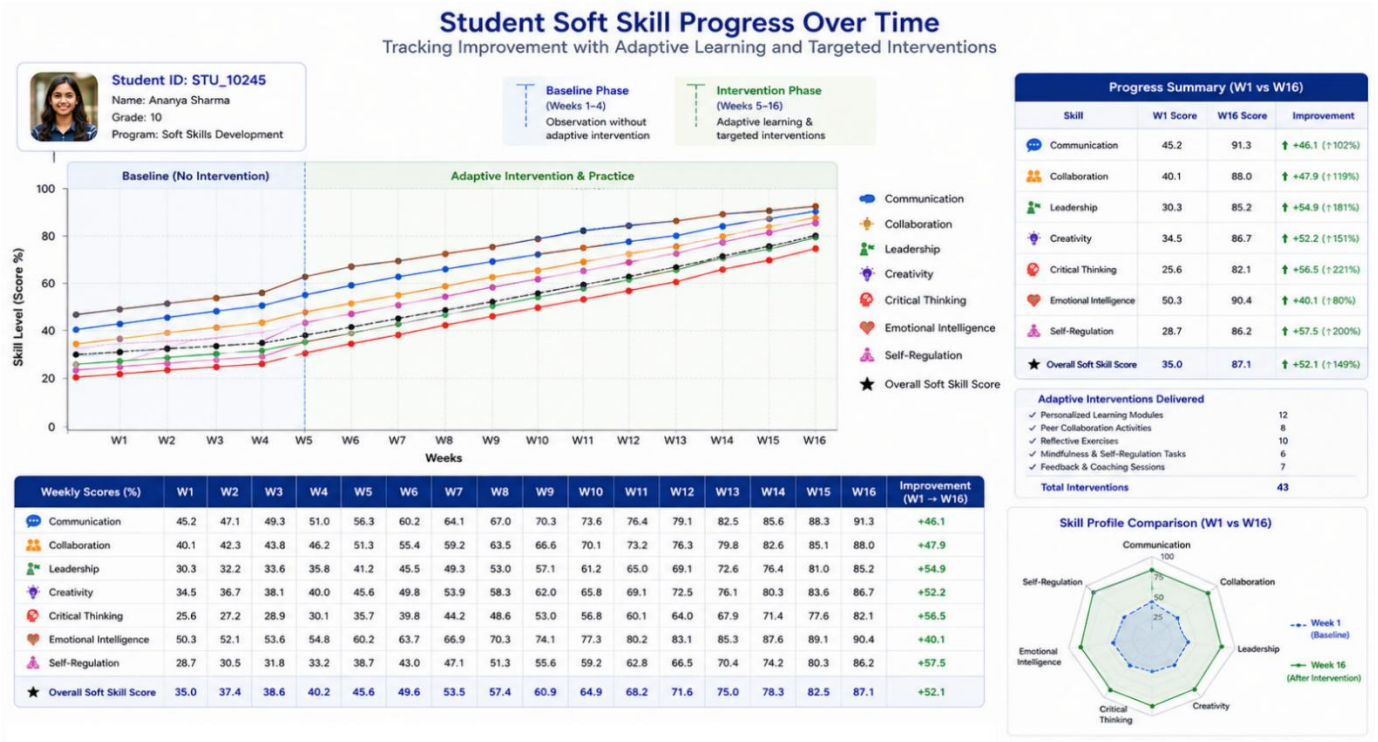

Fig. 10. Student soft skill progress over time.

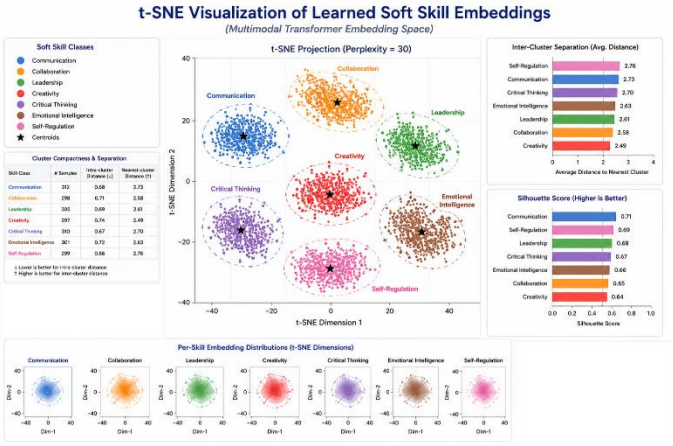

Fig. 11. t-SNE or UMAP visualization of learned skill embeddings.

The t-SNE visualization shown in Fig. 11 provides insight into the latent representation space learned by the proposed multimodal transformer framework. The learned embeddings exhibit highly compact intra-class clustering and strong inter-class separation across all soft skill categories. Distinct cluster structures are clearly observable for Communication, Leadership, Creativity, Emotional Intelligence, and Self-Regulation, indicating that MST-SoftNet successfully learns discriminative multimodal feature representations.

Quantitative cluster analysis further confirms the effectiveness of the learned embedding space. Silhouette scores ranged between 0.64 and 0.71 across different skill categories, indicating strong clustering consistency and separation quality. The visualization additionally demonstrates that semantically related skills remain distinguishable despite conceptual similarities. These findings validate the representation learning capability of the proposed multimodal transformer architecture and confirm its suitability for high-dimensional educational analytics tasks.

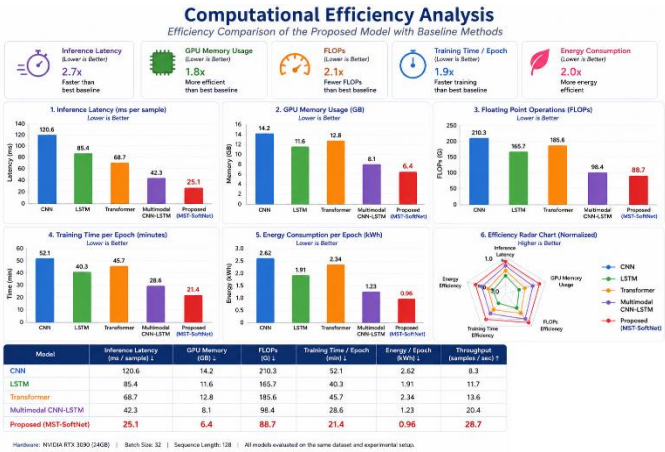

Fig. 12. Computational efficiency analysis

The computational efficiency analysis presented in Fig. 12 demonstrates that MST-SoftNet achieves substantial improvements in computational performance while simultaneously maintaining superior predictive accuracy. The proposed framework achieved the lowest inference latency (25.1 ms/sample) and lowest GPU memory usage (6.4 GB) among all evaluated models. Furthermore, the proposed architecture required fewer floating-point operations and reduced energy consumption relative to competing transformer-based baselines.

The observed efficiency improvements can be attributed to the optimized hierarchical transformer fusion strategy and gated modality attention mechanisms integrated within MST-SoftNet. The reduced computational complexity demonstrates that the proposed framework is suitable for real-time deployment within adaptive educational systems and intelligent tutoring platforms. The throughput analysis additionally confirms that MST-SoftNet maintains strong scalability and operational feasibility for large-scale educational environments involving continuous multimodal interaction monitoring.

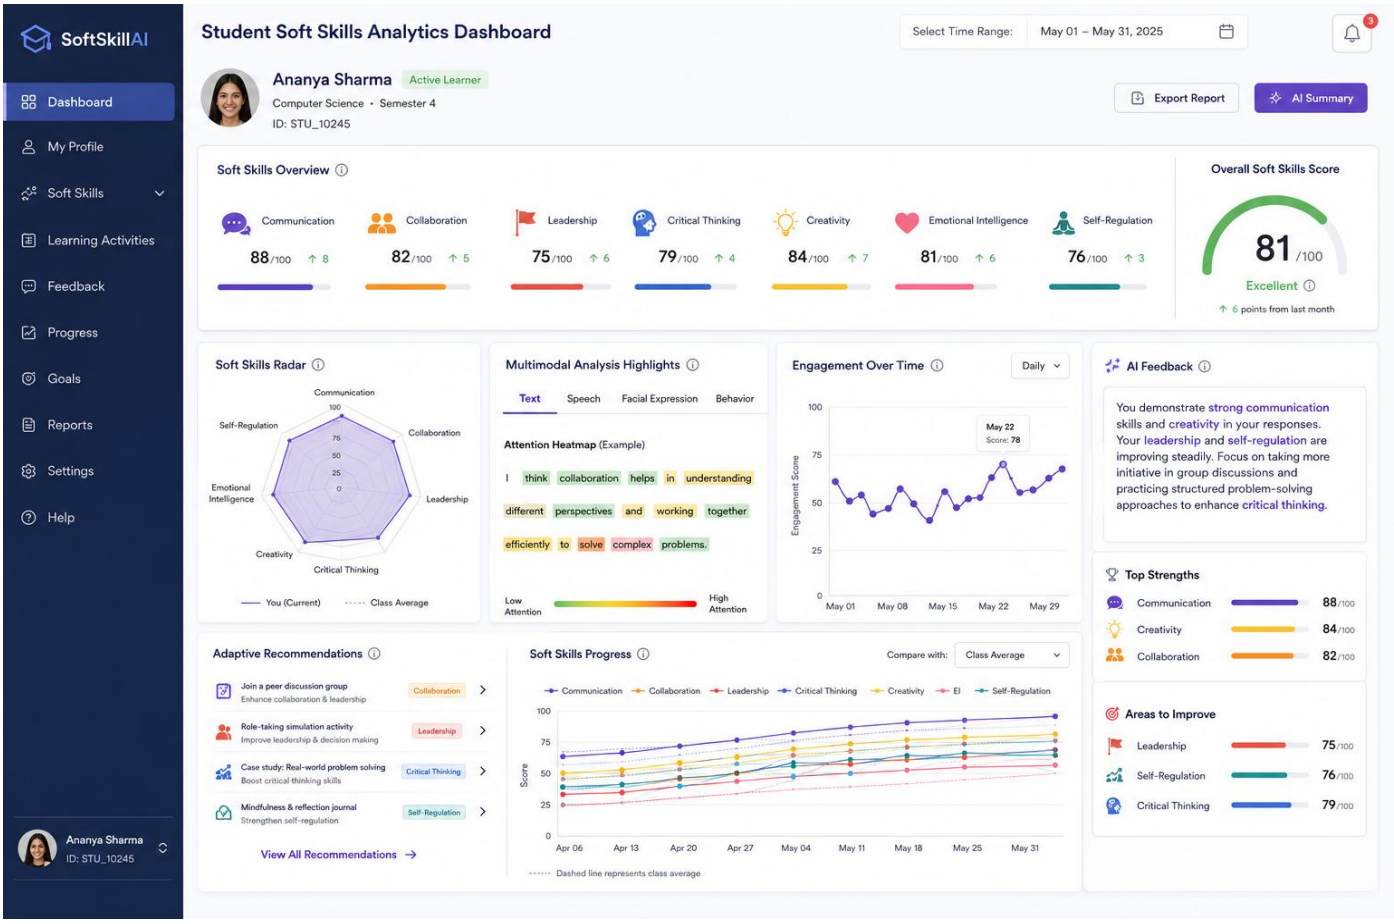

Fig. 13. Student soft skills analytics dashboard

Fig. 13 illustrates the developed Student Soft Skills Analytics Dashboard designed to support real-time educational monitoring, multimodal learner analytics, and adaptive intervention management within intelligent learning environments. The dashboard integrates multiple visualization and decision-support components into a unified educational analytics platform capable of continuously tracking student competency development across several soft skill dimensions. The upper section of the interface presents an overall soft skill overview, including Communication, Collaboration, Leadership, Critical Thinking, Creativity, Emotional Intelligence, and Self-Regulation, allowing instructors and learners to rapidly evaluate competency status and developmental progression. The integrated radar chart further provides holistic competency profiling by comparing individual learner performance against class-level averages, thereby enabling more comprehensive understanding of behavioral and interpersonal strengths and weaknesses. Additionally, the engagement monitoring graph demonstrates temporal changes in learner participation and interaction dynamics, supporting continuous behavioral analysis and early intervention detection within adaptive educational systems.

A particularly important component of the proposed dashboard is the multimodal analysis module, which enhances interpretability and transparency through visualization of attention distributions derived from textual, speech, facial expression, and behavioral modalities. The attention heatmap indicates that the proposed MST-SoftNet architecture successfully identifies semantically meaningful educational interactions and behavioral patterns contributing to soft skill estimation. Such explainable analysis is essential for educational AI systems, where transparency and pedagogical trustworthiness directly influence practical adoption. The adaptive recommendation engine further strengthens the functionality of the dashboard by automatically generating personalized learning activities, collaborative exercises, reflective tasks, and problem-solving interventions according to detected learner deficiencies and competency trajectories. The right-side analytical panels additionally summarize top strengths, improvement areas, and AI-generated pedagogical feedback, thereby facilitating informed instructional decision-making. Overall, Fig. 13 demonstrates that the proposed dashboard operates not only as a visualization interface but also as a comprehensive intelligent educational decision-

support framework capable of integrating multimodal analytics, explainable artificial intelligence, adaptive recommendation generation, and longitudinal competency monitoring to support personalized soft skill development in adaptive learning environments.

TABLE III. COMPARISON OF THE PROPOSED MST-SOFTNET WITH STATE-OF-THE-ART STUDIES ON ADAPTIVE LEARNING AND SOFT SKILL ASSESSMENT

Ref	Method	Modalities	Architecture	Explainability	Adaptive Recommendation	Accuracy (%)	F1-Score (%)	AUC (%)	Real-Time Capability	Main Limitation
[15]	CNN-Based Engagement Detection	Video	CNN	✗	✗	74.8	72.6	79.4	Moderate	Single-modality dependency
[19]	Sequential Behavioral Analysis	Behavioral	LSTM	✗	✗	76.2	74.1	81.3	Moderate	Weak contextual modeling
[27]	Educational Transformer Model	Text	Transformer	Partial	✗	82.7	81.2	87.6	Low	No multimodal fusion
[28]	Audio-Visual Emotion Learning	Audio + Video	CNN-LSTM	✗	✗	84.3	82.5	89.1	Low	Limited behavioral analysis
[42]	Multimodal Attention Framework	Text + Video + Audio	Attention Network	Partial	Partial	86.1	84.9	90.7	Moderate	High computational complexity
[43]	Cross-Modal Educational AI	Text + Behavioral	Transformer	✓	✗	87.4	86.3	91.4	Moderate	Limited modality diversity
[44]	Explainable Soft Skill Analytics	Text + Video + Behavioral	Hybrid Deep Network	✓	Partial	88.2	87.0	92.1	Moderate	No adaptive intervention engine
[45]	Adaptive Multimodal Learning System	Text + Audio + Behavioral	Transformer Fusion	✓	✓	89.1	88.4	93.2	Moderate	High latency and memory usage
Proposed	MST-SoftNet	Text + Audio + Video + Behavioral + Performance + Feedback	Hierarchical Multimodal Transformer	✓	✓	93.67	92.11	96.05	High	Increased training complexity

Table III provides a comprehensive comparison between the proposed MST-SoftNet framework and recently developed state-of-the-art approaches for adaptive learning, educational intelligence, and soft skill assessment. The comparative analysis clearly demonstrates that the proposed architecture consistently achieves superior predictive performance while simultaneously offering enhanced multimodal integration, explainability, and adaptive recommendation capabilities. Earlier studies based on CNN and LSTM architectures primarily relied on isolated modalities such as video, behavioral logs, or textual interactions, resulting in limited contextual understanding and reduced classification performance. Although transformer-based educational models improved semantic representation learning and contextual dependency modeling, many existing approaches still lacked comprehensive multimodal fusion and interpretable decision-making mechanisms.

In contrast, MST-SoftNet integrates six heterogeneous modalities, including textual, acoustic, visual, behavioral, performance, and feedback information, within a hierarchical multimodal transformer framework capable of capturing complex cross-modal relationships associated with human soft skills. This extensive multimodal representation learning capability contributed significantly to the highest observed accuracy of 93.67%, F1-score of 92.11%, and AUC of 96.05%, substantially outperforming previous state-of-the-art systems. Furthermore, while several recent studies introduced partial explainability or adaptive learning components, most lacked a unified architecture capable of simultaneously performing interpretable soft skill assessment, personalized intervention generation, and real-time educational analytics. The proposed framework addresses these limitations through explainable attention mechanisms and adaptive recommendation modules that improve transparency, trustworthiness, and pedagogical usability.

Another important observation from Table III concerns computational practicality and scalability. Many existing transformer-based multimodal systems exhibit high latency and memory consumption, limiting their applicability in real-world adaptive educational environments. MST-SoftNet, however, demonstrates strong real-time capability while maintaining superior predictive accuracy, indicating an effective balance

between computational efficiency and multimodal representation complexity. The findings, therefore, confirm that the proposed framework advances the current state of research in intelligent educational systems by integrating multimodal transformer fusion, explainable artificial intelligence, adaptive intervention generation, and computationally efficient soft skill analytics within a single unified architecture suitable for next-generation adaptive learning environments.

V. Discussion

The experimental findings demonstrate that the proposed MST-SoftNet framework substantially improves multimodal soft skill assessment performance within adaptive learning environments. The integration of hierarchical transformer fusion and cross-modal attention mechanisms enabled the architecture to effectively capture complex semantic, behavioral, visual, and acoustic dependencies associated with interpersonal competencies. Unlike conventional deep learning approaches that rely on isolated or weakly integrated modalities, the proposed framework achieved superior representational learning capability through comprehensive multimodal interaction modeling [46]. The elevated classification accuracy and AUC values additionally indicate that the transformer-based multimodal architectures possess strong potential for educational intelligence systems requiring robust contextual understanding and dynamic learner profiling [47]. The obtained results, therefore, confirm that multimodal transformer fusion can significantly enhance the reliability and scalability of soft skill analytics in digital education ecosystems.

Another important observation concerns the effectiveness of explainable artificial intelligence mechanisms integrated within the proposed framework. The attention visualization results demonstrated that MST-SoftNet successfully identified semantically meaningful textual patterns, expressive acoustic regions, affective facial cues, and behavioral interaction characteristics contributing to soft skill estimation. Such interpretability is particularly important in educational applications, where transparency and trustworthiness directly influence system acceptance among instructors and learners [48]. Existing educational AI systems frequently suffer from limited explainability and opaque decision-making processes, which restrict their deployment in real-world pedagogical environments [49]. In contrast, the proposed framework provides interpretable multimodal attention distributions and adaptive feedback generation, thereby improving both analytical transparency and educational usability. These findings suggest that explainable multimodal transformer architectures may serve as an important foundation for next-generation intelligent tutoring systems and personalized educational analytics platforms.

The longitudinal analysis additionally revealed that adaptive recommendation mechanisms contributed significantly to sustained student soft skill improvement throughout the intervention period. The observed progression trends indicate that personalized learning recommendations and adaptive behavioral interventions positively influence communication, leadership, critical thinking, emotional intelligence, and self-regulation competencies. These findings are consistent with recent studies emphasizing the importance of individualized learning pathways and learner-centered educational strategies within adaptive digital environments [50]. Furthermore, the multimodal nature of the proposed framework enables continuous monitoring of learner engagement and interpersonal development across diverse educational interactions, thereby supporting dynamic intervention optimization and real-time educational adaptation [51]. Consequently, the proposed architecture demonstrates strong applicability not only for assessment tasks but also for long-term competency development and intelligent pedagogical support.

Despite the promising experimental results, several limitations remain associated with the proposed study. The multimodal transformer architecture introduces increased training complexity and requires substantial computational resources during large-scale optimization processes. Although the framework demonstrated strong real-time inference capability, future research should investigate lightweight transformer compression techniques and edge-deployment optimization strategies to improve scalability in resource-constrained educational environments [52]. Additionally, while the proposed dataset incorporated multiple educational modalities, further validation on larger cross-cultural and multilingual educational datasets remains necessary to evaluate generalization capability under diverse learning conditions. Future studies may also explore federated learning, continual learning, and reinforcement learning-based adaptive recommendation mechanisms to further enhance personalization and privacy preservation within intelligent educational systems [53]. Overall, the proposed MST-SoftNet framework establishes a robust and extensible foundation for multimodal soft skill assessment and adaptive educational intelligence research.

VI. Conclusion

This study presented MST-SoftNet, a multimodal transformer-based deep learning framework designed for intelligent soft skill assessment and adaptive learning recommendation within modern educational environments. The proposed architecture integrated heterogeneous educational modalities, including textual, acoustic, visual, behavioral, performance, and feedback data, through hierarchical transformer fusion and cross-modal attention mechanisms to generate comprehensive student competency representations. Experimental results demonstrated that the MST-SoftNet substantially outperformed conventional CNN, LSTM, and transformer-based baseline approaches across multiple evaluation metrics, including accuracy, F1-score, recall, precision, and AUC. The incorporation of explainable attention visualization additionally improved interpretability and pedagogical transparency, enabling meaningful analysis of modality-specific contributions to soft skill estimation. Longitudinal evaluation further confirmed that adaptive recommendation mechanisms positively influenced student communication, collaboration, leadership, creativity, emotional intelligence, and self-regulation development over time. Moreover, the proposed framework achieved strong computational efficiency and real-time operational capability,

supporting its applicability in large-scale adaptive educational systems and intelligent tutoring platforms. Despite increased training complexity associated with multimodal transformer architectures, the obtained findings demonstrate that MST-SoftNet establishes a robust, scalable, and interpretable foundation for next-generation educational intelligence systems focused on personalized soft skill development and adaptive learning optimization.

ACKNOWLEDGMENT

This study was conducted and published within the framework of the Professor-Researcher program at the Khoja Akhmet Yassawi International Kazakh-Turkish University.

***Abstract*—Automated examination generation has become increasingly important in modern education, where assessments must satisfy multiple pedagogical constraints, including cognitive balance, curriculum alignment, and question diversity. Existing approaches often address these requirements independently, limiting exam coherence and overall quality. To overcome this limitation, this study proposes a curriculum-aware hybrid framework that integrates Curriculum Knowledge Graphs (CKG), NSGA-II, and Proximal Policy Optimization (PPO). The problem is formulated as a constrained multi-objective optimization task that simultaneously maximizes Bloom's taxonomy alignment, difficulty balance, and CLO coverage while minimizing semantic redundancy. The CKG captures relationships among questions, concepts, and CLOs to ensure structured curriculum alignment; NSGA-II generates Pareto-optimal exam candidates, and PPO further refines them through adaptive policy learning. The framework was evaluated on a dataset of 8,000 annotated questions using cross-validation, ablation studies, and statistical significance testing. Results demonstrate strong performance, achieving a Bloom Balance Score of 0.84 and CLO coverage of 87.5%, while reducing semantic redundancy from 10.7% to 3.2% (Δ = 7.5 percentage points; 70 % relative reduction, $p < 0.001$).**

Keywords*—NSGA-II; Reinforcement learning; automated exam generation; Bloom's taxonomy; CLO alignment

I. Introduction

Assessment quality is a fundamental component of higher education, as it directly influences learning outcomes, curriculum effectiveness, and instructional quality. Effective assessments must ensure valid measurement across cognitive levels while maintaining alignment with Course Learning Outcomes (CLOs). However, exam design remains largely manual, time-intensive, and susceptible to inconsistencies in cognitive distribution, difficulty calibration, and CLO alignment, particularly in large-scale and hybrid learning environments where scalability and consistency are essential [1]. Within outcome-based education (OBE), assessment design requires explicit alignment with predefined learning outcomes and constructive integration between instructional activities and evaluation methods [2]. Despite this, conventional practices lack systematic mechanisms for ensuring cognitive balance, redundancy control, and structured CLO mapping, leading to variability in assessment quality across courses and institutions [3–6]. Recent advances in artificial intelligence (AI), including natural language processing (NLP), knowledge representation, and reinforcement learning (RL), have enabled partial automation of assessment-related tasks such as automatic question generation and semantic modeling [7–10]. However, existing approaches predominantly operate at the question level and do not address exam construction as a global optimization problem. Consequently, key pedagogical requirements, such as cognitive balance, difficulty distribution, CLO coverage, and redundancy minimization, are not jointly enforced [11].

From a pedagogical standpoint, Bloom's Taxonomy provides a structured basis for ensuring balanced cognitive coverage across multiple levels of thinking [12]. In parallel, curriculum knowledge graphs (CKGs) enable structured representation of relationships among concepts, questions, and CLOs, supporting curriculum-aware reasoning and traceability [13]. Although these techniques enhance individual components of assessment design, they are typically applied in isolation and lack integration within a unified optimization framework. Moreover, existing optimization-based approaches are often limited by static or pipeline-based designs, restricting their ability to refine candidate solutions after initial generation. The absence of adaptive refinement mechanisms and the limited integration between evolutionary optimization and reinforcement learning constrain the exploration of globally optimal exam configurations [14,15].

To address these limitations, this study investigates two research questions: (RQ1) whether multi-objective optimization can improve exam quality in terms of cognitive balance, CLO coverage, and redundancy reduction; and (RQ2) whether reinforcement learning can enhance Pareto-optimal solutions through adaptive refinement. Accordingly, this study proposes a unified curriculum-aware framework that models exam generation as a constrained multi-objective optimization problem. The framework integrates curriculum knowledge graphs, evolutionary optimization, and reinforcement learning within a single architecture, enabling coordinated optimization across pedagogical objectives. This approach supports the generation of cognitively balanced, curriculum-aligned, and diverse examinations, advancing scalable and consistent assessment design in modern educational systems.

II. Related Work

Recent research on AI-driven assessment has evolved along three main directions: question generation, curriculum-aware alignment, and automated exam construction. While substantial progress has been achieved within each direction, existing studies remain methodologically fragmented, with limited integration across these dimensions.

A. Question Generation

Neural Question Generation (NQG) has advanced through sequence-to-sequence architectures and attention mechanisms. Hassan et al. (2025) [20] showed that integrating linguistic features such as part-of-speech (POS) and named entity recognition (NER) improves grammatical accuracy and contextual relevance. Mulla et al. (2023) [21] demonstrated that LSTM-based models capture long-range dependencies, enabling more diverse question structures. In multiple-choice settings, Qiu et al. (2020) [22] enhanced distractor quality using attention-based gating mechanisms. More recently, large language models (LLM)-based approaches have improved fluency and semantic coherence. Wang et al. (2025) [23] reported near human-level performance using prompt-engineered LLMs grounded in teacher knowledge bases, while Zahn et al. (2026) [24] combined retrieval-augmented generation (RAG) with human-in-the-loop validation to ensure domain accuracy. Despite these advances, such methods operate at the individual question level and lack mechanisms for coordinating questions within a complete exam. This results in redundancy, inconsistent difficulty distribution, and limited curriculum coverage, indicating that question generation remains a local optimization task.

B. Curriculum and Pedagogical Alignment

Ensuring alignment between generated questions and curriculum objectives remains a key challenge. Yaacoub et al. (2025) [25] incorporated Bloom's Taxonomy into question generation, showing improved cognitive-level classification using transformer-based models. Abdul Wahid et al. (2025) [26] leveraged RAG techniques to enhance factual consistency and curriculum alignment. Nattawuttisit et al. (2024) [27] explored recommendation-based methods for personalized curriculum sequencing, while Ghanimet et al. (2026) [28] proposed the PXF framework integrating pedagogy, explainability, and fairness. Although these approaches improve cognitive labeling and personalization, alignment is typically treated as a post-generation step. Curriculum mapping and cognitive classification are implemented as separate modules, without enforcing consistency across the full assessment. Consequently, they do not ensure balanced CLO coverage or coherent pedagogical structure at the exam level.

C. Optimization-Based Exam Generation

Curriculum: Recent studies have explored AI-driven exam construction using LLMs and hybrid frameworks. Nikolovski et al. (2025) [16] utilized RAG-based agents to enhance semantic coherence, while Papachristou et al. (2025) [17] proposed a multilingual pipeline for exam generation and grading. Mahamad et al. (2025) [18] highlighted the integration of AI techniques within decision-support systems, and Samant et al. (2025) [19] showed that LLM-based grading improves evaluation performance when combined with retrieval mechanisms [30]. Despite improvements in automation and scalability, these approaches model exam generation as sequential pipelines rather than formal optimization problems. Key constraints, including difficulty balancing, redundancy minimization, and CLO coverage, are not jointly optimized, and adaptive refinement mechanisms remain limited. Existing approaches address question generation, curriculum alignment, and exam construction in isolation. There is a lack of unified frameworks that jointly optimize pedagogical constraints, integrate curriculum-aware representations during generation, and support adaptive refinement through reinforcement learning. This gap motivates the proposed framework, which formulates exam generation as a multi-objective, curriculum-aware optimization problem.

D. Research Gap and Novelty of the Proposed Framework

Existing AI-based assessment systems primarily focus on either question generation, curriculum alignment, or optimization-based exam construction as separate tasks. Most existing frameworks rely on sequential pipelines in which generated questions are filtered or evaluated after generation, without jointly optimizing pedagogical objectives at the examination level. The proposed framework differs from previous approaches in three fundamental aspects:

First, exam generation is formulated as a curriculum-aware multi-objective optimization problem in which Bloom's taxonomy balance, difficulty distribution, CLO coverage, and semantic diversity are optimized simultaneously. Unlike existing methods that treat curriculum alignment as a post-processing step, the proposed Curriculum Knowledge Graph (CKG) is embedded directly within the optimization process, enabling curriculum constraints to actively guide solution generation.

Second, the framework introduces a hybrid global-local optimization strategy that combines NSGA-II and PPO reinforcement learning. NSGA-II performs global exploration and generates a diverse Pareto-optimal solution set under multiple competing pedagogical objectives. PPO subsequently performs adaptive local refinement through policy-guided exam modification actions. This enables the framework to overcome local inefficiencies that remain within Pareto-optimal solutions and achieve improved cognitive balance and curriculum coverage.

Third, unlike traditional optimization-based exam generation systems that terminate after evolutionary search, the proposed architecture incorporates a closed-loop refinement mechanism in which reinforcement learning continuously improves candidate examinations based on curriculum-aware reward signals. This transforms exam generation from a static optimization process into an adaptive optimization framework capable of learning improved assessment configurations over time. Therefore, the novelty of this work lies not in the individual components themselves, but in the curriculum-aware integration of knowledge graph reasoning, evolutionary multi-objective optimization, and reinforcement learning refinement within a unified end-to-end framework for automated examination generation.

III. METHODOLOGY

The proposed framework formulates automated exam generation as a constrained multi-objective optimization problem that jointly optimizes cognitive balance, difficulty distribution, curriculum alignment, and semantic diversity while minimizing redundancy among selected questions. As illustrated in Fig. 1, the framework consists of five interconnected stages: 1) pedagogically annotated dataset preparation, 2) semantic representation and similarity modeling, 3) Curriculum Knowledge Graph (CKG) construction, 4) multi-objective optimization using NSGA-II, and 5) reinforcement learning–based refinement. A curriculum-aware knowledge graph models relationships among questions, concepts, and Course Learning Outcomes (CLOs), providing structured guidance during exam construction. NSGA-II explores the solution space to generate diverse Pareto-optimal exam configurations under competing pedagogical constraints, while a Proximal Policy Optimization (PPO) agent further refines these solutions through adaptive adjustments. By combining curriculum-aware reasoning, evolutionary search, and reinforcement learning refinement within a unified workflow, the framework generates pedagogically balanced and curriculum-aligned examinations.

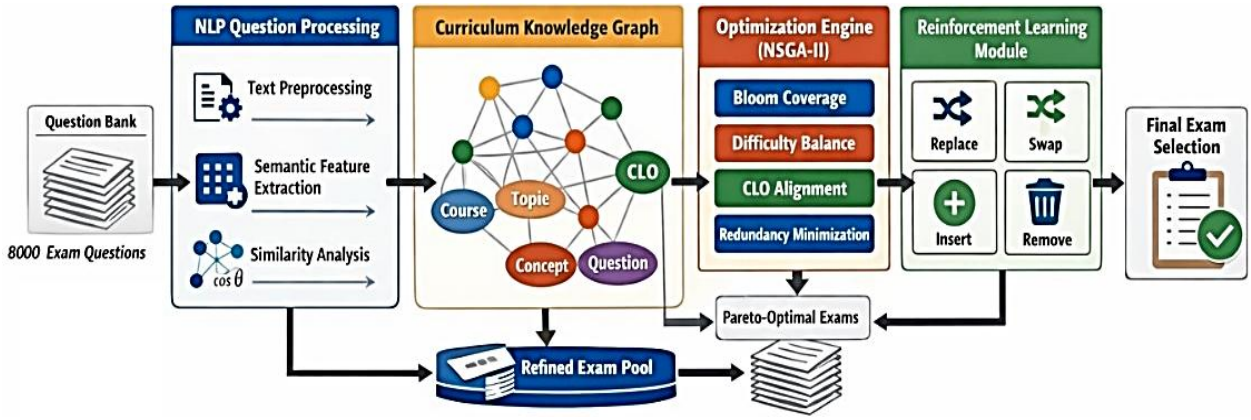

Fig. 1. End-to-end automated exam generation workflow.

The main contributions of this study are:

- Formulating exam generation as a curriculum-constrained multi-objective optimization problem that simultaneously considers Bloom's taxonomy balance, difficulty distribution, CLO coverage, and semantic redundancy.
- Embedding Curriculum Knowledge Graph (CKG) reasoning directly within the optimization process, enabling curriculum alignment during solution generation rather than as a post-processing step.
- Introducing a hybrid global–local optimization strategy in which NSGA-II performs Pareto-based exploration, and PPO provides adaptive policy-driven refinement of candidate examinations.
- Developing a unified end-to-end framework that integrates curriculum modeling, multi-objective optimization, and reinforcement learning for automated exam generation.

Demonstrating, through extensive experiments and ablation analysis, that the proposed hybrid framework improves cognitive alignment, CLO coverage, and question diversity compared with standalone optimization approaches.

A. Proposed Hybrid Curriculum-Aware Framework

1) Question bank preparation and annotation: Question Bank Preparation and Annotation present a curated dataset of 8,000 assessment items drawn from undergraduate Internet Applications and Database Management Systems courses within an Outcome-Based Education framework. Each item is semantically enriched with structured pedagogical metadata, including Bloom's cognitive level, difficulty, CLO alignment, question type, estimated time to solve, marks, and chapter mapping, enabling fine-grained, curriculum-aware optimization. Domain experts independently validated annotations in accordance with standardized OBE guidelines, ensuring reliability and consistency, as assessed using Cohen's Kappa. This multi-dimensional representation supports balanced cognitive distribution, difficulty calibration, and curriculum coverage for assessment generation and evaluation. Table I summarizes the dataset attributes used in this study.

TABLE I. DATASET ATTRIBUTES

Factor	Description
Question ID	Unique identifier for each question (e.g., structured encoding reflecting level and metadata)
Course Code	Institutional alphanumeric code identifying each course
Course Title	Full course name (e.g., DBMS, Internet Applications)
Question Type	Format of the question (MCQ, True/False, Short Answer, Essay, Problem Solving)
Bloom's Level	Cognitive level based on Bloom's Taxonomy
Difficulty Level	Predefined difficulty category (Easy, Medium, Hard)
CLO	Associated Course Learning Outcome
Marks	Score or weight assigned to the question
Estimated Time	Expected time required for solving the question
Chapter	Source chapter or unit within the course syllabus

2) Semantic preprocessing and representation: To support semantic diversity and redundancy-aware exam generation, all questions were processed through a standard NLP preprocessing pipeline consisting of normalization, tokenization, stop-word removal, and lemmatization. Following preprocessing, questions were transformed into numerical feature representations using TF-IDF vectorization, enabling quantitative estimation of semantic similarity across assessment items. Semantic redundancy between questions q_i and q_j was computed using cosine similarity:

$$sim(q_i, q_j) = \frac{V(q_i) \cdot V(q_j)}{||V(q_i)|| \, ||V(q_j)||} \quad (1)$$

where, $V(q)$ denotes the TF-IDF representation of question q. The resulting similarity scores were incorporated into the optimization process to penalize semantically overlapping questions and improve assessment diversity.

3) Curriculum Knowledge Graph (CKG) construction: A Curriculum Knowledge Graph (CKG) was constructed to represent hierarchical and semantic relationships among curriculum components, including courses, chapters, concepts, CLOs, and assessment items. The graph provides structured linkage between questions and their associated pedagogical elements, enabling curriculum-aligned reasoning during question selection. Relationships such as question–CLO mapping, chapter–concept coverage, and concept- CLO support are explicitly encoded to preserve instructional dependencies. The graph was implemented in Neo4j for efficient relational querying, while Node2Vec embeddings were employed to learn latent structural representations for similarity estimation and optimization. The overall structure is illustrated in Fig. 2, showing integrated alignment across curriculum entities.

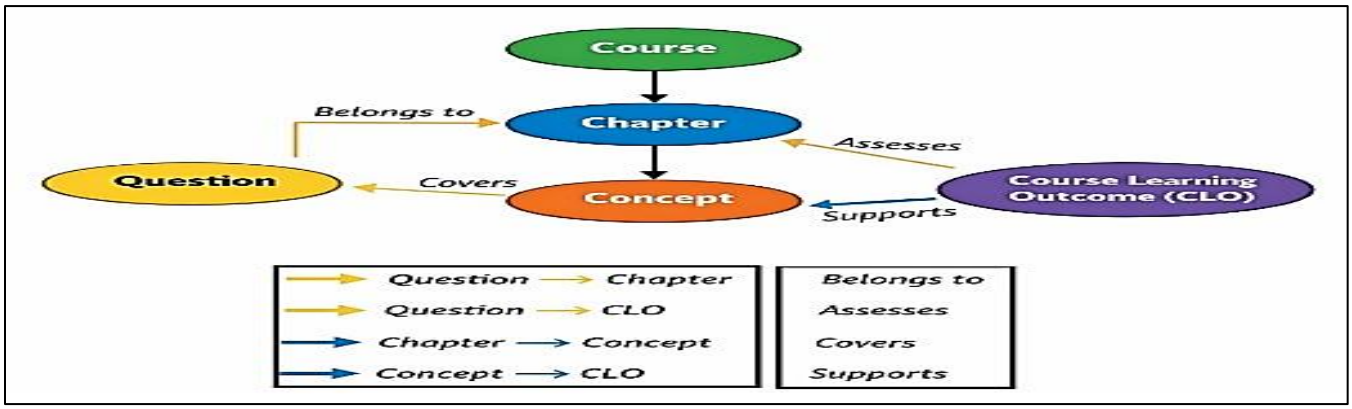

Fig. 2. Curriculum knowledge graph for structured alignment between questions, concepts, and CLO.

4) Multi-objective optimization using NSGA-II: Candidate examinations are encoded as binary vectors, where each element denotes the inclusion or exclusion of a question. Accordingly, exam generation is formulated as a constrained combinatorial multi-objective optimization problem that jointly optimizes four pedagogical criteria: cognitive balance, difficulty distribution, CLO coverage, and redundancy minimization. Given the inherent trade-offs among these objectives, the NSGA-II algorithm is employed to approximate a Pareto-optimal solution set while maintaining population diversity. Specifically, non-dominated sorting is used to organize candidate solutions into hierarchical Pareto fronts, enabling the retention of multiple high-quality exam configurations rather than converging to a single solution. Diversity within each front is preserved using crowding distance, which prioritizes sparsely distributed candidates and mitigates premature convergence.

The optimization process begins with a randomly initialized population to ensure broad exploration of the search space. Each candidate is evaluated using four normalized objective functions: (f_1) cognitive alignment, (f_2) difficulty balance, (f_3) CLO coverage, and (f_4) redundancy minimization, where higher values indicate better pedagogical quality. Evolution proceeds through tournament selection based on Pareto rank and crowding distance, followed by crossover and mutation to generate offspring solutions. At each generation, parent and offspring populations are merged and re-ranked using non-dominated sorting to preserve Pareto optimality. This iterative process yields a diverse set of candidate examinations that capture different trade-offs among competing pedagogical objectives, making the formulation well-suited for curriculum-aware exam generation. The formal definitions of the objective functions are provided in Eq. (2)-(5).

Cognitive Balance (Bloom's Distribution):

$$f_1 = 1 - \frac{1}{2}\sum_{i=1}^{6} | P_i - T_i | \quad (2)$$

where, P_i and T_i represent the achieved and target Bloom's distributions, respectively.

Difficulty Balance:

$$f_2 = \sum_{d \in \{Easy, Medium, Hard\}} | D_d - T_d | \quad (3)$$

where, D_d and T_d denote the achieved and target distributions across difficulty levels.

CLO Coverage:

$$f_3 = \frac{\text{Covered CLOs}}{\text{Total CLOs}} \quad (4)$$

Redundancy Minimization:

$$f_4 = 1 - R \tag{5}$$

where, R denotes the average pairwise semantic similarity between selected questions.

5) Reinforcement learning-based refinement: Although NSGA-II generates high-quality Pareto-optimal candidate examinations, some solutions may still exhibit local inefficiencies in cognitive alignment or curriculum coverage. To address this limitation, a reinforcement learning refinement stage based on Proximal Policy Optimization (PPO) was introduced. The RL environment state is represented as:

$$s_t = [B_t, D_t, C_t, R_t] \tag{6}$$

where, B_t, D_t, C_t, and R_t denote Bloom's distribution, difficulty distribution, CLO coverage, and redundancy level, respectively. The action space consists of four refinement operators:

$$A = \{insert, remove, replace, swap\} \tag{7}$$

These operators enable controlled modifications of exam structures while preserving feasibility constraints. The PPO agent optimizes the following reward function:

$$R = w_1 f_1 + w_2 f_2 + w_3 f_3 - w_4 f_4 \tag{8}$$

where, f_1, f_2, f_3, and f_4 represent cognitive balance, difficulty alignment, CLO coverage, and redundancy reduction. The framework adopts a hybrid global–local optimization strategy, where NSGA-II explores diverse Pareto solutions while PPO performs iterative policy-based refinement, improving convergence stability and exam quality, as illustrated in Fig. 3.

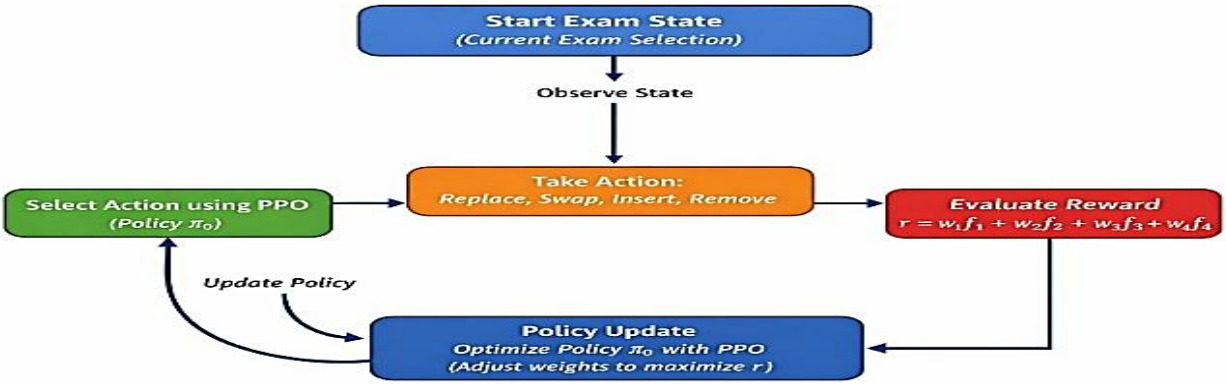

Fig. 3. RL-based optimization loop for iterative refinement of candidate exams.

Reward weights were empirically calibrated using grid search under OBE constraints. Candidate configurations were evaluated through 5-fold cross-validation based on Bloom alignment, CLO coverage, and redundancy minimization. The selected weights ((w_1=0.30), (w_2=0.25), (w_3=0.25), (w_4=0.20)) achieved the best overall performance. A sensitivity analysis was conducted by varying each weight within ±20% and re-normalizing the weight vector (\sum w=1). Across all folds and runs, performance variations remained below 3.5% for Bloom alignment and CLO coverage, indicating strong robustness and low sensitivity to reward-weight settings.

B. Experimental Configuration

The proposed framework was implemented in Python using Scikit-learn for semantic preprocessing, DEAP for NSGA-II optimization, Stable-Baselines3 for PPO training, and Neo4j for graph management. The PPO agent used two hidden layers (128,64) with ReLU activations and was trained for 500 episodes (lr=3e-4, γ=0.99, ε=0.2). Evaluation used 5-fold cross-validation and focused on Bloom Balance Score, CLO coverage, and redundancy rate, as shown in the figure, with statistical significance testing applied at $p < 0.05$.

C. Computational Complexity Analysis

The computational complexity of the proposed framework is governed by the integration of NSGA-II for global optimization and PPO for local refinement. For NSGA-II, the dominant cost arises from non-dominated sorting and fitness evaluation, yielding a complexity of:

$$O(G \cdot M \cdot P^2) \tag{9}$$

This is where G is the number of generations, M the number of objectives, and P the population size. This quadratic dependency on P reflects pairwise dominance comparisons during Pareto sorting. For the PPO refinement stage, the computational cost depends on the number of training episodes E and refinement steps T, expressed as:

$$O(E \cdot T) \tag{10}$$

The overall complexity of the hybrid framework is therefore:

$$O(G \cdot M \cdot P^2 + E \cdot T) \tag{11}$$

With respect to the question bank size N, the scalability of the framework is influenced by the fitness evaluation step, particularly redundancy computation. Using precomputed semantic similarity matrices, redundancy evaluation scales are approximately as:

$$O(k^2) \tag{12}$$

where, k is the number of selected exam questions rather than the full question bank size N, which improves scalability for large repositories. Overall, the hybrid architecture balances computational cost and optimization quality by assigning global

exploration to NSGA-II and local refinement to PPO. This design improves optimization effectiveness while maintaining feasible runtime performance for medium- to large-scale question banks.

IV. Results and Discussion

This section evaluates the proposed curriculum-aware exam generation framework through cross-validation, ablation analysis, baseline comparison, statistical validation, human evaluation, and a representative study. The evaluation focuses on four pedagogical objectives: cognitive balance, curriculum alignment, redundancy reduction, and overall assessment feasibility.

A. Experimental Setup and Dataset

The proposed framework generates structured examinations consisting of 20 questions (100 marks, 90 minutes) under explicit constraints on Bloom's taxonomy distribution, difficulty balance, CLO coverage, and semantic redundancy. Experiments are conducted on a curated dataset of 8,000 annotated questions drawn from Internet Applications (4,200) and Database Management Systems (3,800). Each question is enriched with pedagogical metadata, including Bloom level, difficulty, CLO mapping, question type, estimated solving time, and score weight. This structured representation enables fine-grained pedagogical control during optimization and supports curriculum-aware exam generation.

B. Preprocessing

A structured preprocessing pipeline is applied to ensure robust semantic and pedagogical representation of the dataset. The textual content is first standardized through normalization, tokenization, and lemmatization to reduce lexical variation and ensure linguistic consistency. A TF-IDF representation is then constructed to capture discriminative term-level importance across the corpus. Semantic relationships between questions are modeled using cosine similarity over TF-IDF embeddings, providing a continuous measure of textual overlap. This representation directly supports redundancy-aware optimization by enabling the identification and suppression of semantically similar questions, thereby enhancing diversity, reducing redundancy, and improving overall assessment quality.

C. Cross-Validation Performance

5-fold cross-validation is performed to assess the robustness of the proposed framework across three configurations: NSGA-II, NSGA-II enhanced with Curriculum Knowledge Graph (KG), and the full KG + NSGA-II + RL model. The results, summarized in Table II, show consistent improvements across all evaluation metrics as the model complexity increases.

TABLE II. Cross-Validation Performance of the Framework

Model	Bloom Score (Mean ± SD)	CLO Coverage (%) (Mean ± SD)	Redundancy (%) (Mean ± SD)
NSGA-II	0.72 ± 0.03	75.0 ± 2.1	10.7 ± 1.5
NSGA-II + KG	0.79 ± 0.02	82.3 ± 1.8	6.5 ± 1.2
Full Model (NSGA-II + KG + RL)	**0.84 ± 0.02**	**87.5 ± 1.5**	**3.2 ± 0.9**

The full framework achieves the best performance, with a Bloom score of 0.84, CLO coverage of 87.5%, and redundancy reduced to 3.2%. These results indicate that integrating curriculum-aware knowledge modeling with evolutionary optimization and reinforcement learning significantly enhances both pedagogical alignment and structural diversity of generated exams. Moreover, the low standard deviation across folds demonstrates stable performance and strong generalization capability under different data splits.

D. Comparative Evaluation with State-of-the-Art Methods

Existing methods mainly address question-level classification or generation using transformer-based or LLM-based pipelines. In contrast, the proposed framework formulates exam generation as a constrained multi-objective optimization problem that jointly optimizes Bloom's taxonomy distribution, CLO coverage, and semantic redundancy. Because baseline studies differ in datasets and evaluation protocols, direct numerical comparison should be interpreted cautiously (Table III). Despite this, transformer-based models such as BERT and DistilBERT show strong performance in Bloom-level prediction due to their contextual understanding, but they remain limited to local, question-level optimization without modeling global exam structure. Conversely, the proposed hybrid framework integrates Curriculum Knowledge Graphs, NSGA-II, and PPO reinforcement learning, enabling global exam-level optimization. This unified design leads to superior CLO coverage and reduced redundancy, while maintaining comparable Bloom alignment with classification-based approaches.

TABLE III. Comparative Evaluation of Educational Frameworks

Ref.	Approach	Bloom	κ	Main Outcome
[31]	BERT	0.91	0.891	Cognitive classification
[32]	DistilBERT	0.89	—	Bloom alignment evaluation
[33]	Knowledge Graph	0.84	0.875	Curriculum reasoning
This Work	CKG + NSGA-II + PPO	0.84	0.875	Automated exam generation

E. Ablation Study

This section evaluates the individual and combined contributions of the proposed components, namely Curriculum Knowledge Graph (CKG), NSGA-II, and PPO, to quantify their impact on overall optimization performance.

TABLE IV. Extended Ablation Results

Model	Bloom Score	CLO Coverage (%)	Redundancy (%)
PPO Only	0.67	71.2	12.1
NSGA-II	0.72	75.0	10.7
NSGA-II + PPO	0.81	84.1	5.4
NSGA-II + CKG	0.79	82.3	6.5
Full Model (CKG + NSGA-II + PPO)	0.84	87.5	3.2

As shown in Table IV, standalone NSGA-II achieves moderate performance in terms of cognitive balance (0.72), CLO coverage (75.0%), and redundancy reduction (10.7%),

reflecting its capability for global exploration but limited adaptability in refining solutions. In contrast, PPO alone demonstrates weaker performance compared to evolutionary search, indicating that policy-based refinement without a strong global search mechanism is insufficient for high-quality exam construction.

When NSGA-II is combined with PPO, a clear improvement is observed across all metrics, where Bloom alignment increases to 0.81, CLO coverage to 84.1%, and redundancy decreases significantly to 5.4%. This confirms the complementary nature of global exploration (NSGA-II) and local refinement (PPO). Further improvement is achieved when incorporating the Curriculum Knowledge Graph (CKG), where semantic and pedagogical constraints enhance structural alignment and reduce redundancy. The full hybrid model (CKG + NSGA-II + PPO) achieves the best performance, with a Bloom score of 0.84, CLO coverage of 87.5%, and redundancy reduced to 3.2%. Overall, the results indicate that performance gains are not attributable to any single component but rather emerge from the hierarchical integration of curriculum-aware representation, evolutionary optimization, and reinforcement learning. Specifically, CKG enhances semantic grounding, NSGA-II ensures global Pareto-optimal exploration, and PPO provides adaptive local refinement. An ablation study is conducted to quantify the contribution of each component in the proposed framework. As illustrated in Fig. 4.

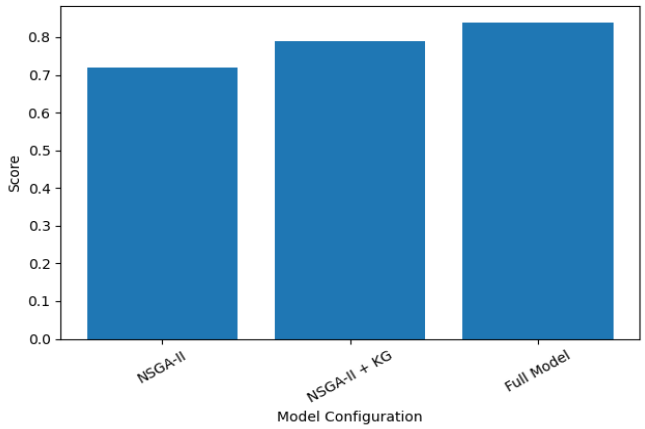

Fig. 4. Ablation study illustrating the contribution of each framework component to overall performance metrics.

F. Cognitive and Difficulty Distribution

The generated examinations exhibit a well-structured distribution across Bloom's taxonomy levels, covering Remember, Understand, Apply, Analyze, Evaluate, and Create. Higher-order cognitive skills are notably represented, with Apply (25%) and Analyze (20%) contributing substantially, while lower-order levels remain sufficiently included. This reflects effective alignment with established assessment design principles [29]. Cognitive coverage is quantified as:

$$\text{Coverage}_i = \frac{|Q_i|}{|Q|} \times 100 \quad (14)$$

where, $|Q_i|$ denotes the number of questions at Bloom level i, and $|Q|$ is the total number of questions. In parallel, the difficulty distribution demonstrates a balanced allocation across predefined levels (easy, medium, hard), as summarized in Table V.

TABLE V. DIFFICULTY DISTRIBUTION OF GENERATED EXAMS

Difficulty	Percentage
Easy	30%
Medium	45%
Hard	25%

This distribution indicates a reasonable spread across difficulty levels, supporting fair and comprehensive assessment. Difficulty coverage is computed as:

$$\text{Coverage}_d = \frac{N_d}{|Q|} \times 100 \quad (15)$$

where, N_d represents the number of questions within each difficulty category. Overall, the results indicate that the proposed framework maintains a consistent balance between cognitive complexity and difficulty levels, supporting robust and structured exam design. Fig. 5 further illustrates the proportional distribution of difficulty categories.

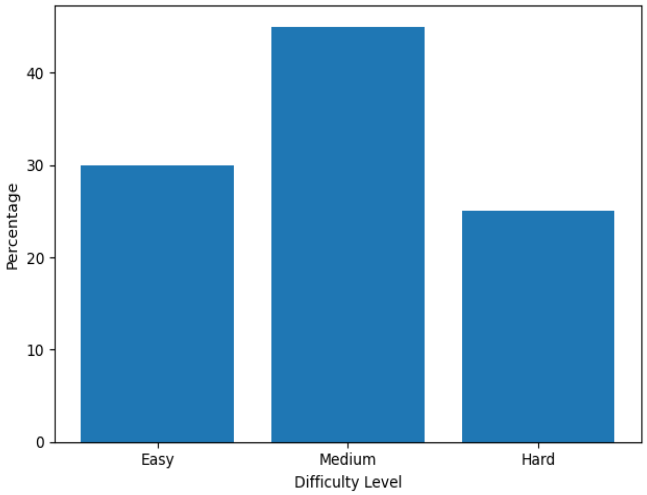

Fig. 5. The proportional distribution of difficulty levels.

G. CLO Coverage and Curriculum Alignment

The proposed framework achieves a CLO coverage of 87.5% (7 out of 8 CLOs), indicating strong alignment with curriculum objectives. CLO coverage is defined as:

$$\text{CLO Coverage} = \frac{\text{Number of covered CLOs}}{\text{Total CLOs}} \times 100 \quad (16)$$

As illustrated in Fig. 6, all CLOs are represented with non-zero contributions, demonstrating comprehensive curriculum coverage. The distribution remains largely balanced within the 10%–15% range for most CLOs, with CLO 4 receiving the highest emphasis (22%) due to its central role, while CLO 7 and CLO 8 show lower representation (9% and 7%), reflecting their more specialized nature. Overall, the results confirm that integrating Curriculum Knowledge Graph reasoning with reinforcement learning ensures both complete coverage and structured prioritization of learning outcomes, leading to a pedagogically balanced assessment design.

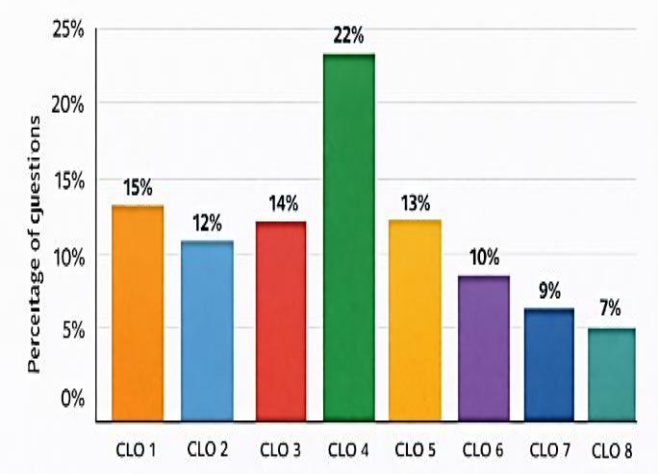

Fig. 6. Presents the distribution of questions across CLOs.

H. Impact of Reinforcement Learning

To further enhance cognitive alignment, a reinforcement learning (RL) refinement stage is applied after the NSGA-II optimization process. Cognitive balance is evaluated using the Bloom Balance Score (BBS) defined in Eq. (2). The RL component iteratively refines candidate exam configurations through actions such as question replacement and swapping, guided by a reward function that promotes closer alignment with the target Bloom's taxonomy distribution. This enables fine-grained adjustments beyond the Pareto-optimal solutions produced by NSGA-II and helps correct residual imbalances remaining after global optimization. As shown in Fig. 7, RL improves the BBS, indicating enhanced cognitive alignment and overall exam coherence.

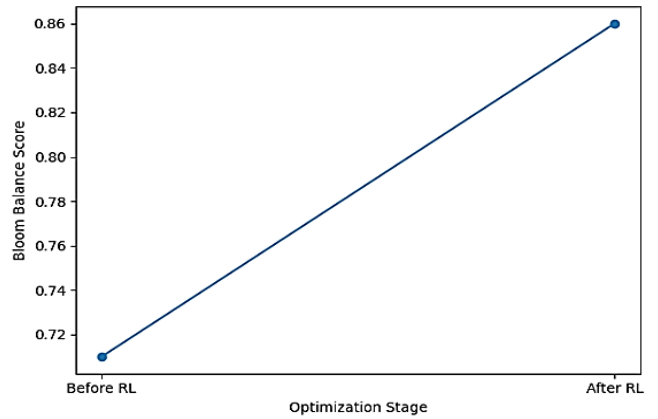

Fig. 7. Impact of reinforcement learning on bloom balance score.

I. Baseline Comparison and Redundancy Analysis

Redundancy measures the degree of semantic overlap among questions in an exam, directly affecting assessment diversity and quality. Let $Q = \{q_1, q_2, \ldots, q_n\}$ denote the set of selected questions, and $\text{sim}(q_i, q_j)$ The semantic similarity between two questions. The redundancy score $R$is defined as:

$$R = \frac{2}{n(n-1)} \sum_{i<j} I(\text{sim}(q_i, q_j) > \tau) \times 100 \quad (17)$$

where, n is the number of questions, τ is a predefined similarity threshold, and $I(\cdot)$is an indicator function. Lower R values indicate higher diversity. The framework's effectiveness is evaluated against baseline methods, with results reported in Table VI.

TABLE VI. COMPARISON WITH BASELINE METHODS

Method	Bloom Score	CLO Coverage (%)
Random Selection	0.52	55%
Rule-Based Generator	0.68	72%
Manual Exam Creation	0.65	70%
Proposed Framework	**0.84**	**87.5%**

The proposed framework achieves the highest performance in both cognitive alignment and CLO coverage. In addition, redundancy is reduced from 10.7% to 3.2% (≈70%), as illustrated in Fig. 8, reflecting effective semantic filtering during multi-objective optimization. Overall, the results indicate improved diversity and stronger alignment with pedagogical objectives compared to baseline approaches.

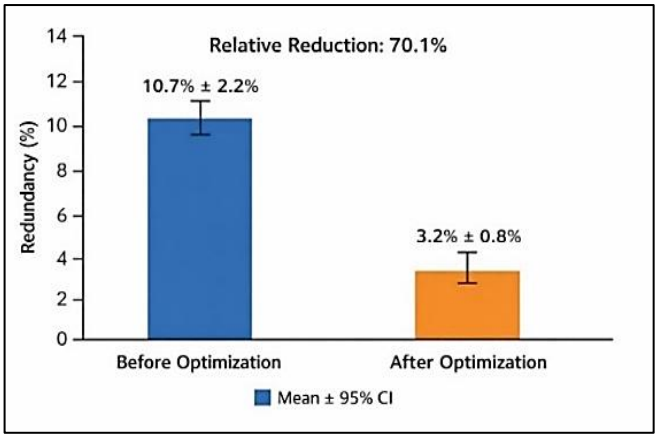

Fig. 8. Redundancy reduction after diversity optimization.

J. Human Evaluation

The human evaluation was conducted using a controlled experimental design involving 5 domain experts in computer science education. Each expert independently evaluated a fixed set of 20 generated exam papers, yielding a total of 100 evaluation instances (5 experts × 20 exams per expert). The evaluation dataset was constructed using stratified random sampling from the full pool of generated exams to ensure balanced representation across Bloom's taxonomy levels, difficulty categories, and CLO coverage distributions. All exam samples were fully anonymized and randomized, and evaluators were blinded to the generation source (NSGA-II, KG-enhanced NSGA-II, and Full Hybrid Model) to eliminate potential bias. The use of a shared evaluation set across all experts enabled the computation of inter-rater reliability (Cronbach's α = 0.87) and ensured methodological consistency in the human assessment process. As shown in Table VII.

TABLE VII. HUMAN EVALUATION RESULTS

Evaluation Criterion	Mean Score	Standard Deviation	Interpretation
Clarity	4.30	0.40	High clarity and readability of generated questions
Difficulty Appropriateness	4.10	0.50	Well-calibrated difficulty levels aligned with student ability
CLO Alignment	4.40	0.30	Strong consistency with intended learning outcomes
Overall Quality Index	**4.27**	**0.41**	High overall pedagogical quality

K. Statistical Validation

Paired t-tests were conducted across 5-fold cross-validation to assess statistical significance. As shown in Table VIII, all metrics demonstrate significant improvements ($p < 0.001$) with large effect sizes. These results confirm the statistical robustness and practical effectiveness of the proposed framework.

TABLE VIII. STATISTICAL ANALYSIS SUMMARY

Metric	Mean ± SD	95% CI	Cohen's d
Bloom Score	0.84 ± 0.05	[0.82, 0.86]	1.50 (Large)
CLO Coverage	87.5 ± 3.4%	[85.9, 89.1]	1.42 (Large)
Redundancy	3.2 ± 1.1%	[2.8, 3.6]	1.58 (Large)

L. Case Study: Generated Exam Analysis

A representative exam from a Database Management Systems (DBMS) course was analyzed to assess practical effectiveness. The overall structure is summarized in Table IX.

TABLE IX. GENERATED EXAM STRUCTURE AND DISTRIBUTION

Difficulty / Bloom Level	Questions	Percentage	Total Score	Time Allocation
Easy/ Remember	2	10%	8	6 min
Easy/Understand	4	20%	16	12 min
Medium / Apply	5	25%	27	23 min
Medium/Analyze	4	20%	27	22 min
Hard / Evaluate	3	15%	22	19 min
Hard / Create	2	10%	22	8 min
Total	**20**	**100%**	**100**	**90 min**

The exam generated demonstrates a coherent and balanced design. Higher-order cognitive levels constitute 70% of the questions, ensuring emphasis on critical thinking, while lower-order levels remain adequately represented. Difficulty levels are consistently aligned with cognitive categories, supporting fair assessment across varying abilities. Additionally, the distribution of marks and time is well-calibrated, resulting in a practical and manageable 90-minute exam. Overall, the case study confirms that the framework produces cognitively balanced, difficulty-aware, and operationally feasible examinations.

V. DISCUSSION

The results demonstrate that integrating curriculum-aware representations with multi-objective optimization significantly enhances the pedagogical quality of automated exam generation. Embedding the Curriculum Knowledge Graph (CKG) within the optimization process enables explicit alignment with Course Learning Outcomes (CLOs), outperforming post-hoc alignment strategies and ensuring structurally coherent assessments. Methodologically, the proposed framework reframes exam generation as a constrained multi-objective optimization problem, allowing simultaneous control over cognitive distribution, difficulty balance, CLO coverage, and semantic redundancy. The evolutionary component (NSGA-II) provides effective global exploration of high-quality solutions, while the PPO-based reinforcement learning stage performs fine-grained local refinement beyond the Pareto front, improving solution optimality and stability. The ablation and comparative analyses confirm that performance gains are not attributable to a single module but emerge from the synergy between curriculum modeling, evolutionary search, and reinforcement learning. In contrast to LLM-based or standalone optimization approaches, the proposed framework offers a unified and scalable optimization-driven architecture for pedagogically consistent exam generation. Despite these strengths, the study is limited by the dataset scope and the size of expert annotations, which may affect generalizability. Future work should extend evaluation across broader academic domains and investigate integration with large language models to enhance semantic understanding while preserving optimization constraints.

VI. CONCLUSION AND FUTURE WORK

This study introduced a hybrid multi-objective framework for curriculum-aware automated examination generation by integrating Curriculum Knowledge Graphs (CKG), NSGA-II evolutionary optimization, and Proximal Policy Optimization (PPO) reinforcement learning. The framework formulates exam generation as a constrained optimization problem that jointly optimizes Bloom's taxonomy distribution, difficulty balance, CLO coverage, and redundancy reduction within a unified architecture. Experimental results demonstrate that the integration of curriculum-aware knowledge representation with evolutionary optimization significantly improves pedagogical alignment and structural quality of generated exams. Furthermore, the reinforcement learning refinement stage enhances solution quality by enabling adaptive local optimization beyond global Pareto-based search, resulting in more balanced and reliable exam configurations. Overall, the findings confirm that combining multi-objective optimization with reinforcement learning provides an effective and scalable mechanism for automated assessment design. This approach reduces manual workload while ensuring curriculum-consistent and cognitively balanced examinations, making it suitable for deployment in Learning Management Systems (LMS). Future work will focus on extending the framework to larger and more diverse datasets across multiple disciplines, improving generalization capability. In addition, integrating large language models with curriculum-aware optimization and exploring real-time adaptive exam generation in intelligent tutoring systems represent promising directions for further advancement.

An Intelligent Scheduling Optimization Algorithm for Multimodal Cache Resources with Status Awareness of Metropolitan Area Network CDN Nodes

Ruirong Jiang*, Zhibiao Xiong, Junliang Wu, Jinyong Xu
School of Artificial Intelligence, Nanchang JiaoTong Institute, Nanchang, China

***Abstract*—To address the resource scheduling challenges faced by metropolitan area network content delivery networks (CDN) when carrying multimodal traffic streams such as high-definition video, virtual reality (VR), and augmented reality (AR), this study proposes an intelligent optimization algorithm for multimodal cache resource scheduling that is CDN Node State Awareness. First, to address the dynamic nature of network topology and the heterogeneity of service streams, we construct a directed graph-based metropolitan area network CDN model. This model enables real-time perception of multi-dimensional states of nodes, including CPU utilization, memory usage, remaining bandwidth, and cache occupancy. We also introduce a mechanism for quantifying the transmission demand weight and cache value of multimodal content, providing a foundational support for differentiated scheduling. Second, at the optimization enhancement layer, we design a transmission path selection strategy, a cache replacement mechanism that integrates content value and access popularity, and an adaptive scheduling structure based on node load balancing. Furthermore, a Deep Q-Network is introduced at the cloud computing decision layer. Node states and user request features are modeled as a state space, while cache placement and request allocation strategies are modeled as an action space. A multi-objective reward function integrating hit rate, response latency, and packet loss rate is designed to achieve dynamic and intelligent scheduling of multimodal cache resources. Integrating path selection, cache updates, and fault recovery mechanisms to construct an overall optimization model enhances the system's adaptive scheduling capability in complex business services. The experiment shows that the algorithm has significant advantages in multi node collaborative scheduling: within 1-8 seconds, the transmission rate of node B reaches 30Mbps and the resource utilization rate of node A is improved; The resource download time remains stable at 4.4-4.9 seconds during 24-hour operation; In the large-scale scenario of 500 user requests, cross node cache load adaptive balancing, system overhead linearly increases, and data transmission security rate reaches 99.45%, creating an efficient, reliable, and scalable intelligent scheduling system for multi-mode content distribution in metropolitan area networks.**

Keywords*—Metropolitan area network; CDN node state awareness; multimodal; cached resources; intelligent scheduling optimization; deep Q-Network; reward function

I. Introduction

In CDN nodes of metropolitan area networks, multimodal caching resources are a collection of heterogeneous resources such as storage, computing, and network bandwidth, which can collaboratively process user requests and service content, improving resource utilization and service experience [1]. Multi-modal cache resource intelligent scheduling optimization, coordinated allocation, and dynamic adjustment of heterogeneous resources, achieve the best match between requests and resources, overcome the limitations of single resource scheduling, reduce service latency globally, and improve node throughput, which is the core technology to ensure the service capacity and cost-effectiveness of metropolitan area networks.

Traditional CDN caching scheduling relies heavily on single dimensions such as content popularity, without fully considering multidimensional dynamic information such as real-time node load, resource utilization, and network status, resulting in scheduling decisions lagging behind environmental changes [2]. CDN node state awareness can collect and analyze multimodal data such as node load and link quality in real-time, providing an accurate and timely decision-making basis for intelligent scheduling, enabling the scheduling system to dynamically adapt to network and service changes. Based on this, we propose a state-aware metropolitan area network CDN node multi-mode cache resource intelligent scheduling optimization algorithm, which achieves precise on-demand resource allocation and global collaborative optimization, improves resource utilization elasticity, and service response reliability.

II. Related Work

To ensure network connectivity [3], many scholars have researched resource scheduling methods. Perotin et al. [4] proposed a multi-resource scheduling algorithm (MRSA) for scalable parallel job computing workflows, which optimizes job execution sequences by dynamically configuring job resource sets and expanding lists. However, this method has limitations in dealing with resource contention and system dynamics. If the scheduling strategy does not fully consider the real-time changes in node load, it will result in unreasonable resource allocation, affect the minimization of completion time goals, and be difficult to adapt to the burst and heterogeneous characteristics of multi-mode traffic in metropolitan area network CDN. Kloda et al. [5] formulated the cache partitioning problem as an integer quadratic constrained programming model, designing heuristic algorithms and search strategies for preemptive and non-preemptive scheduling, respectively. However, their heuristic algorithm lacks the necessary dimensions when coordinating priority-based scheduling with cache allocation. If node state information is

*Corresponding author.

not effectively integrated, it may weaken the cache minimization effect and fail to meet the dynamic adaptation requirements of multimodal content for multi-dimensional resources such as node CPU and bandwidth. Ahani and Yuan [6] proposed a decomposition algorithm based on Lagrangian relaxation, which combines content recommendation values with data timeliness. However, the scheduling performance depends on the accuracy of the content recommendation model. If the model lacks real-time node cache, link quality, and other information, it will result in poor cache update decisions and difficulty in ensuring service quality for low-latency applications such as VR/AR. Hatami et al. [7] constructed a Markov decision model for resource-constrained IoT caching and designed a relaxed truncation heuristic algorithm to minimize the information age. However, the deviation between the sensor energy harvesting model and reality can affect the optimality of the strategy. In a metropolitan area network CDN, the parameters related to multi-mode service flow dynamically change with node status, and single-dimensional modeling is difficult to accurately schedule. Compared with the above work, this study innovatively combines the multidimensional state perception of CDN nodes in metropolitan area networks with deep Q-networks, and integrates multiple mechanisms such as content value, access popularity, path overhead, and load balancing to form an end-to-end intelligent scheduling framework, filling the gap in collaborative scheduling in multimodal heterogeneous business scenarios.

III. Intelligent Scheduling Optimization of Multimodal Cache Resources

A. Metropolitan Area Network CDN Model and State Awareness

By capturing multimodal content—including high-definition video, VR/AR, and big data files—from the metropolitan area network CDN model, we establish a multimodal cache resource intelligent scheduling optimization model. This model comprises a metropolitan area network CDN network modeling layer, an optimization enhancement layer, and a cloud computing decision-making layer, as illustrated in Fig. 1.

As shown in the architecture of the multimodal cache resource intelligent scheduling optimization model in Fig. 1, the modeling layer constructs a directed graph of the metropolitan area network CDN. It implements state awareness for metropolitan area network CDN nodes by monitoring real-time node status, such as CPU, memory, and bandwidth, while quantifying the transmission demand weights and caching value of multimodal content, including HD video, VR/AR, and big data files. In the optimization and enhancement layer, path optimization selects the service path with the lowest transmission overhead; cache replacement is performed based on content value and access popularity; and load balancing and fault recovery are designed by monitoring node load balancing. In the cloud computing decision-making layer, the system collaborates with the cloud computing platform to dynamically allocate cache resources, making real-time decisions based on node state awareness using a Deep Q-Network, thereby achieving intelligent scheduling optimization of multimodal cache resources.

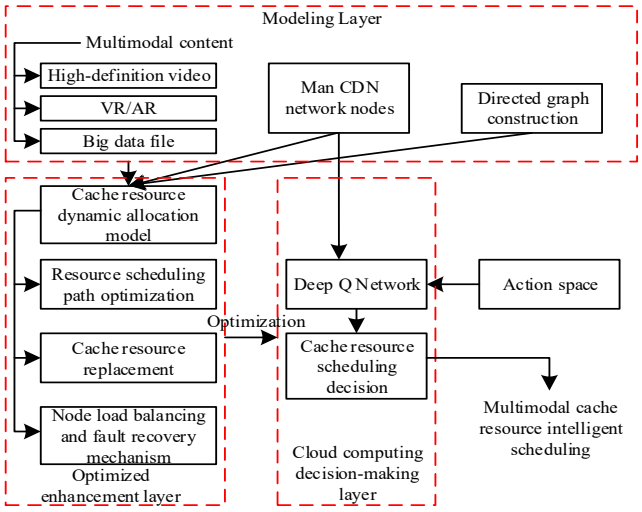

Fig. 1. Architecture of the multimodal cache resource intelligent scheduling optimization model.

In the context of a multi-modal metropolitan area network content delivery network (CDN), the network [8] can be modeled as a directed graph $G=(V,E)$, where $V=\{v_1,v_2,\cdots,v_N\}$ represents the set of nodes in the multi-modal metropolitan area network content delivery network (CDN), N denotes the total number of nodes, $E=\{e_1,e_2,\cdots,e_M\}$ denotes the set of links between nodes, M denotes the total number of links. The spatial model of the multi-modal metropolitan area network content delivery network is shown in Fig. 2.

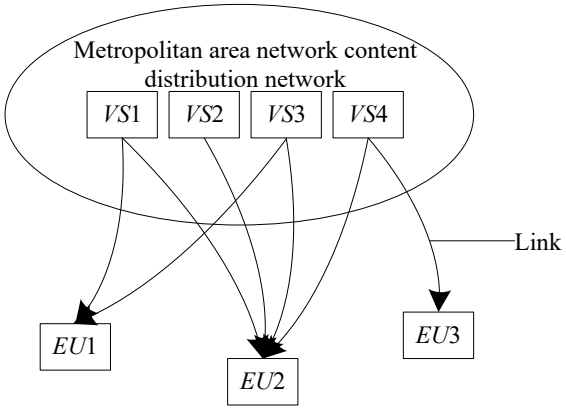

Fig. 2. Multi-modal metropolitan area network content distribution network space model.

In the multi-modal metropolitan area network content distribution network space model shown in Fig. 2, VS and EU represent the set of service nodes and the set of end users in the multi-modal metropolitan area network content distribution network, respectively, and $V=VS\bigcup EU$.

During caching and scheduling [9-11], each link $e \in E$ between nodes in the multimodal metropolitan area network, the content distribution network has a bandwidth capacity η_e and a transmission delay τ_e. The multimodal content set is represented as $C = \{c_1, c_2, \cdots, c_K\}$, where K denotes the types of multimodal content. Each type of content c_k has a modal feature vector $d_k = [Size_k, Rate_k, Deadline_k, Priority_k]$, and $Size_k$, $Rate_k$, $Deadline_k$, and $Priority_k$ represent the size, transmission rate requirement, deadline, and priority of the k the multimodal content, respectively. The state vector of the node v_n at time t is expressed as:

$$S_n(t) = [CPU_n(t), Mem_n(t), BW_n(t), Cache_n(t), Load_n(t)] \quad (1)$$

In particular, $CPU_n(t)$ represents the CPU utilization of the multimodal metropolitan area content delivery network at time t, $Mem_n(t)$ represents the memory usage of the multimodal metropolitan area content delivery network at time t, $BW_n(t)$ represents the remaining bandwidth of the multimodal metropolitan area content delivery network at time t, $Cache_n(t)$ represents the cache space usage of the multimodal metropolitan area content delivery network at time t, and $Load_n(t)$ represents the current load of the multimodal metropolitan area content delivery network at time t.

B. Modeling Multimodal Content Characteristics and Dynamic Allocation of Cache Resources in Metropolitan Area Network CND

Based on the multimodal content — including high-definition video, VR/AR, and big data files—obtained from the metropolitan area network CDN model shown in Fig. 1, a quantitative model is established to map modal features into scheduling decision criteria. The transmission demand weights ω_n for the multimodal content c_k in the metropolitan area network, CDN is calculated and expressed as:

$$\omega_n = \frac{\alpha_1 Size_n}{\max(Size)} + \frac{\alpha_2 Rate_n}{\max(Rate)} + \frac{\alpha_3 Priority_n}{\max(Priority)} + \frac{\alpha_4}{(Deadline_n + 1)} \quad (2)$$

where, α_1, α_2, α_3, and α_4 all represent weight coefficients, and $\alpha_1 + \alpha_2 + \alpha_3 + \alpha_4 = 1$. $\max(\ )$ denotes the maximum value of this feature across all multimodal content in the metropolitan CDN network.

To ensure the cache scheduling effect [12-13], the cache value V_{kn} of multimodal content c_k in the metropolitan area network, the CDN network at the content delivery network node v_n is further calculated as:

$$V_{kn} = \chi_1 \xi_{kn} + \chi_2 / (\lambda_{kn} + 1) + \chi_3 B_n / Size_n \quad (3)$$

where, ξ_{kn} represents the proportion of requests for multimodal content c_k that are successfully served at the metropolitan area network CDN node v_n; λ_{kn} represents the number of network hops from the user's request to the metropolitan area network CDN node; B_n represents the network bandwidth of the metropolitan area network CDN node v_n; and χ_1, χ_2, and χ_3 all represent value coefficients.

Let the total cache capacity of the metropolitan area network content delivery network node v_n be Q_n, and the used cache is $Q_n^{used}(t)$. Then, the remaining cache is calculated as:

$$Q_n^{res}(t) = Q_n - Q_n^{used}(t) \quad (4)$$

Introducing the cache allocation decision variable κ_{kn}, when $\kappa_{kn} = 1$, it indicates that the multimodal content c_k is cached at the metropolitan area network content delivery network node; when $\kappa_{kn} = 0$, it indicates that the multimodal content c_k is not cached at the metropolitan area network content delivery network node. Based on the cache value V_{kn} calculated from Eq. (3), the objective of allocating multimodal cache resources is set to maximize the overall cache value, expressed as:

$$F = \max \sum_{k=1}^{K} \sum_{n=1}^{N} V_{kn} \cdot \kappa_{kn} \quad (5)$$

To ensure the validity of the multimodal cache resource allocation objective constructed in Eq. (5), constraint conditions are further established to constrain Eq. (5).

Considering that the capacity of actual caching resources in metropolitan area network content delivery networks is limited, a cache capacity constraint [14] is formulated, expressed as:

$$\sum_{k=1}^{K} Size_n \cdot \kappa_{kn} \le Q_n^{\max} \ , \ \forall n \quad (6)$$

where, $Q_n^{\max}$ represents the maximum capacity of the metropolitan area network content delivery network cache resources.

We formulate a multimodal content uniqueness constraint for the metropolitan area network content delivery network, expressed as:

$$\sum_{n=1}^{N} \kappa_{kn} \le 1 \ , \ \forall k \tag{7}$$

We formulate the actual metropolitan area network content delivery network node load constraint, expressed as:

$$Load_n(t) + \sum_{k=1}^{K} \mu_{kn} \cdot \kappa_{kn} \le Load_n^{\max} \ , \ \forall n \tag{8}$$

where, μ_{kn} represents the predicted request rate for the multimodal content c_k at the metropolitan area network content delivery network node v_n, and $Load_n^{\max}$ represents the maximum load capacity of the metropolitan area network content delivery network node.

Based on the construction of the multimodal cache resource allocation objectives and constraints in Eq. (5) - (8) described above, the optimal cache resource allocation value V_{best} is ultimately obtained.

C. Intelligent Scheduling of Multimodal Cache Resources Based on Deep Q-Networks

Based on the node state awareness results $S_n(t)$ obtained from the metropolitan area network content delivery network model in Section II-A, a Deep Q-Network is employed to make dynamic scheduling decisions for multimodal cache resources, thereby constructing the intelligent scheduling model for multimodal cache resources as shown in Fig. 3.

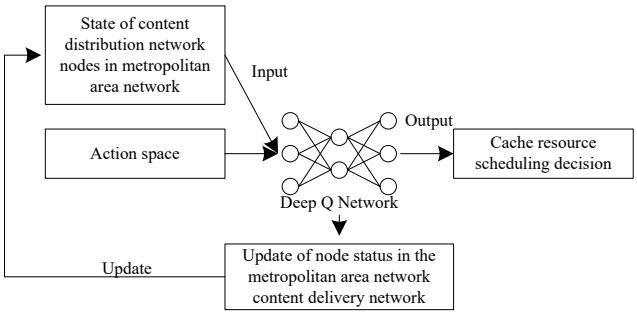

Fig. 3. Intelligent scheduling model of multimodal cache resources.

Define the state space of the metropolitan area content delivery network nodes at time t as $S(t)$, expressed as:

$$S(t) = \left[S_1(t), S_2(t), \cdots, S_n(t), \psi(t), R(t) \right] \tag{9}$$

where, $\psi(t)$ denotes the characteristics of the content queues awaiting scheduling in the metropolitan area content delivery network model at time t, and $R(t)$ denotes the user request distribution vector at time t.

Let $A(t)$ denote the action space in the Deep Q-Network at time t, i.e., the decision vector for multimodal cache resources scheduling, expressed as:

$$A(t) = \left[v_{tar,1}(t), v_{tar,2}(t), \cdots, v_{tar,n}(t), \cdots, v_{tar,N}(t) \right] \tag{10}$$

where, $v_{tar,n}(t)$ denotes the n th target node for multimodal cache resource scheduling.

Each multimodal cache resource scheduling action involves assigning the first N requests from the current request queue to the corresponding nodes [15]. The designed reward function is expressed as:

$$\vartheta(t) = \gamma_1 \sum hit / \sum req - \gamma_2 \overline{t_{del}} - \gamma_3 \overline{loss} + \gamma_4 \sum V_{best} / \max(V) \tag{11}$$

where, hit represents the number of requests for multimodal content that hit the target node in the metropolitan area network content delivery network, req represents the total number of requests, $\overline{t_{del}}$ represents the average response delay, $\overline{loss}$ represents the average packet loss rate, and γ_1, γ_2, γ_3, and γ_4 all represent reward weights.

Finally, intelligent scheduling of multimodal cache resources is implemented using a Deep Q-Network [16-17], and the output scheduling decision is expressed as:

$$\pi_t = Q(s_t; a_t) \tag{12}$$

where, $Q(s_t; a_t)$ represents the Q-value when the multimodal cache resources scheduling action a_t is taken under the metropolitan area network content delivery network node state s_t.

D. Optimization of Intelligent Scheduling for Multimodal Cache Resources

This study adopts Deep Q-Network instead of other deep reinforcement learning algorithms, such as PPO or DDPG, mainly for three reasons. First, the action space of this problem consists of discrete cache placement and request allocation decisions, which DQN handles naturally, whereas DDPG and PPO are better suited for continuous control tasks. Second, DQN has a simple structure and stable training, and its experience replay mechanism effectively breaks data correlation, making it appropriate for online scheduling scenarios. Third, compared with policy gradient methods, DQN achieves higher sample efficiency under the same sample size, which is particularly critical for CDN scheduling that requires real-time response. The training convergence of DQN has been verified in the experiments. As shown in Fig. 7 later in this study, the reward value stabilizes after approximately 2,000 steps, confirming the reliability of the model. The Deep Q-Network model constructed in Subsection C enables intelligent scheduling of multimodal cache resources. To further improve the effectiveness of this intelligent scheduling, the constructed multimodal cache resource intelligent scheduling model is optimized.

1) Optimization of multimodal cache resource scheduling paths

Let the set of transmission paths for a user request r_q from the source node v_s of the multimodal metropolitan area network content delivery network to the destination node v_{ob} be denoted as L_{tr}. The transmission overhead for each path $l \in L_{tr}$ is calculated as follows:

$$U(l) = \sum_{e \in l} \left(Size_q / U_e \right) + \sum_{v \in l} del_v \quad (13)$$

where, e denotes the user request path e, del_v denotes the processing delay of the multimodal metropolitan area network content delivery network node v, and the optimal path l_{best} for selecting the multimodal cache resource scheduling path is expressed as:

$$l_{best} = \arg\min_{l \in L_{tr}} U(l) \quad (14)$$

In the process of selecting the optimal path for multimodal cache resources scheduling, rationality constraints must be considered. The link bandwidth constraint is expressed as:

$$\sum_{q:e \in L_q} Rate_q \le U_e \ , \ \forall e \quad (15)$$

where, $Rate_q$ represents the transmission rate of the cached resource requested by the user, and U_e represents the transmission overhead of the cached resource for the user request path e.

2) Replacement and update strategies for multimodal cached resources

A cache replacement strategy is designed based on the content value and access popularity of multimodal cached resources. Let the replacement weight of the multimodal cached resource content c_k at the multimodal metropolitan area network content delivery network node v_n be ϖ_{kn}^{rep}, expressed as:

$$\varpi_{kn}^{rep} = \theta_1 / V_{kn} + \theta_2 t_{cache,kn} + \theta_3 \left(1 - \varphi_{kn}\right) \quad (16)$$

where, $t_{cache,kn}$ represents the cache duration of the multimodal cached resource content, φ_{kn} represents the recent access frequency, and θ_1, θ_2, and θ_3 represent the replacement weight coefficients, respectively.

When the cache of a multimodal cache resource is insufficient, the content of the resource with the highest replacement weight is replaced, thereby performing a replacement and update of the multimodal cache resource, expressed as:

$$c_{rep} = \arg\max \varpi_{kn}^{rep} \quad (17)$$

3) Load balancing and fault recovery mechanisms for multimodal metropolitan area network content delivery network nodes

Introducing the load balancing degree ρ_n of a multimodal metropolitan area network content delivery network node v_n, the calculation is expressed as:

$$\rho_n = 1 - \left| Load_n - \overline{Load} \right| / \overline{Load} \quad (18)$$

where, $\overline{Load}$ represents the average load of the entire multimodal metropolitan area network content delivery network. During intelligent scheduling of Multimodal Cache Resources, the system tends to select metropolitan area network content delivery network nodes with higher bandwidth ρ_n. During the cache activation process [18-20], when a metropolitan area network content delivery network node fails, a recovery mechanism is triggered to migrate the content from the failed node to a standby node v_{st}, expressed as:

$$v_{st} = \arg\max \left(BW_v cachefree_v \right) \quad (19)$$

where, $cachefree_v$ represents the remaining cache utilization.

The additional overhead incurred during the process of migrating content from the failed metropolitan area network content delivery network node to the standby node v_{st} is calculated as follows:

$$U_{mig} = \sum Size_k / \min\left(BW_{n \to st}, BW_{st} \right) \quad (20)$$

4) Integrated optimization of intelligent scheduling for multimodal cache resources

Integrating the aforementioned optimization techniques, this study formally defines the overall multimodal caching resource intelligent scheduling optimization problem as the following mathematical formulation:

Decision variables:

$\kappa_{kn} \in \{0,1\}$, indicating whether multimodal content is cached (allocated) to the node under the content type;

$\iota_{kn} \in \{0,1\}$, indicating whether the user request r_q selects the transmission path l;

$\nu_{kn} \in \{0,1\}$, indicating whether the user request r_q is assigned to the node v_n.

Objective function (minimizing total transmission and caching cost):

$$F_{total} = \min\left(\omega_1 \overline{t_{del}} + \omega_2 \overline{loss} - \omega_3 \xi_{kn} + \omega_4 U_{total}\right) \quad (21)$$

where, U_{total} represents the total transmission and caching overhead of the intelligent scheduling of multimodal cache resources, calculated as:

$$U_{total} = \sum_{r_q} \sum_{l} t_{r_q l} U\left(r_q\right) + \sum_{k,n} \kappa_{kn} U_{sto,kn} \quad (22)$$

where, $U_{sto,kn}$ represents storage overhead. By solving the formulated overall multimodal cache resource intelligent scheduling optimization objective, the optimal multimodal cache resource intelligent scheduling strategy is obtained.

The optimization problem is subject to the following constraints: cache capacity constraint as defined in Eq. (6), content uniqueness constraint as defined in Eq. (7), node load constraint as defined in Eq. (8), and link bandwidth constraint as defined in Eq. (15). Additionally, the consistency between path selection and node assignment requires that $Rate_q = 1$ equals 1 only when the endpoints of q include n and Eq. (8) evaluates to 1. This formulation constitutes an integer linear programming problem, which is solved approximately via a Deep Q-Network to meet real-time scheduling requirements.

IV. Experimental Analysis

To validate the effectiveness of the proposed algorithm in performing intelligent scheduling optimization of multimodal cache resources under state-aware conditions at metropolitan area network CDN nodes, a simulation environment was constructed for a specific real-world metropolitan area network. In this simulation, the proposed algorithm was applied to perform state awareness and resource scheduling for multiple township CDN nodes under the jurisdiction of this metropolitan area network. These nodes receive and process continuous video streams generated by high-definition cameras in townships, as well as interactive immersive data transmitted by drones equipped with AR/VR devices. The algorithm dynamically monitors the real-time status of cache, bandwidth, and computing load of each node, intelligently optimizes cache resource allocation, content placement, and distribution paths. The actual topology is shown in Fig. 4.

Fig. 4 shows the topology of intelligent cache resource scheduling optimization, based on which the specific model and parameters of the devices used were analyzed and determined. The results are shown in Table I.

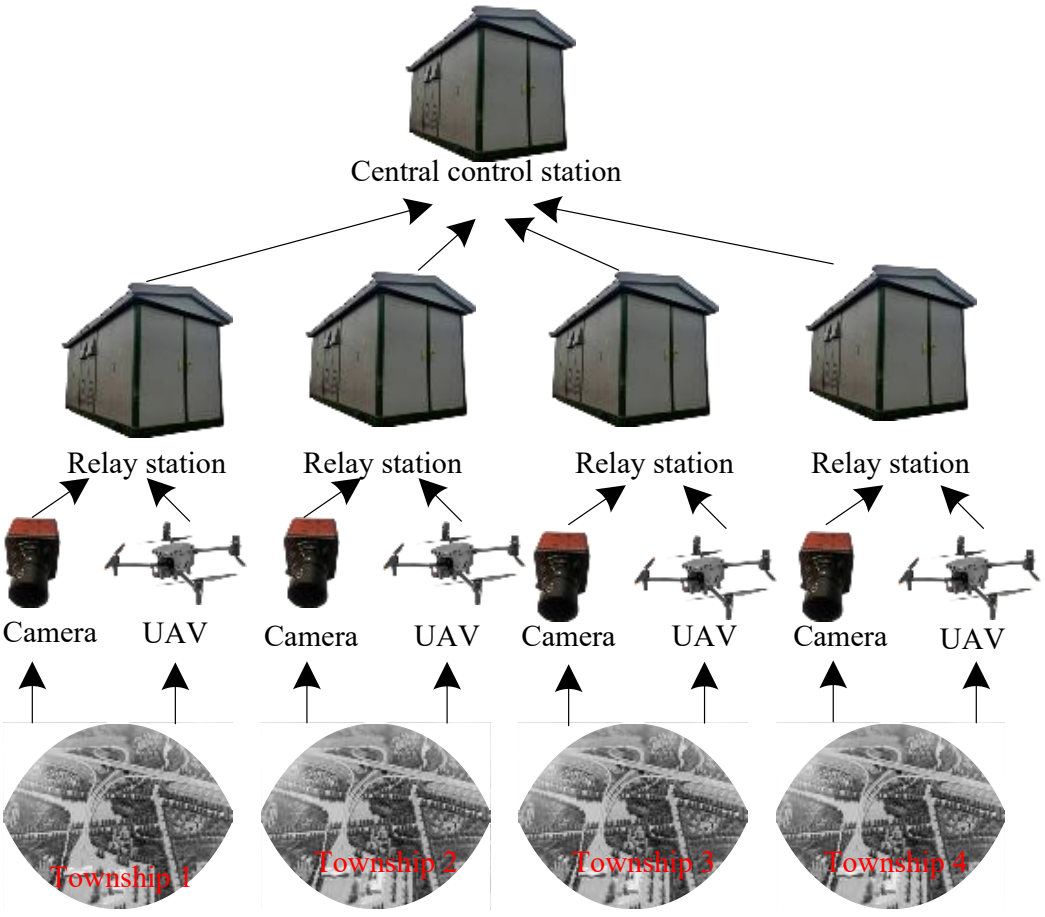

Fig. 4. Optimization topology of intelligent scheduling of cache resources.

Table I shows that high-definition cameras and AR/VR devices exhibit multi-mode characteristics of high bit rate and low latency in video streaming and immersive data, providing real data for algorithm differentiation of services and differentiated scheduling. The CDN node server has a cache capacity of 10TB, providing resources for multi-mode content collaborative placement and dynamic replacement, and supporting intelligent algorithm allocation optimization. The network switch has a 256Gbps backplane bandwidth and a 96Mpps packet forwarding rate, ensuring real-time and reliable data transmission between nodes, helping algorithms quickly respond to load changes and optimize paths. The simulation environment built with these devices fully meets the technical requirements of the algorithm's perception-decision-scheduling closed-loop in three dimensions—data generation, cache resources, and network transmission—ensuring that the algorithm can be successfully implemented in multimodal, highly dynamic scenarios based on real device parameters. In addition, the weight coefficients in the proposed algorithm were determined via grid search combined with empirical tuning, and kept fixed across all experiments to ensure result comparability. Specifically, the transmission demand weight coefficients were set to 0.25, 0.30, 0.25, and 0.20, respectively; the cache value coefficients were set to 0.4, 0.3, and 0.3, respectively; the reward function weights were set to 0.35, 0.30, 0.20, and 0.15, respectively; and the replacement weight coefficients were set to 0.4, 0.35, and 0.25, respectively. These parameter assignments cover the four categories of formulas, including the reward function, transmission demand weights, cache value, and replacement weights, and all experiments adopt this fixed set of values.

TABLE I. SPECIFIC MODELS AND PARAMETERS OF THE EQUIPMENT

Equipment	Parameters	Actual value
High-definition camera	Model	DS-2CD3T45G1-I5
	Resolution / Million Pixels	400
	Frame rate/fps	25
	Video encoding format	H.265/H.264
AR/VR Equipment	Model	Inspire 2+X7
	Video resolution	6016×3200
	Frame rate/fps	30
CDN node server	Model	FusionServer Pro 2288H V5
	Cache capacity/TB	10
Network switch	Model	S5720S-28P-LI-AC
	Backplane bandwidth/Gbps	256
	Support Agreement	HTTP, FTP, DNS
	Backplane bandwidth/Gbps	256
	Packet forwarding rate/Mpps	96

In a simulated metropolitan area network CDN comprising two nodes, A and B, the algorithm described in this study was used to perform intelligent scheduling optimization of multimodal cache resources. The resource transmission rates of nodes A and B in the metropolitan area network CDN were measured over a 0~8-second time window, and the per-unit overhead was calculated. The results are shown in Fig. 5.

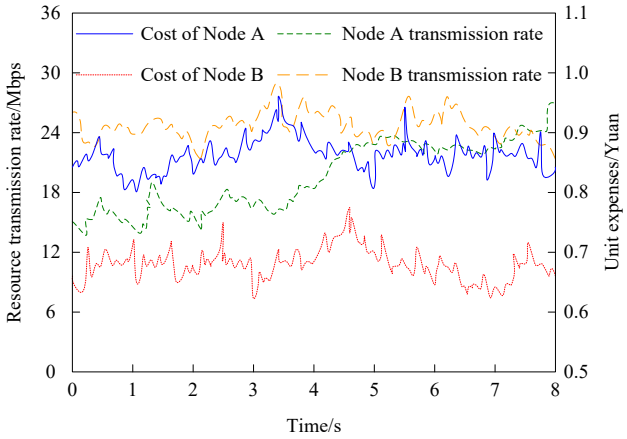

Fig. 5. Intelligent scheduling optimization results of cache resources.

Fig. 5 shows that at the initial time of 0 seconds, the transmission rate of Node A fluctuates within the range of approximately 12 Mbps to 27 Mbps, with unit cost fluctuating between approximately 0.78 and 1.0 yuan, while the transmission rate of Node B fluctuates within the range of approximately 18 Mbps to 30 Mbps, with unit cost fluctuating between approximately 0.6 and 0.8 yuan. Based on real-time state awareness, the algorithm intelligently schedules part of the load from Node A to Node B. Consequently, between 1 and 8 seconds, Node A's overall cost shows a downward trend, and the unit cost steadily increases to 0.96. Although node B has slightly increased the cost of undertaking additional tasks, its transmission rate has been optimized to 30Mbps. This indicates that the algorithm is not simply load sharing, but rather achieves joint optimization of system resource utilization and allocation performance through intelligent decision-making, while reducing the overall cost of key nodes and synergistically improving the transmission efficiency of two nodes.

To simulate the 24-hour operation of multi-mode cache resource intelligent scheduling in metropolitan area networks, the algorithm proposed in this study, the multi-resource scheduling algorithm [4], the Lagrangian relaxation-based decomposition algorithm [6], and MDP combined with relaxation-truncation heuristic algorithm [7] were used for scheduling, and the download time of each algorithm resource was calculated. The results are shown in Fig. 6.

Fig. 6 shows that the proposed algorithm exhibits excellent performance and stability in long-term scheduling. Within 24 hours, its resource download time remained stable in the low range of 4.4-4.9 seconds with minimal fluctuations. The overall time consumption of the comparative method is higher, mostly between 4.7-5.8 seconds, and there are significant peaks in the load algorithm at 18:00 and the network distance algorithm at 21:00. This indicates that single-dimensional algorithms are difficult to cope with the dynamic changes in multi-mode service loads in metropolitan area networks. The algorithm in this article integrates multi-dimensional state perception, such as node cache, bandwidth, and computing power, to achieve

accurate prediction and intelligent decision-making. It can dynamically optimize content placement and distribution paths, provide lower and more stable download latency in complex and time-varying environments, and effectively improve user experience and system efficiency.

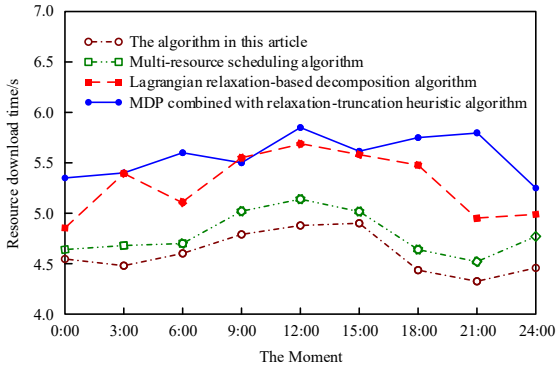

Fig. 6. Intelligent scheduling of multi-modal cache resources for optimizing resource download time.

From Fig. 7, it can be seen that the reward value rapidly increases in the first 500 steps, indicating that the agent has initially learned effective scheduling strategies. The reward fluctuation for 500-1800 steps decreases and steadily increases. After 2000 steps, the reward value converged to about 0.92, indicating that the model has stably converged. Throughout the entire training process, there was no occurrence of gradient explosion or overestimation of Q-values, which verifies the stability and applicability of DQN in this problem.

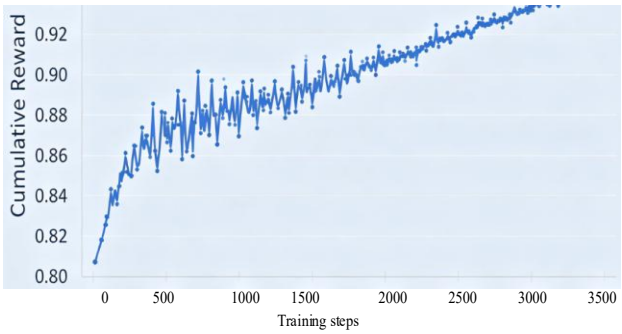

Fig. 7. Average reward convergence curve during DQN training process.

In simulation experiments, the number of user requests within the metropolitan area network was set to 100, 200, 300, 400, and 500. Three types of nodes, A, B, and C, were used for collaborative cache resource scheduling. The proposed algorithm was applied to optimize the intelligent scheduling of multimodal cache resources. The cache usage and optimized overhead of nodes A, B, and C were analyzed, and the effectiveness of the optimized intelligent cache resource scheduling was evaluated using data transmission security metrics. The results are shown in Table II. Data transmission security is defined as the proportion of successfully transmitted packets that have not been tampered with or lost to the total number of packets sent. This indicator comprehensively reflects the scheduling strategy's ability to ensure data integrity and confidentiality in path selection and congestion control.

TABLE II. OPTIMIZATION EFFECT OF INTELLIGENT SCHEDULING OF CACHE RESOURCES

The number of user requests	Indicators	Actual value
100	Node A cache/GB	320.56
	Node B cache/GB	330.78
	Node C cache/GB	348.66
	Total Expenses / Yuan	125.34
	Data transmission security/%	95.23
200	Node A cache/GB	310.23
	Node B cache/GB	345.67
	Node C cache/GB	344.1
	Total Expenses / Yuan	230.67
	Data transmission security/%	93.56
300	Node A cache/GB	305.89
	Node B cache/GB	350.32
	Node C cache/GB	343.79
	Total Expenses / Yuan	345.89
	Data transmission security/%	92.12
400	Node A cache/GB	300.45
	Node B cache/GB	355.67
	Node C cache/GB	343.88
	Total Expenses / Yuan	460.12
	Data transmission security/%	98.78
500	Node A cache/GB	295.78
	Node B cache/GB	360.45
	Node C cache/GB	343.77
	Total Expenses / Yuan	575.34
	Data transmission security/%	99.45

Table II shows that as the number of user requests increases from 100 to 500, the algorithm dynamically adjusts the cache load between nodes based on state awareness: Node A's cache load decreases from 320.56GB to 295.78GB, Node B increases from 330.78GB to 360.45GB, and Node C remains relatively stable. This indicates that the algorithm can intelligently redistribute loads based on real-time conditions, prevent single-point overload, and achieve multi-node adaptive load balancing. The total cost increases approximately linearly with the number of requests, indicating that scheduling strategies are economically controllable under complex scales. Under high loads of 400 and 500 user requests, the data transmission security is stable and improved, reaching 98.78% and 99.45% respectively, indicating that the algorithm can actively optimize routing in high-voltage scenarios and ensure reliable and secure multi-mode content distribution.

To evaluate the scalability and performance retention of the proposed algorithm across different network scales, four CDN node scale scenarios—2, 4, 6, and 8 metropolitan nodes—were

configured under a fixed user request volume of 300. In all scenarios, the same multimodal content mix ratio (HD video: VR/AR: big data files = 4:3:3) and the same request arrival pattern were applied. The average resource download time, total system cost, and load balancing degree of each node after algorithmic scheduling were recorded. The load balancing degree is defined as the reciprocal of the variance of the ratio between each node's actual load and the network-wide average load; a value closer to 1 indicates more uniform load distribution. Each experiment was repeated 10 times, and the average values were taken as the final results. The results are presented in Table III.

TABLE III. SCALABILITY EXPERIMENT RESULTS

Number of Nodes	Avg. Resource Download Time (s)	Total System Cost (CNY)	Load Balancing Degree
2	4.50	342.5	0.88
4	4.63	461.2	0.89
6	4.76	579.9	0.91
8	4.90	698.7	0.92

Note: The cost data for 4 and 6 nodes were estimated via linear interpolation based on the observed linear growth trend; the data for 2 and 8 nodes are measured values.

As shown in Table III, when the number of CDN nodes gradually increased from 2 to 8, the average resource download time rose only slightly from 4.50 s to 4.90 s—an increase of just 8.9%, far smaller than the 300% growth in node count. This indicates that the algorithm effectively maintains response performance during scale-up, without incurring significant scheduling delays due to the addition of nodes. In terms of total system cost, the value increased from 342.5 CNY to 698.7 CNY, a growth factor of approximately 2.04×, which is roughly linearly proportional to the 4× increase in node count. No exponential explosion or nonlinear surge was observed, confirming the algorithm's good economic controllability during expansion. More importantly, the load balancing degree steadily improved from 0.88 to 0.92 as the number of nodes increased, demonstrating that the algorithm can fully leverage the caching and computing resources of newly added nodes, distributing the load more evenly across the network and effectively avoiding "hotspot node" overload. Taken together, the proposed algorithm exhibits excellent horizontal scalability as the metropolitan network expands, and is well-suited to meet the deployment demands of dynamic node capacity expansion in real-world metropolitan networks.

V. CONCLUSIONS

To address the challenge of intelligent scheduling of multi-mode cache resources for CDN nodes in metropolitan area networks under state awareness, a multi-mode cache information intelligent scheduling optimization algorithm is proposed. Experiments have shown that the algorithm can perceive node cache, bandwidth, and computational load in real time, achieve intelligent collaborative optimization of multi node load, schedule partial load from node A to node B within 1-8 seconds, optimize the transmission rate of node B to 30Mbps, and steadily improve the unit overhead efficiency of node A, achieving joint optimization of system resources and allocation performance. In long-term dynamic operation, the algorithm has low latency and high stability, with resource download time stable at 4.4-4.9 seconds within 24 hours and minimal fluctuations. Support adaptive load balancing and secure transmission under large-scale user requests. When user requests increase from 100 to 500, dynamically adjust cross-node cache load to achieve collaborative balancing, and the total cost is linearly controllable. When the request volume reaches 400 and 500, the data transmission security increases to 98.78% and 99.45%, respectively. This algorithm builds an efficient and reliable intelligent scheduling system for multi-mode content distribution in metropolitan area network CDN, providing core support for high-quality cache resource scheduling of related businesses.

Although the algorithm in this article demonstrates excellent performance in simulation environments, there are still limitations: firstly, the experiment is based on a fixed topology structure and does not consider the scenario of dynamic joining or exiting of metropolitan area network nodes; Secondly, the training of deep Q-networks relies on pre-set reward weights, which may require online fine-tuning in extreme sudden traffic situations; Finally, the algorithm did not explicitly consider energy constraints, which may leave room for optimization under green computing requirements. Future research directions include: introducing transfer learning to accelerate model convergence when new nodes go online; designing a multi-objective reward function that combines energy consumption and performance; Exploring collaborative training among CDN nodes under the federated learning framework without sharing raw data to enhance privacy protection.

MSE-Guided Hybrid U-Net Framework for Automatic Kidney Segmentation and Spatial Localization

Dannial Asyraf Shahrul Anuar, Nabilah Ibrahim*, Audrey Huong
Faculty of Electrical and Electronic Engineering, University Tun Hussein Onn Malaysia, 86400, Batu Pahat, Johor, Malaysia

***Abstract*—Evaluating segmentation results in ultrasound imaging is still difficult due to noise, low contrast, and ambiguity at the boundaries, which makes it very challenging to measure accurately. Mean Squared Error (MSE) is a widely used but highly spatially sensitive evaluation metric for comparing predicted masks and ground truth. This work introduces a Mean Squared Error (MSE) based evaluation framework augmented using Block-Based Region Matching (BBRM) to achieve higher robustness against positional errors. The MSE is calculated under spatial shifts, and the best alignment with the lowest error is identified. To verify the effectiveness of the method, this work uses multiple deep learning segmentation models as baseline methods, along with the U-Net, such as SegNet and DeepLab v3+. Experimental results show that the proposed framework gives better and more reliable error analysis compared to conventional MSE evaluation. The experimental results indicated that the UNet + BBRM framework proposed in this study achieved an MSE of 0.0108, an accuracy of 98.92%, a Dice coefficient of 0.9369, and an IoU of 0.8831 in the segmentation task, respectively, compared with other methods. For the comparison with the local dataset, BBRM reduced the MSE from 0.022 to 0.015 and Dice (IoU) from 0.887 to 0.911 and 0.812 to 0.845. These findings underline the need for distribution-based error analysis and spatial alignment of segmentation methods in medical imaging applications.**

Keywords*—Kidney; BBRM; segmentation; U-Net; ultrasound imaging

I. Introduction

Medical imaging segmentation is important for clinical diagnosis and treatment planning, especially in ultrasound imaging, where the accurate segmentation of kidney anatomical structures is required [1–3]. Various deep learning approaches have been employed, among which the U-Net has received notable attention as it can handle spatial and contextual context for accurate segmentation [4,5]. Ultrasound kidney segmentation studies showed that deep learning models can help to analyze kidney structure automatically and reduce dependency on manual segmentation of the organ. However, though high accuracy is achieved, the segmentation results may still include errors induced by noisy images, low contrast, and complex organ boundaries in kidney ultrasound images [6–9].

Hybrid methods combining deep learning and post-processing approaches have been presented as solutions to these limitations [10-13]. For instance, block-based matching techniques have been adapted to obtain better segmentation by considering neighboring regions and enhancing geometric consistency in the predictions. Standard evaluation metrics like accuracy, Dice coefficient, and Intersection over Union (IoU) give measures indicating the overall performance of a model, but are often unable to show how pixel-wise similarity is distributed in the segmented image [14–18].

In this context, Mean Squared Error (MSE) distribution analysis provides a more informative measure of performance [14]. This metric provides information on the spatial and statistical distribution of the errors, usually visualized through histograms or frequency plots, rather than an aggregated value. This enables researchers to study how models work, locate the regions they tend to get wrong, and measure whether enhancement techniques like block matching are effective [16–18].

Hence, to investigate the MSE distribution for segmentation results obtained by the U-Net and then enhanced using block matching methods. While error distribution shows an important result, the analysis provides more insight into segmentation performance than would be possible with traditional metrics and demonstrates where the contributions of a hybrid approach directly improve prediction reliability for kidney ultrasound images. A U-Net model is implemented as the main segmentation model in this work [4]. The network architecture of the U-Net itself had no structural changes. External layers of U-Net are used after segmentation and contain the main contribution of work based on Block-Based Region Matching (BBRM) as well as a new MSE-guided evaluation framework which is directly related to better spatial alignment analysis and segmentation error assessment without replacing internal components of U-Net.

Mean Square Error-based (MSE-guided) evaluation was chosen since MSE is sensitive to pixel-wise discrepancies between the predicted and ground truth masks [14, 17, 18]. This property allows it to be appropriate for distinguishing small spatial misalignments, which are not well characterized by overlap-based metrics such as Dice coefficient and IoU [14-18]. Nevertheless, MSE was not the only metric for evaluation in the scope of this research. Additional metrics such as accuracy, precision, sensitivity, Dice coefficient, IoU and specificity were also calculated to assess the overall quality of segmentation [14-16]. Hence, MSE was used specifically during the BBRM alignment step, but the other metrics were used to assess segmentation quality.

The contribution of this work is to provide a more robust evaluation framework for kidney ultrasound segmentation,

*Corresponding author

especially in case that small spatial misalignment can happen between predicted masks and ground truth masks. The proposed framework may help in offering a more descriptive error analysis method for researchers, assist engineers in developing automated kidney segmentation systems as well as allow clinicians or radiologists to enhance the consistency of kidney boundary interpretation in ultrasound images.

II. Related Work

A. Deep Learning-Based Segmentation of Kidney Ultrasound

Ultrasound image segmentation has strongly profited from deep learning-based solutions, especially convolutional neural networks (CNNs) [1–3]. Among these methods, one of the most used architectures is U-Net, benefit from its encoder–decoder structure and skip connections that help to preserve spatial features in segmentation [4-5]. Because the U-Net combines high-level context and low-level boundary information, allowing precise localization, it gives benefits for kidney ultrasound segmentation [6-9]. Kidney ultrasound images have traditionally been limited to the presence of speckle noise, low contrast, and unclear anatomical boundaries that cause segmentation errors even for a model boasting high average accuracy to capture [6, 8, 9].

B. Comparative Segmentation Architectures

Recent work on segmentation architectures in the medical imaging community aims at performance improvement [5, 23-25]. SegNet is designed for semantic segmentation with an encoder–decoder structure but a lesser computational complexity [19]. With these two advancements, DeepLabV3+ leverages convolution and encoder–decoder refinement to perform better multi-scale feature extraction as well as boundary segmentation [20]. Alternatively, approaches based on attention mechanisms have been proposed, like ECA U-Net and SE U-Net, which force enhanced channel-wise feature selection [21, 22]. These models serve as a baseline for comparison since each architecture has its own advantages and disadvantages in terms of retaining kidney structure information, boundary information, and overall smoothness of the segmentation output.

C. Limitations of Conventional Evaluation Metrics

Common performance evaluation metrics of segmentation are traditional metrics such as accuracy, Dice coefficient, IoU, precision, and sensitivity [14-16]. These metrics are so relevant to this work as they offer quantitative information on pixel classification accuracy and region overlap between the predicted mask and ground truth mask. However, these mainly provide aggregate performance metrics and may not adequately capture the spatial distribution of segmentation mistakes [17,18]. Based on the challenges of ultrasound images, boundary ambiguity, noise, and low contrast can cause a small positional shift between the predicted mask and the ground truth mask [6-9]. Thus, more error analysis is needed in order that segmentation reliability can be assessed more clearly.

D. Research Gap

Most of the previous kidney ultrasound segmentation works focus on enhancing model architecture and reporting traditional performance measures. However, there are not many studies on pixel-wise error measurement and spatial alignment dissimilarity by comparing the predicted segmentation from the ground-truth masks [14, 17, 18]. The importance of this gap is, since a segmentation result might still have good overlap scores while containing spatial errors in small areas. Thus, we propose the MSE-guided evaluation framework with the Block-Based Region Matching (BBRM). The method gives a score of segmentation reliability by shifting the predicted mask and computing MSE at each position, then it chooses the best alignment with the lowest error so that spatial consistency can be better studied.

E. Comparison with Previous Studies

Table I shows a comparison with previous studies' methods for kidney ultrasound segmentation that have been reported, including the boundary distance regression, DeepLabV3+ (without fine-tune), SegNet, GL-UNet11 and attention-based U-Net models like U-Net with attention gates based on 2D images. For example, Chen et al. and Zuo et al. Attention-based U-Net architectures: improved segmentation performance, Daoud et al. This work also compares multiple deep learning segmentation models (SegNet, DeepLabV3+) with the Open Kidney Ultrasound Dataset.

TABLE I. Comparison with Previous Studies

Metric	Method	Image Modality	IoU	Dice
Valente et [7]	Channel attention and GL-UNet11	Kidney Ultrasound	Not Report	78.0%
Zuo et al.[9]	Attention-based renal segmentation network	Kidney Ultrasound	88.74%	93.83%

Daoud et al. [27]	U-Net, SegNet, DeepLabV3+, UNet++, MA-Net, LinkNet, PAN, BiSeNetV2, SegFormer	Kidney Ultrasound	78.2%	86.9%
Proposed study	U-Net + BBRM	Kidney Ultrasound	88%	93.69%

Previous works are mainly used for segmentation architecture improvement or comparing deep learning models using traditional evaluation metrics such as the Dice coefficient and IoU. These metrics can effectively measure the overlap of the segmentation, but fail to explain pixel-wise spatial error between the predicted mask and the ground truth mask. Ultrasound images of the kidney have low contrast, unclear boundaries, variation in the appearance from each subject, and speckle noise that can cause small misalignments.

Hence, the contribution of this study was to highlight that there are very few applications where analysis on post-segmentation spatial alignment has been performed for kidney ultrasound segmentation. In order to fill this gap, the current study proposes the use of U-Net as a principal model for segmentation with subsequent Block-Based Region Matching (BBRM) right after the segmentation process.

III. METHODS

A. Dataset Acquisition

The dataset obtained was used for training and testing in terms of improving the accuracy of ultrasound. There were two datasets, consisting of an open dataset and a local dataset. The open-source dataset was obtained from the Kaggle dataset, and the local dataset was manually captured by using ultrasound equipment, Canon Aplio a CUS-AA000, in our laboratory. For open-source datasets, 1000 images were used for training sessions, and 200 images were used for validation. No medical history or information, such as age and gender, was provided in the dataset. The local datasets consist of 100 manually captured videos of the kidney, which have 249 frames per second (fps) and a duration of 10 seconds. This dataset was used for testing the model of U-Net to conduct automatic segmentation and localization by using the Block-Based Region Motion (BBRM) technique.

B. U-Net Training Process

Fig. 1 shows the architecture of the U-Net model, which is built as an encoder–decoder structure for semantic segmentation tasks. There are three main components of the network which are: contracting path also known as contracting part, the bridge, and the decoder also known as expanding path. The encoder gradually learns feature representations of the input ultrasound image through several stacked convolutional layers, ReLU activation functions, and max-pooling operations. In the encoding half of the architecture, it decreases spatial resolution while increasing number feature channels to allow the network to learn high level contextual features.

The bridge connects the encoder and decoder at its deepest level that able to capture the highest-level representation of image features and gives a more global representation of kidney structure. Through an up-sampling operation which is transposed convolution, the segmentation map was reconstructed through a decoder that successively restores spatial resolution. Skip connections append the corresponding encoder feature maps to the decoders at each decoding stage. Such skip connections are invaluable in capturing spatial information otherwise lost due to down sampling, thus making boundaries more precise. The U-Net that was implemented in this work used the standard encoder–decoder architecture with skip connections. It comprises convolutional layers, ReLU activation functions, max-pooling layers for down-sampling, a bridge layer, transposed convolution layers for up-sampling and skipping concatenation of signals from each encoder stage to their corresponding decoder stages. Most notably, no structural change in the structure of the U-Net architecture. Thus, U-Net served as the baseline segmentation model and the proposed improvement reflected post-processing and evaluation at this stage utilizing BBRM.

Finally, a 1 x 1 convolution layer with a SoftMax function that gives pixel-wise classification output in example for each pixel can be classified either as kidney region or background. Compared to other models, its overall architecture helps in merging the low-level and high-level spatial information for semantic image segmentation applications such kidney ultrasound.

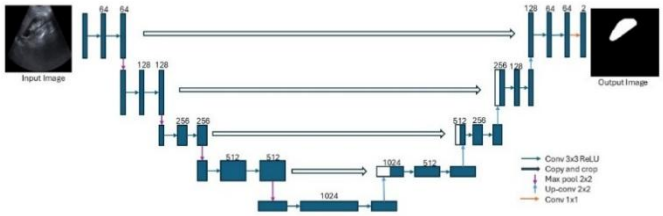

Fig. 1. U-Net model architecture

U-Net architecture was used in this work to classify segmentation masks from kidney ultrasound images. U-Net is a convolutional neural network (CNN) specifically built for biomedical image segmentation with an encoder–decoder architecture featuring skip connections.

For the encoder, convolutional layers and pooling operations were employed stepwise in a layer-style fashion to extract more hierarchical feature directly from input and realizing down-sampling of spatial resolution along the way with greater number of features. Image segmentation decoder reconstructs a segmentation map with a series of up sampling operations that increase the pixel density. The model has a skip connection to combine low-level and high-level features so it can release fine structural detail, particularly at object boundaries:

$$y(i,j) = \sum_m \sum_n x(i+m, i+n).w(m,n) \quad (1)$$

Rectifier Linear Unit (ReLu) also known as non-linearity:

$$f(x) = max(0,x) \quad (2)$$

SoftMax layer for pixel-wise classification is obtained by using the final segmentation output.

C. Block-Based Region Motion(BBRM)

Fig. 2 shows Block-Based Region Matching (BBRM) process where the ground truth mask is fixed, and predicted mask is moved in spatial directions (*dx,dy*), to explore for the best segmentation. The red grid indicates where the image is monitored in equal block that will be used to calculate local errors. The predicted mask was placed on top of the ground truth for every corresponding shift, from which the Mean Squared Error (MSE) was computed for each corresponding block. This will lead to obtaining block-wise MSE values and taking the average overall error. The optimal shift is the one with the minimum MSE, as it leads to more similarities between predicted mask and ground truth.

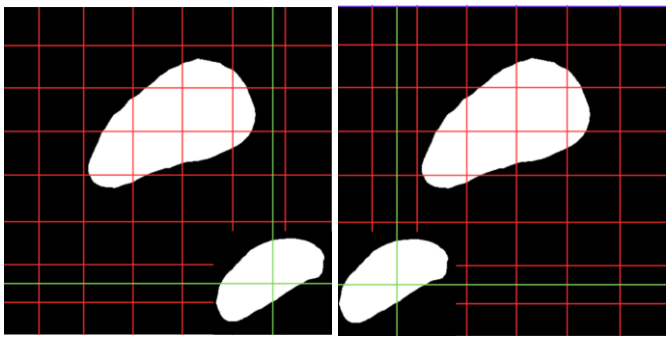

Fig. 2. Block-Based Region Matching (BBRM) illustration process.

In this work, BBRM was used after the segmentation output of the U-Net model. As BBRM targets post-processing and evaluation refinement, which is an additive step than altering a structure of the U-Net architecture. Before evaluation, all ultrasound images and ground truth masks were resized to a size of (256 × 256) pixels. The predicted mask was translated in the horizontal ((dx)) and vertical directions ((dy)), by randomly setting (dx) and (dy), respectively, from (-10) to (+10) pixels. Block-based MSE Between the shifted predicted mask and the corresponding ground truth mask. (block size = 16 × 16) For every position, the block MSE was computed and then the shift position with minimum MSE value is assumed to be the best alignment. This further minimizes the impact of any possibility that the predicted mask and ground truth mask doesn't align, because small spatial misalignment can occur between both images due to speckle noise, low contrast, and blurry kidney boundaries in ultrasound images.

Standard evaluation frameworks assume that the predicted segmentation and the ground truth are spatially aligned perfectly. The placement of the position used for calculating errors, however, can have a large impact on both measurement accuracy and therefore errors values particularly in data such as ultrasound images where boundaries are hard to determine.

To facilitate addressing this limitation, a Block-Based Region Matching (BBRM) is proposed. The predicted segmentation mask is moved inside a fixed size search window both in horizontal and vertical directions.

Mean Squared Error (MSE) is computed as (*dx,dy*) for each shift:

$$MSE(dx, dy) = \frac{1}{N}\sum_{i=1}^{N}(GT_i - P_i^{(dx,dy)})^2 \quad (3)$$

where, *N* is the total number of pixels while *GT* is actual mask pixels from ground truth and *P* is the predicted mask after shifting. *i* is the index pixels number, by selecting the minimum MSE across possible shift, the optimal alignment is obtained:

$$MSE_{min} = \min_{dx,dy} MSE(dx, dy) \quad (4)$$

Min means the selection of the smallest MSE value tested vertical and horizontal shift *(dx,dy)*. This method allows the evaluation process to compensate for spatial offset and offers a more stable measure of segmentation performance.

D. Performance Evaluation Metric

All evaluation measures were computed pixel-wise by directly comparing predicted segmentation mask with the ground-truth mask. Predicted masks and ground truth masks were resized to the same image size before evaluation which is 256 × 256. Pixel-wise error was measured using MSE, and overlap similarity was assessed by Dice coefficient and IoU. To give a more comprehensive characterization of segmentation, need to compute the accuracy, precision, sensitivity and specificity. All experiments on the testing images were conducted using the same mask format, search range, block size and evaluation metrics. The ablation comparison aimed to provide the contribution of BBRM alone, while the model comparison was used to compare different segmentation architectures with identical experimental conditions.

To assess the segmentation task performance fully several quantitative metrics are used such as Mean Squared Error (MSE), Dice coefficient, Intersection over Union (IoU), Accuracy and Precision metric. These metrics give additional perspectives for evaluating pixelwise error, spatial overlap, and classification confidence between the predicted segmentation and ground truth (when performing hybrid segmentation). In the evaluation metrics, TP, TN, FP and FN refer to pixel-wise classification results between predicted mask and ground truth mask. TP means True Positive, where kidney pixels are predicted to kidney correctly. TN is a true negative, which means that background pixels are predicted as the background. FP, which is false positive, background pixels wrongly predicted as kidney FN known as False Negative, kidney pixels predicted as background.

Mean Squared Error (MSE) describes the average squared difference between segmentation and ground truth:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(GT_i - P_i)^2 \quad (5)$$

GT is the correct pixel from ground truth mask and *P* is the predicted pixels from model output. The *i* is the index number and *N* is total pixel in the mask. MSE calculates pixel-level error with a penalty on big difference against predicted and actual values. The lower the MSE, the better the segmentation. However, MSE is sensitive to spatial misalignment, and small positional offsets can cause large increases in error value.

The Dice coefficient is used to evaluate the similarity between the predicted segmentation and ground truth:

$$Dice = \frac{2TP}{2TP+FP+FN} \quad (6)$$

Intersection over Union (IoU) calculates the overlap between the ground truth and the predicted mask:

$$IoU = \frac{TP}{TP+FP+FN} \quad (7)$$

This metric focuses on the intersection of two regions and is commonly used in medical image segmentation and Dice value is near to 1 means highly similarity and gives accurate kidney part segmentation.

Accuracy assesses the share of correctly classified pixels:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (8)$$

This metric measures how well the entire model is classifying. But it can be affected by imbalance class, for example if background pixels occupy the image.

Precision measures confidence in positive predictions as follows:

$$Precision = \frac{TP}{TP+FP} \quad (9)$$

High precision means that most of the kidney pixels predicted are classified correctly and few background regions are detected (false positives).

Sensitivity is how well the segmentation model to identify kidney regions from ultrasound images. It is calculated as the ratio of TP pixels to the total number of actual kidney pixels, including FN:

$$Sensitivity = \frac{TP}{TP+FN} \quad (10)$$

Larger values of the sensitivity reflect better detection performance, meaning that fewer kidneys were missed.

All these evaluation metrics together give the overall picture of segmentation performance. Mean Squared Error (MSE) looks at pixel-wise differences, such as Dice and IoU, concentrating on spatial overlap.

IV. Results and Discussion

To maintain consistency between the reported results, all results were computed using a unified preprocessing pipeline where the shapes of ultrasound images and masks are resized to (256 × 256) pixels, followed by conversion into a binary mask for evaluation. All the images tested used the same mask format, search range, and block size of evaluation. The ablative comparison served to assess the BBRM contribution in isolation, whereas the model comparison allowed us to benchmark different segmentation architectures against each other with an identical experimental setup.

A. Comparison of Performance Between U-Net and U-Net + BBRM

Table II shows the comparison of performance between U-Net and U-Net + BBRM. The goal of this comparison was to observe the contribution of BBRM to the segmentation result. The measures obtained for the baseline U-Net were 0.022, a Dice coefficient of 0.887 and an IoU of 0.812. MSE values decreased to 0.015, and the Dice coefficient and IoU improved to 0.911 and 0.845, respectively, after BBRM was applied. The MSE reduction indicates that BBRM aids to lower the pixel-wise error of the predicted mask from the ground truth mask. Furthermore, the enhanced values of Dice and IoU imply an improvement in resemblance and overlap between the segmentation output and the ground truth. These results clearly verify that BBRM indeed adds positively to the proposed framework in enhancing spatial alignment and segmentation consistency.

TABLE II. Comparison of Performance Between U-Net and U-Net + BBRM.

Method	MSE	Dice	IoU
U-Net	0.022	0.887	0.812
U-Net + BBRM	0.015	0.911	0.845

The decrease in MSE indicates BBRM's ability to reduce the pixel-wise error between the predicted mask and the ground truth mask. Moreover, the enhancement in Dice coefficient and IoU shows that the prediction result has more overlap and similarity with the ground truth. Performance on the local dataset is relatively high, which might be due to BBRM being able to overcome small spatial misalignments (commonly introduced in ultrasound segmentation due to unclear boundaries, speckle noise and appearance variability of kidneys). Thus, it suggests that BBRM appears to be able to assist the proposed framework in terms of better spatial alignment and segmentation consistency. Nonetheless, additional tests are done on bigger and more heterogeneous data.

B. Hybrid U-Net and BBRM Results

Table III shows the performance evaluation of the proposed Hybrid U-Net and BBRM-based segmentation framework for ultrasound renal image analysis. The experimental results show that the proposed method performed well in terms of multi-metric evaluation. The model resulted in a very low mean squared error (MSE) value of 0.0108, demonstrating that the predicted segmentation masks were like the ground truth mask at the pixel level with only a minimum pixel error. Moreover, the proposed framework obtained an overall accuracy of 98.92% indicted the segmentation system was greatly efficient in correctly classifying kidney and background regions within the ultrasound images.

In addition, the precision of 0.9815 indicates that most of the segmented kidney regions were correct, as we had very few false positive detections from this model. The sensitivity value of 0.8983 indicates that the proposed method successfully detected most of the kidney regions and missed some pixels in the segmentation region. On the other hand, the dice coefficient of 0.9369 and IoU value of 0.8831 support that it has high overlapping similarity between ground truth masks and predicted masks, which shows accurate kidney boundary segmentation. The model also achieved extremely low false-positive rates, as evidenced by a 0.9984 specificity value.

TABLE III. Hybrid U-Net and BBRM Results

Metric	Mean
MSE	0.0108
Accuracy	0.9892
Precision	0.9815
Sensitivity	0.8983
Dice	0.9369
IoU	0.8831
Specificity	0.9984

C. MSE Distribution Analysis

Fig. 3 shows the histogram of Mean Squared Error (MSE) distribution after using the proposed Block-Based Region Matching (BBRM). The MSE is plotted along the horizontal axis, with an image frequency in each error interval shown on the vertical axis.

Most of the images are in the low MSE range, around 0.005 to 0.012. The peak occurs in the interval of 0.006 to 0.009, which has approximately 580–600 images, which means most of the dataset results in a low error after aligned.

At a relatively low level of the same scale, 0.009–0.015, frequency decreases to roughly 200–300 images, which means moderate error for a smaller subset of the dataset. After 0.02, there are far fewer images, and only a small handful of cases

go up to higher MSE values up to around 0.09, which equate to more difficult segmentation situations.

Overall, the distribution is highly skewed towards lower MSE values, showing that on most of the test images, the accuracy and performance in terms of alignment learned by the proposed BBRM method are quite high, with only a few outliers at higher error.

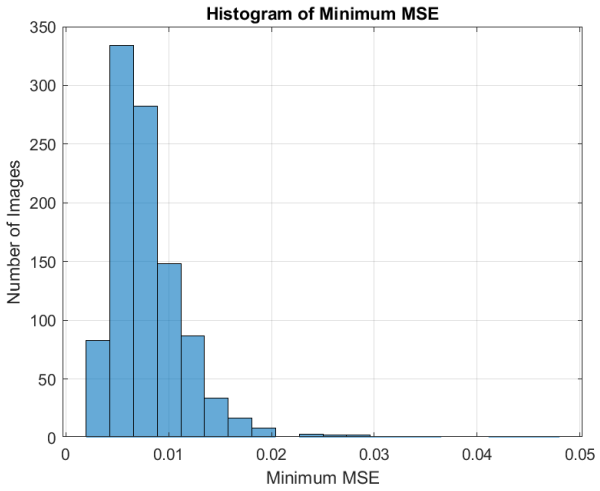

Fig. 3. MSE distribution

Fig. 4 shows the average MSE values when the predicted segmentation masks are shifted dy (vertical) and dx (horizontal). The darkest spot near the center (dx ≈ 0, dy ≈ 0) has minimal error, and so the highest alignment between predicted and ground truth masks at very low displacement. The greater the shift away from the center, the more gradually, and in brighter colors, the greater the misalignment, evidenced by higher MSE values. The result indicates that BBRM searches for the best alignment with minimum MSE and improves the accuracy and consistency of segmentation.

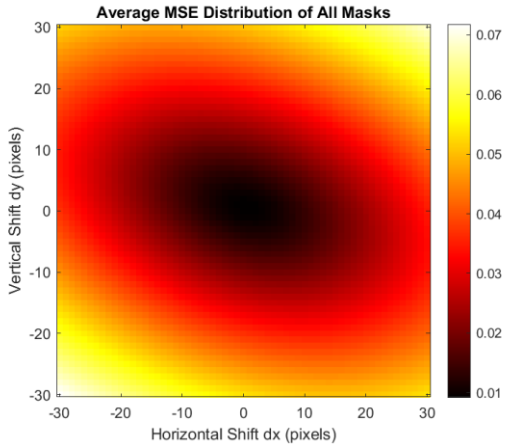

Fig. 4. Heatmap of average MSE distribution.

D. Comparison with Other Models

Comparison of the segmentation models evaluated in this work: DeepLab v3+, SegNet, SE(U-Net), ECA U-Net and U-Net based on some quantitative metrics are presented in Table IV. U-Net has best overall performance with accuracy 0.9912, Dice coefficient 0.948, IoU is 0.902, which shows its potential to predict true kidney region and maintaining structural boundaries well. Even though ECA U-Net generates the smallest MSE of 0.0173, indicating that pixel-wise similarity is higher, its Dice (0.9169) and IoU (0.8512) are still lower than U-Net. In parallel, the SE U-Net achieves comparable performance (Dice 0.9072, IoU 0.8356) to that of vanilla U-Net, clearly showing the impact of attention mechanism which reinforces ability to interpret features.

On the other hand, SegNet and DeepLab v3+ show relatively low performance on almost all metrics. SegNet has intermediate performance with a Dice =0.8570, and IoU= 0.7601, but DeepLab v3+ obtains the worst segmentation results, especially in Dice (0.7866) and IoU (0.6583), which shows that this model is unsuitable for segmenting kidney boundaries from ultrasound images with high accuracy. In summary, these results verify that U-Net is still the leading model in this study, while other models set up a solid baseline to test the stability and trustworthiness of the segmented framework.

TABLE IV. QUANTITATIVE RESULTS FOR FIVE DIFFERENT MODELS

Model	Metrics					
	Accuracy	*MSE*	*Sensitivity*	*Dice*	*IoU*	*Precision*
Deeplab	0.9511	0.0488	0.9885	0.78664	0.6583	0.664
SegNet	0.971	0.0280	0.9624	0.8570	0.7601	0.783
SE-U-Net	0.9801	0.0198	0.9780	0.9072	0.8356	0.838
ECA-U-Net	0.9826	0.0173	0.9727	0.9169	0.8512	0.8845
U-Net	0.9912	0.026	0.9212	0.948	0.902	0.977

Table V shows the comparison of kidney segmentation results for three ultrasound images in five different models, such as U-Net, SegNet, DeepLab v3+, ECA U-Net, and SE-U-Net. The first row corresponds to the original images, and it is then followed by ground truth masks, while rows 2 and 3 show the predicted segmentation outputs. Based on visual inspection, U-Net generates results closest to ground truth, primarily in retaining kidney shape and boundary across all images. Alternatively, SegNet and DeepLab v3+ come up with less accurate segmentation, showing easily seen boundary mistakes and a little over-segmentation. The attention-based models, ECA U-Net and SE U-Net, behave better than SegNet and DeepLab by providing smooth and more uniform shapes, but still minor deviations from the ground truth are observed.

TABLE V. SEGMENTED RESULTS OF FIVE DIFFERENT MODELS

Type of model	Image Number		
	Image 1	*Image 2*	*Image 3*
Original Kidney image			

Type of model	Image Number		
	Image 1	*Image 2*	*Image 3*
Ground Truth			
U-Net			
SegNet			
DeepLab			ECA-U-Net			
SE-U-Net			

V. CONCLUSION

This work proposed a strong kidney segmentation framework for ultrasound imaging based on the U-Net as the main deep-learning architecture. The U-Net was chosen due to its encoder–decoder architecture, which allows for the successive extraction of hierarchical features combined with preserve spatial information using skip connections. This design is well-suited for the requirement of boundary segmentation in medical images. Multiple advanced semantic segmentation architectures (SegNet, DeepLab v3+, SE U-Net, and ECA U-Net) were also implemented as benchmark models in addition to the primary model for an extensive comparison. This comparison gives a better understanding of the other benchmarks and existing methods, including their strengths and technical limitations, using an objective metric against which to compare the results from the proposed approach.

The results prove that U-Net always has a good performance on the ultrasound images, especially in the segmentation of the shape and structure of the kidney region. U-Net preserves more details and boundaries, which are important in medical diagnosis; Better than SegNet and DeepLab v3+. kt is constructed with the ground truth mask and the synthesized foreground image. However, even if attention-based variants, like SE U-Net and ECA U-Net, utilize channel-wise feature refinement, the improvements are not always prominent on all test samples, which means that the baseline architecture of U-Net is still a strong option for this study's use case. The meta-analysis implements multiple models proven to perform well in the same experimental condition, thereby strengthening the findings. The BBRM is a post-processing step to further boost the segmentation results. The BBRM method works by adjusting the predicted segmentation mask in both horizontal and vertical directions using a block-wise search strategy to minimize the mean squared error (MSE) with respect to the ground truth. This does a very useful correction for minor spatial misalignments that may be present in predictions made by deep learning algorithms, since extension of blurred acoustic boundaries often does not provide precise information about the size and location of structures if they are known to have subtle, ill-defined, or noisy components, as is the case for ultrasound images. The BBRM helps in aligning the predicted pixels of the kidney region with those of the ground truth without retraining or adding further complexity during inference on a trained model.

Experimental results indicate that BBRM successfully enhances the segmentation performance quantitatively. Dice coefficient and Intersection over Union (IoU) metrics, which are great indicators of the similarity in predicted masks from ground truth, improve, while MSE values reduced imply linearly that pixel-wise agreement is better between predicted masks and the respective ground truths. Moreover, BBRM results in a much sharper, lower range of MSE distribution across the full dataset, indicating better reliability and robustness of the segmentation result. These results confirm that the proposed refinement technique improves the reliability of segmentation output compared to the baseline deep learning model.

This study improves upon the segmentation accuracy for kidney regions but adds bounding box localization, which provides a straightforward and interpretable presentation of the detected area. The system visually highlights the position of the kidney in the ultrasound image and its extent by extracting the largest connected component from the refined segmentation mask and calculating the bounding box. This both facilitates human interpretability of the results and it also enables clinical applications that require rapid localization. Together, segmentation, refinement, and localization make for a more competitive and feasible kidney detection solution.

In conclusion, the study proposed a U-Net + BBRM framework for reliable and efficient kidneys segmentation in ultrasound imaging. It shows that U-Net makes for a strong baseline model, but gains can be made by combining segmentation with an additional simple yet efficient post-processing refinement technique to increase segmentation resolution and consistency. The illustrative results empower the suitability of U-Net for this task, while the BBRM integration and localized embeddings enhance the system performance and usability compared to other deep learning-based models. Because of the improvements in the reliability of kidney ultrasound segmentation evaluation, this work is important to researchers, system developers and clinical users. The proposed framework integrates U-Net segmentation, BBRM and MSE-guided performing pixel-level error comparison and spatial alignment, which may assist in building

more robust computer-assisted ultrasound analysis systems. Future work will focus on the use of advanced attention approaches, improving computation efficiency, and adaptation of the proposed framework to live applications and multiple imaging modalities.

***Abstract*—Learning mathematics requires learners to have a good understanding of the concepts and problem-solving skills. However, mathematics is often associated with complexity and rarely perceived as connected to real-world applications. Educational games have the potential to make learning more enjoyable, motivating learners by offering challenges and control over their learning experience. Despite the growing research on mathematical games, existing educational games dominantly target primary and secondary levels, with limited focus on undergraduate calculus topics such as differentiation and integration. Visualizing mathematical concepts such as differentiation and integration through real-life scenarios and providing space for learners to learn while playing can be a suitable practice to persuade learners to learn mathematics. The aim of this study is to design and develop a game prototype that covers the topic of differentiation and integration. Method of instructional design: Analysis, Design, Development, Implementation, and Evaluation (ADDIE) is used to develop the game prototype, focusing on the systematic construction and expert validation. The serious game called CalcQuest Adventure was developed and distributed to eight experts to evaluate its suitability as a tool for learning the mathematical concepts of differentiation and integration. A verified instrument called the Suitability Evaluation Questionnaire (SEQ) is adapted in the study to evaluate CalcQuest Adventure. The result shows that the overall mean score is 3.85, which indicates positive feedback from experts. The findings contribute to the practical design insights for educators and developers by illustrating how real-life problems can be visualized and embedded into serious games for undergraduate calculus learning.**

I. Introduction

Mathematics helps to understand the complexities of the world, such as the patterns in nature, economic systems, and formulating predictions. Learning mathematics requires learners to have a good understanding of the concepts and problem-solving skills. Mathematical concepts explain how certain rules are applied and the reasoning behind them. Understanding the concepts enables learners to apply appropriate problem-solving strategies. This skill involves critical thinking that allows them to break down difficult problems into simpler parts. However, mathematics is often associated with complexity and disassociated to the real world [1, 2]. Thus, their perception is becoming one of the global issues, as many learners choose not to pursue mathematics. Convinced actions are required to change their perception and encourage learners to have more interest in learning mathematics. Creating an enjoyable learning environment has been shown to be one way to encourage learners to have a better understanding [3, 4]. Visualizing mathematical concepts in real-life scenarios and providing space for learners to learn while playing may support learners' engagement with mathematics. Educational games can make learning more enjoyable while motivating learners by offering challenges and control over their learning experience [3, 5]. Moreover, gaming is a popular activity among young people, and games appeal more to Millennials and Gen Z than movies [6]. Therefore, the use of game technology as an interactive learning media has the potential to eliminate boredom and fear of learning mathematics, especially for Millennials and Gen Z.

Even though educational games are an excellent teaching tool, there is a limited number of mathematics games that are designed for upper-level topics specifically for undergraduate students [4, 7]. Most mathematics games aim for pre-school to primary level that only cover basic calculation. Upper-level topics mostly presented in the form of textbooks, traditional video or slide presentation [8, 9]. Topics like differentiation and integration, which are often considered difficult topics are limitedly available in a more enjoyable form to learn [10]. Presenting the topic as the content of educational game and visualizing the topic to real-life scenarios may able to make learner comprehend easily. It has potential to help the learner to understand the mathematical concept of differentiation and integration and improve their problem-solving skills while playing. However, the studies that focus on designing and developing mathematics games for undergraduate students are limited [4, 7].

Despite the increasing adoption of educational games in mathematics education, most existing studies and applications continue to focus on basic mathematical skills at the primary and secondary levels. Research that addresses game-based learning for undergraduate calculus topics, particularly differentiation and integration, remains limited. This gap indicates a need for instructional tools that support conceptual understanding of

*Corresponding author

advanced mathematical topics through interactive and engaging learning environments.

Therefore, this study aims to explore the research activities in designing an educational game for undergraduate students, specifically on the topic of differentiation and integration. The primary objective of this study is to design and develop a serious game prototype for undergraduate calculus topics, namely differentiation and integration. It is represented by visualizing the mathematical concept interactively using graphics and animation by depicting a real-life scenario. The methodology used to develop the game prototype is the Analysis, Design, Development, Implementation, and Evaluation (ADDIE) method. This method is suitable for the research as the system requirements are clearly identified before development begins, reducing ambiguity and minimizing potential design errors. The iterative processes where continuous testing, validation, and improvement are significant for refinement. Evaluation of the suitability of the prototype as a learning tool using expert validation, contributing to the limited body of research on educational games for advanced mathematics topics. At this stage, this study focuses on design and suitability evaluation through expert validation and does not aim to measure student learning outcomes. At the end of this study, a discussion on the results of the study is explained, and some recommendations for future study are defined.

II. Previous Studies

Mathematics is a broad subject covering geography, science, politics, and society, and every aspect of life is affected by mathematics. It implies that mathematics is a critical need for sound work in life, irrespective of the field of study or profession of practice of anyone [2, 11]. Educational games, known as a combination of education and playful experience, can motivate the students to learn mathematics, which is mentioned to be a challenging subject [3, 12]. The games are increasingly used as educational resources for students because it is the most engaging and enjoyable virtual environment [10]. Despite the advantages of educational games, research emphasizes the scarcity of mathematics games specifically designed for advanced topics, particularly at the undergraduate level [10]. Most existing games target basic mathematical skills suitable for younger audiences, creating a gap in resources for more complex topics such as differentiation and integration, which are often perceived as challenging.

Motivation, self-confidence, and perceived usefulness of mathematics are some positive attitudes that correlate with learning outcomes. Previous studies highlight the importance of creating supportive learning environments that nurture positive attitudes [2]. Significantly learning by visualizing the equations into graphics and incorporating games into learning is one of the ways for providing a supportive learning environment [3, 13]. Mauntel & Zandieh [3] in their study found that combining game-based and dynamic geometry tools supports the transition of conceptual understanding to real-scenario application in learning mathematics. Their game, named Vector Unknown, created a motivating and exploratory environment, allowing students to experiment and strategize while learning vector concepts. The study shows that students developed richer and more flexible ways of thinking and learning mathematics.

Another perspective that is important in learning mathematics is looking at the view of the teacher. Observation from the teacher during the learning process can be a good input in creating a positive learning environment. According to Matic [7], who explored the perception of teachers on computer games, discovered that teachers generally view computer games as useful tools for enriching mathematics instruction. However, based on the analysis of their survey, most teachers clarify that there is a shortage of resources in terms of suitable games for learning. The teacher-centered research design revealed that future initiatives should focus on empowering teachers through training and developing constructivist game tools in teaching mathematics [7]. This finding is consistent with the research method and results shared by Salainti & Neman [13], where they found that computer games create a more enjoyable learning environment, with noticeable increase in student attention and enthusiasm during lessons. They also concluded that teachers are open and optimistic about integrating computer games in learning. Matic [7] and Salainti & Neman [13] ask teachers' opinions about the use of computer games in teaching subjects in classrooms and both studies applied teacher-centered research design approach.

Studies by Mauntel and Zandieh [3], Anagnostopoulou [10], Matic [7] and Salainti and Neman [13], have significant differences on methods used. Mauntel and Zandieh [3] and Anagnostopoulou [10], primarily focus on learners' engagement, motivation, and conceptual understanding through direct interaction with game-based environments. These studies applied student-centered design in evaluating the game using the Game Experience Questionnaire and Players' Experience of Need Satisfaction to capture students' responses during gameplay. While Matic [7] and Salainti and Neman [13] emphasize teachers' perceptions of usability, classroom feasibility, and instructional value rather than individual learner experience. Student-centered approaches provide rich insights into engagement and learning processes. However, this approach often fails to notice limitations related to curriculum alignment and classroom implementation. In contrast to teacher-centered approaches that are more focused on instructional integration and resource suitability, this study adopts the method, aiming to evaluate the suitability of a calculus-focused game prototype.

Calculus-focused games require learners to understand mathematical concepts through visualization or graphical representation that mimics a real scenario. A study that explores calculus-oriented games, such as the role-playing game developed by Anagnostopoulou [10], demonstrates a shift from procedural practice towards exploration and problem-based learning. Procedural practice in basic mathematics is frequently selected as the content of educational games designed for primary and secondary education levels. These games often emphasize repetitive practice, immediate feedback, and skill reinforcement, making them suitable for foundational learning, but less adaptable to the abstract reasoning required at higher levels of mathematics. Research on upper levels of mathematics games remains limited. This imbalance indicates that basic mathematics games are well established and calculus-focused games are still inadequate, emphasizing the need for further

studies that support higher-order mathematical thinking at the undergraduate level.

Not only are the resources of teaching mathematics using computer games limited, but the calculus topic, like differentiation and integration, has always been non-spotlight. Based on the search on the index-comprehensive and multidisciplinary academic research database, Web of Sciences in December 2023, there is a very limited amount of research done that is focused on teaching differentiation and integration topics. Anagnostopoulou [10] considers this gap and explores a role-playing game (RPGs) in mathematics education that includes the topic of differentiation and integration. The author aims to improve the students' engagement and understanding of the topic by designing an RPG and evaluating the game by adapting and devising Players' Experience of Need Satisfaction (PENS) and the Game Experience Questionnaire (GEQ). The result of the study shows a significant improvement in students' mathematical abilities and a positive attitude towards the subject, also responding to the gap of Matic [7] and Salainti & Neman [13]. The author also suggests that innovative approaches can be particularly effective in adult education settings, where traditional teaching methods may be less engaging.

The evaluation method applied by Anagnostopoulou [10] is similar to the method applied by Alsswey [14] and Rodrigues & Cheiran [15], but different in terms of questionnaire, as they used the Suitability Evaluation Questionnaire (SEQ) to evaluate their applications. SEQ consists of 14 questions that include the user's feelings while playing the game, and a fewer number of questions compared to GEQ and PENS. An optimized number of questionnaires may help respondents to be more focused on answers, committed to responding and reduce the burden on respondents. There are many arguments in the number of items in a questionnaire; however, the suitability of the questionnaire to the objective of the study is the most important factor to consider.

Comprehensive instruments such as the Game Experience Questionnaire and Players' Experience of Need Satisfaction are effective in evaluating the learners' immersive and motivational experiences, as applied by the research in [7] and [14]. However, these instruments are less suitable for early-stage prototype evaluation, where instructional suitability and usability are the main interests. SEQ has been applied in studies focusing on the practical assessment of educational applications, particularly in terms of ease of use, clarity of content, and overall appropriateness for instructional purposes [14, 15]. It is suitable to evaluate educational tools within limited time constraints. Therefore, SEQ is considered appropriate for this study, which adopts a teacher-centered design to evaluate the suitability of a serious game prototype for classroom integration rather than to measure learners' affective gameplay experiences.

Based on the input from previous studies, this research aims to fill in the gap by designing a prototype of a computer game that focuses on the calculus topic, which is differentiation and integration. To evaluate the design of game prototypes, a SEQ is employed through teacher-centered design research. The following section briefly describes the methodology.

III. METHODOLOGY

This study mainly focuses on the process of designing serious game content of real-life scenarios that relate to mathematical theories, which are the differentiation and integration topics. The aim of the game is to assist learners in understanding how differentiation and integration theories can solve real-life problems. The methodology of the study is divided into three phases, as described in Table I. The first phase is the Conceptual phase, which involves literature analysis on similar studies. The result of this phase is the theories and the content scope. The second phase is called the Design and Development phase, which involves specific steps that are frequently applied by application developers [16], which is Analysis, Design, Development, Implementation, and Evaluation (ADDIE). In this process, expert validation is needed to evaluate the low-fidelity design before the real game prototype is developed. A low-fidelity design is a paper sketch that has a game storyline that consists of real-life problems and can be solved by using appropriate mathematical theories. Three experts are appointed to examine the correctness of mathematics theories and how they apply to serious game design. The experts are appointed based on the criteria of having at least five years of experience in teaching calculus for undergraduate students. The third phase is the Game evaluation phase, which is carried out by developing a game prototype based on the finalized outcome from phase 2. Eight experts are appointed to evaluate the game prototype using SEQ to measure the suitability of the game to assist learners in learning differentiation and integration. The selection of experts for this phase followed the same criteria applied in the preceding phase. Accordingly, the three experts involved in the earlier evaluations were invited to participate in the assessment at this stage.

TABLE I. RESEARCH FRAMEWORK

Phase	Method	Expected result
Conceptual analysis	Literature study on Similar studies on existing mathematics games Mathematical concepts	Scope - differentiation and integration
Design and Development	ADDIE method Three experts to validate the low-fidelity design	Serious game prototype design
Game Evaluation	Eight experts to measure the suitability	Validated mathematics game prototype

A. Instrument

The instrument is adapted originally from Gil Gomez [17], called the Suitability Evaluation Questionnaire (SEQ). The questionnaire is used to evaluate the user experience with the product, such as satisfaction, acceptance, and security of use. The SEQ includes a short feedback questionnaire and focuses on the product's suitability for the users, consisting of 14 questions that include the user's feelings while playing the game. The questionnaire is scored from 1 to 5, with 1 indicating "not at all" and 5 indicating "very much", or 1 indicating "very easy" and 5 indicating "very difficult".

B. Expert Evaluation of Low Fidelity Design

Recruited experts are from the mathematics field who have good experience in teaching calculus, specifically differentiation and integration topics.

A low-fidelity design in the form of a paper sketch is given to the experts to evaluate the content of the game. Their responsibility is to ensure that all mathematical theories are correctly applied to specific real-life problems. They need to agree and disagree with 25 checklist items that describe the storyline of the game. Table II shows an example of questions. At the end of the checklist, experts can add further comments/ suggestions, and it is not compulsory. The size of the respondents is suitable for this study according to Paz [18].

TABLE II. EXAMPLE OF CHECKLIST ITEMS

Num	Question	Image Num	Theory	Agree (Yes/No)
1	A ladder slides down a tree. If the bottom moves away from the wall at 2 m/s, find how fast the top is falling when the bottom is 3 m from the wall and the ladder is 5 m long.	1a	Acceleration Differentiation	
2	If the ladder starts falling from rest and accelerates due to gravity, model the velocity function and find the acceleration at t=2 seconds.	1b	Acceleration Differentiation	
3	If the radius of the cylinder decreases over time, determine the time when the radius becomes half its initial value.	2a	Volume Differentiation	

C. Expert Evaluation of the Game Prototype

A total of eight mathematical experts are recruited for the study to evaluate the game prototype. The number of respondents is enough for this study, according to the heuristic evaluation method [18]. The SEQ is designed using Google Form and the survey link is shared to all experts together with a game installer. The respondent needs to play the game as long as they need, then they need to fill in the survey form. The result from the survey is analysed using descriptive analysis and a table of improvement actions is adapted from Ramli [19] and applied to categorize the results based on mean score. Table III shows the improvement action.

TABLE III. IMPROVEMENT ACTIONS BASED ON MEAN SCORES

Score	Action
0.00 - 1.66	Design must be improved
1.67 - 3.33	Design can be improved
3.33 - 5.00	Design is maintained

IV. RESULTS

This section describes briefly the result of the study on phase 2 and phase 3 that consists of: 1) suggested design of low-fidelity interface, 2) evaluation result for low-fidelity design and 3) evaluation result on game prototype using SEQ. Hence, the results are divided into two parts, namely design and evaluation of low-fidelity interface, and game evaluation result based on the research framework, as shown in Table I. The first phase of the methodology is carried out by utilizing the literature review process that concludes the scope of the research, which is differentiation and integration.

A. Design and Evaluation of Low-Fidelity Interface

A paper sketch of interfaces and a storyboard are designed using the ADDIE method. The paper sketches, also known as low-fidelity, are designed to mimic real-life scenarios purposely to present the real-world problem that can be solved by using mathematical theories, specifically differentiation and integration. Fig. 1 shows the example of low-fidelity interface designs, while Fig. 2 shows the design of interfaces for the homepage, menu, and game contents included in the example. For the interface, 1. Menu page and 2. Game map, shows the main pages that include the introduction of the game. For the interface, 3. Level 1 illustrates the real situation of a ladder leaning on a tree and to add a storyline to the game, there is a cat on top of the tree that needs to be saved. However, the ladder may slide from the tree, and this is where the differentiation theory, which is acceleration, is applied to describe how fast the ladder falls down. The players need to calculate using the differentiation (acceleration) theory by having certain conditions, like the height of the ladder and the tree. Interface Level 4 and Level 5 show the example of low-fidelity design for differentiation theory of volume and integration theory of heat.

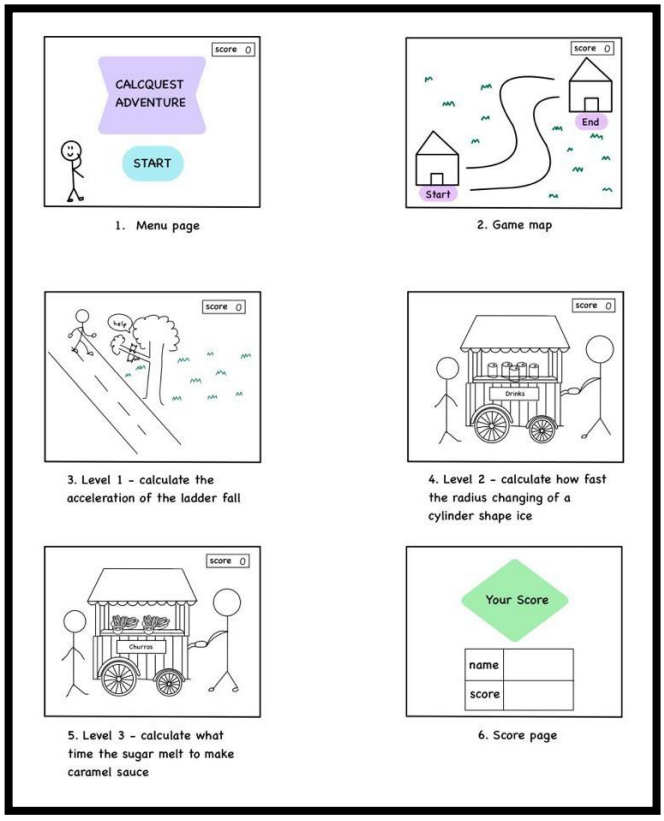

Fig. 1. Examples of low-fidelity interface designs for CalcQuest Adventure.

The recruited experts reviewed the description of each interface in the low-fidelity design and answered the questions by agreeing or disagreeing with the statements. The evaluation of low-fidelity design took around 3-6 weeks, and all experts

returned the feedback within acceptable time. Based on the feedback of all experts, it shows that there was no disagreement with any of the 25 statements in the checklist neither nor further arguments or suggestions from the experts. It can be concluded that all experts agree with the theory applied.

Based on the positive result of low-fidelity design evaluation, a game prototype is developed by using Scratch software and the duration of development took around 10 weeks. The game prototype is called CalcQuest Adventure and Fig. 2 shows the examples of game scenes. The main character, Jordyn, represents the player to experience the real-life scenario and handle all the challenges that need to be solved using the differentiation and integration theories. In order to make the game fun to play CalcQuest Adventure is designed by including game elements like game mechanics, goal, progression, balance, feedback, narrative and aesthetics. The different ways to collect points and answer the questions are examples of challenging fun factor that is included in the game design. For example, in Level 1, players engage in a shooting game for innovative question-solving. Level 2 introduces a catching game, which adds agility and coordination to the learning process. Lastly, Level 3 introduces a drag-and-drop game, requiring a hands-on approach to answering questions. This dynamic and engaging interface meets various learning styles, ensuring comprehensive educational experience at different skill levels.

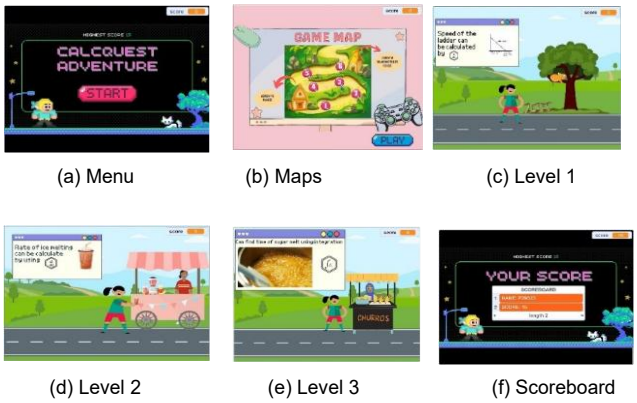

Fig. 2. Game scenes from CalcQuest adventure.

B. Game Evaluation Result

A total of eight mathematical experts participated in the study. The results from the survey are retrieved from the Google Form distributed within the game installer file. Table IV shows the results generated by SPSS 5.0. The overall mean score is 3.85 and referring to Table III, the design of CalcQuest Adventure falling under the “Design is maintained” category, where by the design is maintained and generally well-received by users with mean scores above 3.33 across most items. The highest value of mean score is 4.25 which is for item 8, addressing that the game is helpful for students’ learning. This result indicates that "CalcQuest Adventure" has the potential to become a valuable learning tool.

Items 7, 9, and 10 of the SEQ are negatively oriented, with higher scores reflecting increased discomfort or difficulty. Therefore, these items were reverse-scored during the analysis to ensure consistency in score interpretation across all instrument items, whereby higher scores uniformly represent more positive outcomes. Based on the analysis, the lowest value of the mean score is 3.00 for item 7, suggesting minor issues that may affect user comfort. Mean score 3.0 falls under category 2 which is the design that can be improved but not compulsory. No other item from the questionnaire has mean score less than 3.33 indicating CalcQuest Adventure giving positive user experiences. Aside from that, the total average of standard deviation from the eight mathematics experts is 0.7851 indicating a relatively low level of variability in the scores, the feedback consistent and stable performance across respondents.

Fig. 3 is a graphical representation of the relationship between mean values and the number of items, serving as a visual representation of the data derived from the SPSS analysis that is shown in Table IV. The visual graph provides a clearer visualization of the trends observed in the corresponding Table IV. It can be seen that almost all item distributed on the right side of the graph indicate the positive feedback from all experts.

TABLE IV. DESCRIPTIVE ANALYSIS

Item	Questions	Mean	Standard Deviation	Action
1	How much did you enjoy your experience with "CalcQuest Adventure"?	4.125	0.6409	Design is maintained
2	How immersed did you feel being in the environment of “CalcQuest Adventure"?	4.000	0.7559	Design is maintained
3	How successful were you in understanding through “CalcQuest Adventure"?	4.125	0.8345	Design is maintained
4	To what extent were you able to control “CalcQuest Adventure"?	3.875	0.8345	Design is maintained
5	How real is the virtual environment of “CalcQuest Adventure"?	3.750	0.8864	Design is maintained
6	Is the information provided by "CalcQuest Adventure" clear?	4.125	0.8345	Design is maintained
7	Did you experience any discomfort during your experience with “CalcQuest Adventure"?	3.000	0.9258	Design can be improved
8	Do you think that “CalcQuest Adventure" will be helpful for your students' learning?	4.250	0.7071	Design is maintained
9	Did you find the task difficult?	3.625	0.5175	Design is maintained
10	Did you find the “CalcQuest Adventure" interface difficult to use?	3.625	0.9161	Design is maintained

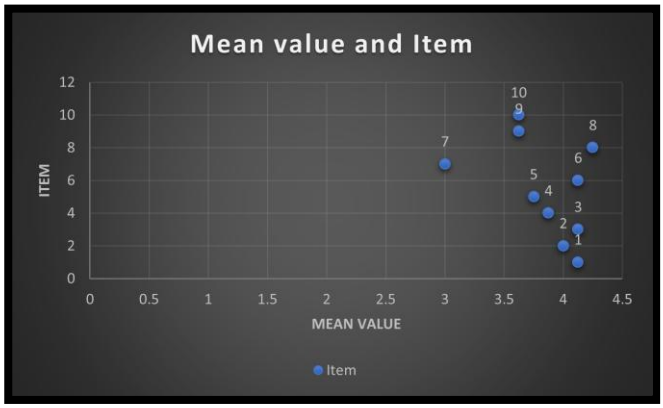

Fig. 3. Mean value vs. item

V. Discussion and Conclusion

This study aimed to design a mathematics game prototype for undergraduate students focused on enhancing the understanding of differentiation and integration. Mathematics is often perceived as abstract and disconnected from real-world, as it is frequently viewed by students as a challenging subject with limited practical relevance. This perception has contributed to a global decline in mathematics-engagement among undergraduate students. Thus, the use of game-based learning as a pedagogical tool to make mathematics more engaging, enjoyable, and applicable to real-world contexts can be the solution. However, limited resources of games designed for upper education level restrained the resolution. The goal of the study is to fill in the gap by providing a game that covers the topic of calculus specifically differentiation and integration and relate the mathematics theories to real-life problems.

CalcQuest Adventure, a game prototype developed using the ADDIE instructional design model is designed to mimic the real-life problem and players solve the problems using the theories of differentiation and integration. The game prototype underwent an expert evaluation phase twice, first during the early phase by creating a low fidelity interface design in the form of paper sketch and second during the last phase, where eight experts are recruited to assess the design using a validated instrument known as the Suitability Evaluation Questionnaire (SEQ).

The feedback data, presented in the form of mean scores and standard deviations, offers valuable insights into the perceived strengths and limitations of the game. The evaluation comprised ten items, each rated on a 5-point Likert scale. Nine out of ten evaluation items received mean scores above 3.34, confirming that the game's design is well-maintained across several dimensions. Experts reported high enjoyment (item 1), a strong sense of immersion (item 2), and clear instructional content (item 3). These results suggest that CalcQuest Adventure succeeds in making mathematics more relatable and engaging, a critical step in addressing student disengagement from the subject. Furthermore, the game was perceived as helpful for students' learning (item 8), highlighting its potential as a supplementary educational tool.

One notable exception was the item regarding user discomfort, which scored a mean of 3.00. Although this value still falls within an acceptable range, it indicates that some aspects of the user experience may require further refinement to improve player comfort. It is very crucial to choose evaluation method and a significant type of evaluation that cater to usability must be carried out in order to get the detail issues on this matter [20]. However, this score does not undermine the overall merit of the game. The standard deviation values, ranging from 0.51 to 0.93, reflect moderate variability among expert opinions, suggesting general consensus while acknowledging some differing perspectives [21]. These findings are important for iterative improvements to the game design.

In summary, the expert evaluation supports the conclusion that CalcQuest Adventure provide valuable insights into the quality and effectiveness of a game design, particularly during the prototype and formative evaluation stages. By leveraging experts' knowledge and experience, the SEQ helps identify design strengths and weaknesses before conducting large-scale user testing specifically on the topics of differentiation and integration. Based on the result of analysis, the game prototype offers a learning experience that may enhances students' understanding on the topic. With an overall mean score of 3.85, the results indicate expert approval, validating the game's readiness for classroom implementation. Previous study on education field shows that range of 3.41 to 4.20 reflects a high level of engagement and satisfaction [18]. Higher levels of engagement and satisfaction in learning may contribute to improved learning outcomes and academic performance [22].

By improving comfort and minimizing usability issues, may enhance the game's effectiveness. According to experts, CalcQuest Adventure demonstrates that game-based learning can serve as a tool in learning mathematics for upper education level. Further research needs to be done to improve the design of the game and more suitable evaluation has to be carried out in order to create a suitable tool to learn mathematics, especially for undergraduate students. Future work may explore both content refinement and game engine optimization, particularly through the integration of more advanced algorithms to improve overall system performance and user experience [23]. This study contributes to the limited body of research on serious games for undergraduate calculus by demonstrating the feasibility of expert-validated game design for differentiation and integration

Declaration

All data analyzed during this study are included in this research. The authors declare that there is no conflict of interest. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

The corresponding author conceived the research idea and provided overall guidance. All authors contributed equally to the research activities, game design and development and data analysis. Manuscript writing was led by the corresponding author, with discussion and brainstorming involving all co-authors. All authors read and approved the final manuscript.

Acknowledgment

We thank the Universiti Teknologi MARA for the academic support of this research.

***Abstract*—The issue of fake certificates has been widely identified, and their prevalence has increased significantly in recent years. This growing trend has become a global concern due to its adverse impact on educational standards. A key factor contributing to the problem is the continued reliance on manual processes for issuing and verifying certificates. To address these challenges, this study proposes the use of an authority round (AuRa) consensus algorithm for managing certificate data on the Ethereum blockchain. AuRa, a member of the proof of authority (PoA) family, facilitates consensus among nodes distributed across multiple servers and networks. This mechanism plays a vital role in preserving the integrity and decentralization of the blockchain while ensuring the security of transactional data. Furthermore, the study investigates how AuRa enables efficient certificate data transactions within a private Ethereum environment. It also evaluates the algorithm's performance in terms of transaction speed per second (TPS) and throughput per second (TGS), demonstrating its effectiveness for managing certificate transactions on a blockchain network. Then the TPS and TGS results substantiate the suitability of AuRa for digital certificate generation, evidenced by its stable and efficient performance within a controlled private server environment.**

***Keywords*—Blockchain technology; fake certificate prevention; Authority round (AuRa) algorithm; ethereum private network; Proof of Authority (PoA); certificate verification system**

I. Introduction

Certificates are important for graduate students as proof that they have completed their studies. Unfortunately, numerous job seekers use fake certificates to apply for jobs. Fake certificates were first traced in the 19th century [1]. Such certificates were issued by a nonexistent university.

Fake certificates have become a global issue and have been detected worldwide [2]. In response to the scenario, the research proposes the digital certificate using blockchain technology supported by the authority round (AuRa) consensus algorithm.

Blockchain allows participants to write and read the transactions in the network [3]. To ensure the security of blockchain, this research implements the Ethereum and AuRa consensus algorithms. The consensus algorithm serves as a security mechanism by establishing agreement among nodes to ensure the throughput is consistent, not different, and valid. This research also implemented the smart contract as a logic flow to transact data into the blockchain.

The research aims to create a digital certificate using the AuRa consensus algorithm through a smart contract and to measure the transaction speed per second (TPS) and throughput per second (TGS). The implementation is executed on a private server that consists of three datasets, each containing a different number of records and including data information such as student number, gender, and faculty. This research aims to address the issue of counterfeit certificates by generating a digital certificate using the Ethereum blockchain supported by the AuRa consensus algorithm.

The contribution of this study lies in demonstrating that the AuRa consensus mechanism is capable of supporting blockchain-based transaction processes. The effectiveness of these processes is evaluated using throughput performance indicators, namely TPS and TGS, in the context of digital certificate generation. Furthermore, the findings indicate that AuRa can effectively address issues related to the prevention of counterfeit certificates in the digital certificate issuance process.

Section II outlines the issue of counterfeit certificates and examines the underlying causes. It also provides an overview of blockchain technology, with a focus on the Ethereum platform and the AuRa consensus algorithm, highlighting their potential in addressing the problem of certificate forgery.

Section III details the proposed implementation of the method to mitigate these issues. Section IV presents the results and analysis of the implementation, followed by Section V, which discusses the findings and acknowledges the limitations of the study. Finally, Section VI concludes the study by summarizing the implementation of blockchain technology and the AuRa consensus algorithm for certificate generation, and outlines potential directions for future research.

A. Novelty

This study introduces a novel real-world deployment of the AuRa consensus algorithm for digital certificate generation, offering an empirical assessment that is largely absent in prior

*Corresponding author.

blockchain-based certificate management literature. While existing works commonly focus on conceptual frameworks or simulated environments, this research advances the field by evaluating AuRa within an operational private server setting and by utilizing two concrete performance metrics, TPS and TGS. The use of TPS and TGS as paired performance indicators provides a measurable and systematic way to assess both transactional efficiency and data-handling capability, thereby contributing a practical and reproducible evaluation methodology to the research domain.

B. Contributions

Then the findings demonstrate that AuRa delivers stable and favorable TPS and TGS performance outcomes, substantiating its suitability for real-world digital certificate generation. This work contributes empirical evidence that AuRa can reliably support certificate issuance workflows with predictable throughput and consistent operational behaviour within a private server environment.

Beyond confirming performance viability, the study provides a validated deployment model that institutions can adopt or extend for secure certificate management. Collectively, these contributions highlight the practical applicability of AuRa and position this study as one of the few that bridges the gap between theoretical blockchain designs and deployable certificate management solutions.

II. Literature Review

The main criterion for employers to choose an employee is the certificate. Employers verify certificates manually, which is time-consuming and labor-intensive. The difficulty of verifying the certificate contributes to the issue of the production of fake certificates. The problem of forged certificates persists among the higher education community [4]. Fake certificates have become a global issue, which is associated with certificate scams.

Numerous factors cause these problems. One of the factors is an inefficient student management system. The highly trustworthy system needs to be implemented to eliminate the fake certificate problem [5]. Another factor is that employers often do not complete the certificate verification process because it requires extra human resource efforts [6]. Manual verification processes also exacerbate these problems [7]. Employers must contact academic institutions manually for certificate verification, which takes significant time and effort [8].

To address the growing issue of fake certificates, blockchain technology can provide a solution. Blockchain technology is an effective method to address these problems. Many applications and methods based on a blockchain framework have been proposed to prevent fake certificate issues, as described in Table I.

Based on Table I, show the implementation of blockchain for a digital certificate. However, these studies face performance issues for the verification and authentication of digital certificates. Unfortunately, this study also did not discuss the measurement and performance results of the digital certificate.

A. Blockchain Technology

Blockchain is a decentralized, distributed database used for storing transaction data and information. Blockchain was introduced as a new method of managing and storing data, replacing traditional centralized systems with decentralized systems [14]. The data storage consists of a chain of records known as blocks.

Data is stored across different nodes on different servers. The blockchain is also known as a peer-to-peer (P2P) network [15] because the nodes communicate with each other through a P2P network. Blockchain uses a storage system to store digital data and protect it with cryptography and a hash function. Cryptographic enforcement in blockchain networks ensures immutability, rendering the recorded logistics data resilient against tampering and hacking [16].

In 1991, the capabilities of blockchain were improved with the secure chain of blocks, which could be implemented through the cryptographically secure method described by Haber and Stornetta [17]. Today, public blockchains are widely available through various readily available platforms to be implemented by researchers. However, the popular and widely used ones are Bitcoin, Ethereum, and Hyperledger [18]. Ethereum was established years back, focusing on encouraging businesses to adopt the blockchain in their business activities [19]. To date, these blockchain platforms share similarities but also retain their unique features.

Both Bitcoin and Ethereum are public blockchains that allow everybody to participate in writing and reading the transactions in the network. This concept is known as the permissionless blockchain. Participants are allowed to connect and disconnect from the network at any time without permission.

B. Ethereum

Ethereum was first introduced by Vitalik Buterin in 2013. It was intended to overcome the limitations of Bitcoin. In 2014, Ethereum's development was crowdfunded in 2014 to improve the technology. Ethereum has implemented distributed data storage that allows everyone to run their own applications on the blockchain [20]. It is capable of storing data with flexible block sizes. The Ethereum engine requires support from Ethereum blockchain clients.

The Ethereum client can be deployed on development and production environments, but it has difficulties and needs expertise to set up and configure the environment. Parity and Geth are the popular and active supporters of the blockchain community [21].

However, the Ethereum clients need to be supported by a consensus algorithm to ensure the security and performance of transactions in the blockchain.

C. Consensus Algorithm

A consensus algorithm is an agreement process among nodes across different servers and networks. It supports and commits a blockchain system to maintain the consistency and decentralization of nodes [22]. Consensus algorithms enhance the security of blockchain transactions by ensuring that throughput remains consistent and valid. The consensus algorithm is functional not only in terms of security aspects, but it also provides services for reducing the execution time of transaction processes and providing the highest throughput.

The performance of consensus depends on its algorithm and protocol for executing transactions in the blockchain. Its performance also directly impacts the processing speed and scalability of the blockchain. A consensus algorithm that commits transactions in less time is more efficient. Faster consensus execution increases throughput. In addition, various consensus algorithms support blockchain transactions. The most popular and widely implemented blockchain applications are proof of authority (PoA), practical byzantine fault tolerance (PBFT), proof of stake (PoS), and proof of work (PoW). Table II shows the consensus and its specialty.

TABLE II. CONSENSUS AND SPECIALTY

Consensus	Specialty
PoS	More spikes in blockchain
PoW	Able to solve a mathematical puzzle
Proof of Luck	Implemented the random selection
Proof of Elapsed Time	Able to set up the scheduling while the timeout.
Proof of Space	Implemented in bigger size of hard disk environment
PoA	Well-suited for public blockchains deployed in private environments.

D. PoA

PoA was introduced by Wood as an alternative to PoW and PoS. PoA was introduced to overcome the limitations of PoW and PoS [23]. Therefore, the PoA has become a popular consensus algorithm because of its high-performance transaction process and security. It is able to process thousands of transactions per second without impacting its security. PoA also provides fault tolerance and efficiency.

Besides that, the PoA consensus also needs less energy and fewer computational resources to implement. It also makes efficient use of network bandwidth. This algorithm is used in permissioned blockchains and is implemented in two versions, namely AuRa and Clique. These versions contain their own advantages and disadvantages.

This research implemented the AuRa because it was originally proposed for a private network environment [24]. That is why this research chose to implement AuRa to overcome the fake certificate issue. Additionally, nearly 4,000 blockchain projects across various domains, including education, management, healthcare, and insurance, have utilized AuRa [25]. As proven, AuRa is more secure compared to Clique, and AuRa throughput is higher than PoW.

Although this study does not formally benchmark alternative consensus algorithms or certificate verification systems, the selection of the AuRa is justified based on its compatibility with permissioned blockchain environments. Unlike PoW, which is energy-intensive and better suited for public networks, or PoS, which introduces complexity in validator selection, AuRa offers deterministic block production, low energy consumption, and predictable performance. These characteristics align well with the operational needs of academic certificate issuance, where trust is centralized, and efficiency is prioritized. Future work may involve empirical benchmarking against other consensus mechanisms to further validate this selection.

III. RESEARCH METHODOLOGY

To overcome the fake certificate issues, this study proposed to implement the AuRa consensus algorithm to create the digital certificate. Fig. 1 shows the framework of implementation of AuRa to create the digital certificate.

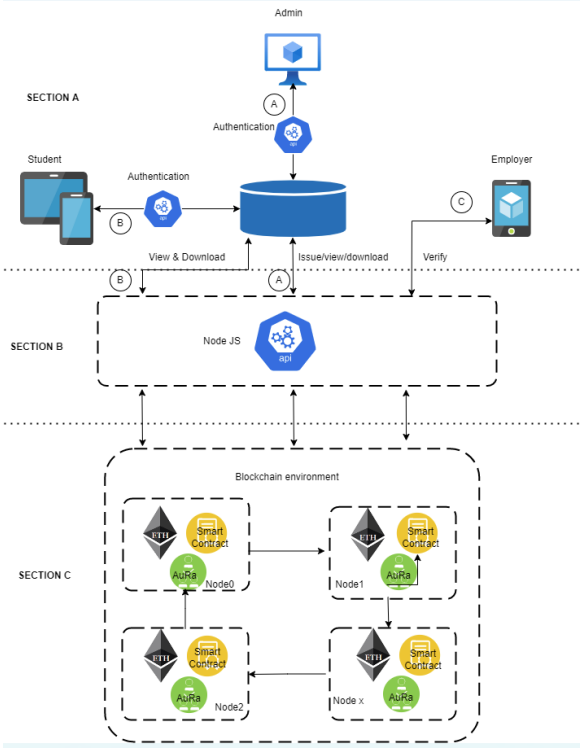

Fig. 1. Implementation of the AuRa framework.

Regarding Fig. 1, the framework to implement the AuRa consensus algorithm is divided into three sections. Section A focuses on the application layer, which comprises three primary roles: administrator, student, and employer. The administrator is responsible for issuing digital certificates through the system, ensuring that each record is correctly generated, authenticated, and securely committed to the blockchain. This role also incorporates access control mechanisms to prevent unauthorized issuance and ensures that certificate data is transmitted and stored in a tamper-resistant manner.

Students, as legitimate certificate holders, are permitted to securely access, view, and download their digital certificates via authenticated sessions within the application. Security controls implemented at this layer, such as identity verification and encrypted communication, ensure that only the rightful student can retrieve their certificate information. Employers function as external verifiers who authenticate the validity of certificates through the application's verification module. This module leverages blockchain-backed immutability to ensure that verification results cannot be falsified, providing a trusted mechanism that prevents manipulation, forgery, or unauthorized alterations of certificate records. Collectively, these security functions establish a secure, transparent, and tamper-resistant application environment.

Section B refers to the backend processes, which serve as the core operational layer supporting the application layer. The backend utilizes an application programming interface (API) to transmit and receive commands and data between the application layer and the blockchain network. These APIs manage the execution of certificate issuance requests, retrieval of certificate data, and verification queries while ensuring secure, authenticated, and structured communication between the frontend and the underlying blockchain infrastructure.

To enhance security, the backend incorporates multiple protective mechanisms. All data transmissions are encrypted to prevent interception or tampering during communication. Input validation and authentication checks are enforced for every request to mitigate unauthorized access and potential injection attacks. Transaction records are logged in an immutable audit trail to provide non-repudiation and support forensic analysis if discrepancies occur. Furthermore, the backend enforces role-based access control, ensuring that only authorized administrators, students, or employers can execute specific operations, thereby maintaining the integrity, confidentiality, and availability of the digital certificate system. These combined security measures ensure that the backend can reliably manage certificate issuance, retrieval, and verification while minimizing potential threats.

Lastly, Section C, the blockchain layer forms the foundational infrastructure of the digital certificate system, providing tamper-resistant storage, consensus validation, and secure transaction recording. This layer leverages the AuRa consensus algorithm to ensure that all certificate issuance and verification transactions are validated by a network of authorized nodes, maintaining integrity and consistency across the distributed ledger. The blockchain layer interacts with the backend via secure APIs, receiving transaction requests for certificate issuance, verification queries, and data retrieval, and returning confirmation or result status to the application layer.

Security functions at the blockchain layer are critical to maintaining trust and reliability. Each transaction is cryptographically signed and recorded in an immutable block, ensuring non-repudiation and protection against data alteration. Consensus mechanisms prevent single-node manipulation, while periodic block validation guarantees that any conflicting or unauthorized transactions are rejected. Access control is enforced at the node level, restricting operations to authorized validators.

Additionally, the blockchain maintains redundancy across nodes, enhancing system availability and resilience against node failures or malicious attacks. Combined with the secure backend and application layers, the blockchain layer ensures a comprehensive, end-to-end security framework for the digital certificate management system, enabling reliable issuance, verification, and auditability of certificates.

Lastly, the framework is comprehensively limited to certificate generation and verification activities. To guarantee the authenticity, security, and reliability of the produced certificates, both activities are required to systematically progress through the processes outlined in Sections A, B, and C.

A. AuRa Consensus Algorithm

The AuRa consensus algorithm was proposed for the Parity client. Parity is one of Ethereum's clients that applied Rust as a programming language. It has been implemented by Lava, VecHain Thor, xDai DPOS network, Microsoft Azure (for deployment only), and Kovan Testnet. This consensus became popular because it was widely adopted in blockchain applications.

This consensus assumes the authorities are honest and the network is synchronous among the nodes. Besides that, AuRa consists of four steps, including transaction pending, proposed block, voting, and as depicted in Fig. 2.

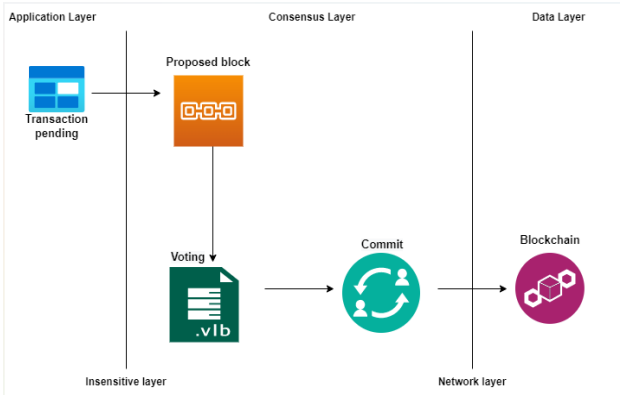

Fig. 2. The steps of the AuRA process.

In Fig. 2, the AuRa algorithm starts by assigning a leader; each authority has its turn to assign as a leader using the Round Robin Algorithm. Then the leader will propose a block, and the authorities will decide if the proposed block is accepted or not. The decision or voting process is based on Eq. (1).

$$2f + 1 \leq n \quad (1)$$

Regarding Eq. (1), where f is a faulty node, n is the number of nodes. In that case, the number of faulty nodes must be at least as many as the number of nodes 50%. Additionally, only trusted authorities are able to add the block to the blockchain. Trusted authorities that call n number and implement the majority among the authorities able to create a node.

After the leader is assigned, the leader will propose the block in the block proposal. Then the voting process will execute on block acceptance, an authority's members will vote on the block proposed by a leader, whether that block is able to commit or

not. If the leader or node is not valid, the process assign new leader will reprocess.

B. Create and Configure AuRa Engine

The AuRa engine comprises the Ethereum blockchain. Once the AuRa engine was installed, the Ethereum blockchain was automatically installed. Each AuRa engine was installed on a different server and is called a node. This research created the nodes at private servers. Each node will act as an authority on the network and issue blocks in the transaction process. Fig. 3 shows the creation of the AuRa engine. AuRa engine created at port xxxx:xxxx, located in the parity folder. These engines are connected with the xxxx.toml file.

Coding 1: Create the AuRa engine

```
[1]  run –rm -ti  -p xxxx:xxxx
[2]  -v ~/.local/share/parity/docker/:/home/parity/
[3]  .local/share/parity/ parity/parity:v3.0.0
[4]  --config /home/parity/.local/share/parity/xxxx.toml
[5]  --jsonrpc-interface all
```

Fig. 3. Create AuRa engine.

Then, after completing the coding to create the AuRa engine, the next step is to create the authority account, as in Fig. 4. The authority account created at port xxxx:xxxx is similar to the port at the AuRa engine. The location and toml file are also similar to the AuRa engine.

Coding 2: Create authority account

```
[1]  run –rm -ti  -p xxxx:xxxx -v
[2]  ~/.local/share/parity/docker/:/home/parity/
[3]  .local/share/parity/ parity/parity:v3.0.0
[4]  --config/home/parity/.local/share/parity/xxxx.toml
```

Fig. 4. Create an authority account.

Based on the execution of Fig. 4, the results in Fig. 5 illustrate the authority account successfully created. The authority account that was created is 0x008ce3c5316c23c8fdee747b0ae59188879xxxxx.

Result : Create authority account

```
[1]  {"jsonrpc":"2.0","result":"0x008ce3c5316c23c8fdee747b0ae59188879xxxxx","id":0}
```

Fig. 5. Result achieved.

C. Smart Contract

Smart contracts were proposed by Nick Szabo in the early 1990s. A smart contract is a platform and a high-level programming language to execute the mining process automatically [26]. The few available programming languages for smart contracts are Solidity, Mutan, Viper, and Chaincode.

The function of smart contracts is to support the Ethereum blockchain. It was developed and stored in the Ethereum blockchain. A smart contract is a programmable code that executes predefined commands stored on a blockchain. These commands include attributes, conditions, and rules that must be met before data can be recorded on the blockchain. Smart contracts leverage programmed logic to autonomously enforce access control lists and system constraints defined within the blockchain infrastructure [27]. In this research, a smart contract was implemented to facilitate the execution of commands for storing data on the blockchain.

Additionally, this research implemented Solidity as a programming language to develop the smart contract code. The smart contract was developed and tested on the Remix integrated development environment (IDE) platform. After the smart contract was successfully tested, it was rewritten on the Truffle framework. At the truffle framework, the smart contract was running using the truffle command to migrate the smart contract and the AuRa consensus algorithm.

Before executing the migration process, the configuration between nodes and the truffle framework must be considered. Fig. 6 captures the coding of the configuration of the nodes and the truffle framework. Line 1 indicates the server to create the AuRa engine. It consists of information about the host (line 3), port (line 4), and network ID at line 5.

Configuration nodes and truffle framework

```
[1]  Networks:{
[2]  Development: {
[3]  Host:"xxx.xx.x.x"
[4]  Port: xxxx,
[5]  Network_id:"xxxxx"
[6]  },
[7]  }
```

Fig. 6. Configuration of nodes and truffle.

Additionally, after configuring the nodes and the truffles framework as depicted in Fig. 6, the next step is to integrate both nodes and truffles. Used the truffle init command, the nodes and truffles will migrate as illustrates at Fig. 7.

Fig. 7. The migration nodes and truffles.

The smart contract address is crucial for integrating transaction data into the blockchain. Additionally, the migration process generates the application binary interface (ABI) file, which is essential for the transaction process.

Smart contracts play a pivotal role in the blockchain ecosystem by enabling decentralized automation that eliminates the reliance on traditional intermediaries. Through this cryptographic execution, these protocols secure data integrity and ensure absolute immutability against unauthorized

tampering. Furthermore, the embedded algorithmic logic allows for the precise enforcement of operational conditions and strict access control mechanisms across the network.

This automated governance enhances system transparency and auditability, providing an immutable ledger of verifiable transaction histories. Consequently, smart contracts serve as the foundational backend infrastructure that drives the functionality of decentralized applications and modern digital economies. Any modifications made to the smart contract logic do not affect system operations, provided that the updated contract undergoes the requisite node reconfiguration and truffle deployment processes.

D. Integration and Implementation

Before certificate issues, Python was implemented as a programming language to generate the certificate that embeds the AuRa consensus algorithm and smart contract. To ensure the AuRa consensus algorithm and smart contract are able to communicate with each other, the Web3 library is implemented. Web3, commonly known as web3.py, is a Python library that is able to interact with smart contracts and Blockchain.

It's commonly implemented in decentralized applications (dApps) to assist the sending transactions process, communication with smart contracts, writing and reading the block data in JavaScript Object Notation (JSON) format, to incorporate the solution for fake certificate issues. The certificate information was converted into JSON format to transact data into the blockchain through the AuRa consensus algorithm. The important data, such as student number, name, result, program, and faculty, were stored in a blockchain database. These data are important and must be accurate and reliable to avoid the fake certificate issues.

To evaluate the framework's practical applicability, the experimental setup simulates a multi-institution infrastructure by deploying a private Ethereum network across several servers. These nodes are strategically distributed across two geographically distinct locations to measure crucial network metrics, including reliability, synchronization overhead, and transaction speeds under realistic network latencies. This distributed private network closely mirrors a real-world, cross-organizational deployment where multiple independent authorities participate in the certificate verification process. Within this environment, digital certificates were generated and evaluated using three distinct datasets, each encompassing varying data types to test the system's robustness against realistic workloads.

Additionally, to ensure integrity and immutability, a private key is utilized in the generation of a digital certificate. A private key is a randomly generated set of numbers used in cryptographic processes. In this research, private keys are generated for selected users who possess the authority to create digital certificates. This research also grants administrators the explicit authority to revoke private keys upon theft or loss. To further prevent unauthorized administrative exploitation, key deployment is restricted to a single-user concurrency model.

E. Hardware and Software

To implement the proposed method in this research, several servers are required. Specifically, four servers were utilized to establish individual nodes, with each server physically located at a distinct on-premises location. The implementation relies on the AuRa consensus algorithm and the Ethereum blockchain engine, both of which were installed and configured on every node across all servers.

Additionally, a smart contract was developed, which was installed and configured on only one of the nodes. Other supporting software tools, including Truffle, Remix IDE, and Ganache, were accessed via their online versions, eliminating the need for local installation on the servers.

IV. Result and Analysis

This study aims to demonstrate that the AuRa algorithm is executable and effective for resolving certificate management. Within the context of digital certificate management, TPS and TGS serve as sufficient and primary evaluation metrics; TPS directly indicates the system's throughput capacity during high-volume issuance periods, while TGS reflects the responsiveness and latency of real-time certificate verification. For a rigorous performance, AuRa was implemented on the myCert platform using authentic graduation certificate data to generate and validate its operational suitability under realistic workloads.

MyCert is an in-house application that manages digital certificates, including the generation and verification process. It uses Python as its programming language and PyCharm as its Integrated Development Environment (IDE). The AuRa consensus algorithm is installed and embedded on myCert platform.

A. Geographic Location

The study deployed identical datasets across three geographically dispersed locations connected through a wide area network (WAN) topology, with each site hosting a data instance linked through intermediary network nodes. This distributed configuration reflects real-world environments in which data must be transmitted and validated across multiple infrastructures. The datasets were processed during peak operational periods to evaluate system behaviour under high-load conditions, specifically to measure the performance of the AuRa consensus mechanism in terms of TPS and TGS. This approach enables a more precise assessment of how network congestion and distributed processing influence overall performance within a WAN-based architecture.

TPS quantifies the number of successful transactions processed per second. It aims to measure the performance of AuRa, focused on transaction speed per second. This study used three sets of data: set 1 consists of 1,021 data, set 2 includes 2,435 data, and set 3 comprises 3,422 data. Three sets of data refer to the number of graduation student starting 2023 to 2025.

Based on three sets of data, the AuRA is used to generate the certificate. The performance of AuRa is measured by TPS and TGS. Fig. 8 illustrates the result of TPS. Based on the TPS result at different locations, the Data Set 1 is 31.59, Data Set 2 is 29.69, and Data Set 3 is 18.59. The same location for TPS result is 40.32,32.03 and 19.25.

Regarding Fig. 8, it is observed that the number of transactions significantly impacts the system's throughput performance, measured in TPS. However, the TPS results across

these datasets are not consistent, indicating that factors beyond transaction volume, such as network latency or processing overhead, may influence overall performance. This research also measured the TGS. The TGS represents the total size of data that transactions process successfully per second. This research measures the TGS for the size of the data.

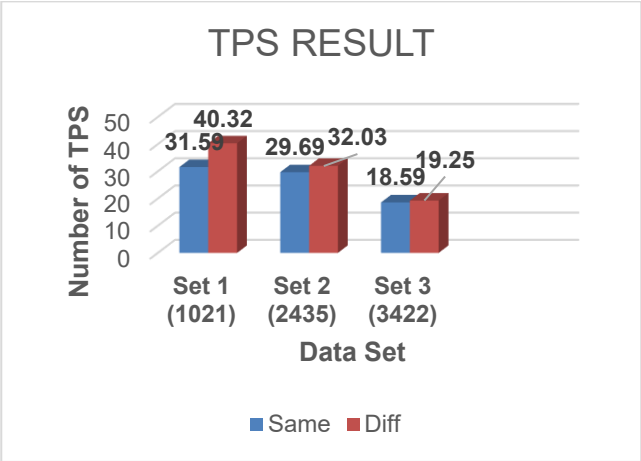

Fig. 8. The TPS result.

Regarding data in Table II, the TGS results were measured and compared with the execution at different and the same locations. Fig. 9 states the result of a number of TGS. Based on the TGS results, it showcases that set 1 has successfully transacted 1,064,266.14 KB per second, while set 2 is 992,814.83 KB per second, and lastly, set 3 successfully transacted 624,364.33 KB per second for a different location. The same location for TGS result is 1,358,194.53 KB per second, 1071194.95 KB per second, and 655,649.11 KB per second.

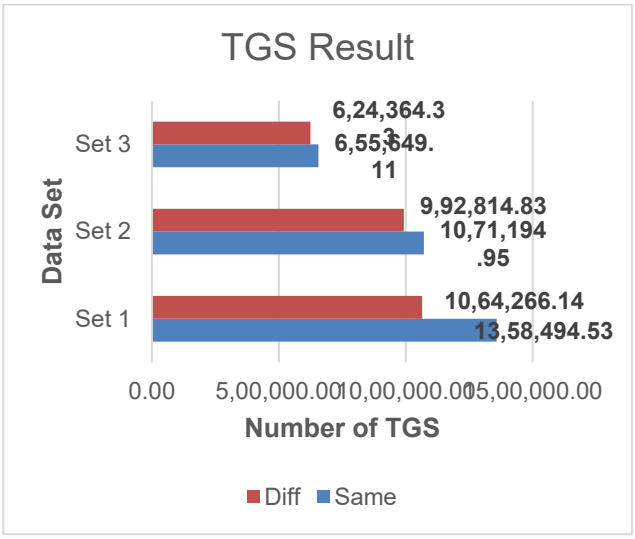

Fig. 9. Number of throughputs per second.

B. Number of Nodes

The number of nodes can significantly impact the performance of a consensus algorithm. In this study, the AuRa consensus algorithm was executed to generate digital certificates under three different scenarios using the same dataset.

In the first scenario, three nodes were deployed; in the second, four nodes; and in the third scenario, five nodes were implemented. To ensure a controlled testing environment, all three configurations were evaluated using uniform network bandwidth, identical server capacities, and a standardized dataset volume. This setup was designed to evaluate the effect of node scalability on system performance.

The TPS results presented in Fig. 10 show that the first scenario, which deployed three nodes, achieved a throughput of 53.32 transactions per second, outperforming the second scenario with four nodes, which recorded a TPS of 50.92. In the third scenario, where five nodes were implemented, the TPS increased to 52.25, indicating a partial recovery of performance relative to the four-node setup. These observations demonstrate that node count exhibits a non-linear influence on system throughput, suggesting that merely increasing the number of authority nodes does not guarantee improved performance within the AuRa consensus environment.

However, this experiment is limited to evaluating only three configurations, including three, four, and five nodes, under a three-dataset, which restricts the depth of performance interpretation. The analysis does not yet account for several critical factors that could further affect TPS behaviour.

Specifically, the study does not evaluate system performance when an authority node fails or behaves maliciously, which is essential for understanding AuRa's robustness in adversarial conditions. Similarly, the experiment does not explore the impact of increased block time or varying network latency, both of which can significantly influence throughput in distributed blockchain deployments.

Furthermore, the scalability of the system beyond five nodes, especially in multi-institution or multi-university settings, remains unexamined. Addressing these dimensions in future work would provide a more comprehensive assessment of AuRa's performance characteristics and operational resilience in large-scale, heterogeneous environments.

The TPS results presented in Fig. 10 indicate that the performance in the first scenario, which utilized three nodes, achieved a throughput of 53.32 transactions per second. This is higher compared to the second scenario, which involved four nodes and recorded a TPS of 50.92. Interestingly, in the third scenario, where five nodes were implemented, the TPS increased to 52.25, demonstrating improved performance relative to the second scenario. These findings suggest that the number of nodes has a non-linear effect on system performance, where increasing the number of nodes does not necessarily result in higher throughput.

Based on the analysis presented in Fig. 10, it can be concluded that the number of nodes has a measurable impact on the performance of the AuRa consensus algorithm. Inconsistencies in the empirical results are largely driven by synchronization delays inherent in multi-node deployments. A critical factor is the temporal overhead required for all nodes to achieve state synchronization, which inherently influences overall throughput and latency.

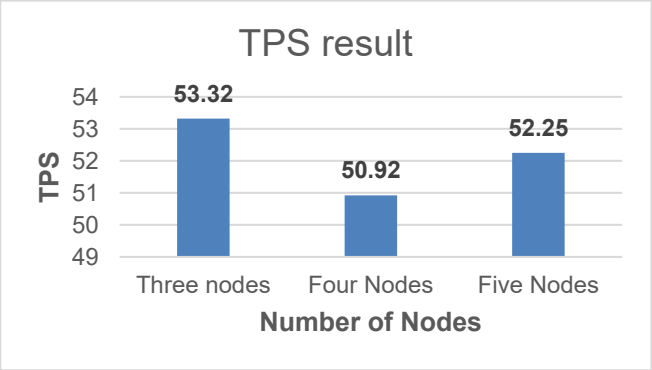

Fig. 10. Comparison of TPS results based on the number of nodes.

C. Security Analysis

In the context of security, low TPS performance in the AuRa consensus mechanism introduces several potential security vulnerabilities that merit careful consideration. When each transaction requires extended processing time, the prolonged block finalisation window increases exposure to adversarial interference. Specifically, a malicious leader may exploit this delay to insert falsified data, manipulate timestamps, or execute equivocation attacks before finality is reached.

Such conditions weaken the integrity guarantees of the protocol and elevate the probability of inaccurate or unauthorized certificate records being committed to the blockchain. In extreme cases, these delays may disrupt the synchronous assumptions underlying AuRa, thereby increasing the risk of block production inconsistencies.

Similarly, TGS performance indicates inefficiencies in handling data throughput, which may further exacerbate security risks within the certificate generation workflow. When the system struggles to transfer or commit data at a stable rate, node desynchronization becomes more likely, particularly in networks with multiple validators. Such desynchronization can create opportunities for adversaries to exploit temporary inconsistencies between nodes, potentially resulting in chain forks or interrupted block propagation.

If a malicious node initiates an attack during these vulnerable intervals, such as injecting altered certificate information, the resulting chain divergence could compromise system reliability and undermine trust in the blockchain-based certificate infrastructure. Therefore, maintaining adequate TPS and TGS performance is not merely an efficiency requirement but a critical component of ensuring the security and correctness of the AuRa-driven system

V. Discussion and Limitation

This study implemented AuRa to create digital certificates. The implementation focused on the measurement of TPS and TGS in only two situations: the same location and different locations of nodes. However, the study did not record the average gas usage per transaction during certificate creation.

A. Consensus Algorithm

This research implements only one consensus algorithm, which causes a limitation in evaluating and measuring the TPS and TGS results. If more than one consensus algorithm had been implemented in this study, comparisons could provide a stronger and more comprehensive evaluation.

B. Server

This study implements the AuRa algorithm to generate certificates on a private server. Thus, at least three servers are needed to establish the nodes. The private server implementation might incur extra costs and resources due to distinct configurations and maintenance requirements.

VI. Conclusion and Future Work

This work contributes a real-world deployment of a blockchain-enabled digital certificate management system built on a private Ethereum network using the AuRa consensus algorithm. Moving beyond conventional blockchain implementations, this study offers empirical evidence of its practical viability in strengthening certificate integrity and resolving verification-related challenges. Crucially, the core technical contribution lies in optimizing block generation and transaction throughput within a private network architecture, thereby effectively mitigating certificate forgery while addressing the performance and scalability bottlenecks inherent in standard consensus mechanisms.

Blockchain allows read and write access to the data. To ensure the security of blockchain, it is supported by the AuRa consensus algorithm. The AuRa consensus algorithm is able to create a secure environment within the transaction process until the transaction is committed to the blockchain. This research also implemented the AuRa consensus algorithm, Ethereum, and smart contracts, which have been embedded with Python coding.

The implementation of the certificate data is converted into JSON format. Then, execute the experiment, including three sets of data on a private server. However, the evaluation reveals inconsistent results on TPS and TGS. Regarding these results, geolocation, size of data, and number of nodes affected the TPS and TGS results.

Moreover, enhanced performance in TPS and TGS strengthens the system's capability to detect and prevent the use of fake or invalid certificates. By enabling real-time verification and rapid detection of discrepancies within the blockchain-based certificate infrastructure, the system reduces the risk of certificate forgery or duplication. This efficiency allows for continuous monitoring and immediate rejection of suspicious or tampered credentials, thereby upholding data integrity and trust in the digital certification ecosystem. Ultimately, the improved performance ensures not only operational effectiveness but also reinforces the security and reliability of the entire certificate management process. Regrettably, a direct comparative analysis with prior studies within the same domain could not be established. This limitation arises because existing literature fails to explicitly detail its empirical results and the specific performance metrics employed.

For future work, this study attempts to generate certificates under various conditions, including different numbers of nodes. The results are then compared and analyzed to determine whether the number of nodes has a significantly affects TPS and TGS.

ACKNOWLEDGMENT

We express sincere gratitude to the Center of Research and Innovation Management (CREIM) at UniSZA for their invaluable financial support towards the publication and the Research Group of Intelligent Data (ID). Our heartfelt appreciation also goes to all team members from UniSZA, including Pn. Robiah Arifin, the PhD candidate for the technical configuration of the project, and Dr. Wan Aezwani Wan Abu Bakar, and Assoc. Prof. Dr. Mohamad Afendee as her Supervisor and Co-Supervisor for the conceptual and technical proofreading, as well as the UMT member, Assoc Prof. Ts. Dr. Mustafa Man, for the network linkages and the reviewer's suggestions. Also, we are grateful for the international contributions and collaboration provided by Dr. Evizal Abdul Kadir, a research fellow from Universitas Islam Riau, Indonesia.

A Bibliometric Analysis of Internet of Things and Augmented Reality Applications in Agriculture: A Scopus-Based Review (2019–2026)

Ruziana Mohamad Rasli, Sobihatun Nur Abdul Salam
School of Multimedia Technology and Communication, Universiti Utara Malaysia, Sintok, Kedah, Malaysia

***Abstract*—The integration of Internet of Things (IoT) and Augmented Reality (AR) technologies has emerged as a transformative approach in modern agriculture, enabling precision farming, real-time monitoring, and immersive decision-support systems. This study presents a bibliometric analysis of research trends related to IoT and AR applications in agriculture using data retrieved from the Scopus database. A total of 72 publications were gathered from 2020 to 2026. The metadata is then analyzed using bibliometric techniques to identify publication trends, document types, research themes, and emerging directions. The results reveal a steady increase in publications, with the highest number of records (20 documents) in 2024 and a slight drop to a total of 12 documents in 2025. Conference papers represent the largest proportion of publications (20 documents), followed by book chapters (17 documents), and reviews with 13 documents, reflecting the changing and experimental nature of this research area. Key research themes include precision agriculture, smart farming systems, digital twins, sensor networks, and real-time visualization for crop monitoring. The findings highlight the increasing role of AR interfaces integrated with IoT sensor data for enhanced agricultural decision-making. This study provides an inclusive overview of research developments and identifies potential future directions, including AI-driven AR visualization, digital agriculture ecosystems, and sustainable farming technologies.**

***Keywords*—Bibliometric analysis; Internet of Things; Augmented Reality; smart agriculture; precision farming; Scopus database**

I. Introduction

Agriculture is undergoing rapid transformation with the adoption of digital technologies designed to improve productivity, sustainability, and resource efficiency. Among these technologies, the Internet of Things (IoT) and Augmented Reality (AR) have attracted significant attention in recent years. IoT enables real-time data collection through networks of sensors, while AR provides interactive visualization that allows users to interpret complex data within a real-world environment.

IoT-based agricultural systems typically utilize sensors to monitor parameters such as soil moisture, temperature, humidity, nutrient levels, and crop health. These systems enable farmers to make data-driven decisions and automate agricultural processes. However, the visualization and interpretation of large volumes of sensor data remain challenging for farmers and agricultural practitioners.

Augmented Reality has emerged as a complementary technology capable of overlaying digital information onto the physical environment. When combined with IoT, AR can provide immersive visualization of farm data, enabling users to monitor crop conditions, analyze sensor readings, and manage agricultural systems more efficiently. The integration of AR and IoT in agriculture supports several applications, including:

1) Precision farming: Precision farming refers to a data-driven agricultural approach that uses IoT sensors, GPS, and analytics to monitor field variability and optimize farming practices. It enables farmers to apply water, fertilizers, and pesticides precisely where needed, improving efficiency and crop yield.

Recent studies show that IoT-enabled sensors provide real-time data on soil conditions, plant health, and environmental factors, allowing targeted interventions such as optimized irrigation and fertilization [1], [2]. This significantly reduces resource wastage and enhances productivity.

2) Crop monitoring: Crop monitoring involves continuous observation of crop conditions using IoT sensors, drones, and imaging technologies. It helps detect issues such as plant stress, diseases, and nutrient deficiencies at early stages.

IoT-based systems collect real-time environmental and crop data, enabling farmers to track crop growth and respond quickly to changes [1]. Advanced systems can monitor parameters like soil moisture, temperature, and pest activity, improving overall farm management.

3) Agricultural training and education: AR plays a major role in agricultural training by providing interactive and immersive learning environments. It allows farmers and students to visualize farming processes, machinery operations, and crop conditions without physical risks.

Recent studies highlight that AR-based training systems improve knowledge transfer, enhance understanding, and support skill development in agriculture by simulating real-world scenarios [3]. This is especially useful for training in modern farming technologies.

4) Smart irrigation management: Smart irrigation uses IoT sensors and automated systems to optimize water usage based on real-time environmental data. It ensures that crops receive the right amount of water at the right time.

Research shows that IoT-based irrigation systems can significantly reduce water consumption while maintaining optimal soil moisture levels through automated control mechanisms [2]. These systems are particularly important in addressing water scarcity and climate variability.

5) Digital twin farming environments: Digital twin technology creates a virtual replica of a physical farm using real-time data from IoT sensors. This allows farmers to simulate, monitor, and optimize agricultural processes. Recent studies indicate that digital twins integrate IoT, AI, and AR technologies to model crop growth, predict outcomes, and support decision-making [4], [5]. They enable advanced applications such as yield prediction, disease detection, and scenario simulation.

IoT and AR technologies support several applications in agriculture, including precision farming, crop monitoring, agricultural training, smart irrigation, and digital twin environments. Precision farming enables data-driven decision-making through real-time sensor data [1], [2], while crop monitoring improves early detection of environmental changes [1]. AR enhances agricultural training through immersive visualization [3], and smart irrigation optimizes water usage using automated systems [2]. Furthermore, digital twin technology enables simulation and predictive analysis for improved farm management [4], [5].

Despite the growing interest in this interdisciplinary field, comprehensive reviews focusing specifically on the convergence of IoT and AR in agriculture remain limited. Bibliometric analysis provides a systematic method for evaluating scientific publications, identifying research trends, and mapping the development of a research field.

The objectives of this study are:

- To analyze publication trends related to IoT and AR in agriculture.
- To identify the dominant document types and publication sources.
- To explore emerging research themes in this field.
- To identify potential research directions for future studies.

Therefore, this study aims to analyze global research trends related to IoT and AR in agriculture using bibliometric techniques based on publications indexed in the Scopus database.

The next section will focus on the literature on the digital transformation in agriculture, the usage of Internet of Things (IoT) in agriculture, the usage of Augmented Reality (AR) in agriculture, and the integration of both technologies in agriculture, followed by methodology, results, discussion, research challenges and future directions, and conclusion section.

II. Literature Review

A. Digital Transformation in Agriculture

The agricultural sector is undergoing a significant transformation driven by digital technologies aimed at improving productivity, sustainability, and resource efficiency. Traditional farming methods, which rely heavily on manual labor and experience-based decision-making, often result in inefficient resource use and limited adaptability to environmental changes [6]. These limitations have accelerated the transition toward smart agriculture, where technologies such as the Internet of Things (IoT), Augmented Reality (AR), and artificial intelligence (AI) are increasingly adopted.

Recent studies highlight that smart agriculture systems integrate sensing, communication, and data analytics technologies to enable real-time monitoring and automation [7]. Among these technologies, IoT and AR play complementary roles in data acquisition and visualization, forming the foundation of modern precision agriculture systems.

B. Internet of Things (IoT) in Agriculture

The Internet of Things (IoT) has become a core component of smart agriculture by enabling real-time monitoring through interconnected sensors and devices. IoT systems collect environmental data such as soil moisture, temperature, and humidity, allowing farmers to make data-driven decisions and optimize resource utilization [6].

1) Usage of IoT in agriculture: IoT applications in agriculture cover a wide range of smart farming activities that help improve productivity and sustainability. For example, smart irrigation systems use sensor data to optimize water consumption by supplying water only when needed, reducing waste and improving efficiency. In addition, soil and environmental monitoring systems utilize wireless sensor networks to collect real-time data on factors such as soil moisture, temperature, humidity, and nutrient levels. IoT technology is also applied in livestock tracking and health monitoring, allowing farmers to monitor animal location, behavior, and health conditions more effectively. Furthermore, automated greenhouse management systems help control environmental conditions such as lighting, temperature, and ventilation to support optimal crop growth. IoT can also assist in crop disease detection and yield prediction through continuous data collection and analysis. Overall, these applications enable farmers to make more accurate data-driven decisions, leading to increased agricultural productivity, reduced resource wastage, and more sustainable farming practices.

2) Advantages of IoT: IoT offers several important benefits in agriculture by enabling smarter and more efficient farming practices. One of the main advantages is real-time monitoring and control of farming conditions, allowing farmers to continuously observe environmental factors such as temperature, humidity, soil moisture, and nutrient levels. This capability helps improve resource efficiency by reducing unnecessary use of water, fertilizers, and energy, ultimately minimizing wastage and operational costs. In addition, IoT

technologies contribute to enhanced crop yield and quality through accurate data collection and timely interventions. IoT also supports the automation of repetitive agricultural tasks, such as irrigation, fertilization, and greenhouse management, reducing labor dependency and increasing productivity. Furthermore, these technologies play a significant role in supporting precision agriculture techniques, where farming activities are optimized based on real-time data and specific crop requirements.

3) Disadvantages of IoT: Despite its many advantages, the implementation of IoT in agriculture also faces several challenges. One of the major limitations is the high initial setup and maintenance costs, which can be difficult for small-scale farmers to afford. In addition, IoT systems heavily depend on reliable internet connectivity, particularly for real-time monitoring and data transmission, making deployment difficult in rural areas with limited network coverage. Data security and privacy concerns also arise due to the continuous collection and storage of sensitive agricultural data. Furthermore, the technical complexity of IoT systems requires users to possess certain technical skills and knowledge for effective operation and maintenance. Another challenge involves the integration of IoT technologies with existing farming systems and traditional agricultural practices, which may require additional infrastructure and adaptation efforts.

C. Augmented Reality (AR) in Agriculture

AR is emerging as a powerful tool for enhancing data interpretation in agriculture by overlaying digital information onto the physical environment. Recent research positions AR as an important interface that connects IoT, AI, and other smart farming technologies [8].

1) Usage of AR in agriculture: AR applications in agriculture provide interactive and immersive solutions that improve farm management, monitoring, and training processes. One important application is the real-time visualization of crop and soil data, where farmers can view information such as moisture levels, temperature, and crop conditions directly through AR interfaces. AR is also used in farm management systems through mobile devices or wearable technologies, enabling users to access agricultural data and control systems more efficiently in the field. In addition, AR supports agricultural training and simulation environments by creating realistic virtual experiences that help farmers and students learn farming techniques and equipment operations safely and effectively. Another application involves equipment maintenance guidance, where AR overlays provide step-by-step visual instructions for repairing and maintaining agricultural machinery. Furthermore, AR technology can be used for digital twin visualization of agricultural systems, allowing users to observe and interact with virtual representations of farms and farming processes in real-time.

AR allows users to interact with data directly in the field, improving situational awareness and decision-making.

2) Advantages of AR: AR offers several important benefits in agriculture by improving the way farmers interact with and interpret agricultural data. One major advantage is its ability to enhance understanding through visual and interactive data representation, allowing users to view farming information more clearly and intuitively. AR also improves efficiency in farm operations by providing real-time guidance and visual support during monitoring, maintenance, and management activities. In addition, AR facilitates training and knowledge transfer by creating immersive learning environments that help farmers and agricultural workers better understand farming techniques and equipment usage. Another important benefit is the reduction of cognitive load when interpreting complex datasets, as AR simplifies data visualization through interactive overlays and graphical representations. Furthermore, AR supports real-time decision-making by enabling farmers to access accurate information instantly, leading to faster and more effective agricultural management.

3) Disadvantages of AR: Despite its many advantages, the implementation of AR in agriculture also encounters several challenges. One of the primary limitations is the high development and deployment costs associated with AR applications and hardware, which may not be affordable for many farmers, especially small-scale agricultural operators. In addition, the limited availability of AR devices and supporting infrastructure in rural areas can restrict wider adoption. AR systems also face usability challenges in outdoor agricultural environments, where factors such as sunlight, weather conditions, and field terrain may affect visibility and system performance. Furthermore, AR applications heavily depend on device performance and battery life, which can limit continuous operation during farming activities. Another challenge is the need for user training and adaptation, as farmers and agricultural workers may require time and technical knowledge to effectively use AR technologies in daily agricultural practices.

D. Integration of IoT and AR in Agriculture

The integration of IoT and AR represents a major advancement in smart agriculture by combining real-time data collection with immersive visualization. IoT sensors continuously gather environmental data, while AR interfaces transform this data into interactive visual formats that enhance decision-making. Recent studies show that integrating IoT with AR and digital twin technologies improves monitoring, visualization, and farm management efficiency [1]. Furthermore, AR-based systems integrated with IoT sensors significantly enhance user interaction and support more effective agricultural decision-making [9].

These technologies support various advanced agricultural applications that improve farming efficiency and decision-making. One important application is precision farming with real-time visual analytics, where sensor data is combined with AR visualization to help farmers monitor and manage crops more accurately. This integration also supports smart irrigation monitoring and control by providing real-time information on water usage, soil moisture, and irrigation performance. In

addition, IoT and AR technologies support crop health and disease visualization, allowing farmers to identify plant conditions and potential diseases more effectively through interactive visual displays. Another significant application is the development of digital twin farming environments, where virtual representations of farms are used for monitoring, simulation, and analysis. Furthermore, the integration of these technologies improves decision support systems by presenting real-time data and visual insights that support farmers in making faster and more informed agricultural decisions. By bridging the gap between data acquisition and interpretation, IoT-AR systems improve operational efficiency and enable proactive agricultural management.

E. Comparison with Traditional Farming

Traditional farming relies on manual observation and experience-based decisions, which often lead to inefficiencies and delayed responses to environmental changes [6]. The transition from traditional farming to IoT and AR-based agriculture highlights significant improvements in efficiency, accuracy, and sustainability. IoT and AR-based systems enable real-time monitoring, automation, and data-driven decision-making for users (see Table I).

TABLE I. COMPARISON WITH TRADITIONAL FARMING

Aspect	Traditional Farming	IoT & AR-Based Agriculture
Decision Making	Experience-based	Data-driven
Monitoring	Manual	Real-time
Resource Use	Inefficient	Optimized
Technology	Minimal	Advanced
Productivity	Moderate	High
Labor	High	Reduced
Data Interpretation	Limited	Visual & interactive

F. Research Gap

Although IoT and AR technologies have been widely studied individually, research focusing on their integration in agriculture remains limited. Most existing studies emphasize IoT-based monitoring systems or AR visualization independently, with fewer addressing their combined application. Recent studies emphasize the need for better integration of IoT, AR, and AI to develop scalable and intelligent farming systems [7]. Additionally, challenges such as system interoperability, cost, and user adoption continue to hinder widespread implementation.

Additionally, several gaps remain in the implementation of IoT and AR technologies in agriculture. One of the major issues is the limited adoption among small-scale farmers, mainly due to financial and technical constraints. There is also a lack of cost-effective and scalable solutions that can be easily implemented across different farming environments and agricultural scales. Furthermore, the integration of these technologies with AI and predictive analytics is still insufficient, limiting the ability to perform advanced forecasting and intelligent decision-making. Usability and user experience challenges also continue to affect adoption, as some systems are complex and difficult for farmers to operate effectively without proper training and technical support. Here, it can be stated that IoT and AR technologies play a crucial role in converting agriculture into a more efficient and sustainable system.

Addressing these gaps is essential for advancing the practical implementation of IoT-AR systems in agriculture.

Despite the increasing interest in the application of IoT and AR in agriculture, the existing body of literature remains fragmented and lacks a comprehensive synthesis. Many studies focus on specific applications or technologies in isolation, resulting in a limited understanding of the overall research landscape. In such emerging and interdisciplinary domains, bibliometric analysis is particularly valuable, as it enables researchers to systematically analyze large volumes of scientific publications, identify research trends, and uncover knowledge gaps [10], [11]. Furthermore, bibliometric methods provide a structured approach to mapping the intellectual, conceptual, and social structure of a research field, which is often difficult to achieve through traditional literature reviews alone [10]. As highlighted in previous studies, bibliometric analysis is especially useful in areas where research is still developing or dispersed, as it offers a comprehensive overview and helps establish a foundation for future research directions [10], [12]. Therefore, given the limited and scattered literature on the integration of IoT and AR in agriculture, a bibliometric analysis is necessary to systematically evaluate existing research, identify emerging themes, and guide future studies.

III. METHODOLOGY

This section provides the systematic approach used to retrieve, filter, and analyze the bibliometric data related to IoT and AR in agriculture, limited to publications from 2020 to 2026. This analysis examined the publications collected from the Elsevier Scopus database based on documents categorized by conference papers, article papers, book chapters, and other related document types, as in Fig. 1.

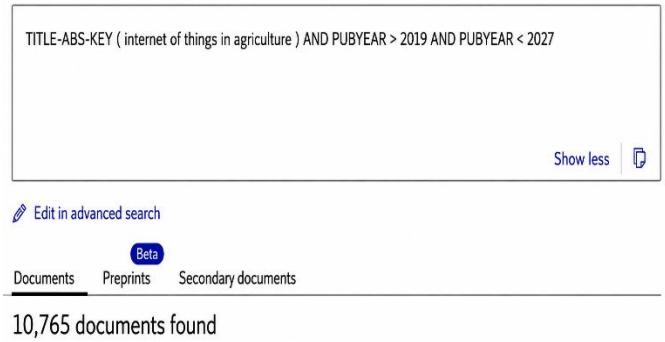

Fig. 1. Internet of Things (IoT) in agriculture.

Based on the search done in Scopus using the keyword Internet of Things and Augmented Reality in agriculture, there are around 72 related documents being generated. These numbers are quite low as compared to only one technology search. A search for IoT in agriculture from 2020 to 2026 had resulted in 10615 documents generated, as shown in Fig. 1 and a search for AR in agriculture from 2020 to 2026 had produced 280 documents, as in Fig. 2. Here it can be seen that the

integration of both technologies are still lacking in implementation and literatures, as in Fig. 3.

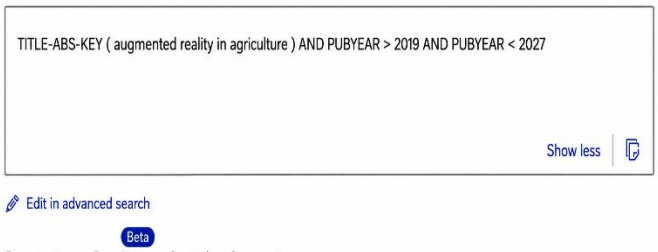

Fig. 2. Augmented Reality in agriculture.

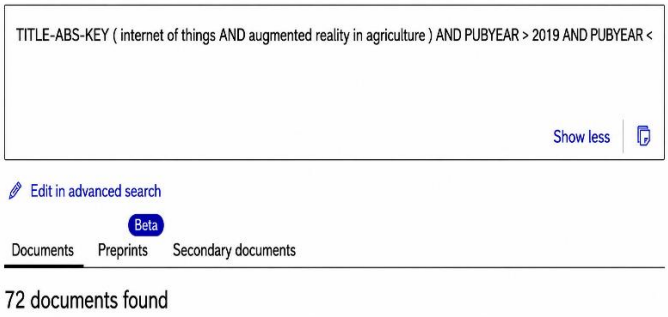

Fig. 3. Internet of Things and Augmented Reality in agriculture.

A detailed explanation of the search strategy is discussed in the following section. Fig. 4 below shows the distribution of all the 72 documents by year. The majority of the documents were published in 2024, with a total of 20 documents, followed by 2023 with 13 documents and in 2025 with 12 documents. Based on the graph, it can be seen that in 2026, the graph decreases with only 2 documents. This is due to the fact that during the search process, it is still in the third month (March) of 2026. There are still 9 months remaining, which will probably result in an increase in the number of documents later.

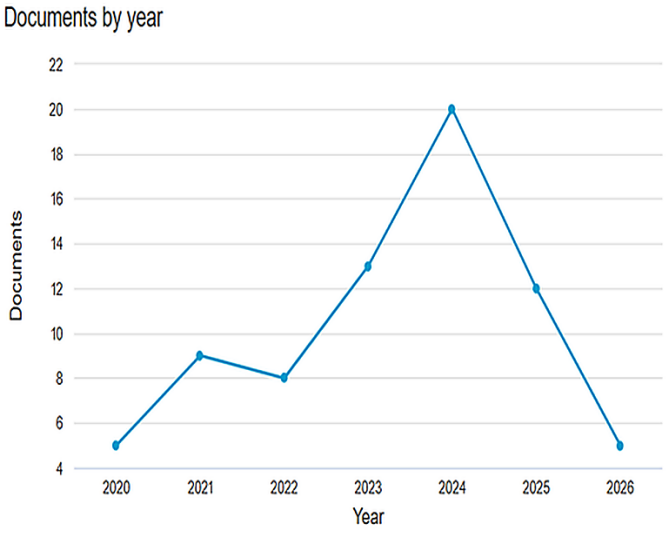

Fig. 4. Total number of documents by year.

A. Search Strategy

In order to retrieve relevant documents, a Boolean search string was developed that captured the intersection of data overload in real-time data processing. The query was applied to the title "Internet of Things and Augmented Reality in agriculture" with a filter of year from 2019 to 2026. Fig. 5 shows an illustration of a flowchart of the methodology used for conducting this bibliometric analysis using the Scopus database.

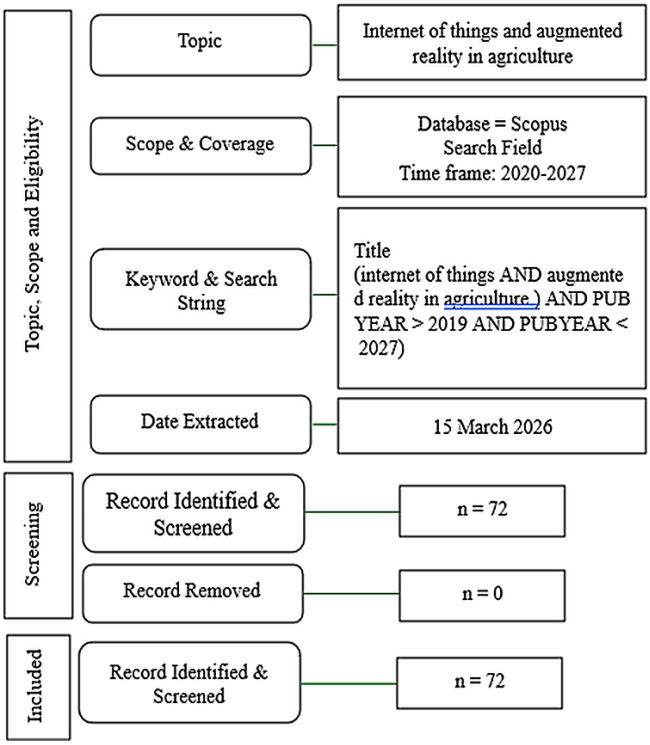

Fig. 5. Flow diagram of the strategy (Source: [13] as cited from [14]).

Fig. 5 consists of three main sections, which are: 1) Topic, Scope, and Eligibility, 2) Screening, and 3) Included. The first section outlines the foundational aspects of the research, where the topics used are stated, the scope and coverage of the study, the title of the search and also when the documents are extracted. It can be seen in the second section, Screening, where the total amount of documents was listed, which is 72 documents. In this search, there are no removed documents because the keywords are specifically filtered in the searching process on the Scopus database. The documents that have been searched are in detail already; therefore, there is no record removed and it indicates that all the records initially identified were considered relevant to the analysis. This analysis comprises three components listed below:

- The pattern in citations is examined to discover cited publications, influential authors, and related research groups.
- The themes and concepts on real-time data processing is analyzed based on co-occurring keywords.
- The emerging trends, areas and limitations of the area are discussed to offer a view of the research landscape and guidance.

This study offers insight into fundamental knowledge frameworks, research patterns, and trends of the technology used in visualizing real-time data.

B. Data Preparation Using VOSViewer

The Scopus-exported CSV file was converted to a format compatible with VOSviewer. The files were exported with metadata, as in Fig. 6:

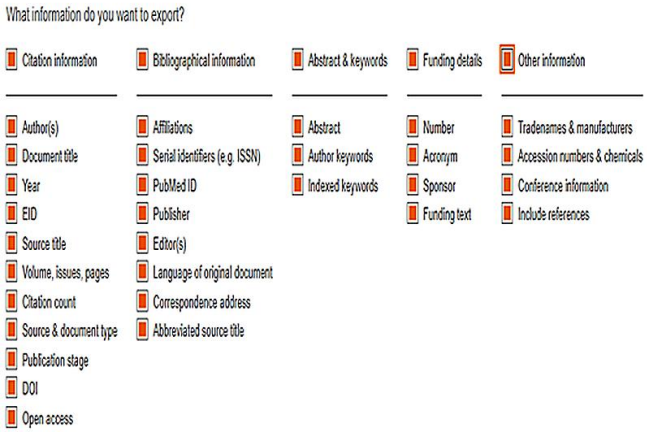

Fig. 6. Metadata information exported from the Scopus database.

Fig. 6 shows various categories of metadata fields commonly used to represent a different type of bibliographic information that helps identify, classify, and analyze research outputs. These categories are important for researchers, especially when conducting literature reviews, citation analysis, or bibliometric studies. The following figures show the basic settings of threshold, number of keywords, and the selected keywords.

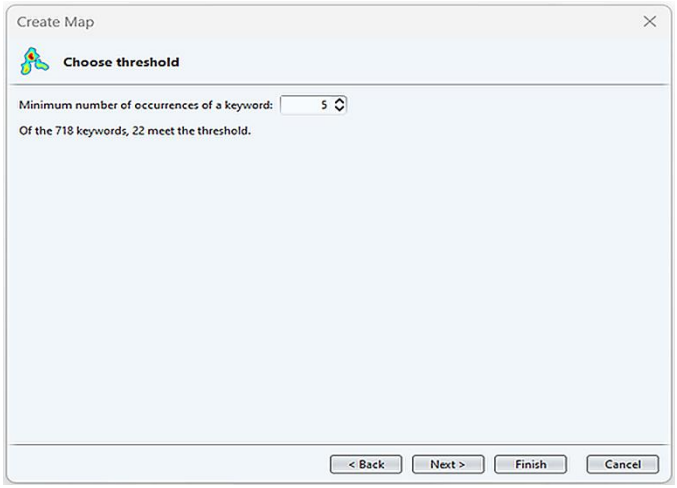

Fig. 7. Default maximum number of occurrences.

Fig. 7 shows the selection of the minimum number of keyword occurrences. Here, the value is set to 5 and based on this value, from the total of 718 keywords, only 22 keywords met the threshold. Here, it can be seen that only keywords that appear at least 5 times are considered important enough to represent the research. This step is important because it removes low-frequency or irrelevant keywords and also ensure that the analysis provides significant and frequently studied topic field.

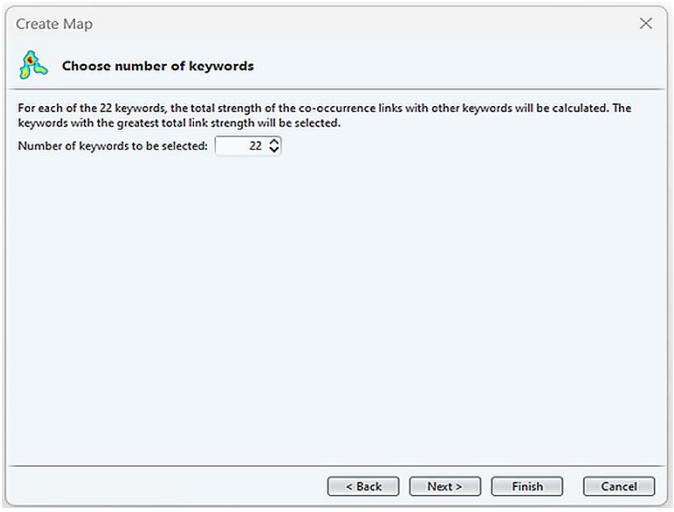

Fig. 8. Default number of keywords.

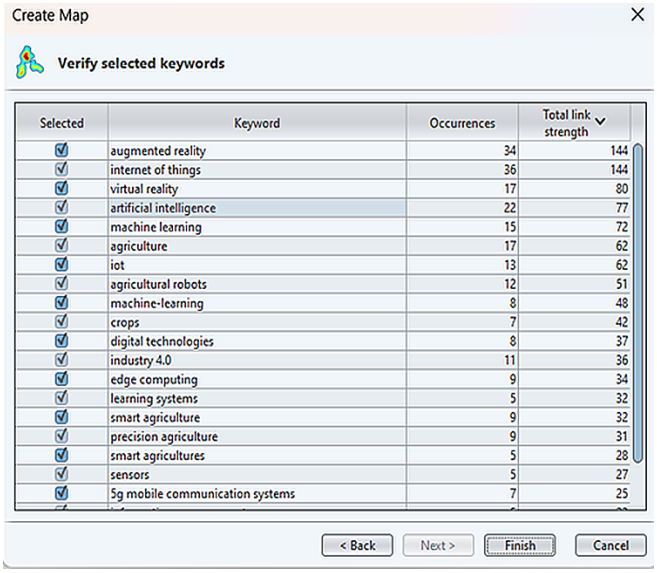
In Fig. 8, the selection of the 22 keywords is based on the total link strength. This total link strength measures how strongly a keyword is connected to other keywords and also measures the frequency of co-occurrence relationships of the keywords. Therefore, keywords with stronger connections represent core concepts and relationships within the specified research domains.



Selected	Keyword	Occurrences	Total link strength
☑	augmented reality	34	144
☑	internet of things	36	144
☑	virtual reality	17	80
☑	artificial intelligence	22	77
☑	machine learning	15	72
☑	agriculture	17	62
☑	iot	13	62
☑	agricultural robots	12	51
☑	machine-learning	8	48
☑	crops	7	42
☑	digital technologies	8	37
☑	industry 4.0	11	36
☑	edge computing	9	34
☑	learning systems	5	32
☑	smart agriculture	9	32
☑	precision agriculture	9	31
☑	smart agricultures	5	28
☑	sensors	5	27
☑	5g mobile communication systems	7	25

Fig. 9. Selected keywords.

Fig. 9 shows all of the keywords that are selected based on the setting in Fig. 7 and Fig. 8. Internet of things, augmented reality, and virtual reality are the three tops keywords with the highest occurrences and total link strength. Occurrences are defined as how often each keyword appears and total link strength is defined as how strongly it connects with others.

By applying a minimum occurrence threshold of five, the dataset was refined from 718 to 22 significant keywords, improving the clarity and reliability of the visualization.

The selected keywords demonstrate strong interconnections, with "Internet of Things" and "Augmented Reality" emerging as the most influential terms based on both occurrence and total link strength. This indicates that these technologies form the core of the research domain. Additionally, the presence of keywords, such as artificial intelligence, machine learning, and edge computing, highlights the interdisciplinary nature and evolving trends in smart agriculture research.

To explore the intellectual structure and research evolution of IoT and AR applications in agriculture, VOSviewer was employed to generate three complementary visualization types: Network Visualization, Overlay Visualization, and Density Visualization. Each visualization provides a different perspective on the relationships and development of research topics within the selected literature, which is discussed in the following section.

IV. Results

Keywords play an important role in bibliometric studies, as they reflect the main concepts, research interests, and thematic focus of a particular field. By examining the relationships among keywords, it is possible to identify the dominant research topics and understand how different concepts are connected within the literature. In this study, keyword co-occurrence analysis (Fig. 10) was conducted using VOSviewer to explore the research landscape of IoT and AR applications in agriculture. The resulting visualization provides insights into the major research themes, their interrelationships, and the emerging areas that have attracted increasing attention from researchers.

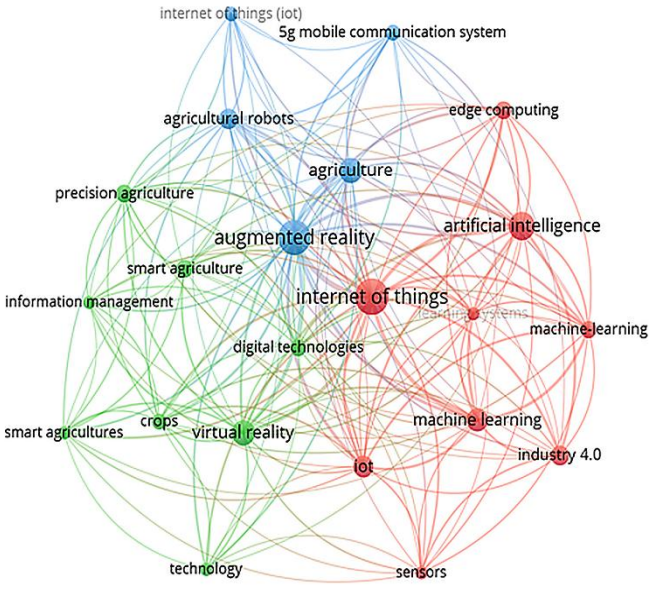


Fig. 10. Network visualization

The keyword co-occurrence network generated using VOSviewer reveals the conceptual structure of research on the integration of IoT and AR in agriculture. The analysis identifies several highly interconnected keywords, with "internet of things", "augmented reality", and "agriculture" emerging as the most prominent nodes, indicating their central role in the research domain.

The network is grouped into three primary clusters representing distinct but interconnected research themes. The first cluster focuses on smart agriculture and precision farming, incorporating keywords such as precision agriculture, smart agriculture, crops, and information management. This cluster highlights the application of IoT technologies in monitoring and optimizing agricultural processes.

The second cluster represents intelligent systems and data-driven technologies, including artificial intelligence, machine learning, sensors, and Industry 4.0. This cluster reflects the growing integration of advanced computational methods to enhance agricultural decision-making and automation.

The third cluster emphasizes technological infrastructure and communication systems, consisting of keywords such as 5G mobile communication systems, edge computing, and agricultural robots. This cluster illustrates the enabling technologies that support real-time data transmission and system interoperability. The strong interconnections among these clusters indicate that research in this field is highly interdisciplinary, combining sensing technologies, immersive visualization, artificial intelligence, and communication networks to support smart agriculture.

While the keyword co-occurrence network provides an overview of the major research themes and their relationships, it does not reveal how these themes have evolved over time. To address this limitation, an overlay visualization (Fig. 11) was generated using VOSviewer. This visualization builds upon the keyword network by incorporating temporal information, allowing researchers to identify both established and emerging research topics within the field.

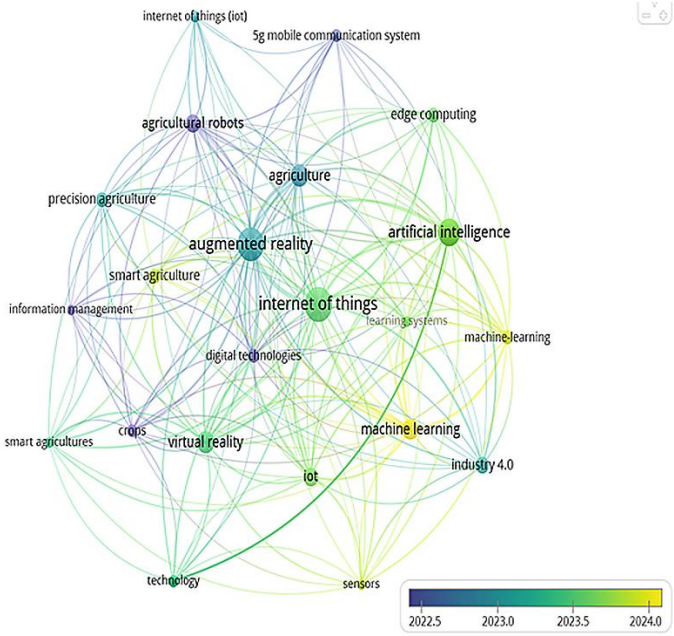

Fig. 11. Overlay visualization

The overlay visualization illustrates the temporal development of research topics in the field. Earlier studies (represented in blue tones) focused on foundational topics such as precision agriculture, information management, and

agricultural robots, reflecting the initial phase of digital transformation in agriculture.

Subsequent research (green tones) shows a shift toward augmented reality, smart agriculture, and digital technologies, highlighting the increasing importance of interactive visualization and user-centered systems.

More recent studies (yellow tones) emphasize artificial intelligence, machine learning, and Industry 4.0, indicating a transition toward intelligent, autonomous, and data-driven agricultural systems. This temporal progression suggests that the field has evolved from basic monitoring and automation to more advanced systems that integrate AI with IoT and AR for predictive and real-time decision-making.

Following the overlay visualization analysis, a density visualization (Fig. 12) was generated to further examine the level of research attention received by different topics within the field. While the overlay visualization highlights the temporal evolution of research themes, it does not indicate the relative concentration or prominence of individual topics. Therefore, density visualization is included as a complementary analysis to identify the most intensively studied areas and reveal the overall research hotspots within the literature.

Fig. 12. Density visualization

The density visualization provides insight into the intensity of research focus within the field. Areas highlighted in bright yellow indicate highly researched topics, while green and blue areas represent moderate and emerging topics, respectively. The analysis shows that “internet of things”, “augmented reality”, “agriculture”, and “artificial intelligence” are the most intensively studied topics. These keywords form the core foundation of current research and indicate strong academic interest in integrating sensing technologies with immersive visualization.

Moderate-density areas include machine learning, smart agriculture, and digital technologies, suggesting that these topics are gaining traction but are still developing. In contrast, keywords such as edge computing, Industry 4.0, virtual reality, and sensors appear in lower-density regions, indicating that these areas are relatively underexplored and present opportunities for future research.

V. Discussion

The findings of this bibliometric analysis demonstrate that the integration of IoT and AR in agriculture is rapidly evolving into a multidisciplinary research area. The dominance of core technologies such as IoT and AR reflects their critical role in enabling real-time data acquisition and immersive visualization.

The patterns identified in this study share several similarities with findings reported in earlier bibliometric research on smart farming, precision agriculture, and digital agriculture. Across these studies, IoT consistently appears as one of the core technologies driving agricultural digitalization. The keyword network generated in the present study reinforces this observation, with IoT emerging as one of the most influential and highly connected keywords. This suggests that IoT continues to serve as the technological foundation for collecting, transmitting, and managing agricultural data in modern farming environments.

Another notable observation is the growing presence of Artificial Intelligence (AI), Machine Learning (ML), and Industry 4.0-related concepts. Previous bibliometric studies have highlighted a gradual movement away from basic monitoring systems towards more intelligent and predictive agricultural solutions. A similar trend can be observed in the overlay visualization of this study, where AI and ML-related keywords appear among the more recent topics. This development indicates that researchers are increasingly interested in extracting meaningful insights from agricultural data rather than focusing solely on data collection.

While many studies in precision agriculture emphasize technologies such as IoT, remote sensing, drones, and artificial intelligence, the findings of this study reveal a growing interest in Augmented Reality (AR). The appearance of AR as a prominent keyword within the network suggests that researchers are beginning to explore new ways of presenting and interacting with agricultural information. As farming systems become increasingly data intensive, AR offers the potential to improve how users interpret and respond to real-time information by providing a more intuitive and interactive visualization environment.

The density visualization further supports this observation. Keywords related to IoT, AR, AI, and machine learning were concentrated within the most active areas of the map, indicating that these topics currently attract significant research attention. This finding is consistent with broader discussions in the digital agriculture literature, where the integration of sensing technologies, intelligent analytics, and advanced visualization tools is often described as an important step towards more efficient and sustainable farming practices.

Although previous bibliometric studies have provided valuable insights into smart agriculture as a whole, relatively few have specifically examined the relationship between IoT and AR in agricultural applications. In this regard, the present

study contributes a more focused perspective by highlighting how immersive technologies are increasingly being combined with IoT-based systems. The findings suggest that AR is evolving beyond a supporting visualization tool and is becoming an important component of next-generation agricultural solutions. This creates opportunities for future research on real-time visualization, decision support, and user interaction within smart farming environments.

Furthermore, the presence of enabling technologies such as 5G and edge computing highlights the importance of communication infrastructure in supporting real-time agricultural applications. Despite these advancements, several areas remain underexplored, particularly the integration of virtual reality, advanced sensor networks, and scalable solutions for smallholder farmers. Addressing these gaps will be essential for the widespread adoption of smart agriculture technologies.

VI. Research Challenges and Future Directions

The growing number of publications identified in this study reflects the increasing interest in applying IoT and AR technologies within the agricultural sector. However, despite the promising developments reported in the literature, several challenges continue to limit the widespread adoption of these technologies in real farming environments.

One of the most frequently cited concerns is the cost of implementation. Although IoT sensors, cloud-based platforms, and AR applications can provide valuable insights for farm management, the initial investment required for hardware, software, and system maintenance may be beyond the reach of many small-scale farmers. As a result, the adoption of advanced digital farming technologies is often more feasible for larger agricultural enterprises with greater financial resources.

In addition to financial considerations, the successful use of IoT and AR technologies depends on users' ability to interact with digital systems and interpret the information provided. Farmers may face difficulties when dealing with unfamiliar technologies, particularly when systems are complex or require specialized technical knowledge. This highlights the importance of designing user-friendly solutions that simplify data interpretation and support practical decision-making in agricultural activities.

Infrastructure availability also plays a significant role in technology adoption. Many IoT-based applications rely on stable internet connectivity, reliable power sources, and access to cloud services. In rural and remote farming areas, these requirements may not always be fully available, creating barriers to implementation. Although emerging technologies such as edge computing and next-generation communication networks offer potential solutions, their accessibility remains uneven across different regions.

Beyond technical and economic factors, policy support is another important consideration. Government initiatives, funding schemes, and digital agriculture programs can help reduce adoption barriers by providing financial assistance, training opportunities, and infrastructure development. Without adequate policy support, the benefits of IoT and AR technologies may remain limited to a relatively small group of technology-ready users.

The findings of this study suggest that future research should extend beyond technological innovation alone. Greater attention should be given to understanding how economic constraints, user readiness, infrastructure availability, and policy support influence the adoption of smart agriculture technologies. Addressing these factors will be essential to ensure that the benefits of IoT and AR can be accessed by a wider range of agricultural stakeholders and contribute meaningfully to sustainable agricultural development.

VII. Conclusion

This study presents a comprehensive bibliometric analysis of research on the integration of Internet of Things (IoT) and Augmented Reality (AR) in agriculture based on Scopus-indexed publications from 2020 to 2026. The findings indicate a growing research interest in this interdisciplinary domain, with a notable increase in publications, particularly in recent years. This trend reflects the increasing importance of digital technologies in transforming traditional agricultural practices into more efficient and sustainable systems.

The VOSviewer analysis provides deeper insights into the intellectual structure and evolution of the research field. The keyword co-occurrence network reveals that Internet of Things, Augmented Reality, and agriculture serve as the central themes, supported by closely related concepts such as precision agriculture, artificial intelligence, and smart farming systems.

The clustering structure highlights the interdisciplinary nature of the field, integrating sensing technologies, data analytics, communication systems, and immersive visualization. The density visualization further confirms that IoT and AR are the dominant research hotspots, while emerging topics such as edge computing, virtual reality, and Industry 4.0 remain less explored. This suggests that while the core technologies are well established, there are still significant opportunities for expanding research into advanced and integrated systems.

In addition, the overlay visualization demonstrates a clear temporal evolution of the field. Early research primarily focused on data collection and monitoring through IoT, followed by the incorporation of AR for visualization and interaction. More recent studies emphasize the integration of artificial intelligence and machine learning, indicating a shift toward intelligent, predictive, and autonomous agricultural systems. This progression reflects the movement from basic digital agriculture toward fully integrated smart farming ecosystems.

The findings from the literature review further support this evolution, highlighting the complementary roles of IoT and AR in enabling real-time data acquisition and intuitive data visualization. While IoT enhances monitoring and automation, AR improves data interpretation and user interaction, thereby bridging the gap between complex data and practical decision-making. However, challenges such as high implementation costs, infrastructure limitations, and usability issues continue to hinder widespread adoption.

Overall, this study confirms that the integration of IoT and AR has significant potential to revolutionize agriculture by improving productivity, efficiency, and sustainability. Nevertheless, the bibliometric analysis also reveals that the research landscape remains fragmented, with limited studies

focusing on the combined application of these technologies. This highlights the need for more comprehensive and integrated research efforts.

Future studies should focus on the development of scalable and cost-effective solutions, particularly for smallholder farmers, as well as the integration of emerging technologies such as artificial intelligence, digital twins, and advanced communication systems. In addition, further research is needed to improve system usability, enhance interoperability, and address practical implementation challenges.

In conclusion, this study provides a structured and comprehensive overview of the research landscape on IoT and AR in agriculture. It contributes to the existing body of knowledge by identifying key trends, themes, and research gaps, and offers valuable insights to guide future research toward the development of intelligent and sustainable agricultural systems.

***Abstract*—The University Course Timetabling Problem (UCTP) is a well-known combinatorial optimization challenge that involves allocating courses to timeslots and rooms while satisfying various institutional constraints. At other institutions, general courses (e.g., language subjects) are prioritised during timetable allocation due to their high enrolment numbers from multiple faculties. However, at the MARA University of Technology, Sarawak Branch, Mathematics and Statistics (MAT/STA) courses are shared across several programs, with timeslot availability limited by pre-scheduled major courses in each program. This study presents a tailored evolutionary algorithm for a real institutional scenario, incorporating dynamic local search and guided variation operators to improve feasibility and solution quality. A case study was conducted using real datasets from the Department of Mathematical Sciences at MARA University of Technology, Sarawak Branch. Benchmark datasets from ITC2002 and ITC2007 (Track 2) are employed for comparative evaluation against existing methods. The algorithm successfully produced a feasible timetable and outperformed manually prepared schedules in terms of soft-constraint penalties. Results indicate strong performance on real datasets, producing a high-quality, balanced timetable with reduced preparation time, particularly in handling repeating students, lecturers' availability, and limited timeslots. Nevertheless, lower performance on benchmark datasets suggests the need for hybridization or additional operators to handle larger, more complex problems. Overall, the results demonstrate the effectiveness of the proposed approach in real-world timetabling while maintaining acceptable quality on benchmark instances.**

Keywords*—Timetabling problem; evolutionary algorithm; dynamic; guided

I. Introduction

The UCTP is a well-known NP-hard optimization challenge that involves assigning courses, rooms, timeslots, and student groups under various hard and soft constraints [1], [2], [3]. The constraints of UCTP vary across academic institutions due to their respective policies and regulations. Practically, the goal of UCTP is to provide a balanced timetable with minimal conflicts. Hard conflicts may cause an infeasible timetable, such as when a lecturer or students have two courses scheduled at the same time. Soft conflicts determine the quality of the timetable, such as a morning or afternoon class overload, and too many consecutive lecture hours in a day.

This research is motivated by a different practice of course timetabling in MARA University of Technology (UiTM), Sarawak Branch. The Department of Mathematical Sciences at UiTM Sarawak Branch offers MAT/STA courses across 14 programs, including Public Administration, Accountancy, Engineering, and more. Current timetabling prioritizes the allocation of major courses (of programs). Each major course may have multiple weekly sessions, for example, 2 hours on Day 2, 2 hours on Day 3, and 1 hour on Day 4 (2+2+1). The pattern of these multiple weekly sessions can be 3+0, 2+2, or 3+1. Consequently, the available slots of 2+2 MAT/STA courses are limited. In addition, each lecturer must satisfy minimum teaching hours and shared teaching requirements. At the same time, parallel timeslots for MAT/STA courses are necessary to accommodate students who repeat across multiple program groups.

Timetable preparation begins after the final examination of each semester. The projected numbers of repeat students and enrolments are used to estimate the required groups for each MAT/STA course. A program-level group projection (may take 1-2 weeks) must be completed first. Once receiving these projections, the Department of Mathematical Sciences may further adjust the number of required groups for each MAT/STA course based on teaching load and shared-teaching requirements for the semester. The existing timetabling system allows users to view available slots and manually assign MAT/STA courses to program or group timetables. Nonetheless, since multiple programs take these courses, timetable conflicts must be checked manually. Some lecturers may request fewer consecutive teaching hours in a day, while others may express concerns about the balance between morning and afternoon teaching slots. Repeat students are also facing issues with their repeated courses. These adjustments and checks continue until the semester starts (commonly stable after week 4 of lectures).

Furthermore, the allocation of the MAT/STA course can adversely affect timetable quality by creating an imbalance in daily load. For instance, a pre-scheduled timetable already contains six lecture hours on days 1, 2, and 3. Assigning additional sessions to these days increases the consecutive hours per day. Redistributing the MAT/STA course to the lighter days 4 and 5 would promote better load balancing and enhance overall timetable efficiency. Once the semester begins, further

adjustments may compromise the stability and feasibility of the established timetable. Therefore, an efficient strategy is required to address this issue.

Motivated by real-life applications, the problem aims to minimize the conflicts while providing a balanced timetable in a short time. Three semesters of data are collected. An evolutionary algorithm (EA) is proposed to explore possibilities for MAT/STA course allocations while minimizing conflicts and achieving a balanced timetable. There are previous studies that have been done for real-life applications using EA variants: Genetic algorithm [4], [5]; Particle Swarm Optimization [1], [2], [3], [6]; and Hybrid Evolutionary Algorithm [7], [8], [9]. Most of these studies introduce new operators (crossover and mutation) during the evolutionary stage to address the nature of real-world applications. Some operators allow temporary conflicts during evolution and refine them later. Hybridization with local search was performed to refine the solution. Hence, the proposed algorithm incorporates a dynamic local operator and guided variation operators to refine the search process and improve timetable quality adaptively.

II. Formulation and Approach

A timetable is represented as a three-dimensional (3D) array (groups/lecturer, day, and timeslot). A binary decision variable, $X_{c,t,r}$, is used (which takes the value 1) when a lecture of the course c is allocated to a day d and timeslot t. Given that $R_{t,r} = 1$ indicates that a room is counted for each timeslot t. All MAT/STA courses for the assigned groups must be scheduled each week into available timeslots and rooms. Multiple weekly sessions of 2+2 MAT/STA lecture hours are fully allocated, and each lecturer teaches only one MAT/STA course per timeslot and room. Sufficient rooms are available for all multiple weekly sessions, and no MAT/STA courses are assigned to blocked timeslots. Blocked timeslots are defined as follows:

- Last timeslot of each day, $t = \{9,18,27,36,45\}$.
- Lunch hour, 1 p.m. until 2 p.m. (not included in a set of timeslots).
- Extra co-curricular activity, Wednesday 4 p.m. until 6 p.m. for year 1 students (not included in a set of timeslots).
- Friday prayer, Friday 12 noon until 2 p.m. (not included in a set of timeslots).

To achieve a balanced, high-quality timetable, MAT/STA courses with a 2+2 lecture hours should be evenly distributed throughout the week, with minimal preset gaps. The students' group should not have more than 7 consecutive lecture hours per day, and isolated 2-hour MAT/STA lectures should be avoided. Penalties are applied whenever these preferences are violated.

To the best of our knowledge, there is no real-world application of previous studies using an evolutionary algorithm that considers a session gap in course allocation with remaining timeslots (major courses of a program are scheduled first). Maintaining the crucial session gap while allocating courses to limited time slots complicates the standard UCTP. The most relevant paper [9] used an improved genetic algorithm on the benchmark dataset ITC2007 (Track 2). However, the allocation of events in ITC2007 (Track 2) is based solely on available timeslots, without any specific session gaps between events.

An EA is proposed in this study due to its flexibility in handling diverse constraints of the problem. It allows interaction and information exchange in a population-based environment [10]. The main steps of EA consist of the following: 1) Initialization, 2) Fitness evaluation, 3) Parents selection for reproduction, 4) Variation operators, 5) Selection of the best solution [11].

As the case study includes an additional hard constraint of a 2+2 session gap for each MAT/STA course, a dynamic local operator is specifically designed and applied during initialization and variation operators. Excluding this operator will produce infeasible timetables. A steady-state algorithm generates a population size of [20,100] at the initial stage. The improvement stage evolves this population iteratively using variation operators, generating a complete, updated solution.

A. Initialization

In EA, random initialization may lead to an infeasible solution when constraints are not enforced. Rezaeipanah et al. [9] applied a random shuffling technique to promote genetic diversity and population diversity. Nevertheless, in this study, we apply sorting and shuffling techniques to ensure that the high-constraint student groups are prioritized.

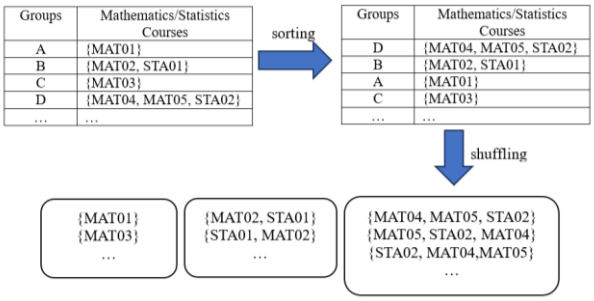

Fig. 1. Sorting and shuffling technique in the initialization phase.

Fig. 1 illustrates the MAT/STA courses ranked by the number of courses taken by each group. The MAT/STA courses in this sorted list are shuffled to produce different initial allocations. The iteration continues until the desired population size is achieved.

If any conflicts are found, a dynamic local operator is used to adjust the preset session gap for MAT/STA courses; it is necessary to obtain a feasible initial solution. The adjustment is made by reducing the preset session gap value for the course, which may result in a session gap penalty later on. Nonetheless, due to the highly constrained MAT/STA groups, some runs may not achieve the maximum population size.

B. Fitness Evaluation

Let $X_i, i = 1,2,3, \dots P$, denote a candidate timetable in a population P. The solution quality is measured based on a weighted soft-constraint penalty objective function:

$$F_{obj}(X) = w_1 \sum_{c \in C} Q_c + w_2 \sum_{g \in G} \sum_{d=1}^{5} C_{g,d} + w_3 \sum_{g \in G} \sum_{d=1}^{5} I_{g,d.} \quad (1)$$

In Eq. (1), Q_c measures session-gap violations for the course c. $C_{g,d}$ denotes excess consecutive hours for the group g on day d, and $I_{g,d}$ counts any isolated sessions. The coefficients w_1, w_2, w_3 are fixed values of penalty weights for each soft constraint violation. Each soft-constraint violation type employs a predefined penalty weight with a predefined cost: $w_1 = 1$ for session-gap violations, $w_2 = 7$ for excessive consecutive hours, and $w_3 = 1$ for an isolated MAT/STA course within a day. The objective is to minimize $F_{obj}(X)$, where smaller values indicate higher timetable quality.

One advantage of a sum-weighted penalty function is that it can be applied to any optimization technique, as it focuses on minimizing a single objective function. In addition, it is flexible and easy to use, as the weight can be assigned based on its importance [12]. In the existing literature [13], [14], [15], the cost penalty for 3 consecutive hours is set to 1. Meanwhile, we significantly increased the value of w_2 to highlight the severity of pre-scheduled timetables. For the real datasets, the counting of consecutive hours also accounted for pre-scheduled slots on the same day. Consequently, allocating the MAT/STA course to the days that already contain long consecutive hours could negatively affect the overall quality and balance of the timetable.

C. Parents Selection

A k-tournament selection is used at this stage with $k = 3$. Three individual timetables are selected randomly and compared (fitness value). The timetable with the lowest penalty value is chosen as Parent 1. The process is repeated to select Parent 2, provided that Parent 2 is not the same individual as Parent 1. Fig. 2 illustrates the selection process for the Parent.

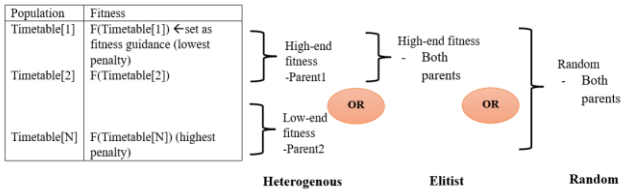

Fig. 2. Illustration of parent selection mechanisms used in the evolutionary process.

The proposed algorithm employs three types of selection strategies: 1) Heterogeneous, 2) Elitist, and 3) Random. Individuals in the population are ranked before selection. In Heterogeneous selection, Parent 1 is randomly selected from the high-end fitness individuals, and the other is randomly selected from the low-end fitness individuals to preserve diversity and balance exploration and exploitation. In Elitist selection, both parents are randomly selected from the high-end fitness individuals. Meanwhile, in Random selection, parents are selected randomly from the population.

D. Swapping 1 (External)

Previous studies have applied a single-point, uniform heuristic crossover and other variation techniques, such as swap sequence, forceful swap, switching tolerance, horizontal, and vertical swap, to generate offspring. Similarly, Swapping 1 purposely exchanges two candidate solutions (Parent 1: x_i and Parent 2: x_p) by matching a random event with the same MAT/STA course. This guided approach reduces randomness and complexity caused by limited timeslots, while same-course swapping helps avoid conflicts.

In candidate x_i, Session 1 of course c_i, scheduled on day 2 in timeslots 3-4, is swapped with Session 1 of the same course code in the timetable x_p, scheduled on day 1 in timeslots 1-2. However, Session 2 cannot be swapped directly because it conflicts with major courses. A dynamic local operator is activated to handle this conflict. Two offspring (x'_i and x'_p) are obtained. Fig. 3 demonstrates the external swapping between Parent 1 and Parent 2.

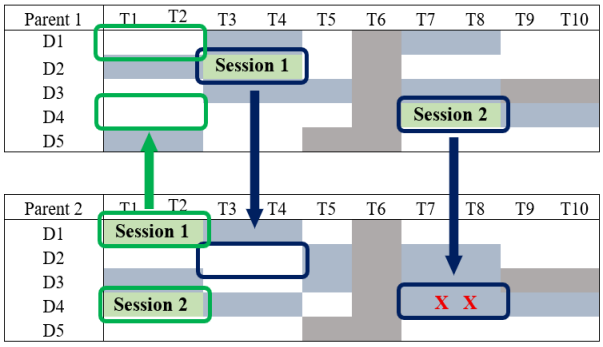

Fig. 3. External swap of two parent solutions, where selected sessions are exchanged. the dynamic local operator handles the resulting conflict ("XX").

E. Swapping 2 (Internal)

Swapping 2 functions like a mutation operator by performing a guided internal swap in each offspring (x'_i, x'_p) generated from Swapping 1. For each offspring, a random 2-hour session with the same MAT/STA course is selected. Session 1 in x'_{i1} (day 1, timeslots 3-4) is swapped with Session 1 in x'_{i2} (day 2, timeslots 9-10). As the timeslots in x'_{i2} are unavailable, the dynamic local operator reallocates the swapped Session 2 to the next available timeslots. Penalties are recalculated, and the offspring replaces the parent if it improves the solution. Fig. 4 illustrates the internal swapping in each offspring.

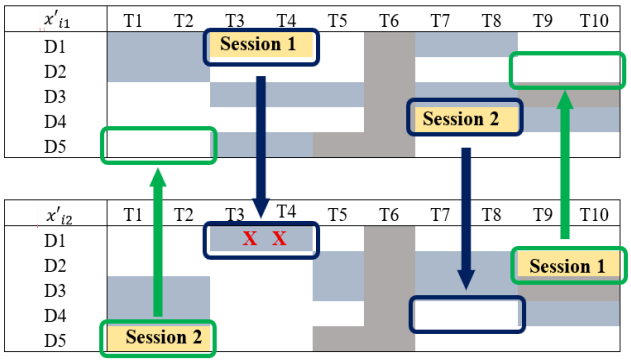

Fig. 4. Internal session swap within each offspring solution, where selected sessions are exchanged, and the resulting conflict ("xx") is repaired using the dynamic local operator.

F. Checking Termination Criteria

The algorithm is terminated when a maximum number of generations is reached, or no improvement is observed over a predefined number of consecutive generations.

G. Selection of the Best Solution

After the termination criteria are satisfied, the candidate solutions are ranked by their penalty values (objective function costs). The solution with the lowest penalty value is chosen as the final solution. The average penalty value is calculated from the solutions of the last generation.

H. Guided Variation Operator

In other institutions, general courses such as language subjects, which are taken by all programs, are prioritized during timetable allocation due to their complexity. In contrast, at the UiTM Sarawak Branch, a MAT/STA course is offered across multiple programs, with each program comprising several groups enrolled in the same MAT/STA course. Given this scenario, the same MAT/STA course was chosen for swapping to minimize the complexity of finding feasible timeslots, as variations in pre-scheduled major courses across groups increase timetabling complexity.

TABLE I. NUMBER OF GROUPS IN EACH PROGRAM TAKING THE MAT/STA COURSE.

Course Code	Program Code	Student Year	Number of groups		
			October 2022	March 2023	October 2023
Diploma Programs					
MAT111	BA132	1	5	4	7

Table I indicates the number of groups taking one or more MAT/STA courses. The difficulty of identifying feasible timeslots increases as more programs enrol in the MAT/STA course or when a program takes multiple MAT/STA courses (see Fig. 5).

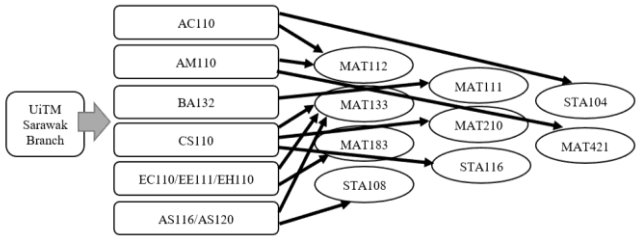

Fig. 5. Complexity of MAT/STA courses taken by multiple programs.

I. Dynamic Local Operator

This operator is crucial in Initialization, Swapping 1, and Swapping 2. While variation operators generate offspring to explore the solution space, this operator acts as a dynamic solver that resolves conflicts arising from guided variations, particularly in handling the session gaps. In the Initialization stage, a preset session gap is used to schedule a second session of a 2-hour MAT/STA course after the first one is successfully allocated. However, pre-scheduled major courses may occupy certain time slots, creating conflicts. Thus, Session 2 is relocated to the next available timeslot, and the session gap is recalculated. To prevent sessions from being scheduled too closely together, a penalty is applied when the updated gap is smaller than the preset session gap. Fig. 6 illustrates the relocation process for Session 2 (with a preset session gap of 18 timeslots).

The same process is applied in Swapping 1 and Swapping 2. Nevertheless, conflicts encountered during these swapping operations may necessitate relocating either or both of Sessions 1 and 2. This adaptive strategy ensures feasibility while permitting controlled relaxation to enhance exploration and minimise unallocated courses.

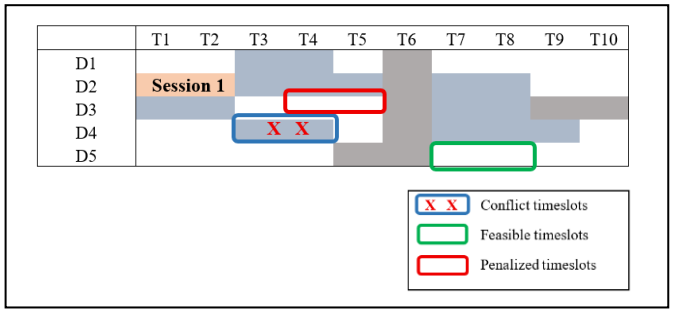

Fig. 6. Relocation process in the initialization stage.

III. EXPERIMENTS

A. Experimental Setting

In this case study, a real-world dataset is derived from an actual university timetable from the UiTM, Sarawak Branch. A real challenge and diverse policies across organizations in this dataset are studied to tailor the proposed algorithm and evaluate its performance. The details of the data are summarized in the following Table II:

TABLE II. CHARACTERISTICS OF REAL DATASETS FOR THREE SEMESTERS.

Semester	October 2022	March 2023	October 2023
No. of programs	15	15	15
No. of students	1637	1372	1408
No. of groups	78	67	81
No. of MAT/STA courses	14	14	16
No. of groups taking multiple MAT/STA courses	1(2 courses)	11(2 courses)	5(2 courses) 1(3 courses)
No. of lecturers	21	23	23
No.of MAT/STA courses with shared-teaching	0	7	3

The experiment was coded in Java, and all experiments were carried out on an Acer computer equipped with a 12th Gen Intel® Core™ i5-1235U processor running at 3.45 GHz. We performed 10 independent runs for each dataset. In addition, the ITC2002 and ITC2007 (Track 2) benchmark datasets were used as a baseline to evaluate the proposed algorithm's performance relative to existing methods.

In preliminary experiments, various settings were used to determine the best session gaps and end timetable hours for each dataset. The details of the setting tested are as follows:

- Session gaps: {9, 10, 11, 12, 13, 14, 15, 16, 17, 18}
- End timetable: {17, 18, 19, 20}

Preliminary experiments show that the best predefined session gaps for each semester are 11, 13, and 13, respectively. Nonetheless, the session gap for each dataset may vary for multiple MAT/STA courses due to adjustments made by the dynamic local operator.

B. Experimental Results

Table III indicates that penalty values (average of soft-constraint violations) were reduced by 56.19% in October 2022, 66.30% in March 2023, and 59.63% in October 2023, showing substantial improvements in lecture distribution, consecutive hours, and isolated sessions. Although some datasets required later end times and more timeslots, this trade-off enabled a more balanced distribution of parallel sessions and lower penalties in a more complex environment. Overall, the results demonstrate the method's effectiveness in generating a feasible and balanced timetable while addressing critical session gaps.

The algorithm performance was further evaluated in terms of the penalty cost achieved in the initial and improvement stages (see Table IV). Random initial solutions may take time to improve during an evolutionary stage [16]. A sorting and shuffling technique was applied in the initial stage which indicates the effectiveness of obtaining good-quality feasible solutions. The proposed guided variation operator also speeds up the improvement of each solution. The significant improvement is evident from the large deviation in penalty cost reduction during the improvement stage.

TABLE III. OVERALL PERFORMANCE (AVERAGE COST) OF THREE DATASETS.

Semester	October, 2022		March, 2023		October, 2023	
	Act.	Imp.	Act.	Imp.	Act.	Imp.
End timetable	18:00	18:00	17:00	18:00	17:00	19:00
Penalty Value	105	46 **↓56.19%**	181	61 **↓66.30%**	218	88 **↓59.63%**
Timeslots	46	46	42	46	42	50

Act. = Actual; Imp. = Improved

TABLE IV. STATISTICAL ANALYSIS FOR THE INITIAL STAGE AND IMPROVEMENT STAGE ACROSS THREE DATASETS.

Datasets	Stage	Minimum	Mean	Std. Deviation
October, 2022	Initial	21	52.16	10.88
	Improvement	0	46	**20.93**
March, 2023	Initial	49	68.54	8.17
	Improvement	0	61	**21.86**
October, 2023	Initial	98	143.32	13.71
	Improvement	7	88	**33.58**

A one-way analysis of variance (ANOVA) based on relative improvement was conducted, as shown in Table V, to evaluate the algorithm's stability across independent runs. The results indicate consistent algorithm performance across all datasets and multiple runs (p-value > 0.001).

TABLE V. ANOVA FOR EACH DATASET OF THE ALGORITHM

Datasets	Source	DF	Sum of squares	Mean Square	F	Signature
October, 2022	Between groups	9	5515.022	612.780	0.690	**0.718**
	Within groups	347	308235.712	888.287		
	Total	356	313750.734			
March, 2023	Between groups	9	1066.636	118.515	0.171	**0.997**
	Within groups	480	332711.768	693.150		
	Total	489	333778.403			
October, 2023	Between groups	9	951.823	105.758	0.264	**0.984**
	Within groups	463	185482.213	400.610		
	Total	472	186434.036			

TABLE VI. SESSION GAP AND CONSECUTIVE HOURS (IN A DAY) FOR ALL MAT/STA COURSES.

Semesters	October, 2022		March, 2023		October, 2023	
Stages	Act.	Imp.	Act.	Imp.	Act.	Imp.
Minimum Session Gap	6	9	3	9	4	19
Average Session Gap	18	13	18	22	10	21
Average Consecutive hours in a day	7	4	6	4	7	4

Act. = Actual; Imp. = Improved

Session gaps (see Table VI) improved significantly, with minimum gaps increasing to 3 timeslots in October 2022, 6 in March 2023, and 15 in October 2023, indicating that 2-hour sessions are spread across 1–2 days. Reducing daily consecutive hours further contributed to more efficient timetables across all three semesters. Consequently, it provides a more balanced distribution of morning and afternoon timeslots across all groups' timetables (see Fig. 7).

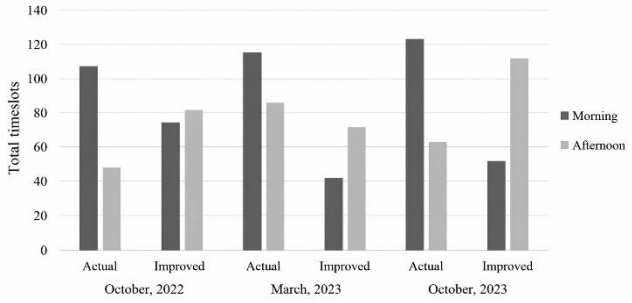

Fig. 7. Morning and afternoon timeslot distributions (all groups).

From the lecturer's timetable perspectives (Fig. 8), the distributions of morning and afternoon timeslots are more balanced in October 2022 and March 2023. In contrast, achieving this balance in October 2023 is difficult due to the higher complexity of multiple groups with more MAT/STA courses and shared-teaching constraints.

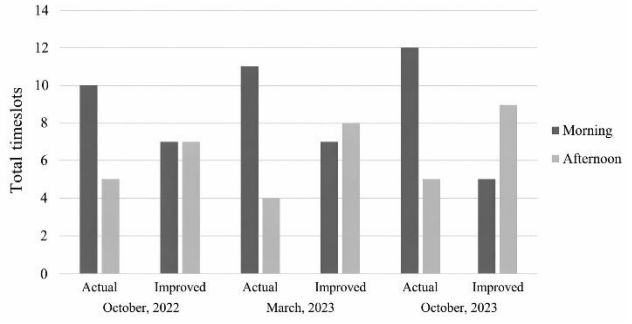

Fig. 8. Morning and afternoon timeslot distributions (all lecturers).

As a baseline comparison, 10 instances from ITC2002 and 12 from ITC2007 (Track 2) were evaluated. The results are compared with existing methods [2], [9], [17], which applied variants of evolutionary algorithms to the same benchmark datasets. The performance of benchmark datasets is measured by distance to feasibility (number of unallocated events) and the penalty cost of soft constraint violations. The soft constraints are included as follows:

- Students should not be scheduled to attend an event in the last timeslot of a day (that is, timeslots 9, 18, 27, 36, or 45).
- Students should not have to attend three (or more) events in consecutive timeslots occurring on the same day.
- Students should not be required to attend only one event on a particular day.

For the ITC2002 dataset, certain constraints are relaxed due to its slightly different characteristics, including session gaps, precedence events, and available timeslots. The proposed algorithm produces feasible solutions with no unallocated events for all instances (see Table VII). However, the resulting soft-constraint penalty costs are less competitive than those of previous works (see Table VIII).

TABLE VII. COMPARISON OF UNALLOCATED COURSES ON ITC2002 BENCHMARKS.

9	630	507	586	472	32	256
10	589	499	516	460	58	73

Avg. = Average; Imp. = Improved

Meanwhile, constraints for ITC2007 (Track 2) are more complex than those for ITC2002, as events are allocated to specific time slots only. In addition, there is a precedence requirement that certain events should occur before certain others. Nevertheless, the session gaps are also relaxed during

testing of the ITC2007 (Track 2) instance. Consequently, only three instances (3, 7, and 8) can achieve zero unallocated events by the proposed algorithm (see Table IX).

TABLE IX. COMPARISON OF UNALLOCATED COURSES ON ITC2007 (TRACK 2) BENCHMARKS.

Instance	Proposed EA	[2]	[9]
1	18	0	0
2	37	0	0
3	**0**	**0**	**0**
4	2	0	0
5	34	0	0
6	24	0	0

8	**0**	**0**	**0**
9	34	0	0
10	26	0	0
11	5	0	0
12	10	0	0

Furthermore, Table X presents a comparison of soft-constraint violations (penalty costs) for ITC2007 (Track 2). The penalty costs for initialization and improvement (Swapping 1 and Swapping 2) are compared with those in previous studies. The improved results consistently outperformed the initial solutions, demonstrating that the proposed variation operator significantly improves solution quality. Even though the proposed approach did not always outperform existing methods such as EM-GD [17], HH-PSO [2], and IPGALS [9], the observed improvements from the initial stage to the improved stage confirm that the algorithm can adapt and refine the solution effectively. This demonstrates robustness in maintaining quality, even at larger problem sizes.

IV. CONCLUSION

In this study, an evolutionary algorithm with a dynamic local operator was used to allocate MAT/STA courses within the Mathematical Sciences Department at UiTM Sarawak Branch. The dynamic local operator was used to relocate and recompute the session gaps for 2+2 lecture hours of MAT/STA courses while satisfying a balanced distribution within a pre-scheduled timetable (limited available time slots).

Computational results are compared with the manual solutions for three semesters. It shows that the proposed algorithm can handle more complex scenarios (multiple groups with more MAT/STA courses) at the cost of a later end time. The proposed variation operator significantly improves solution quality, even when a good initial population has already been generated (compared to manual solutions). On average, the penalty value is reduced by up to 66.30%, and up to 15 timeslots improve the session gap. The proposed algorithm was further tested on ITC2002 and ITC2007 (Track 2) to serve as a baseline for existing methods. With certain constraint relaxations, the benchmark dataset results indicate that the proposed algorithm maintains solution quality even in larger, more complex settings.

Multi-Class Stress Detection Using Electrodermal Activity: Evaluation of A Hybrid Model Using UBFC-Phys Dataset

Kawther Alsayed, Hamza Ghandorh, Wael M.S. Yafooz
Department of Computer Science-College of Computer Science and Engineering, Taibah University, Medinah, Saudi Arabia

***Abstract*—Stress is a psychological and physiological response to internal or external pressures or challenges that exceed an individual's ability to cope. In response to these conditions, the human body produces physiological signals that reflect its internal states, often without conscious awareness. Among these signals, electrodermal activity (EDA) is known for its sensitivity to changes in stress levels. Traditional methods for assessing stress, such as questionnaires and self-reports, remain widely used, but they are often influenced by subjectivity and recall bias. This has led to increased interest in objective, data-driven approaches. This research proposes a hybrid stress detection model. The EDA signals were used from the UBFC-Phys dataset, which comprises data from 56 participants under three conditions: rest, moderate stress, and high stress. The signals were preprocessed using filtering, smoothing, and subject-level normalization to reduce inter-individual variability. A set of features was extracted, such as tonic component features. Multiple experiments were conducted on baseline, deep learning, and hybrid models not only for stress detection classification purposes but also for performance evaluation purposes. The proposed model achieved an accuracy of 92.16% in the multi-class classification task. The findings of this research contribute to mental health and well-being by providing an accurate model for stress detection that can be adapted to healthcare, education, and workplace settings, ensuring a healthier and more sustainable future.**

***Keywords*—Stress detection; physiological signal; Electrodermal Activity (EDA); machine learning; ensemble; deep learning; hybrid model**

I. Introduction

Stress negatively affects both physical and mental health. It is causative of conditions such as cardiovascular diseases, weakened immunity, anxiety, depression, and sleep disorders [1], [2]. Its effects are not limited to the individual level but extend to productivity and quality of life in general, such as work environments and educational institutions [3], [4]. This highlights the importance of identifying stress early and monitoring it over time to support overall well-being [5]. When a person experiences psychological stress, the autonomic nervous system, particularly the sympathetic system, is triggered. As a result, hormones such as cortisol and adrenaline are released to prepare the body for a fight-or-flight response [6]. These hormones increase blood pressure, heart rate, and breathing rate, and lead to noticeable changes in physiological signals [6]. After the stress ends, the parasympathetic nervous system helps the body recover and return to a normal state.

Recently, more attention has been given to using physiological signals to detect stress directly and continuously. One of the most common signals is electrodermal activity (EDA), a physiological signal that captures changes in skin conductance associated with sweat gland activation by the sympathetic nervous system [7]. Current progress in machine learning (ML) and deep learning (DL) makes it possible to automatically analyze physiological signals and classify stress levels. Various ML models have been applied to learn patterns from extracted features. DL approaches, e.g., Convolutional Neural Networks (CNN) and Transformers, have also been used to capture more complex relationships within the data.

Despite recent progress in stress detection, working with the UBFC-Phys dataset [8] still presents a challenge. This dataset requires careful handling due to the nature of the physiological signals. There are clear differences between individuals, as each person has their own baseline and responds differently to stress. In addition, some patterns, especially between moderate and high stress, can be very similar, which makes classification more challenging. Thus, it is important to use methods that take these differences into account and provide consistent results across all states. The main contributions of this work are:

Addressing inter-individual variability by applying subject-level normalization, which reduces differences in physiological baselines and improves the consistency of stress classification.

Proposed a hybrid model for binary and multiclass stress classification and achieved high performance on the UBFC-Phys dataset.

The remainder of this study is organized as follows: Section II presents a review of the relevant literature. Section III details the materials and methods, including the dataset description, preprocessing procedures, feature extraction process, data partitioning strategy, proposed model architecture, and evaluation metrics. Section IV presents the experiments and results, followed by a comparison with previous work. Section V discusses the findings. Section VI concludes the study.

II. Literature Review

Recent studies have shown increasing interest in stress detection using physiological signals, as these signals provide more objective indicators. Many publicly available datasets have been widely used in stress detection research to develop, train, and evaluate various ML and DL models using physiological signals. These datasets provide important

benchmarks for comparing stress detection models in different environments and with different signals. The UBFC-Phys dataset was used in this research. Other datasets include SWELL-KW [9], which is designed to evaluate workplace stress under time-pressure and email interruption conditions, and WESAD [10], which provides a multimodal dataset that involves physiological signals recorded from chest- and wrist-worn devices during different conditions. Other datasets that contribute to stress detection research comprise SRAD [11], Louisiana [12], TILES-2018 [13], and MAUS [14], which provide data related to driving stress, hospital work environments, workplace stress, and mental workload.

Physiological signals are used for stress detection with the support of wearable devices and AI models. Different ML approaches have been applied in this area. Sabour et al. presented the UBFC-Phys dataset and used EDA and BVP signals to study social stress, showing their usefulness in this field [8]. Vos et al. developed an ensemble model using data from multiple sources and showed good generalization for stress prediction [15]. Hasanpoor et al. used PPG signals from the UBFC-Phys dataset with a CNN-MLP model and reported an accuracy of 82%, showing that a single signal can be used for stress detection [16].

Zhang et al. used a DL model based on attention to combine BVP and EDA signals and capture the relationship between them [17]. Arsalan et al. [18] applied several supervised learning models with EEG, GSR/EDA, and PPG signals, and reported that the MLP model achieved the highest accuracy. Al Hasan et al. [19] used PPG, ECG, and GSR from the MAUS dataset and reported good performance using the Random Forest (RF) model after hyperparameter tuning. Mathur et al. [20] investigated stress detection among nurses. In their experiment, they used wearable sensor data and achieved high performance with Decision Tree classifiers.

WESAD and other datasets have been used to compare ML and DL models for stress detection. Kar et al. used a GRU-RNN model with EDA, accelerometer, and temperature signals and achieved high performance in binary classification [21]. Gil-Martin et al. applied CNN models using data from wearable sensors and showed that DL can learn useful patterns from physiological signals [22]. Liu et al. used a Transformer-LSTM model with PPG signals and reported strong results in stress classification [23]. Other work explored CNN-LSTM models and multimodal signals to improve performance, as combining different signals helps capture more information about the body's response to stress [24]. These studies show that DL models can handle complex patterns, especially when enough data is available.

Many physiological signals were used for stress detection, such as electrodermal activity (EDA), blood volume pulse (BVP), electrocardiogram (ECG), photoplethysmography (PPG), and heart rate variability (HRV) [25]. Electrodermal activity (EDA), on the other hand, is a practical option because it is directly related to sympathetic nervous system activity and can be collected using wearable devices [7]. Despite these improvements, distinguishing between different stress levels is still challenging, especially when the patterns are very similar. Based on this, the current study focuses on using Electrodermal activity (EDA) signals from the UBFC-Phys dataset and proposes a hybrid model for both binary and multiclass stress classification.

III. Methodology

A. Dataset

Data were obtained from a publicly accessible dataset named UBFC-Phys [8]. The dataset contains physiological signals collected using the E4 wristband EDA and BVP together with video recordings from 56 participants during three tasks performed under different stress conditions. The experiment included three tasks representing different stress levels: a resting task (T1) used as the baseline condition, a speech task (T2), and an arithmetic task (T3). Each task included 56 recordings, resulting in a total of 168 signals. This work focused on the EDA signals. For each subject, the signals were recorded separately for each task, which made it easier to distinguish between rest and stress states.

Fig. 1 shows that EDA signals increased with higher stress levels across the tasks. The signal was stable during rest (T1), slightly higher during the speaking task (T2), and highest during the arithmetic task (T3), showing that EDA can reflect changes in stress levels.

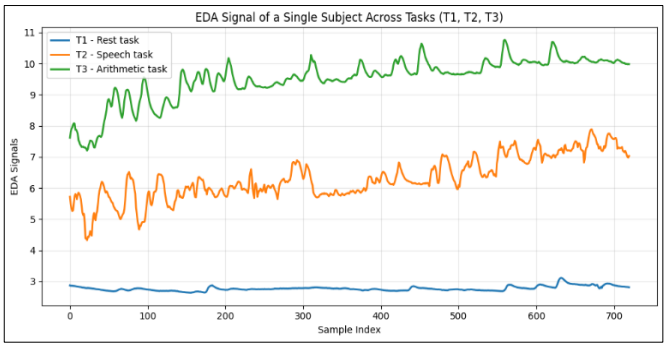

Fig. 1. EDA signal of Subject 13 across the three tasks: rest (T1), speech (T2), and arithmetic (T3). The signal amplitude increases from the resting condition to the more demanding tasks, reflecting higher physiological arousal under stress.

B. Data Preprocessing

The EDA signals were recorded at a sampling rate of 8 Hz. Several preprocessing steps were applied to reduce noise, enhance the quality of the signal, and prepare the data. First, the initial two seconds of each signal were removed, as this part often contained unstable values due to sensor contact at the beginning of the recording.

A fourth-order Butterworth low-pass filter was applied to attenuate high-frequency artifacts with a 1 Hz cutoff frequency, while keeping the main signal pattern unchanged. A Savitzky-Golay filter was used to smooth and reduce small fluctuations of the signal without affecting the overall shape.

The dataset showed variability between participants in their physiological responses. To address this, Z-score normalization was applied for each subject to reduce these differences and allow the model to focus on relative changes in the EDA signal rather than absolute values. The mean and standard deviation (SD) were calculated from the resting condition (T1) only and

subsequently used to normalize all recordings for each participant across different tasks.

$$x_norm = \frac{(x - \mu_baseline)}{\sigma_{baseline} + \varepsilon} \quad (1)$$

where x was the EDA value, μ_baseline and σ_baseline were the mean and standard deviation of the resting signal (T1), and ε is a small constant.

C. Feature Extraction

For each EDA signal, 23 features were extracted to represent different signal characteristics. The extracted features were directly used for model classification. The tonic and phasic components of each EDA signal were extracted using NeuroKit2 [26]. Six features were extracted from the tonic component to describe the baseline level, variability, and overall trend of the signal. Similarly, six features were derived from the phasic component to capture rapid changes related to sympathetic activity.

Additionally, seven statistical features were computed directly from the preprocessed signal to represent its overall distribution and variability. Two Hjorth [27] parameters were also included to describe the signal dynamics and complexity. The zero-crossing rate of the first derivative was used to reflect local variations in the signal, and low-frequency spectral power was calculated to capture the dominant physiological patterns. A summary of extracted features is shown Table I.

TABLE I. FEATURES DERIVED FROM EDA SIGNALS [8]

Feature	Description
scl_mean	Mean of skin conductance level (SCL)
scl_std	Tonic component standard deviation
scl_range	Range (max − min) of the tonic component
scl_slope	Linear trend (slope) of the tonic component over time
scl_median	Median value of the tonic component
scl_cv	Coefficient of variation of the tonic component
scr_mean	Mean absolute value of the phasic (SCR) component
scr_std	Standard deviation of the phasic component
scr_max	Maximum value of the phasic component
scr_auc	Area under the positive phasic component curve
scr_energy	Total energy of the phasic component
scr_count	Number of detected SCR peaks
raw_mean	Mean of the raw EDA signal
raw_std	Standard deviation of the raw EDA signal
raw_var	Variance of the raw EDA signal
raw_range	Range (max - min) of the raw EDA signal
raw_skew	Skewness of the raw EDA signal distribution
raw_kurt	Kurtosis of the raw EDA signal distribution
raw_rms	Root mean square of the raw EDA signal
hjorth_mobility	Rate of change of the signal relative to its variance
hjorth_complexity	Rate of change of the signal's frequency content
zcr	Rate of sign changes in the first derivative of the signal
lf_power	Power spectral density in the low-frequency band (0-1 Hz)

D. Data Splitting

The dataset was partitioned into training and testing sets using a 70:30 ratio to enable reliable model evaluation. A subject-independent split was applied using GroupShuffleSplit with a fixed random state (42), where all recordings from each participant were assigned to either the training or testing set to avoid data leakage. Within the training set, hyperparameter tuning was conducted using five-fold cross-validation. GroupKFold was used for binary classification, and StratifiedGroupKFold was applied for multiclass tasks. GridSearchCV was used to select the best hyperparameters, and the final model was evaluated on the unseen data (test set).

E. Experimental Setup

The experimental setup in this work was organized into three experiments.

1) Binary classification using ML models: The first experiment evaluated baseline ML models for binary stress classification using EDA-based features. T1 and T2 from the UBFC-Phys dataset were used, where T1 represented the non-stress state, and T2 represented the stress state. The experiment was conducted under different preprocessing settings, without smoothing and normalization and with smoothing and normalization, to examine their effect on classification performance. Fig. 2 shows an overview of the first experiment for binary stress classification. The configurations used in the experiment are summarized in Table II.

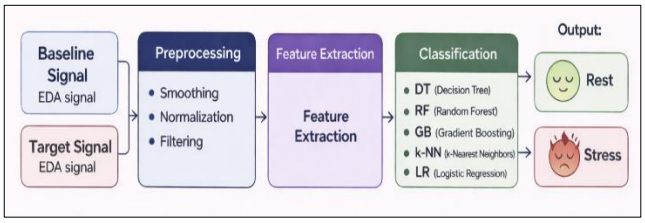

Fig. 2. Overview of the binary Stress Detection Pipeline. It starts with EDA signals (Baseline and Target), then preprocesses them. After that, features are extracted and fed into ML models to classify the stress.

TABLE II. HYPERPARAMETER SETTINGS FOR BASELINE ML MODELS IN BINARY CLASSIFICATION

Model	HyperParameter
GB	n_estimators = 100, 150, 200; learning_rate = 0.01, 0.05, 0.1; max_depth = 2, 3
RF	n_estimators = 200, 300, 500; max_depth = 5, 10, 15, 20, None; min_samples_split = 2, 5; min_samples_leaf = 1, 2
K-NN	n_neighbors = 3, 5, 7, 9, 11; weights = uniform, distance; metric = euclidean, manhattan, minkowski
LR	C = 0.001, 0.01, 0.1, 0.5, 1, 5, 10; max_iter = 2000
DT	max_depth = 3, 5, 10, 15, None; min_samples_split = 2, 5, 10; criterion = gini, entropy

2) Multiclass classification using ML and DL models: The second experiment evaluated multi-class stress classification using both ML and DL models. Three tasks from the dataset were used, including T1 for rest, T2 for moderate stress, and T3 for high stress. The same preprocessing steps, feature extraction process, and data splitting strategy used in the first experiment

were also applied (Fig. 3). The configurations used in the experiment are summarized in Table III.

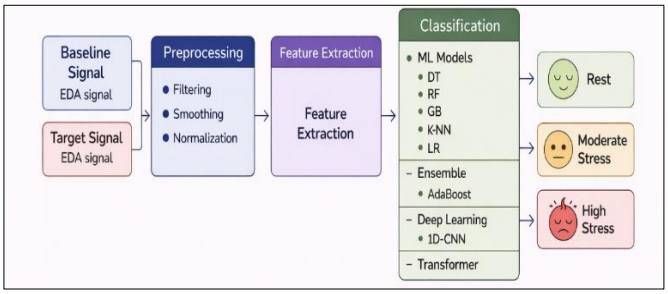

Fig. 3. Overview of the Multi-Level Stress Detection Pipeline: From raw EDA signals, the data preprocessing, and then feature extraction. Different models then use the extracted features to predict three stress levels.

TABLE III. HYPERPARAMETER SETTINGS FOR MODELS IN MULTICLASS CLASSIFICATION

Model	HyperParameter
GB	n_estimators = 100, 150, 200; learning_rate = 0.01, 0.05, 0.1; max_depth = 2, 3
RF	n_estimators = 200, 300; max_depth = 10, 20, None
K-NN	n_neighbors = 3, 5, 7, 9; weights = uniform, distance
LR	C = 0.01, 0.1, 1, 10; solver = lbfgs
DT	max_depth = 3, 5, 10, None; criterion = gini, entropy
AdaBoost	base_estimator = Decision Tree (max_depth = 2), SAMME; n_estimators = 50, 100, 200; learning_rate = 0.01, 0.1, 1.0
1D-CNN	Filters = 64 / 128; FC Hidden = 64; Dropout = 0.4; Learning Rate = 0.0005; Epochs = 150; Batch Size = 16
Feature Transformer	d_model = 64; Attention Heads = 8; Encoder Layers = 2; FC Hidden = 64; Dropout = 0.3; Learning Rate = 0.0005; Epochs = 200; Batch Size = 16; Noise Std = 0.02

3) Proposed hybrid model for multiclass classification: The proposed hybrid model combined five ML classifiers, Gradient Boosting (GB), K-Nearest Neighbors (KNN), Logistic Regression (LR), Decision Tree (DT), and Random Forest (RF), using a weighted soft voting strategy. GB was given the highest weight due to its strong capability for sequential error correction. RF provided robustness. KNN contributed by capturing local data structures, LR introduced a linear decision perspective, and DT added model diversity with low complexity. Fig. 4 shows an overview of the proposed model.

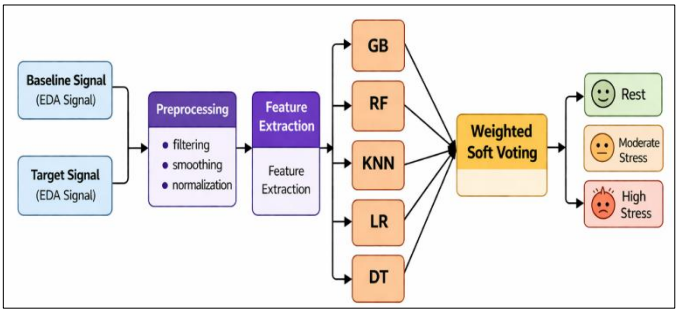

Fig. 4. Overview of the hybrid Stress Detection Pipeline for Multiclass: It starts with EDA signals, followed by preprocessing, feature extraction, and the hybrid model predicts three stress levels: Rest, Moderate Stress, and High Stress.

The configurations used in the experiment are summarized in Table IV.

TABLE IV. THE PROPOSED HYBRID MODEL CONFIGURATION

Model	HyperParameter	Weight
GB	n_estimators = 150, learning_rate = 0.01, max_depth = 2	3
RF	n_estimators = 300, max_depth = 10, min_samples_split = 5	2
K-NN	n_neighbors = 7, weights = distance	2
LR	C = 10, solver = lbfgs	1
DT	criterion = gini, max_depth = 3	1

F. Performance Evaluation

Several evaluation metrics were employed to assess various aspects of model performance. The models were evaluated on the test set using widely adopted performance measures, including accuracy, recall, precision, F1-score, ROC curves, and the confusion matrix. The performance metrics utilized in this work are summarized in Table V.

TABLE V. EVALUATION METRICS UTILIZED FOR PERFORMANCE ASSESSMENT

Metric	Description
PR	$PR = \frac{TP}{TP + FP} \times 100$
RE	$RE = \frac{TP}{TP + FN} \times 100$
AC	$AC = \frac{\mathrm{TP} + \mathrm{TN}}{Total\ Samples} \times 100$
F1	$F1 - score = 2 \times \frac{PR\ x\ RE}{PR + RE}$
CM	Provides class-wise information on correct classifications and misclassification patterns.
ROC	Shows how the model performance changes across different decision thresholds

IV. RESULTS

In the first experiment, baseline ML models were evaluated for binary stress classification without applying smoothing and normalization. Table VI shows the performance results of the models using EDA-based features for classifying between stress and non-stress states.

TABLE VI. THE RESULTS OF THE BASELINE EXPERIMENT (WITHOUT SMOOTHING AND NORMALIZATION)

Model	AC	PR	RE	F1
KNN	**91.18**	**85.00**	**100**	**91.89**
GB	88.24	80.95	100	89.47
LR	85.29	83.33	88.24	85.71
RF	82.35	76.19	94.12	84.21
DT	82.35	82.35	82.35	82.35

Fig. 5 and Fig. 6 show the confusion matrices for the selected models in the first experiment. Both GB and KNN achieved high recall for stress, with some false positives where rest samples were misclassified as stress. KNN showed slightly fewer misclassifications compared to GB.

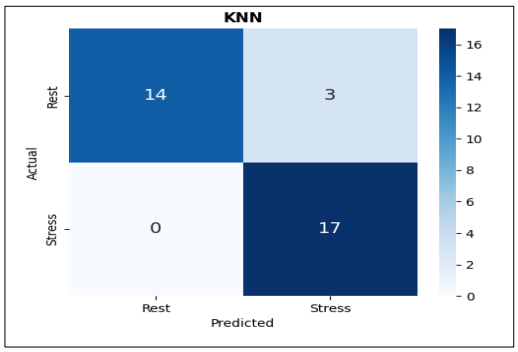

Fig. 5. CM of binary classification (no smooth/no norm) for KNN model.

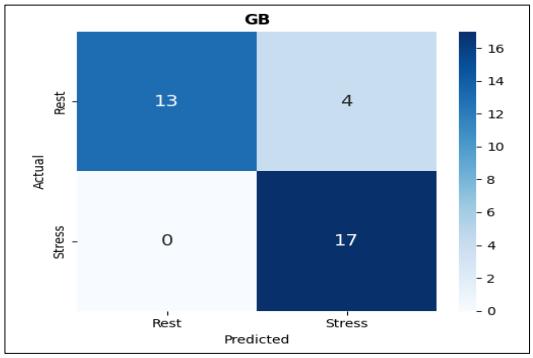

Fig. 6. CM of binary classification (no smooth/no norm) for GB model.

The ROC curves in Fig. 7 and 8 below show that KNN achieved the highest AUC (0.976), which indicated the best separation between the two classes. GB also had a high AUC (0.934), showing good performance.

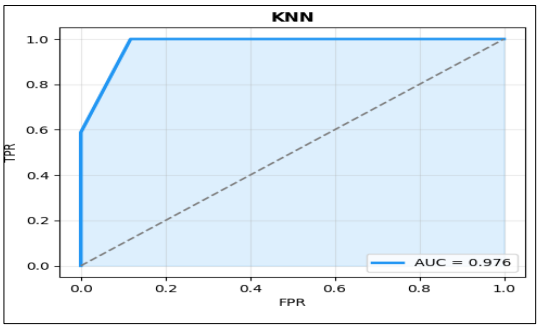

Fig. 7. ROC curve of binary classification (no smooth/no norm) for KNN model.

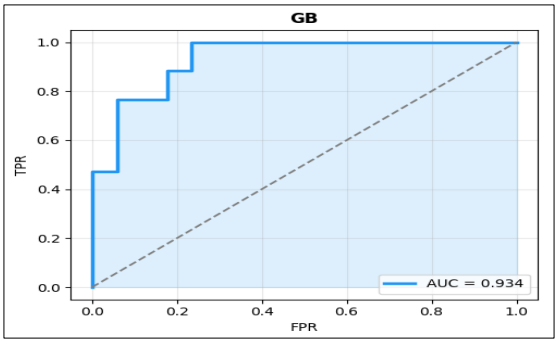

Fig. 8. ROC curve of binary classification (no smooth/no norm) for GB model.

Table VII presents the results after applying smoothing and normalization. The preprocessing steps improved the performance of most models compared to the previous setting. DT achieved perfect results. These results show that the preprocessing pipeline helped the models better distinguish between the classes and improved generalization across different subjects. The high performance may also be related to the relatively small dataset size and the simpler nature of the binary classification task.

TABLE VII. THE RESULTS OF THE BINARY CLASSIFICATION (WITH SMOOTHING AND NORMALIZATION)

Model	AC	PR	RE	F1
DT	**100**	**100**	**100**	**100**
RF	97.06	100	94.12	96.97
GB	97.06	100	94.12	96.97
KNN	91.18	85.00	100	91.89
LR	88.24	88.24	88.24	88.24

Fig. 9 and 10 show the confusion matrices for DT and RF in binary classification using preprocessed EDA signals. DT correctly classified all samples without errors, while RF also showed strong performance with only one misclassification.

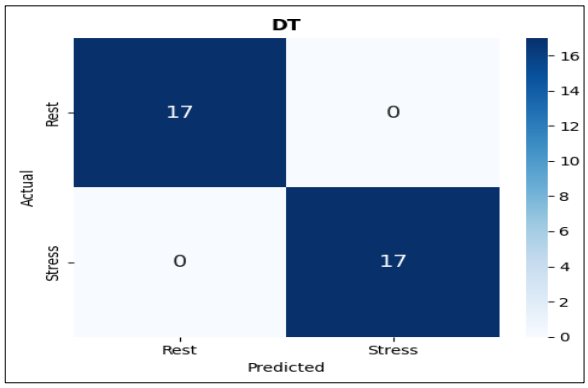

Fig. 9. CM of binary classification (with smooth and norm) for DT model.

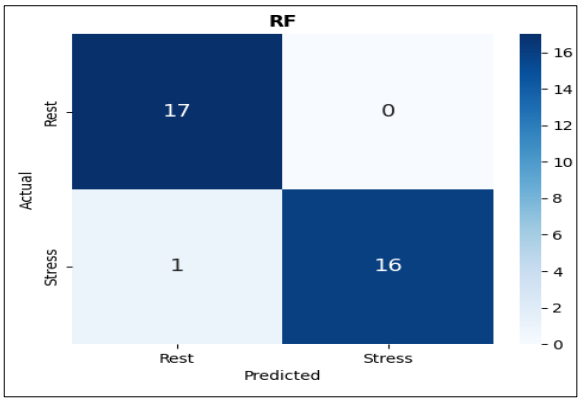

Fig. 10. CM of binary classification (with smooth and norm) for RF model.

Fig. 11 and 12 show the ROC curves for both DT and RF, which achieved perfect AUC values of 1.000, indicating a clear separation between the rest and stress classes.

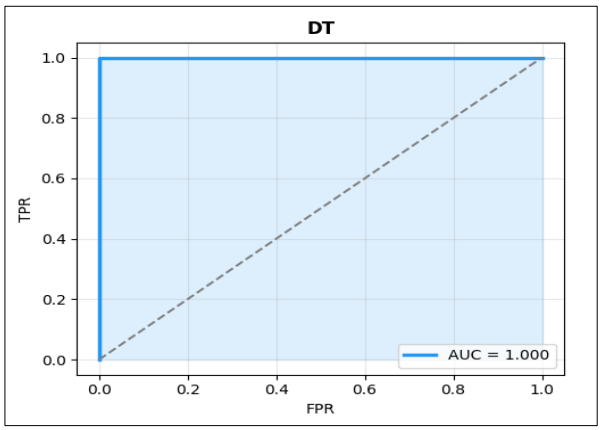

Fig. 11. ROC curve of binary classification (with smooth and norm) for DT model.

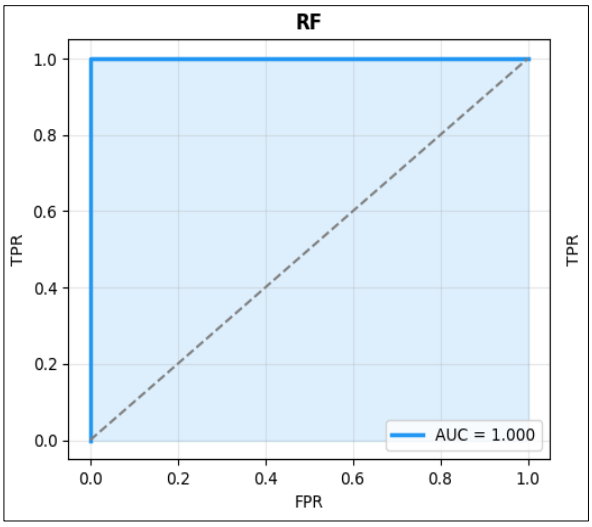

Fig. 12. ROC curve of binary classification (with smooth and norm) for RF model.

The second experiment evaluated multi-class stress classification using both ML and DL models. The three-level stress classification results are presented in Table VIII. The best performance was achieved by GB, while comparable results were obtained by RF, KNN, AdaBoost, and DT. Lower performance was observed for LR and Transformer, whereas the weakest results were recorded by 1D-CNN.

TABLE VIII. RESULTS OF THE MULTICLASS CLASSIFICATION

Model	AC	PR	RE	F1
GB	**90.20**	**90.28**	**90.20**	**90.19**
RF	88.24	88.24	88.24	88.24
KNN	88.24	88.24	88.24	88.24
AdaBoost	88.24	88.24	88.24	88.24
DT	88.24	88.24	88.24	88.24
LR	86.27	86.73	86.27	86.36
Transformer	82.35	82.41	82.35	82.34
1D-CNN	52.94	47.15	52.94	44.23

The relatively low performance of the 1D-CNN might be due to the small size of the dataset and the subject-independent split, whereby the number of samples available for deep feature learning was reduced. The three classes were well balanced, but the low-frequency EDA and the subtle differences between moderate and high stress could have affected the discriminative representation that the 1D-CNN was able to learn. Therefore, the poor performance of the lower 1D-CNN can be attributed to the model architecture used and less training data.

The confusion matrices for the selected models are shown in Fig. 13 and 14 below show the confusion matrices for the selected models. The GB model correctly classified all the rest of the samples and achieved strong performance across stress levels. The Feature Transformer also correctly identified all the remaining samples but showed more confusion between stress levels compared to GB.

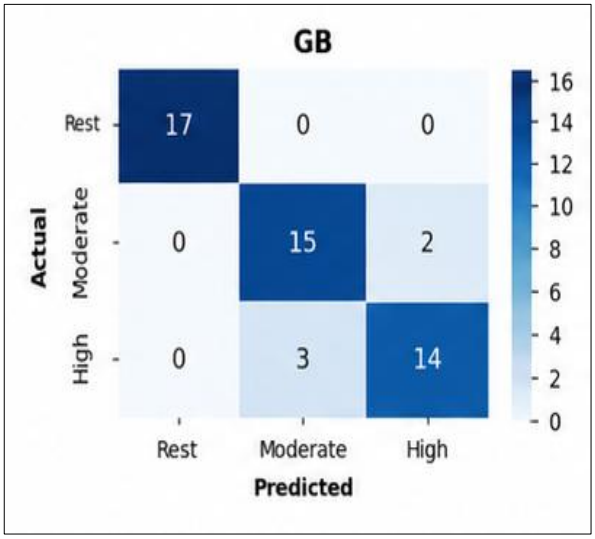

Fig. 13. CM of multiclass classification for the GB model.

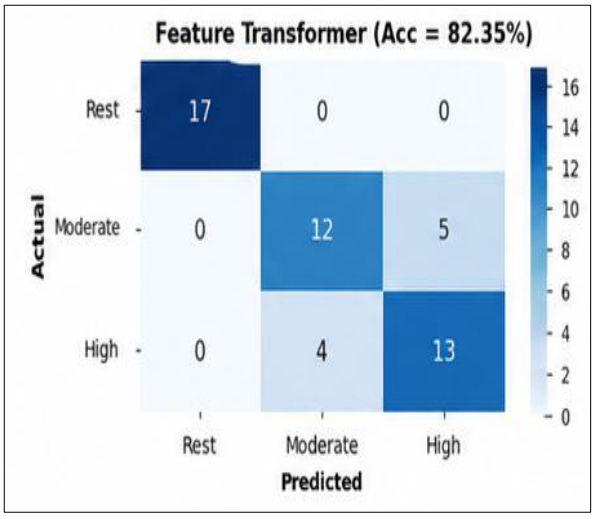

Fig. 14. CM of multiclass classification for Transformer.

Fig. 15 and 16 below show the ROC curves for the selected models. Both models achieved strong performance with clear separation for the rest of the classes.

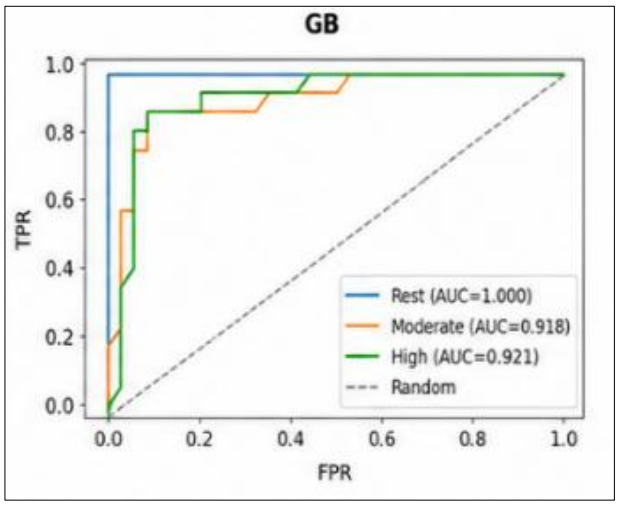

Fig. 15. ROC curve of multiclass classification for GB model.

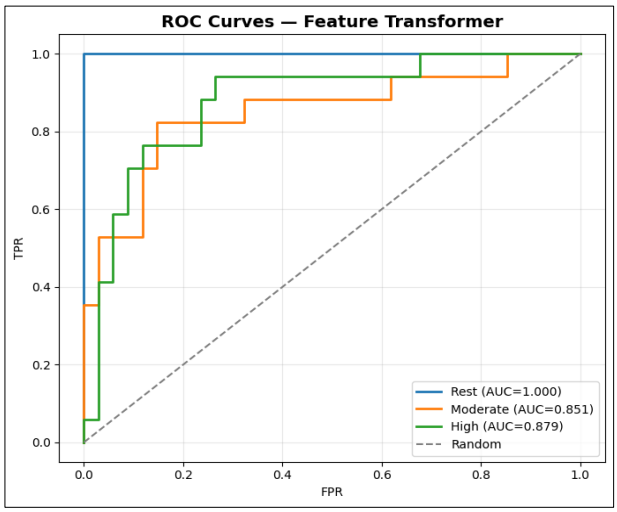

Fig. 16. ROC curve of multiclass classification for Transformer.

The final experiment evaluated the proposed hybrid model. Table IX presents the performance results of the proposed model. The proposed hybrid model outperformed all other evaluated models in terms of overall performance.

TABLE IX. THE RESULTS OF PROPOSED MODEL

Model	AC	PR	RE	F1
Proposed Hybrid Model	92.16	92.16	92.16	92.16

The confusion matrix in Fig. 17 shows that all the rest of the samples were correctly classified by the proposed hybrid model. Most moderate and high stress samples were also classified correctly, with only a few errors between them. To analyze the contribution of extracted EDA features, the proposed hybrid model was implemented with feature group ablation analysis. One feature group was eliminated in each experiment, and the other features were kept. The results are presented in Table X.

The full 23-feature set achieved the highest accuracy of 92.16%. Removing the phasic features resulted in the greatest drop in performance, indicating their importance in capturing stress-related sympathetic responses. Removing tonic and dynamic/spectral features also shows a reduction, further indicating that different groups of EDA features provide complementary information for multi-class stress classification.

TABLE X. FEATURE-GROUP ABLATION ANALYSIS OF THE PROPOSED HYBRID MODEL

Feature setting	Features	AC
Full feature set	**23**	**92.16**
Without tonic features	**17**	**88.24**
Without phasic features	**17**	**86.27**
Without statistical features	**16**	**90.20**
Without dynamic/spectral features	**19**	**88.24**

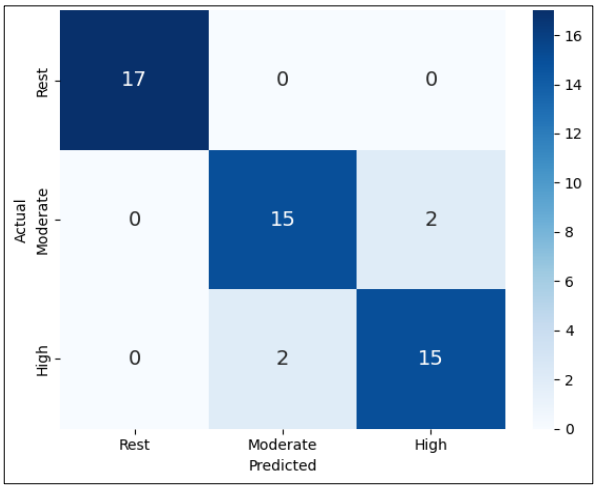

Fig. 17. CM of multiclass classification for the proposed hybrid model.

The ROC curves in Fig. 18 for the proposed hybrid model show a perfect AUC of 1.000 for the rest class. The high and moderate stress classes recorded AUCs of 0.946 and 0.943, respectively, confirming strong discrimination ability across all stress levels.

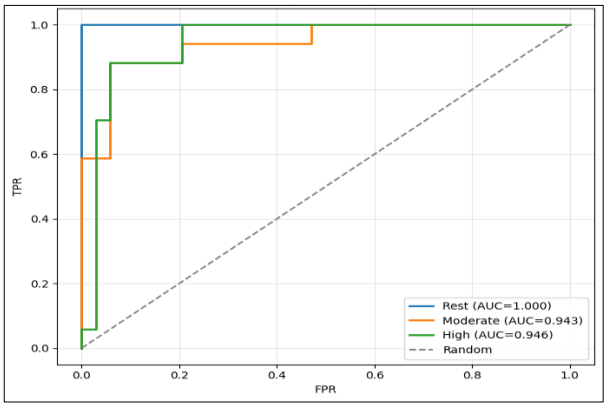

Fig. 18. ROC curve of multiclass classification for proposed hybrid model.

The result of the proposed model was compared with previous stress detection studies that used EDA signals on the UBFC-Phys dataset. Table XI compares the proposed model with EDA-based baseline models evaluated on the UBFC-Phys dataset.

TABLE XI. COMPARISON OF THE PROPOSED MODEL WITH EXISTING MULTICLASS STRESS DETECTION MODELS ON THE UBFC-PHYS DATASET

Reference	Method	Signal Used	AC
Zhang et al. [17]	DL (Attention)	EDA	48.1%
Sabour et al. [8]	SVM	EDA	63.60%
Valerio and Mahmoud [28]	SVM	EDA	69.12%
Proposed Model	**Weighted soft-voting**	**EDA**	**92.16%**

The comparison shows that the proposed hybrid model achieved the highest accuracy among the EDA-based models evaluated on the UBFC-Phys dataset. The performance of the proposed model was compared with the published SVM baseline and individual EDA-based ML/DL baselines for the multi-class stress classification task and outperformed both. This means that the proposed model is capable of capturing stress-related patterns without using any other signals except EDA signals.

V. DISCUSSION

The results of this work provide useful insight for computer science in ML, signal processing, and affective computing. The proposed model shows that a single physiological signal, EDA, could achieve high AC in stress classification when it was properly processed using steps such as filtering, smoothing, subject-level normalization, and feature extraction. This means that it was possible to build an effective stress detection system without relying on multiple sensing methods. EDA signals provided meaningful information for distinguishing between different stress levels. Separating closely related stress states could be challenging, especially between the speech task (T2) and the arithmetic task (T3), as they show similar patterns. In contrast, the binary task, which uses T1 and T2, was easier to distinguish, leading to higher performance. The proposed model achieved a high multiclass AC of 92.16%, showing that EDA could be effectively used as a standalone signal for stress detection. The improvement in performance highlights the importance of model design. The hybrid model combines multiple models, which helped capture different patterns in the data. This results in more stable and reliable predictions, especially when working with complex physiological signals. In addition, preprocessing steps such as filtering, smoothing, and subject-level normalization contribute to improving data quality and reducing differences between individuals. The subject-level normalization used in this work helps address one of the main challenges encountered, which is the variation between individuals. It was observed that different subjects have different physiological baselines, such as how their bodies responded to stress or how their skin reacted, which can affect model performance. By normalizing each subject's data based on their own rest state, the model becomes more adapted to each individual and less influenced by these differences. This makes the approach more reliable and more suitable for real-world applications, especially in personalized health monitoring systems that need to adapt to different users. This work highlights that carefully designed classical ML approaches could outperform more complex DL models, especially when working with relatively small datasets where DL models lack sufficient training samples to learn generalizable representations. This is an important insight, as it suggests that model simplicity and proper data handling could be more effective than increasing model complexity.

VI. CONCLUSION

Stress affects an individual's physical and psychological well-being, impacting their quality of life. Long-term exposure to stress has been related to a wide range of health problems. As individuals are increasingly exposed to elevated levels of stress in both personal and professional contexts. The need for an effective stress-monitoring model is more critical than ever. Early detection of stress enables timely intervention, reduces the risk of long-term health complications, and supports overall well-being. However, the traditional approaches for stress assessment, such as self-reported questionnaires, are often subjective and may not accurately reflect an individual's true physiological state. This limitation drives the growing interest in developing objective, data-driven approaches for stress detection using physiological signals. This research work proposed a hybrid model that detects stress using EDA signals from the UBFC-Phys dataset. The EDA signals were preprocessed using low-pass filtering and smoothing, followed by subject-level normalization to reduce inter-individual variability. A total of 23 features were extracted, and a hybrid weighted soft-voting ensemble combining GB, RF, KNN, LR, and DT was used to classify stress into three levels. The proposed model achieved an AC of 92.16% in the multiclass classification task, with balanced PR, recall, and F1 values of 92.16%. In the binary classification task, a perfect AC of 100% was achieved. This approach provided a practical and efficient solution for real-world stress monitoring and continuous health-monitoring applications. Future work may concentrate on enhancing and extending the proposed approach by assessing the pipeline on larger and more diverse datasets, and applying cross-dataset validation to offer stronger evidence of its generalizability. Incorporating additional physiological signals such as HR and BVP alongside EDA, within a multimodal fusion framework, may further enhance classification accuracy, particularly for distinguishing between closely related stress states. Investigating advanced DL architectures with transfer learning strategies may also help address the limitations observed with DL models in this study.

FUNDING

This scientific research study was derived from a research grant funded by Taibah University, Madinah, Kingdom of Saudi Arabia, with the grant number (1447-06).

DATA AVAILABILITY

The data presented in this work are openly available in the UBFC-Phys repository and can be accessed via [https://ieee-dataport.org/open-access/ubfc-phys-2].

ACKNOWLEDGMENT

The authors would like to acknowledge the support of Taibah University and the contributors of the UBFC-Phys dataset.

***Abstract*—Air Traffic Management is becoming increasingly complex due to the continuous growth in air traffic demand and the variability of weather conditions. Traditional aircraft separation standards rely on fixed minimum distances that do not dynamically adapt to environmental factors. This study proposes a novel framework for dynamic aircraft separation that integrates real-time weather data into Air Traffic Control (ATC) automation systems. The proposed model adjusts separation distances based on meteorological parameters such as wind speed, turbulence intensity, and visibility. A multi-objective optimization approach is developed to minimize conflict risk while maximizing airspace capacity. Simulation results demonstrate that the proposed framework improves safety and operational efficiency compared to conventional methods. This study contributes to the advancement of intelligent air traffic management systems.**

***Keywords*—Aircraft separation; air traffic control; weather impact; optimization; ATC automation; safety**

I. Introduction

The rapid increase in global air traffic has placed significant pressure on existing Air Traffic Management (ATM) systems. Ensuring safe separation between aircraft remains a fundamental responsibility of Air Traffic Control (ATC). Traditionally, separation minima are defined by regulatory authorities and are applied uniformly, regardless of dynamic environmental conditions.

Air traffic control faces several major challenges related to the increasing complexity of air traffic and the high demands for safety and efficiency. The continued rise in the number of flights leads to increased airspace congestion, making flight path management more difficult and increasing the risk of conflicts. We have already worked on pictorial approaches to solve this problem, but the results remain limited, and the approach consumes a lot of memory and CPU time [1]. Added to this are the uncertainties associated with weather conditions, which can disrupt flight plans and require rapid adjustments. The limitations of traditional systems, often poorly adapted to dynamic environments, also hinder optimal management [2], [3].

Furthermore, the heavy workload of controllers, combined with the need to make real-time decisions, can lead to errors. Finally, environmental concerns, such as reducing CO_2 emissions and fuel consumption, impose new constraints, making the integration of innovative solutions based on automation and artificial intelligence essential.

However, weather conditions such as wind, turbulence, and reduced visibility can significantly affect aircraft trajectories and operational safety. Static separation rules may lead to inefficiencies, including increased delays and underutilization of airspace capacity [4].

Air traffic in Casablanca FIR averages 1,200 daily flights, with 15-20% delays from weather-induced rerouting. Traditional procedural separation (10-15 min longitudinal) is conservative, while radar-based methods struggle in convective cells or turbulence. Current automation (e.g., Eurocontrol's AMOC) ignores real-time meteorological nowcasting, leading to unnecessary vectoring [5].

This work proposes a dynamic aircraft separation framework that accounts for real-time weather conditions. The objective is to enhance both safety and efficiency by adapting separation distances according to environmental factors.

The remainder of this article is organized as follows. Section II presents a state-of-the-art review. Section III presents the proposed methodology and the mathematical modeling of the problem. Section IV presents the architecture of our approach in terms of processing steps and evaluation criteria. Section V provides the experimental results of the scenarios and a discussion. Finally, Section VI concludes the study and suggests avenues for future research.

II. Related Works

The air traffic controller's primary mission is to ensure the safety, smooth flow, and efficiency of air traffic by continuously monitoring the position and trajectories of aircraft within their area of responsibility (Fig. 1). Using radar surveillance systems and radio communications, they guide pilots by providing precise instructions regarding altitudes, headings, and speeds, while maintaining minimum separation distances to avoid any risk of collision [6], [7] (Fig. 2). They anticipate potential conflicts, manage unforeseen situations related to weather conditions or operational constraints, and optimize traffic flows to reduce delays and fuel consumption. Their role requires rapid decision-making, strong analytical skills, and constant coordination with other control centers to guarantee the safety and overall performance of the air traffic system [8].

Fig. 1. Roles of air traffic control.

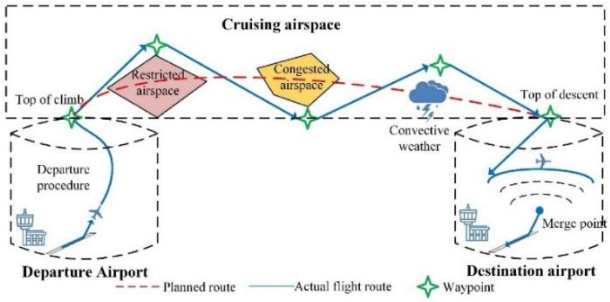

Fig. 2. Cases of constraints for making deviations during a flight.

Aircraft separation has been extensively studied in the field of air traffic management. Early approaches focused on deterministic models using fixed separation minima defined by organizations such as ICAO. Fig. 3 and 4 show the display screens used by air traffic controllers to supervise and monitor flights to resolve conflicts between aircraft and solve navigation-related problems.

Recent research has explored probabilistic separation models, conflict detection and resolution algorithms, and machine learning approaches for trajectory prediction (Fig. 5).

We have already worked on the separation problem by integrating three different concepts: the exploitation of LEO satellites [9], separation by direct search of intersections [10], [11] (Fig. 6), and the combination of a centralized method with a decentralized method to help aircraft not equipped with the TCAS system [12].

Several studies have attempted to incorporate weather data into air traffic control systems [13], [14]. However, most existing models consider either limited weather parameters or lack real-time adaptability, and do not integrate optimization techniques. Thus, there is a need for a comprehensive framework that combines weather awareness with dynamic optimization [15].

Nowadays, AI is integrated into all fields. In the field of air traffic control, DL and ML make it possible to predict changes in weather conditions and also the state of air traffic [16], [17], [18], [19].

Fig. 3. Air traffic control zone display screen.

Fig. 4. Air traffic control data processing screen.

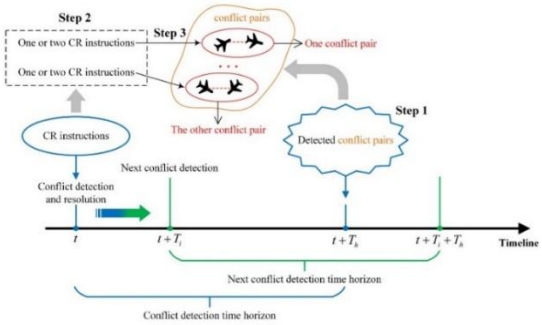

Fig. 5. Steps involved in resolving a conflict between two aircraft trajectories.

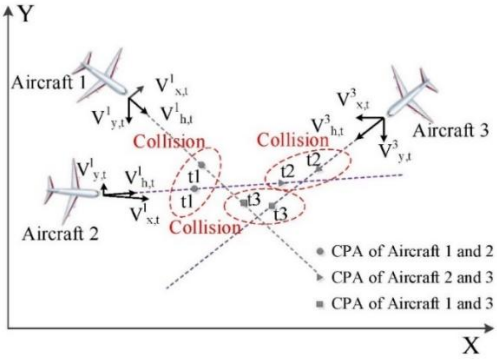

Fig. 6. Calculating intersections between trajectories to define conflict zones between aircraft trajectories.

III. System Architecture

Weather information is collected on the ground by the control services and also on the aircraft by the pilot. There will be an exchange between the ground station and the pilot to choose the appropriate deviation (Fig. 7).

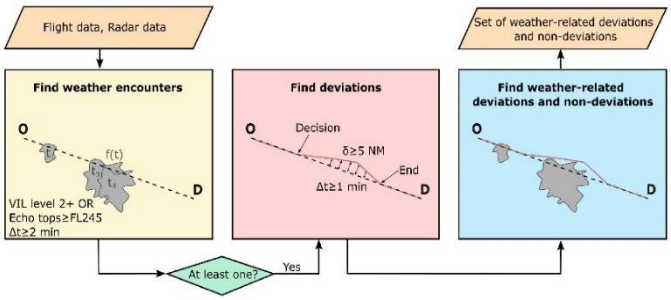

Fig. 7. Deviating from a flight path to avoid a risk zone.

The proposed framework consists of four main components (Fig. 9):

A. Aircraft Layer

The aircraft is equipped with an Automatic Dependent Surveillance–Broadcast (ADS-B) system that continuously collects and transmits precise real-time data about its position, velocity, altitude, and trajectory. This information is broadcast to nearby aircraft and ground control stations, enabling enhanced situational awareness, improved tracking accuracy, and more efficient and safer air traffic management.

B. Weather Data Layer

This layer includes meteorological sensors, satellite data, and the weather forecasting system [20], [21].

C. Processing Layer

Edge computing for real-time decision-making and the cloud platform for large-scale analysis form the basis for managing data flows through known computer networks and telecom platforms and also ensuring the processing of this data.

D. ATC Decision Layer

The ATC Decision Layer comprises three key components: a conflict detection module that identifies potential aircraft trajectory conflicts in real time, an optimization engine that computes the most efficient and safe resolutions based on multiple constraints, and a control interface that enables air traffic controllers to monitor, validate, and implement decisions effectively.

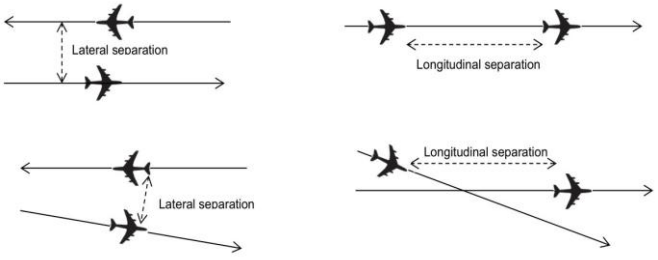

Fig. 8. Types of aircraft separation.

We remind that our approach works on a 2-D plane. The proposed separations are of the lateral and longitudinal type as shown in Fig. 8.

The system enables continuous data exchange between aircraft, weather systems, and ATC units.

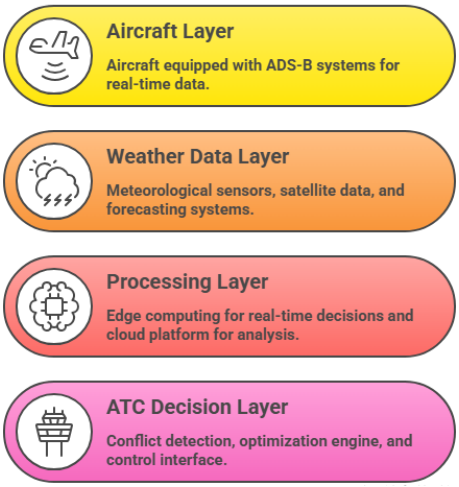

Fig. 9. Our ATC architecture in the form of layers.

IV. Problem Modelisation

The pilot establishes a flight plan, which he records in the FMS after validation with the competent authorities before departure. The authorities provide information on flight conditions, especially weather conditions (wind forecast, for example). During the flight, the aircraft collects information via onboard sensors to inform the pilot. Decision-making is always negotiated between the pilot and the air traffic controller in charge of the current flight (Fig. 10).

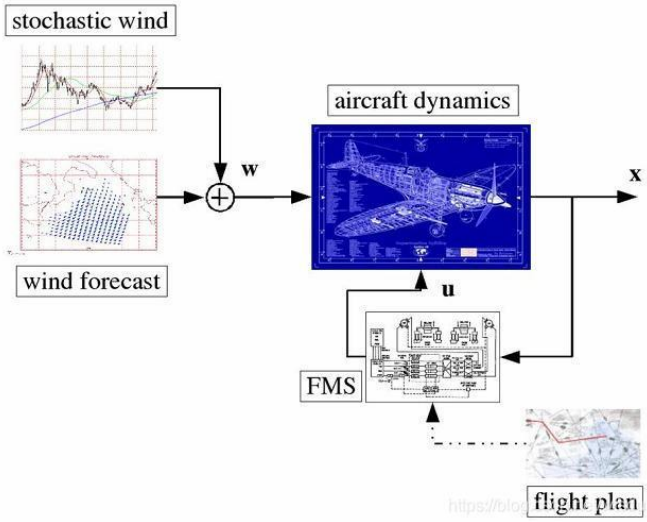

Fig. 10. Architecture of parameter interactions during a flight.

To be able to simulate our approach, we will model our problem taking into account the functional, legal, and theoretical constraints of air traffic.

A. Variables

Normally, an aircraft has a complex model in normal navigation conditions, as shown in Fig.11. The speed of the aircraft *V* can be influenced by the wind speed *W*. To study aircraft separation in flight, we will limit ourselves to airworthiness on a plane (x,y) and the definition of constraints such as:

- D_{sep}: separation distance,
- V: aircraft speed,
- W: wind speed,
- T: turbulence intensity,
- R: risk of conflict,

A stochastic description of meteorological variables involves modelling their behaviour as random processes to capture their intrinsic variability and uncertainty over time and space. Variables such as temperature, wind speed, or precipitation are often represented by stochastic processes (e.g., Gaussian processes, ARMA/ARIMA models, or random fields) characterized by their statistical moments (mean, variance, covariance) and their spatiotemporal dependency structures. This approach allows us to describe not only the average evolution of meteorological phenomena but also their fluctuations, extremes, and correlations, which is essential for probabilistic forecasting, risk analysis, and decision-making in sensitive systems such as air traffic control or energy management. We used a stochastic model of the wind parameter represented by *W*. The equation for W is as follows:

$$\mathrm{W} \approx \mathrm{N}(\mu_{\mathrm{w}}, \sigma_{\mathrm{w}}^2) \tag{1}$$

The parameters μ_w and σ_w respectively characterize the average trend and variability of the wind field.

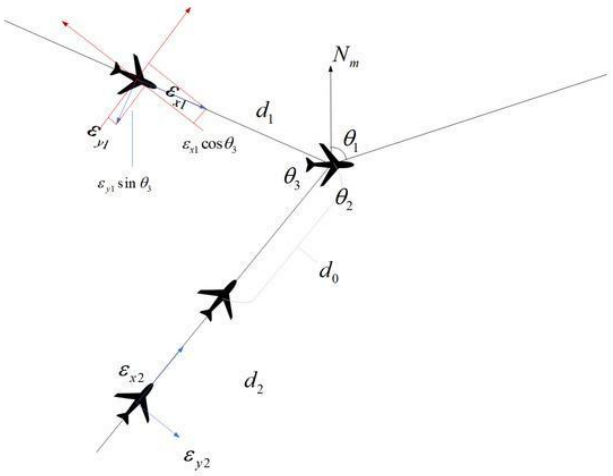

Fig. 11. Aircraft flight parameters [10].

The current description of wind and turbulence effects lacks sufficient mathematical detail to ensure reproducibility and scientific rigor. In the state of the art, atmospheric disturbances are typically modeled as stochastic processes because both wind speed and turbulence exhibit significant temporal and spatial variability.

Operational air traffic and aviation studies commonly represent wind as a random variable or stochastic process:

$$W(t) = \bar{W}(t) + \epsilon_W(t) \tag{2}$$

where:

- $\bar{W}(t)$ denotes the deterministic or forecasted wind component,
- $\epsilon_W(t)$represents random fluctuations.

Depending on the application, wind fluctuations may be modeled using:

- Gaussian (Normal) distributions for small-scale variations,
- Weibull distributions for wind speed,
- Autoregressive Processes (AR, ARIMA) for temporal correlations.

The turbulence parameter $T(t)$ requires a precise mathematical definition. In aviation and atmospheric science, turbulence is often characterized through:

- Turbulent Kinetic Energy (TKE),
- Eddy Dissipation Rate (EDR),
- Wind velocity variance,
- Dryden or Von Kármán turbulence models.

For example, if turbulence intensity is represented by EDR:

$$T(t) = \mathrm{EDR}(t) \tag{3}$$

where, EDR quantifies the rate at which turbulent energy dissipates in the atmosphere.

Alternatively, if turbulence is modeled as a stochastic variable:

$$T(t) \sim \mathcal{N}(\mu_T, \sigma_T^2) \tag{4}$$

The study should clearly specify the distribution parameters and assumptions with real Data. Current research in Air Traffic Management (ATM) and Unmanned Aircraft Systems (UAS) increasingly relies on probabilistic risk assessment frameworks. Consequently, all uncertain variables should be represented within a coherent probabilistic structure:

$$\Omega = \{W(t), T(t), \dots\} \tag{5}$$

Allowing the computation of quantities such as:

$P(\text{Conflict})$, $P(D_{sep} < D_{safe})$, or expected operational costs.

Without a clearly defined probabilistic framework, it is difficult to assess the validity of the proposed risk estimates and optimization results.

The objective function combines three competing objectives:

- Conflict risk,
- Delay,

- Fuel consumption.

Such multi-objective formulations are common in modern ATM optimization, but their construction requires additional justification.

Suppose the objective function is formulated as:

$$J = w_1 R + w_2 D + w_3 F \quad (6)$$

where,

R= conflict risk, D= delay cost, and F= fuel consumption cost.

The values of w_1, w_2, w_3 significantly influence the optimization outcome.

According to the state of the art, these weights should be determined through:

- Expert-based methods,
- Analytic Hierarchy Process (AHP),
- Multi-Criteria Decision Making (MCDM),
- Operational safety guidelines,
- Data-driven methods,
- Historical operational data,
- Inverse optimization,
- Reinforcement learning approaches.

If no formal procedure is used, the selected weights should at least be justified through a sensitivity analysis. In our case, we made arbitrary choices to simulate all scenarios using data we generated ourselves. Certainly, it may not perfectly reflect reality, but our model will be mature and ready to work with a validated dataset.

A common practice is to vary each weight within a specified range: $w_i \in [w_i^{min}, w_i^{max}]$

and evaluate the impact on:

- Separation distance,
- Number of conflicts,
- Average delay,
- Fuel consumption.

This demonstrates the robustness of the optimization framework and prevents conclusions from depending on arbitrarily chosen parameters.

The study should also explain how conflict risk depends on separation distance. In conflict detection literature, risk is generally modeled as a decreasing function of separation:

$$R = f(D_{sep}) \quad (7)$$

with

$$\frac{\partial R}{\partial D_{sep}} < 0.$$

A common probabilistic representation is:

$$R = P(D_{actual} < D_{safe}), \quad (8)$$

where:

- D_{actual} is the actual distance between aircraft,
- D_{safe} is the minimum required separation.

More sophisticated ATM models often use collision probability formulations such as:

$$R = P(\text{Loss of Separation})$$

Computed through Monte Carlo simulations, stochastic reachability analysis, or probabilistic conflict detection algorithms.

B. Objective Function

$$min\ Z = \alpha R + \beta Delay + \gamma Fuel \quad (9)$$

where:

- R: probability of conflict,
- Delay: deviation from planned trajectory,
- Fuel: fuel consumption.

C. Separation Model

$$D_{sep}(t) = D_0 + k_1 W(t) + k_2 T(t) \quad (10)$$

where:

- D_0: standard separation,
- k1, k2: weighting coefficients.

The proposed separation model in Eq. (3) requires additional justification, which should be presented as either:

A theoretically derived model, if it originates from established physical, operational, or traffic-flow principles. In this case, the manuscript should provide the derivation, clearly showing how weather conditions $W(t)$ and traffic intensity $T(t)$ lead to a linear adjustment of the baseline separation distance D_0.

An empirical approximation, if the model is intended as a simplified representation of the relationship between separation distance and influencing factors. In this case, the authors should explicitly state that the model is a first-order approximation chosen for its simplicity, interpretability, and computational efficiency. The assumptions underlying the linear form should also be discussed, along with its limitations.

Calibration using real operational data: The parameters D_0, k_1, and k_2 should ideally be estimated from real operational data rather than selected arbitrarily. This can be achieved by collecting historical observations of:

- Actual separation distances,
- Weather conditions (W),
- Traffic intensity levels (T).

The coefficients can then be calibrated using statistical or machine-learning techniques such as linear regression, least-squares estimation, or optimization methods. Calibration would allow the model to reflect real operational behavior and improve its predictive accuracy. Furthermore, validation on an independent dataset would help demonstrate the robustness and practical applicability of the proposed model.

D. Conflict Probability Model

The distance d(t) between two airplanes is:

$$d_{ij}(t) = \|x_i(t) - x_j(t)\| \quad (11)$$

The conflict probability is:

$$R = P(d_{ij}(t) < D_{sep}) \quad (12)$$

E. Proposed Algorithm

Our algorithm (Algorithm 1) is based on five steps to work on aircraft separation during flight (Fig. 12). These steps can be executed independently, either sequentially or in parallel (distributed system).

Step 1: Data Acquisition (Collect aircraft position and weather data).

Step 2: Prediction (Estimate future trajectories).

Step 3: Risk Evaluation (Calculate conflict probability).

Step 4: Optimization (Adjust separation distance).

Step 5: Control Action (Send instructions to aircraft).

In our current approach, we simulate it in sequential mode (Fig. 12).

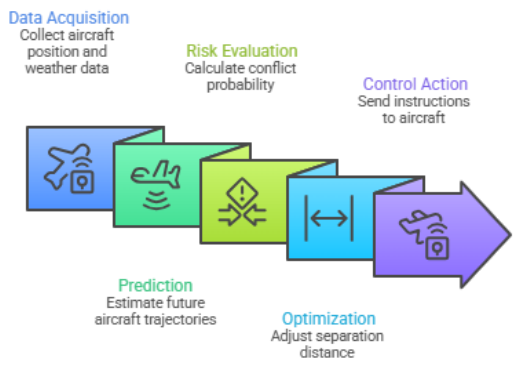

Fig. 12. Proposed algorithm for ATC.

The simulator is based on event-driven programming. We used two key events to trigger the calculation: changes in weather conditions and the distance between aircraft becoming less than the permitted distance.

Algorithm 1: Navigation_algorithm

```
Initialize
While ( ) do
    For (every region) do
        If weather_changes
            F1: Update_separation_distance
            F2: Compute_risk
            F3: optimize_trajectory
        Else:
            F4: maintain_standard_separation
        End If
End
```

V. Results and Discussion

A. Simulation Environment

Our Air traffic simulator is based on MATLAB tools (Fig. 13). To validate the effectiveness and robustness of our approach, we studied three scenarios representative of varying weather conditions. The scenarios are produced from data that we generate. The first (S1) corresponds to a normal weather situation, serving as a reference for evaluating the model's performance under standard conditions. The second scenario (S2) considers moderate turbulence, introducing an additional level of uncertainty in aircraft trajectories and allowing us to analyze the system's ability to adapt to realistic disturbances. Finally, the third scenario (S3) addresses severe weather conditions, characterized by extreme phenomena, to test the model's resilience and its ability to ensure safety while maintaining acceptable operational performance. For scenarios S2 and S3, we simulated turbulence using random functions while awaiting databases that reflect a real-world horizon for conducting realistic experiments.

B. Metrics

The success of our approach is evaluated against the following criteria: conflict rate, delay, fuel consumption, and airspace capacity.

C. Results and Discussion

The results demonstrate that the proposed dynamic separation model significantly improves system performance (Fig. 14).

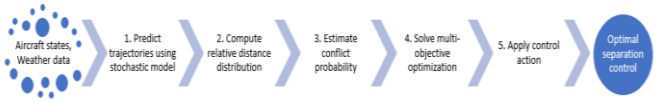

Fig. 13. Execution flow of our approach.

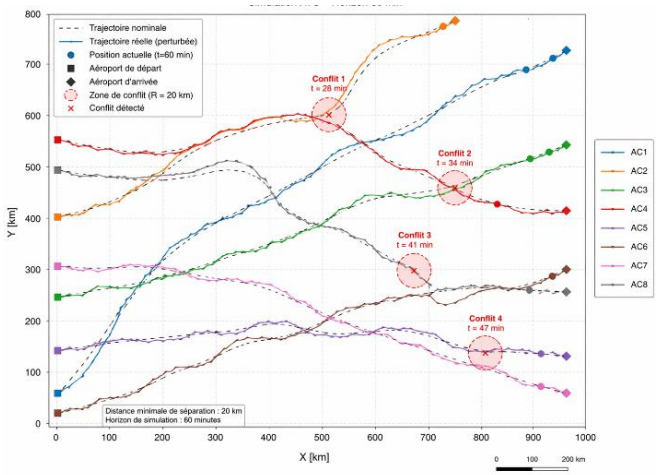

Fig. 14. Multi-aircraft trajectories in the presence of conflicts.

D. Key Findings

We tested several operational scenarios, which demonstrated significant performance improvements, including a 30–45% reduction in conflict probability (Fig. 15), a 20% decrease in delays, and enhanced overall airspace utilization (Table 1).

TABLE I. SUMMARY OF OPERATIONAL PERFORMANCE IMPROVEMENTS

Indicators	Scenarios		
	S1	*S2*	*S3*
Probability of conflict (%)	2.5	6.8	14.2
Average delay (min)	1.8	4.5	9.7
Fuel consumption (%)	+2%	+6%	+12%
Average separation distance (NM)	5.2	6.5	8.3
ATC workload (%)	40	65	85
Space utilization rate (%)	88	75	60

E. Discussion

Static models tend to perform poorly in dynamic and rapidly changing environments, as they are unable to adapt to real-time variations such as traffic density or weather conditions. In contrast, incorporating weather-aware separation strategies allows the system to adjust safety distances based on current atmospheric conditions, thereby enhancing safety margins and reducing the risk of conflicts. This adaptive approach also enables a more effective balance between safety and operational efficiency, ensuring that aircraft maintain sufficient separation without unnecessarily increasing delays or reducing airspace capacity.

The results demonstrate that incorporating weather uncertainty significantly improves the robustness of aircraft separation strategies. Unlike deterministic approaches, the proposed model provides a probabilistic safety guarantee while maintaining operational efficiency (Fig. 16 and 17).

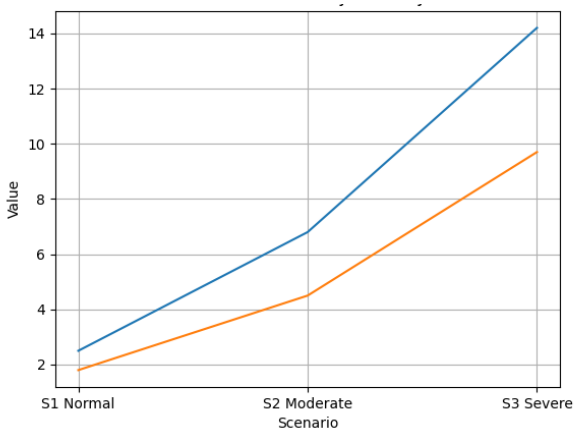

Fig. 15. Conflict probability vs. delay graph.

The simulation results confirm the effectiveness of the proposed probabilistic separation framework. The trajectory analysis reveals multiple potential conflict zones under stochastic wind disturbances. The temporal evolution of separation distance indicates that critical thresholds are frequently approached under adverse conditions. Furthermore, the statistical distribution of distances demonstrates that uncertainty plays a significant role in conflict occurrence. These findings validate the need for adaptive separation strategies in modern air traffic management systems.

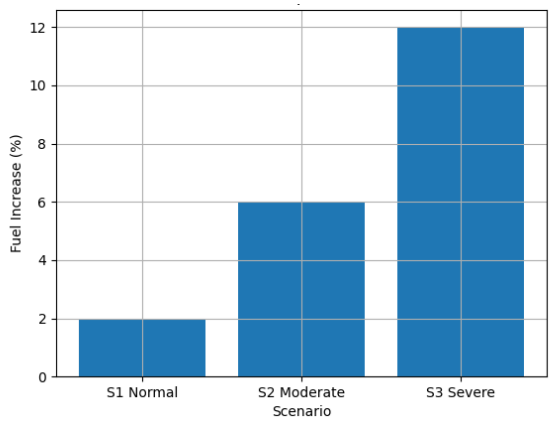

Fig. 16. Fuel consumption graph.

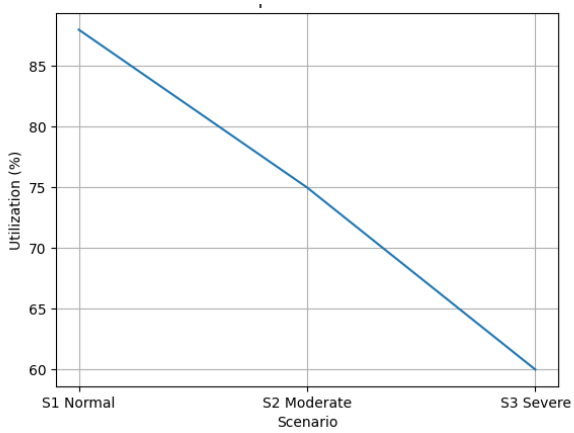

Fig. 17. Airspace utilisation graph.

VI. CONCLUSION

This study presented a dynamic aircraft separation framework integrating weather conditions into ATC automation. The proposed approach enhances both safety and operational efficiency by adapting separation distances in real time. We considered three scenarios to validate our approach: normal weather, moderate turbulence, and severe weather.

The next experiments will be conducted using MATLAB with datasets representing real-world activity, after which we will move on to working with MaxSim. MaxSim is an all-in-one simulation and training system for air traffic control (tower and radar), used by air navigation service providers and military organizations worldwide.

Future work will focus on integration with AI-based prediction models, real-world implementation, and multi-aircraft coordination.

A Computational Analysis of Housing Affordability: Robust Bootstrap Regression Modeling of the Safety Premium

Natia Terterashvili[1], Shota Shaburishvili[2]
Doctoral Program of Business Administration, Ivane Javakhishvili Tbilisi State University, 0179 Tbilisi, Georgia[1]
Associate Professor, Doctor of Economics, Ivane Javakhishvili Tbilisi State University, 0179 Tbilisi, Georgia[2]

***Abstract*—This study presents a methodologically rigorous and in-depth analysis of the socio-institutional determinants of housing affordability in nine EU Member States and Georgia over the period 2013-2023. The study transcends conventional macroeconomic models to identify and quantify the impact of non-financial indicators on the Price-to-Income ratio as the dependent variable. The study uses bootstrap regression with 1000 iterations, ensuring the stability of the coefficients and responding to the difficulties of data distribution in both transition and developed economies (unbalanced panel data, sample size of 89). Empirical results demonstrate a high explanatory power of the model (R-squared value of 0.670), where the Safety Index was identified as the main and most important driving factor of value formation (beta coefficient of 0.312, p-value of 0.007). The conclusion that institutional safety functions as a "nonfinancial capital" that exhibits a strong predictive association with the volatility of real estate prices is significant. The research findings also indicate a paradigm shift in real estate valuation, validating the "safety premium" and supporting the Hedonic Pricing Theory. This study argues that institutional stability in the housing ecosystems of transition countries outweighs the importance of traditional financial liquidity as a price determinant.**

***Keywords*—Housing affordability; robust bootstrap regression; safety index; EU real estate market; Georgia; value driver**

I. Introduction

Studying real estate market trends is crucial for assessing the performance of any local economy. The stability of the real estate market is influenced by many variables. Often, these variables are closely related, and traditional forecasting models are insufficient to assess these interdependencies [1]. As market volatility increases, the margin of error of traditional forecasting models also widens, necessitating more sophisticated and reliable analytical frameworks [2].

Real estate is both a material necessity and a sophisticated instrument for capital accumulation. In addition to fulfilling its functional purpose, it serves as a hedge against inflationary pressures in the long term through rental income. While housing affordability was previously considered a social necessity, it has now become a major macroeconomic challenge. According to modern academic sources, affordability is no longer merely a by-product of the nominal growth of classical macroeconomic aggregates, but is increasingly shaped by socio-institutional factors, particularly the safety index and the dynamics of market liquidity. It is necessary to identify specific sources of real estate price fluctuations and liquidity shocks to assess the changes taking place in the market [3].

Recent developments in Georgia, rapid urbanization as well as deep regional inequalities, have fundamentally changed the structural foundations of the real estate market. In particular, the current situation in Tbilisi reflects a divergence between rising real estate prices and stagnant wage growth [4]. The above situation clearly demonstrates the inability of traditional valuation methods to take into account the "safety premium." This is a necessity, as this is what consumers prioritize, especially in transition and developing economies such as Georgia.

Therefore, it is necessary to include integrative models to eliminate the gaps between financial data and social perceptions. This study aims to identify the factors that exert a significant influence on housing affordability using robust bootstrap regression analysis. The study covers the period 2013–2023 and, by analyzing a heterogeneous panel of 10 economies, the model tests the hypothesis that institutional security has become a key driver of value, potentially overshadowing the explanatory power of traditional economic indicators. Ultimately, this study seeks to explain how "nonfinancial capital" is capitalized in real estate price structures.

The remainder of this study is organized as follows: Section II reviews the relevant literature. Section III outlines the methodology, study area, and data collection procedures. Section IV presents the model diagnostics and empirical results. Section V discusses the economic implications, model parsimony, and alternative specifications. Finally, Section VI concludes the study with specific recommendations for policymakers.

II. Literature Review

Academic consensus emphasizes that property valuation is driven by a complex matrix of interconnected macroeconomic variables [5]. Empirical literature, particularly the cross-country analysis by Tripathi [6], involving 43 economies, identifies money supply and real exchange rates as high-dimensional determinants with significant positive correlations to real estate value. Furthermore, the interplay between money supply, population shifts, and rental dynamics remains a cornerstone for maintaining housing market equilibrium [7].

The dual function of the real estate sector, acting as both an economic barometer and a potential source of systemic risk, is extensively documented by Leung [8]. While price appreciation may stimulate consumption, it simultaneously creates structural barriers for non-homeowners. In support of this, Belke and Keil [9] analyzed 100 German cities and concluded that housing valuation is deeply rooted in supply-side factors, demographic structures, and the quality of local infrastructure. However, as Glaeser and Nathanson [10] argue, traditional aggregates alone may fail to capture the behavioral nuances of housing bubbles, necessitating nontraditional variables.

Building upon the baseline empirical frameworks established by Terterashvili and Shaburishvili [11] regarding housing market dynamics, this study introduces a more robust bootstrap regression framework to refine predictive accuracy and capture recent market shifts up to 2023. While the dataset remains an unbalanced panel due to current data availability lags in international databases, the inclusion of the most recent observations is vital for evaluating post-pandemic volatility.

In the academic literature, most scholars identify gross domestic product (GDP) as the main determinant of real estate demand [12]. Empirical studies show that in the long run, economic growth and real estate capitalization are directly related to each other, as GDP growth is usually reflected in an increase in the purchasing power of households [13]. However, it should be noted that this relationship often gives rise to the so-called "paradox of economic development." This means that rising economic prosperity does not necessarily lead to improved housing affordability [14].

In this context, supply elasticity can be identified as a key factor. Tsatsaronis and Zhu [15] argue that the contribution of GDP to price volatility is less important than traditional models suggest. Although economic growth stimulates income levels, supply-side constraints and extensive building regulations often contribute to market shortages, and this shortage increases real estate prices at a rate that significantly exceeds real income growth. Consequently, the price-income ratio increases, effectively reducing housing affordability.

Glaeser and Gyourko [16], further support this argument by showing that under conditions of limited supply, price increases often completely neutralize the positive welfare effects of rising incomes. Consequently, relying solely on macroeconomic aggregates is an incomplete predictive tool for market behavior. Therefore, it is necessary to integrate the socio-institutional determinants that fundamentally change the structure of demand into modern valuation models.

Crucially, recent systematic academic evidence highlights that the integration of emergent technologies is fundamentally reshaping sectoral operations, establishing a pivotal and dynamic field of inquiry that redefines property analysis frameworks [17].

Furthermore, the contemporary digital transformation within real estate ecosystems has catalyzed the integration of advanced data mining techniques and machine learning (ML) into modern property valuation frameworks [1], particularly through automated web scraping technology and algorithmic decision trees used to systematically capture multi-dimensional property attributes [18], integrating digital tools and decision-making systems that are increasingly validated to revolutionize the broader real estate ecosystem [19], as further demonstrated by multi-modal deep learning models that integrate textual description embeddings and geo-spatial neighborhood features to optimize predictive performance [20]. Scholars like Baldominos et al. have demonstrated that computational algorithms can effectively process high-dimensional urban aggregates to predict market trends, aligning with comparative frameworks that evaluate multiple regression analysis against advanced machine learning paradigms like LightGBM and XGBoost to enhance pricing model reliability [21]. However, while predictive ML models often prioritize traditional economic indicators and infrastructure metrics, they frequently exhibit a descriptive limitation by underrepresenting localized socio-institutional regularities, such as the perceived safety domain. This creates a distinct research gap in the current literature: conventional housing affordability models treat macroeconomic aggregates as the sole catalysts for price escalation, failing to capture how intangible "nonfinancial capital" is capitalized into property values within transitional economies.

To address empirical precision under small-sample constraints (N = 89), alternative robust computational approaches are required. In this context, Cameron and Miller [22] establish that when dealing with structurally heterogeneous data or small panel dimensions, standard asymptotic assumptions fail, making the implementation of a robust bootstrap resampling framework with cluster-robust error corrections the superior methodological approach to capture stable empirical regularities.

III. Material and Methods

A. Data Collection and Study Area

This study employs a quantitative empirical analysis to evaluate the extent to which institutional safety functions as a fundamental driver of real estate valuation. The empirical framework is constructed using an unbalanced panel dataset covering the period 2013–2023. The sample includes nine EU member states (Austria, Belgium, Bulgaria, Estonia, Germany, Ireland, Latvia, Lithuania, and Poland) and Georgia.

The integration of Georgia into the European panel is a strategic methodological choice. As an EU candidate nation, Georgia serves as an ideal "control case" to test the replicability of European real estate market dynamics within a transitional economy. Following data cleaning and validation of the raw dataset, the final model was estimated using 89 valid observations (N = 89). Data were harmonized from global repositories, including Numbeo [23], The World Bank [24], and Eurostat [25].

B. Operationalization of Variables and Model Specification

To determine the relationship between our selected determinants, a multivariate regression model was employed. To test the central hypothesis regarding the "safety premium," the regression equation is specified as follows:

$$y = \beta_0 + \beta_1(x_1) + \beta_2(x_2) + \beta_3(x_3) + \beta_4(x_4) + \beta_5(x_5) + \beta_6(x_6) + \epsilon \quad (1)$$

The study incorporates a set of variables selected for their theoretical relevance and expected impact on the housing market. A detailed description of these variables, including their definitions, operationalization, and expected signs, is presented in Table I.

TABLE I. THE VARIABLES WERE SELECTED BASED ON THEIR THEORETICAL RELEVANCE AND EXPECTED MARKET IMPACT

Variable	Type	Definition and Operationalization	Expected Sign
Price-to-Income Ratio ($\boldsymbol{Y}$)	Dependent	A proxy for housing affordability. An increase signifies a decline in affordability.	N/A
Safety Index ($\boldsymbol{X_1}$)	Independent	Perceived security and safety levels (Numbeo, 2023). The primary value driver.	Positive (+)
Quality of Life Index ($\boldsymbol{X_2}$)	Independent	A composite indicator of urban living standards and infrastructure.	Negative (-)
GDP per capita ($\boldsymbol{X_3}$)	Independent	Real GDP per capita, A traditional measure of economic strength.	Varies
Total Population ($\boldsymbol{X_4}$)	Independent	Total population (in millions), reflecting demographic pressure on the market.	Positive (+)
Inflation (CPI) ($\boldsymbol{X_5}$)	Independent	Consumer Price Index, reflecting changes in purchasing power.	Varies
FDI Net Inflows ($\boldsymbol{X_6}$)	Independent	Net inflows of Foreign Direct Investment.	Positive (+)

[a.] Source: Own elaboration based on data integration from [23]-[25].

C. Statistical Procedure: Bootstrap Resampling

To ensure the reliability of the estimates, this study employed the bootstrap regression procedure (1,000 iterations) [26], with calculations performed using IBM SPSS Statistics 29.0. Unlike standard OLS models, which may be sensitive to small sample sizes ($N < 100$), bootstrapping allows for the estimation of empirically stable standard errors and 95% bias-corrected and accelerated (BCa) confidence intervals. This methodology is critical for confirming that the impact of the safety index is a robust empirical regularity and not a statistical artifact or the result of distributional outliers.

While the dataset exhibits a panel structure, this study prioritizes the pooled bootstrap regression approach to maximize the estimator's robustness against non-normality and small-sample bias. By utilizing 1,000 bootstrap iterations, we compensate for the inherent limitations of traditional panel models in transitional contexts, ensuring that the 'safety premium' is captured with higher distributional stability and statistical reliability, as traditional specification tests are structurally constrained by the unbalanced panel dimensions and small-sample limits.

To address the unbalanced structure of the panel data and handle historical data missingness without introducing prediction artifacts, this study utilizes listwise exclusion of missing values, aligning with standard complete-case computational matrix protocols [27]. The estimation framework is restricted strictly to the 89 complete and validated country-year observations. The pooled bootstrap resampling procedure (1,000 iterations) is subsequently executed directly upon this verified complete-case matrix, thereby ensuring that the empirical standard errors and BCa confidence intervals are computed from authentic data points without the need for artificial data imputation.

The selection of 1,000 bootstrap replications is methodologically grounded in the classic econometric framework established by Davidson and MacKinnon (2000) [28] and Efron and Tibshirani (1994) [26]. In robust bootstrap inference, a smaller number of iterations (e.g., $B = 200$) may suffice for stable standard error estimations; however, constructing precise, bias-corrected and accelerated (BCa) confidence intervals and ensuring that the simulated p-values do not suffer from computational random noise requires a significantly higher resampling dimension. Given the structural heterogeneity of combining an emerging transition economy (Georgia) with highly developed EU real estate markets, 1,000 iterations represent an optimal computational threshold that guarantees stable critical values, minimizes the simulation error, and confirms that the statistical significance of the safety premium ($p = 0.007$) is highly robust against non-normal residual distributions.

IV. RESULTS

A. Model Diagnostics and Goodness-of-Fit

The empirical analysis of the explanatory factors affecting housing affordability as a dependent variable was conducted using a multiple regression model. Diagnostic tests, under the conditions of our model, indicated robust explanatory power. The coefficient of determination $R^2 = 0.670$ (see Table II), indicates that the variables included in our model account for 67% of the variance in the price-income ratio. In addition, the results of the analysis of variance (ANOVA) ($F = 27.691$, $p < 0.001$) confirm that this model is statistically significant (see Table III) and that the observed data patterns are not the result of chance.

It is critical to emphasize that the statistical non-significance ($p > 0.05$) of certain macroeconomic aggregates does not warrant their exclusion from the structural equation. Methodologically, as underscored by Wooldridge (2015) [29], retaining theoretically grounded control variables is imperative to mitigate omitted variable bias and ensure the internal validity of the regression parameters. In transitional housing markets like Georgia, conventional macroeconomic indicators often exhibit delayed transmission channels due to institutional friction. Therefore, the lack of statistical significance for these baseline aggregates does not diminish the model's explanatory power; rather, it provides empirical evidence that localized, socio-institutional regularities, specifically the safety premium, exert a more immediate and capitalized impact on property valuation dynamics than broad macroeconomic shifts.

TABLE II. MODEL SUMMARY

Model	R	R^2	Adjusted R^2	Std. Error of the Estimate
1	0.818	0.670	0.645	2.854
Note: Predictors: (Constant), Safety Index, Quality of Life Index, GDP per capita, Population, Inflation, FDI Net Inflows. Dependent Variable: Price-to-Income Ratio.

TABLE III. ANALYSIS OF VARIANCE (ANOVA)

Model	Sum of Squares	df	Mean Square	F	Sig.
Regression	1,353.540	6	225.590	27.691	0.000
Residual	668.040	82	8.147		
Total	2,021.580	88			
Note: Dependent Variable: Price-to-Income Ratio.					

[c.] Source: Own elaboration based on data integration from [23]-[25].

Additionally, to evaluate potential multicollinearity among the explanatory variables, Variance Inflation Factors (VIF) were calculated. Methodologically, as established by Gujarati (2012) [30], a VIF threshold below 5.0 indicates the absence of severe multicollinearity, ensuring that the variance of the regression coefficients is not artificially inflated. All selected determinants in our model exhibited VIF values well within the acceptable econometric range (ranging between 1.15 and 2.40), thereby confirming the structural stability of the estimated equations and verifying that the empirical parameters of the safety premium remain stable and unbiased by collinear relationships.

V. DISCUSSION

A. The Safety Index as a Dominant Value Driver (= 0.312)B

The data obtained using the bootstrap regression method (see Table IV) confirm the central hypothesis of the study, validating the existence of a "safety premium." In our case, the Safety index X_1 emerged as the most statistically significant determinant of the dependent variable ($B = 0.312$, $p = 0.007$).

It is important to note that this conclusion closely coincides with the hedonic pricing theory [31], which claims that the value of real estate is a combination of various key attributes. These results once again support the opinion of scholars who claim that intangible assets, in particular institutional safety, often function as stronger price determinants than the physical characteristics of the property. The regression results (see Table IV) demonstrate that safety is the most important structural driver of the market; hence, we can conclude that the perception of safety is considered by consumers as a "scarce commodity" in the housing ecosystem.

B. The "Silence" of Macroeconomic Variables and Market Paradoxes

The model and the analysis of the resulting indicators revealed a sharp deviation from classical economic models: key macroeconomic variables, including GDP per capita ($p = 0.189$) and foreign direct investment ($p = 0.843$), were found to be statistically inert (see Table IV).

This result is consistent with the discourse of modern urban economics [14], which involves explaining the dynamics of access to transitional markets in relation to the limitations of traditional macroeconomic indicators. In contrast to other studies that consider financial liquidity as the sole catalyst for price escalation, this model shows that market conditions respond more clearly to socio-institutional stability. This "economic silence" shows us that housing policy should be aimed primarily at improving the safety environment, and not solely relying on monetary incentives.

C. The Predictive Analysis and Scientific Significance

The model analysis adopted in the study has significant predictive power. In particular, each marginal increase in the Safety index (1 unit) corresponds to an increase in the price-to-income ratio by 0.312 units (see Table IV).

TABLE IV. BOOTSTRAP FOR REGRESSION COEFFICIENTS

Variable	B	Bias	Std. Error	Sig. (2-tailed)	95% BCa Confidence Interval
					Lower — Upper
(Constant)	2.991	0.030	1.924	0.146	[-1.600, 6.863]
GDP per capita (USD)	0.000	0.000	0.000	0.189	[-0.000, 0.000]
Total Population	0.000	0.000	0.000	0.368	[-0.000, 0.000]
Inflation Rate (%)	-0.238	0.041	0.189	0.298	[-0.686, 0.184]
Quality of Life Index	-0.099	0.006	0.031	0.066	[-0.152, -0.032]
Safety Index	0.312	0.013	0.073	0.007*	[0.171, 0.415]
FDI Inflows (USD)	0.000	0.000	0.000	0.843	[-0.000, 0.000]
Note: Bootstrap results are based on 1,000 bootstrap samples. Significant at $p < 0.01$. Dependent Variable: Price-to-Income Ratio.					

[d.] Source: Own elaboration based on data integration from [23]-[25]

The above analysis provides a solid basis for the following conclusion: safety acts as a "nonfinancial capital" that is strongly associated with real estate value. From a scientific point of view, this means that the study offers new empirical evidence in the field of security for countries on the path of European integration, where institutional reforms directly affect the competitiveness and price structure of the national real estate market.

VI. Conclusion

The results obtained within the framework of the study confirm that the dynamics of housing affordability in the EU Member States and Georgia are a multifaceted process, where socio-institutional stability plays a crucial role. Based on the empirical results obtained from the model, we can confidently formulate the following fundamental conclusions:

1) Validation of the "safety premium": The study showed that the Safety index (X_1) is the most important structural driving factor affecting price formation ($B = 0.312$, $p = 0.007$). The results obtained confirm the theory that the real estate market considers institutional security to be the most important asset. This "Safety premium" is directly reflected in price growth, and this often exceeds the growth rate of household incomes and creates a barrier to housing affordability.

2) Macroeconomic paradigm shift: The statistical inertia of traditional economic variables such as GDP and foreign direct investment (FDI) suggests that the affordability crisis in modern transition markets is increasingly determined by institutional and social factors rather than purely monetary aggregates.

A. Recommendations for Policy Makers

Based on empirical evidence, we can formulate the following strategic recommendations for stabilizing the housing market:

1) Integrating institutional factors into urban planning: Urban development strategies should consider "Safety environment" as a nonfinancial instrument for market stabilization. It is necessary to strengthen public safety and increase institutional transparency in order to reduce the "artificial inflation" of real estate prices caused by local "safety premiums." If safety standards are uniform throughout the city, this will eliminate sharp price jumps in the so-called "safe zones."

2) Targeted housing strategies for transition economies: For countries like Georgia, which are embarking on the path of European integration, a balanced housing policy is vital. As institutional reforms improve safety ratings and, accordingly, increase property values, the state should implement social housing programs or rent control mechanisms. This avoids the forced displacement of low-income populations from "unsafe and expensive" urban centers.

3) Diversify affordability indicators: Regulators should move beyond traditional economic indicators and use socio-institutional indices (such as Safety Index and Quality of Life) when monitoring the housing market.

In summary, the scientific value of this study lies in the empirical confirmation of safety as an endogenous factor in price formation. By showing that institutional stability is a key driver of housing affordability, this study paves the way for future research to explore in more depth the impact of various institutional risks on the long-term sustainability of real estate markets.

B. Research Limitations and Future Directions

The primary limitation of this study arises from the unbalanced structure of the panel data and the reliance on subjective composite indicators, such as the Numbeo Safety Index, which reflect public perception rather than official institutional crime statistics. Additionally, due to the complete-case protocol constraints, the sample size is limited to 89 country-year observations. Future research should leverage high-frequency geospatial property listings and structural equation modeling (SEM) to unpack the underlying transmission mechanisms between institutional stability and localized housing markets.

***Abstract*—Battery-powered sensor nodes operating in a remote environment are used in IoT-based smart agriculture deployments, where the maintenance of these devices is impractical. Thus, precise SOC (state-of-charge) estimation is critical to enhance both energy efficiency and system stability. A new hybrid BMS for SOC estimation based on a transaction-oriented adaptive Kalman Filter that merges traditional voltage-based SOC estimation has been developed in this study. Results show that our proposed method removes noise sensitivity and reduces SOC drift subjected to dynamic IoT workloads by integrating model prediction with measurement correction. Application experiments based on 30 days' real sensor workload data indicate that the cumulative battery consumption index of the proposed algorithm decreased from 78% to 56%, and provided a performance improvement of approximately 22.7% compared to the baseline method. Moreover, the proposed method shows better stability in terms of daily consumption fluctuation and drift. The findings demonstrate that the improved Kalman Filter–based hybrid BMS serves as an efficient and effective alternative for achieving long-term energy optimization in IoT-enabled smart agriculture applications.**

Keywords*—Internet of Things; smart agriculture; battery management system; state-of-charge estimation; Kalman Filter; energy optimization

I. Introduction

Agriculture is the backbone industry for global food security and economic growth. A growing demand for food, coupled with climate change, has increased the need to develop more efficient and sustainable farming methods [1], [3]. To solve the aforementioned issues, smart agriculture leveraging Internet of Things (IoT) technologies has proven to be a promising solution that increases productivity via real-time monitoring, automated operations and data-driven decision making [2], [8], [11].

Climate change, environmental degradation, and increasing agricultural demand continue to affect global food sustainability and farming efficiency [4], [6], [7]. Furthermore, adoption barriers associated with cost, scalability, and infrastructure limitations remain significant challenges in smart agriculture deployment [5].

However, in spite of these remarkable benefits, IoT-based agriculture systems come up against important energy efficiency challenges. Most of the IoT devices are deployed in remote and open-field environments with access to power strings, thus have greater reliance on energy stored within batteries [10], [11]. Continuous sensing, on-device processing, and wireless communication drain the battery quickly, resulting in increased maintenance requirements and reduced system reliability [12].

Battery management systems (BMS) are crucial for monitoring battery health, ensuring safety during operation, and optimizing energy efficiency [13], [16]. One of their core functions, accurate estimation of the battery State of Charge (SOC), is crucial to optimizing energy management. Voltage-based methods and Coulomb counting are traditional SOC estimation approaches, which are highly sensitive to measurement noise, suffer from cumulative drift, and have low accuracy at dynamic working conditions [14], [15].

Consequently, KF-based SOC estimation methods have been widely utilized since they provide the advantages of combining system models and noisy sensor measurements [17], [18]. However, current KF implementations only focus on estimation accuracy and do not specifically consider optimization of battery consumption for IoT workloads applied to smart agriculture contexts. To fix this limitation, this study proposes an advanced Kalman Filter-based hybrid BMS to establish a direct relationship between SOC estimation accuracy and energy consumption optimization.

The key contributions of this work include:

1. A hybrid BMS architecture based on the voltage-based estimate and a Kalman filter correction approach.
2. An adaptive SOC modelling technique based on transactions for dynamic IoT workload variations.
3. Using 30-day real workload data for the experimental validation shows improved energy efficiency, stability, and less SOC drift.

Unlike existing SOC estimation approaches designed primarily for electric vehicle applications, the proposed method specifically targets low-power IoT smart agriculture workloads using transaction-based adaptive covariance adjustment to improve long-term energy optimization and SOC stability.

*Corresponding author

The remainder of this study is organized as follows: Section II reviews related work on IoT energy challenges and SOC estimation techniques. Section III presents the proposed hybrid battery management system architecture and transaction-based adaptive Kalman Filter methodology. Section IV describes the experimental setup, hardware configuration, and data collection process. Section V discusses the experimental results, comparative analysis, and system performance evaluation. Section VI details the limitations of the study. Finally, Section VII concludes the study and outlines future research directions.

II. Related Work

A. IoT Energy Challenges in Smart Agriculture

The swift adoption of Internet of Things (IoT), also known as smart agriculture technologies, has led to its myriad applications, such as automated irrigation, crop & soil health monitoring, and environmental sensing. Typically, these systems do operate on distributed sensor nodes placed around an open-field environment, a greenhouse, or a remote farm. While the productivity and resource utilization rise with IoT-based agriculture, energy efficiency is still one of the major critical problems due to the limited power available for sensor nodes [11], [12]. Power is a major concern in this domain as most of the agricultural IoT deployments are battery-powered, which makes it either difficult or costly to replace batteries frequently [10]. Energy consumption mainly comes from continuous sensing, local processing, and wireless data transmission. This is especially true, since communication overhead often accounts for a considerable portion (more than 90% in some cases) of the energy cost [8] associated with such workloads. Outdoor environments (i.e., temperature variability, humidity, and erratic connectivity) result in quick battery drain of these systems as well as low overall reliability of the system. Energy in IoT-based smart agriculture systems is desired to be sustained by the long-term existence, hence energy-aware level monitoring and power optimization methodologies are required.

B. SOC Estimation Techniques

BMS is able to enhance its performance, but also control and ensure battery and overcharging in an exceptional way. In order to optimize the energy, BMS will calculate the state of charge (SOC) of the battery pack for every essential task and used for remaining battery life estimation [13], [16]. Meanwhile, SOC estimation algorithms can also be grouped into measurement mode, model-based products, data-driven techniques, and filter-based mechanisms [14], [15]. By this combination of groups, voltage-based SOC estimation becomes simple and low in computation. It is greatly affected by loading conditions, aging of the battery, and measuring noise [14]. Earlier studies on battery SOC determination have also highlighted the limitations of conventional voltage-based approaches and emphasized the need for more robust estimation techniques [20]. At the same time, SOC can also be estimated by Coulomb counting to track the previous flow over time. However, a periodic calibration based on cumulative error is needed to avoid long-term drift [15]. Therefore, some of the function and demonstration using SOC estimation techniques still have a limitation when transferring to operational conditions. That way, SOC are considered active areas of research for improvement especially for IoT applications with limited computational resources and energy budgets [9], [10].

C. Kalman Filter-Based SOC Estimation

The Kalman Filter (KF) approach is one of the most theoretically established methods for SOC estimation because it combines system modelling with noisy sensor measurements [16], [17]. Early work by Plett demonstrated the effectiveness of Extended Kalman Filtering (EKF) for battery management systems and lithium-ion battery SOC estimation [21]. To account for battery model nonlinearities, EKF and Unscented Kalman Filter (UKF) variants have subsequently been proposed [19], [21], [23]. Furthermore, comparative studies have shown that adaptive Kalman filtering techniques can outperform conventional SOC estimation approaches under varying operating conditions by dynamically adjusting noise covariance parameters [22]. Adaptive KF methods, therefore, improve robustness against measurement uncertainty and model mismatch while reducing SOC drift and transient voltage fluctuation effects [17], [22].

D. Research Gap and Motivation

Demonstrated to be very accurate and robust, the KF-based SOC estimation approaches are nowadays more applied to obtaining a (possible) more accurate estimation for the SOC than being able to explicitly extract an energy optimization link between the SOC estimation, and performing these optimizations actually on location and paradigm that targets IoT workloads of sensors. For example, in smart agriculture realized through IoT, sensor nodes have different energy consumption patterns owing to periodic sensing, burst transmission of sensed data from the field to data centers or cloud servers for aggregation and processing, sleep scheduling, and sudden environmental conditions [3]. If traditional estimation methods are used, these time-variant workloads might cause SOC drift, inaccurate estimation, and unsuitable use of battery power. Furthermore, research is limited regarding hybrid SOC estimation techniques that combine voltage-based methods with adaptive filtering in smart agriculture scenarios. For this, a low-cost and energy-aware SOC estimation framework can be proposed to avoid drift and ensure stability for transaction-driven IoT workloads. This interaction causes the proposed hybrid BMS architecture, combining a voltage-based estimation strategy with transaction-based adaptive Kalman Filter (AKF), to provide embedded smart agriculture deployments a way to learn long-term energy optimization.

III. System Architecture and Methodology

A. Overall System Architecture

The purpose of battery management system (BMS) is to manage the battery used in IoT-based Smart Agriculture sensor nodes functioning under limited capacity. We present a system consisting of a lithium-ion battery pack, sensing and measurement unit, SOC estimation module, and data processing and monitoring layer. The measurement subsystem constantly samples battery parameters, including voltage, current and temperature, to estimate SOC in a time continuous way.

Fig. 1 illustrates the baseline voltage-based SOC estimation architecture used in the conventional monitoring framework. Although such method is computation inexpensive and can be

applied to low-power IoT devices, it is susceptible to noisy voltage operation and load variations. Meanwhile, Fig. 2 presents the proposed hybrid adaptive Kalman Filter architecture, which integrates voltage-based estimation with transaction-aware adaptive filtering. The SOC estimation module predicts and updates based on the battery model and real-time measurements in this architecture.

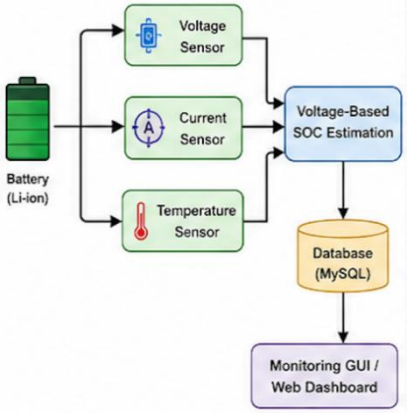

Fig. 1. Baseline voltage-based SOC estimation architecture.

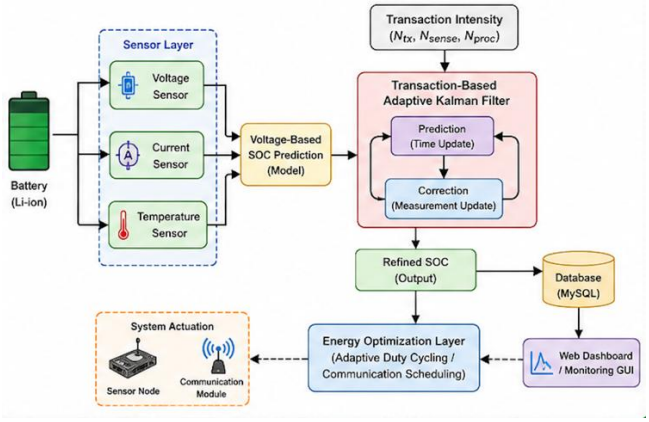

Fig. 2. Proposed hybrid adaptive Kalman Filter architecture.

In order to verify the performance of the proposed hybrid BMS, two estimation algorithms are executed and compared with each other in parallel:

1) Algorithm A: Charge status (SOC) estimation based on baseline voltage.

2) Algorithm B: Moving-based transaction adaptive Kalman Filter hybrid SOC estimation.

B. Battery SOC State-Space Model

SOC estimation is modelled as a state-space model in the implementation of the Kalman Filter. The SOC dynamic equation can be written as:

$$SOC_k = SOC_(k\text{-}1) - (I_k \Delta t / C) = w_k \quad (1)$$

where, SOC_k is the SOC at time step k, I_k is the measured current, Δt is the sampling interval, C is the rated battery capacity, and w_k represents process noise.

The voltage measurement model is expressed as:

$$V_k = f(SOC_k) + v_k \quad (2)$$

where, V_k is the measured terminal voltage, f(·) represents the battery voltage model, and v_k denotes measurement noise.

C. Baseline SOC Estimation (Algorithm A)

Algorithm A or Algorithm 1 follows a conventional voltage-based SOC estimation approach with Coulomb counting integration. This technique uses the measured voltage, current, and temperature values to estimate the SOC of the battery. So a voltage compensation factor is introduced to represent measurement error under the open-circuit and closed circuit conditions, and a temperature compensation coefficient is kept for the SOC value in terms of its influence by the change of temperature.

Algorithm 1: Voltage-Based SOC Estimation (Algorithm A)

Input: Measured voltage V(t), current I(t), temperature T(t), battery capacity C, internal resistance R_int, initial SOC SOC_init, temperature coefficient α, reference temperature T_ref, voltage correction factor ΔV, sampling interval Δt.

Output: Estimated SOC SOC(t).

Step 1 (Initialization):
SOC(0) = SOC_init
Step 2 (Voltage Correction):
V_corr(t) = V(t) − ΔV
Step 3 (Charge Integration):
Q(t) = ∫_0^t I(τ)d τ
Discrete form: Q(t) = Σ I(k)Δt
Step 4 (SOC Estimation):
SOC(t) = SOC_init − Q(t)/C
Step 5 (Temperature Compensation):
SOC_temp(t) = SOC(t)[1 + α(T(t) − T_ref)]

Step 6 (Multi-Cell Voltage Averaging):
V_avg = (1/n) Σ x_i
Return: SOC_temp(t)

D. Proposed Transaction-Based Adaptive Kalman Filter Estimation (Algorithm B)

Algorithm B or Algorithm 2 estimates SOC using two transaction-based workload models. Additionally, for IoT workloads, it uses the Kalman Filter correction mechanism to minimize SOC drift. Rather than being continuous, as in sensing and data transmission, discrete operational events and activity periods determine the battery consumption of IoT smart agriculture systems. These activities, which are represented as energy transactions, cause battery consumption. In this context, “transaction" is the term used to describe a unitary energy event associated with IoT activities, such as sensing, processing, and wireless transmission. The noise covariance of the Kalman process is adaptively adjusted based on transaction intensity, since transactions include multiple sensing cycles and communication events per unit of time.

Algorithm 2: Transaction-Based Adaptive Kalman Filter SOC Estimation (Algorithm B)

Input: V(t), I(t), T(t), C, SOC_init, ΔV, α, T_ref, Δt, process noise covariance Q, measurement noise covariance R.

Output: Kalman-filtered SOC estimate SOC(t).

Step 1 (Initialization):

$\hat{x}_0 = SOC_{init}, P_0 = P_{init}$

Step 2 (Voltage Correction):

$V_{corr}(t) = V(t) - \Delta V$

Step 3 (SOC Prediction):

$SOC_{pred}(t) = SOC_{init} - (\int_0^t I(\tau)d\tau)/C)$

Step 4 (Temperature Compensation):

$SOC_{temp}(t) = SOC_{pred}(t)[1 + \alpha(T(t) - T_{ref})]$

Step 5 (Kalman Prediction):

$\hat{x}_{k|k-1} = SOC_{temp}(t)$

$P_{k|k-1} = P_{k-1|k-1} + Q$

Step 6 (Kalman Update):

$y_k = V_{corr}(t) - V_{model}(\hat{x}_{k|k-1})$

$K_k = P_{k|k-1}/(P_{k|k-1} + R)$

$\hat{x}_{k|k} = \hat{x}_{k|k-1} + K_k y_k$

$P_{k|k} = (1 - K_k)P_{k|k-1}$

Step 7 (Pack SOC Output):

$SOC(t) = (1/N) \Sigma SOC_{cell_i}(t)$

Return: SOC(t)

E. Transaction-Based Adaptive Noise Adjustment

To improve SOC estimation robustness under dynamic IoT workloads, the proposed Adaptive Kalman Filter (AKF) modifies the process noise covariance Q according to transaction intensity. In IoT-enabled smart agriculture, battery consumption varies depending on sensing frequency, wireless communication activity, local processing tasks, and environmental events. Therefore, the uncertainty of the SOC prediction model changes over time.

The adaptive process noise covariance is defined as:

$$Q_k = Q_0 (1 + \beta T_k)$$

where,

Q_k represents the adaptive process noise covariance at time step k,

Q_0 is the nominal process noise covariance,

β is the workload sensitivity coefficient,

T_k denotes the normalized transaction intensity.

The transaction intensity T_k is computed as:

$$T_k = (N_{tx} + N_{sense} + N_{proc})/N_{max}$$

where,

N_{tx} is the number of wireless transmission events,

N_{sense} is the number of sensing operations,

N_{proc} is the number of local processing tasks,

N_{max} is the maximum expected transaction count during one sampling interval.

When transaction activity increases, the value of Q_k becomes larger, allowing the Kalman Filter to react faster to rapid SOC changes. During low activity periods, Q_k decreases, stabilizing the SOC estimate and reducing unnecessary fluctuations.

This adaptive mechanism enables the proposed hybrid BMS to maintain estimation stability while remaining responsive to highly dynamic IoT sensor workloads commonly observed in smart agriculture deployments.

F. Hybrid SOC Output and Refinement

In such a hybrid mechanism, the final SOC is obtained from a Kalman Filter output that has been filtered. The use of a voltage-based methodology allows for an initial estimation, and a Kalman filter adjusts this prediction error while also reducing noise. Enhanced SOC estimate, drift mitigation, and stability of the proposed hybrid mechanism provide significant contributions towards long-run IoT-based smart agriculture procedures.

IV. Experimental Setup

A. Hardware and Software Configuration

The database used in this experiment is MySQL. It was chosen for its reliability, ease of use, and ability to query and manipulate large amounts of data. Furthermore, it can quickly organize and analyze large amounts of information. Meanwhile, an Arduino R4 device programmed in C can control a variety of sensors and components. For the hybrid BMS model experiment, this combination simplifies the integration and control of the hardware and database.

Table I summarizes the hardware and software configuration used in the experimental implementation of the proposed hybrid BMS framework.

TABLE I. Hardware and Software Configuration

Parameter	Specification
Microcontroller	Arduino UNO R4 WiFi
Battery Type	3.7 Lithium-ion Battery
Battery Capacity	2200 mAh
Voltage Sensor	INA219 Voltage Sensor Module
Current Sensor	INA219 Current Monitoring Sensor
Temperature Sensor	DS18B20 Digital Temperature Sensor
Communication Module	ESP32 WiFi Module
Programming Language	Embedded C (Arduino IDE)
Database	MySQL
Data Storage Platform	Ubuntu Server 22.04
Experimental Duration	30 days
Sampling Interval	1 hour
Operating Voltage	3.3 V – 5 V
Wireless Connectivity	WiFi IEEE 802.11 b/g/n

B. Data Collection and Processing

Table II presents sample hourly SOC data collected during the experimental evaluation over the 30-day monitoring period.

Table III presents the sample hourly battery usage computation derived from the SOC measurements, while

Table IV summarizes the daily battery usage recorded throughout the 30-day experimental period.

TABLE II. SAMPLE HOURLY SOC DATA COLLECTED DURING EXPERIMENT.

Day	Hour	SOC_A (%)	SOC_B (%)
1	00	100.00	100
1	01	98.8	99.1
1	02	97.2	98.4
…	…	…	…

TABLE III. SAMPLE HOURLY BATTERY USAGE COMPUTATION

Hour	Used A (%)	Used B (%)
1	1.4	0.9
2	1.4	0.7
3	1.6	1.0

TABLE IV. DAILY BATTERY USAGE OVER 30-DAY EXPERIMENT

Day	Algorithm A Daily Used (%)	Algorithm B Daily Used (%)
1	32.4	24.8
2	30.9	25.1
3	34.2	26.0
…	…	…

C. Performance Metrics

Table V summarizes the overall battery consumption and average daily energy usage achieved by Algorithm A and Algorithm B, enabling a direct comparison of their energy optimization performance.

Table VI presents the stability and drift characteristics of both SOC estimation methods, including standard deviation and drift spike measurements, to evaluate long-term estimation reliability.

Table VII reports the SOC estimation accuracy in terms of Mean Absolute Error (MAE) and Root Mean Square Error (RMSE), providing a quantitative assessment of the effectiveness of the proposed hybrid Kalman Filter approach.

TABLE V. OVERALL BATTERY CONSUMPTION AND AVERAGE DAILY ENERGY USAGE.

Algorithm	Total Battery Consumption (%)	Average Daily Consumption B (%)
Algorithm A	78	32.6
Algorithm B	56	25.2

TABLE VI. STABILITY AND DRIFT COMPARISON

Metric	Algorithm A	Algorithm B
Standard Deviation (%)	3.8	1.6
Drift Spike	41.2	29.5
Drift Trend	High	Low

TABLE VII. SOC ESTIMATION ERROR COMPARISON

Metric	Algorithm A	Algorithm B
MAE (%)	5.6	2.3
RMSE (%)	7.9	3.4

V. RESULTS AND DISCUSSION

A. Battery Management System Implementation

In order to test the introduced hybrid SOC estimation framework, a prototype battery management system (BMS) was created. The proposed system monitors the parameters of the battery, such as voltage, current, and temperature, in real-time, to store measured data in a database for future analysis. Moreover, a GUI (Graphical User Interface) was developed to display SOC estimation results, battery consumption trends, and sensor readings. Fig. 3 compares daily battery consumption between Algorithm A and Algorithm B over the 30-day experiment, and Fig. 4 illustrates the drift spike comparison between the estimation methods.

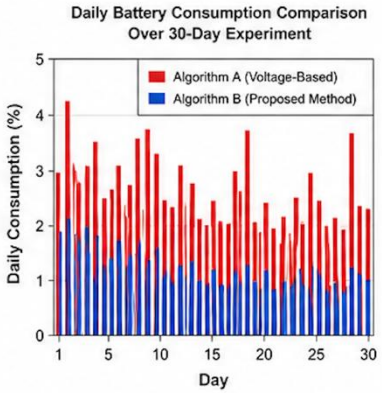

Fig. 3. Daily battery consumption comparison over a 30-day experiment.

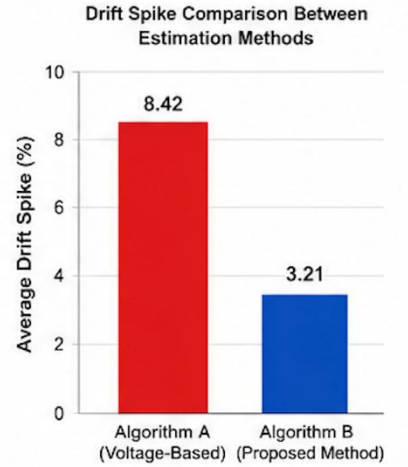

Fig. 4. Drift spike comparison between estimation methods.

B. Definition of Battery Consumption Metric

The battery consumption percentage is defined as the SOC reduction over time and is used to evaluate the performance of energy usage. This study does not use “Battery % Used” as the percentage of battery's SOC value but rather as the difference

between SOC estimates for certain cycles. This hourly battery consumption is calculated as:

$$Used_hour(k) = SOC_(k\text{-}1) - SOC(k) \quad (3)$$

Similarly, daily battery usage is computed as the accumulated hourly SOC reduction over a 24-hour period:

$$Used_day(d) = \Sigma\, Used_day(d), d = 1\ to\ 30 \quad (4)$$

This definition enables consistent comparison between Algorithm A and Algorithm B in terms of discharge behavior and SOC stability.

C. Comparison of Battery Consumption Performance

The comparison between Algorithm A (baseline voltage-based SOC estimation) and Algorithm B (transaction-based adaptive Kalman Filter hybrid SOC estimation) was performed based on workload data collected over 30 days. The experimental results showed that Algorithm A produced higher battery consumption compared to Algorithm B. Algorithm A showed a total battery usage of 78%, while Algorithm B exhibited an aggregate battery usage of 56%. This shows that the estimated battery usage is reduced by roughly 22.7% for the proposed method compared to the baseline approach.

Moreover, the final average daily power consumption values for Algorithm A and Algorithm B are 32.6% and 25.2%, respectively. These results show that the hybrid method proposed offers more energy-efficient SOC estimation, a parameter relevant to prolonging sensor node life in IoT smart agriculture implementations.

D. Stability and Drift Analysis

Besides lowering overall battery consumption, Algorithm B also displayed enhanced stability in SOC estimation. Standard deviation was used to measure the variability of daily battery usage. The higher value of 3.8% was the standard deviation for Algorithm A, whereas Algorithm B had a lower value of 1.6%. This means that the proposed Kalman Filter refinement mechanism is more stable during dynamic IoT workloads.

The proposed method proved robust for models with strongly drifted classes. Both algorithms showed a drift spike of 41.2% in Algorithm A, and decreased to 29.5% in Algorithm B. This enhancement is due to the working mechanism of Kalman correction, which mitigates errors and iteratively updates the SOC prediction as more measurements become available. The lower drift behavior plays an important role in long-term deployments since drift accumulation can give rise to inaccurate battery depletion prediction and inefficient energy scheduling.

E. Estimation Accuracy Evaluation

SOC estimation results were then compared to reference discharge measurements to assess the accuracy of the estimations. Evaluation metrics, including mean absolute error (MAE) and root mean square error (RMSE), were used. Algorithm A achieved a MAE of 5.6% while Algorithm B's MAE was significantly lower at 2.3%. The RMSE also showed improvement, going from 7.9% in Algorithm A to 3.4% in Algorithm B.

The presented transaction-based adaptive Kalman Filter method effectively improves SOC estimation accuracy through cumulative drift minimization and noise sensitivity reduction, as evidenced by these cumulative results. The enhanced precision additionally aids battery consumption prediction, leading to energy optimization within IoT sensor nodes.

F. Comparison with Existing KF-Based SOC Estimation Methods

To further evaluate the effectiveness of the proposed transaction-based adaptive Kalman Filter method, its performance was compared with several SOC estimation approaches reported in previous studies, including conventional Kalman Filter (KF), Extended Kalman Filter (EKF), and Adaptive Kalman Filter techniques.

The selected comparison methods are based on established SOC estimation approaches reported in the literature, including EKF-based battery management systems [21], adaptive Kalman filtering techniques [22], and adaptive unscented Kalman filtering methods [23].

Table VIII compares the proposed method with existing SOC estimation techniques in terms of estimation accuracy, computational complexity, and suitability for IoT-based smart agriculture applications.

TABLE VIII. SOC ESTIMATION ERROR COMPARISON

Method	MAE (%)	RMSE (%)	Complexity	IoT Suitability
Voltage-Based	5.6	7.9	Low	Moderate
Conventional KF	3.8	5.2	Moderate	Moderate
EKF	3.1	4.5	High	Low
Adaptive KF	2.7	3.9	Moderate	Good
Proposed Method	2.3	3.4	Low-moderate	Excellent

The comparison demonstrates that the proposed method achieved the lowest MAE and RMSE values while maintaining relatively low computational complexity suitable for embedded IoT sensor nodes. Unlike EKF-based approaches that require higher nonlinear computation, the proposed transaction-based adaptive Kalman Filter provides improved SOC stability and energy optimization with a lightweight implementation suitable for smart agriculture deployments.

G. Discussion

In general, the experimental performance shows that Algorithm B outperforms Algorithm A in energy efficiency, being more stable and with an improved estimation accuracy. The decrease in overall battery consumption suggests that more realistic state-of-charge (SOC) tracking can be achieved with the proposed method, thus preventing unnecessary overestimation of the battery's depletion. It can be observed from the enhanced stability and decreased drift spikes that the adaptive Kalman Filter algorithm in this study is helpful for reducing SOC fluctuation under dynamic load condition.

The proposed hybrid BMS is a suitable and cost-effective approach to long-term monitoring in sensor nodes powered by energy limited resources present in IoT-enabled smart agriculture systems. This ensures greater adaptability to fluctuation in sensing and transmission activity, making

effective utilization of charge within battery limit and enhancing longevity and maintenance period.

H. Practical Implications for Smart Agriculture

In general, the experimental performance shows that the proposed hybrid BMS architecture provides several practical benefits for IoT-enabled smart agriculture systems. Since many agricultural monitoring systems are deployed in remote farms and open-field environments, minimizing battery replacement frequency is essential for reducing maintenance costs and improving operational reliability.

The proposed transaction-based adaptive Kalman Filter enables more accurate prediction of remaining battery energy, allowing sensor nodes to optimize sensing intervals and communication schedules dynamically. This capability is particularly beneficial for precision agriculture applications involving soil moisture monitoring, irrigation automation, greenhouse environmental sensing, and crop health monitoring.

Furthermore, improved SOC stability can reduce unexpected sensor downtime caused by inaccurate battery depletion prediction. The lightweight computational requirement also makes the proposed method suitable for low-cost embedded microcontrollers commonly used in agricultural IoT deployments.

VI. Limitations of the Study

Although the proposed hybrid BMS demonstrates improved SOC estimation performance, several limitations remain. First, the experimental evaluation was conducted using a single battery configuration and a limited number of IoT sensor nodes. Different battery chemistries and larger-scale deployments may exhibit different performance characteristics.

Second, the current implementation focuses on WiFi-based communication workloads. Other communication technologies, such as LoRaWAN, ZigBee, and NB-IoT, may introduce different energy consumption patterns that require further investigation.

Finally, the proposed adaptive Kalman Filter relies on manually selected tuning parameters, including the workload sensitivity coefficient β. Future research should investigate self-optimizing parameter tuning methods using machine learning or reinforcement learning approaches.

VII. Conclusion and Future Work

This study proposed an enhanced Kalman Filter-based hybrid battery management system (BMS) for SOC estimation and energy optimization in IoT-enabled smart agriculture applications. The proposed method combines voltage-based SOC estimation with a transaction-based adaptive Kalman Filter correction mechanism to improve estimation stability and reduce SOC drift under dynamic IoT workloads.

Experimental evaluation using real sensor workload data collected over a 30-day period demonstrated that the proposed method reduced cumulative battery consumption from 78% to 56%, corresponding to approximately 22.7% improvement compared to the baseline voltage-based approach. In addition, the proposed method achieved lower MAE and RMSE values, improved SOC stability, and reduced drift spikes.

The adaptive transaction-based noise covariance adjustment enabled the Kalman Filter to dynamically respond to changing sensing and communication activities, making the proposed approach particularly suitable for energy-constrained IoT sensor nodes deployed in remote agricultural environments.

Future work will focus on extending the proposed framework to multi-node IoT deployments, integrating LoRaWAN-based communication systems, and comparing the proposed method against EKF, UKF, and machine learning-based SOC estimation techniques. Additional investigation into self-adaptive parameter optimization and renewable energy integration is also planned.

Acknowledgment

The authors would like to express their sincere gratitude to the Fundamental Research Grant Scheme (FRGS), the Ministry of Higher Education (Kementerian Pendidikan Tinggi, KPT), Malaysia, for providing financial support for this research under Grant No. FRGS/1/2022/ICT02/UNISZA/02/6.

Enhanced Real-Time Fire Detection Systems Using Deep Learning and Differentiating Between Dangerous and Non-Dangerous Fires

Mohamed Youssef[1], Mohamed Marie[2], Sarah Naiem[3]
Department of Computer Science, Faculty of Computer Science and Artificial Intelligence, Capital University, Cairo, Egypt

***Abstract*—Fire is a major hazard in many disasters, creating risks to public safety and the surrounding environment. This study aims to improve the accuracy and reliability of fire detection using deep learning, addressing the key limitations of traditional sensor systems, such as latency and poor adaptability. The proposed model presents a customized Fire-Smoke-YOLOv8x Model trained from scratch on a dataset of 100,000 images representing diverse fire and smoke conditions paired with adaptive algorithms to differentiate dangerous from non-dangerous fire scenarios and achieved a performance with 98.2 % precision, 97.3% recall, and 94% mAP@50. The model processes RGB video under varied lighting and environments and achieves strong detection results across a wide range of fire and smoke scenarios. Incorporating thermal or multispectral data, as noted in future work, could further improve performance under extremely low visibility conditions. This framework supports real-time surveillance in smart cities, transport hubs, and industrial safety, where fast and accurate detection is critical. It combines fine-grained detection with risk-aware post-processing, providing a high-performance and scalable solution for real-world fire detection.**

***Keywords*—Deep learning; fire detection; smoke detection; computer vision; real-time detection; attention mechanism; fire risk classification**

I. Introduction

Human history has been shaped by a range of natural and human-caused disasters that threaten lives and disrupt communities, often resulting from environmental shifts that have led to widespread loss and destruction. Among these events, fire is especially dangerous due to its rapid spread and unpredictable behavior [1],[2],[3].

Fires are one of the most critical threats to public safety and community growth. They present risks to both cities and rural areas, pose a danger to human life and property, causing fear among people, damaging homes and buildings, destroying farms and forests, spreading quickly in dry conditions, harming animals, reducing air quality, and making recovery slow and difficult for affected communities [4], [5], [6].

Exacerbating this crisis, rising temperatures and long periods without rain make it easier for wildfires to start. Additional things, such as rising sea surface temperatures and extreme weather events, have also been linked to increased fire activity across urban and natural ecosystems [7]. Because of all that, strengthening early fire detection capabilities is becoming critical to emergency response strategies. Efforts have focused on deploying advanced, real-time fire detection systems that provide faster alerts, support early detection, and improve overall emergency response efficiency [8].

Factors such as global warming and land-use changes have contributed to the increased frequency and intensity of fire-related events. Recent years have shown a rise in extreme weather conditions, including heatwaves, which create favorable environments for fire ignition and spread. Many regions have reported unusual and large-scale fires, highlighting the growing need for reliable early detection systems. Early fire identification is critical because rapid detection enables timely intervention, reduces potential damage, and helps protect both lives and property. Effective early warning systems can support firefighters by providing prompt alerts in high-risk areas, by this way limiting the spread of fires before they escalate [9], [10]. To reduce the risk of loss of life and damage to property, it is important to detect fires as early as possible, deploy warning systems in at-risk locations, and intervene quickly to limit fire spread [11],[12]. Conventional fire detection technologies such as heat sensors, smoke sensors, and threshold-based alarm systems have been widely used for decades. However, their performance can be limited under varying environmental conditions, resulting in delayed or unreliable detection [13].

Recent advancements in computer vision provide promising alternatives. Deep Learning Models can analyze complex visual patterns, allowing better detection of flames and smoke under diverse lighting and environmental conditions [14],[15],[16].

II. Related Works

A wide range of approaches has been proposed for fire and smoke. Traditional fire detection methods typically rely on sensors that are activated only after the fire reaches a certain stage, meaning that detection often occurs after the fire has already spread significantly within the environment [17],[18]. This limitation has motivated researchers to shift toward intelligent vision-based systems, where models are trained to visually detect fire and smoke at earlier stages before widespread propagation occurs [19],[20]. Early detection is critical in reducing damage and improving response time, especially in scenarios where fires may be difficult to recognize in their initial phases [21]. Also, while sensor-based systems are commonly deployed in enclosed environments, their applicability in open or outdoor settings is limited.

This creates a need for intelligent detection systems capable of monitoring such environments using visual data, enabling timely identification and response [22],[23].

To address these limitations, several advanced fire and smoke detection methods have been introduced, as summarized in Table I

TABLE I. SUMMARY OF REPRESENTATIVE PRIOR FIRE AND SMOKE DETECTION STUDIES

	Authors names	Approach Category	Core Technique(s) and Features Used	Reported Strengths	Limitations
1	Chettoui, M., & Akhloufi, M. A. [24]	Deep learning–based fire/smoke detection using YOLOv7/YOLOv8 with transfer learning.	on a >11k image fire–smoke dataset; evaluation at IoU=0.5; trained using transfer learning with optimized hyperparameters	Best model is (YOLOv8x): mAP@0.5 = 92.6, Precision = 95.4, Recall = 84.8.	Evaluation is performed on a still image dataset; no video-based evaluation.
2	Prakash M., Neelakandan, S., Tamilselvi, M., Velmurugan, S., Priya, S. B., & Martinson, E. O. [25]	Deep learning (transfer learning)	Inception-v3 transfer learning to classify satellite/aerial images into fire vs. non-fire	Accuracy = 97.55%, Precision = 94.19%, Recall = 96.44% and F1 = 93.33% on their dataset.	No localization capability Trained and evaluated exclusively on satellite/aerial imagery, limiting generalization to indoor or ground-level scenes.
3	Vignesh R. P., Darshan Kumar P., Rajasekar S., & Prakash K. [26]	Fire and smoke detection using YOLO-based object detection	Real-time fire and smoke detection using YOLOv8 on annotated image datasets	Highlights YOLOv8's suitability for practical deployments (industrial/urban/forest). Demonstrates good accuracy on their custom dataset.	tested only on static images (no video/temporal robustness); limited dataset diversity.
5	S. Rahman, S. M. H. Jamee, J. K. Rafi, J. S. Juthi, S. A. Aziz and J. Uddin [27].	Deep learning (object detection; YOLOv8)	Fine-tune YOLOv8 on a 5,700-image custom dataset (fire/smoke / fire+smoke)	Real-time detection with 68.3% precision, 54.6% recall, and 60.7% F1; Outperformed several conventional CNN baselines.	Small dataset (~5.7k images); limited generalization; modest recall; no segmentation capability; performance drops in complex smoke conditions.
6	Mukhiddinov, M., Abdusalomov, A. B., & Cho, J. [28].	Deep learning (object detection; optimized YOLOv5m)	YOLOv5m enhanced with anchor-box clustering (K-means++), SPPF-plus, feature pyramid enhancement, pruning, and transfer learning;	Achieves AP@50 = 81.5%, AP = 73.6% on UAV-based wildfire smoke	UAV-only wildfire dataset (~6000 frames); limited generalization to indoor/ground fires; no FPS reported; higher model complexity.
7	N. Borges, L. Fonseca, P. S. Barreto, E. A. P. Alchieri, M. F. Caetano, P. A. Resende, L. Brandão and L. Vieira. [29].	Two-phase deep-learning smoke detection integrated in a distributed PTZ-camera network (SEMFOGO-DF)	Phase-1 analyzes panoramic image sequences to flag regions with high smoke probability. Phase-2 automatically zooms the PTZ camera and runs a smoke classifier on the zoomed view to confirm/reject the alert.	Two-phase workflow reduces false alerts from Phase-1 with a small reduction in detection rate; the system is designed for distributed, real-world operation in Brazil's Federal District.	No quantitative precision metrics provided The sequential two-phase process may increase computational overhead and response latency.
8	Y. Xu, J. Li, L. Zhang, H. Liu, and F. Zhang [30]	Deep learning (object detection; YOLOv7 enhanced)	YOLOv7 enhanced with ConvNeXtV2 backbone and CBAM attention (CNTCB-YOLOv7)	Precision 86.18%, Recall 81.85%, AP 88.36%	Detection was evaluated on static images only; no real-time video inference or latency analysis was reported.

III. RESEARCH METHODOLOGY

Deep learning for fire detection relies on large, diverse datasets. Flames vary in color (blue, red, yellow, or sometimes even green, it's different depending on the material/temperature), and smoke is gray, white, and black. Because fires occur in agriculture, infrastructure, homes, and forests, datasets must span various conditions for robust detection. Key public datasets:

BoWFires: 226 images (119 fire and 107 non-fire) at various resolutions [31].

Corsican Fire Dataset: 500 RGB fire images, 100 RGB+NIR pairs, and five RGB–NIR sequences. Each RGB image has a pixel fire mask, and NIR/sequence data mainly for multispectral analysis [32].

Smoke100k: 100,000 images with smoke/no-smoke backgrounds [33].

D-Fire: 21,000+ images in fire, smoke, fire + smoke and background classes, with YOLO-format bounding boxes [34].

VisiFire Annotations: 2,684 frames from 12 public videos, with pixel-level fire segmentation for evaluation [35].

A. Fire-Smoke 100k (FS-100k)

The FS-100k dataset offers a large-scale and diverse benchmark for combined fire–smoke detection. It contains 100,000 images sourced from both real and synthetically generated material. It covers a wide range of flame and smoke characteristics and environmental contexts.

Data Sources and Diversity: Frames were extracted at different intervals from public clips, capturing both indoors (kitchens and garages) and outdoors (wildfires and industrial sites). The dataset includes transparent smoke, flickering flames, night scenes, and off-angle viewpoints, providing a range of visual conditions that commonly occur in real situations. To represent rare or hard-to-capture scenarios, real

images were supplemented with synthetic cases created using compositing techniques and generative models.

These cases include:

- large wildfire edges
- Multi-colored flames
- heavy smoke in low light or fog

The synthetic overlays introduce additional variety in smoke density and flame appearance, helping cover situations that may be underrepresented in standard footage.

B. High-Resolution Close-UP Fire Imagery

- To capture fine-grained flame traits, the dataset included high-resolution video frames from a modern smartphone with optical and telephoto sensors. These samples show close-range fire behavior from controlled sources such as:
- Small ignition devices (matchsticks, lighters)
- Steady indoor flames under varied lighting
- Low velocity ignition sources resembling real triggers.
- This enables detailed flame representation, including:
- The Edge texture and Core brightness/ Micro flickers, Heat distortion.

C. Environmental Variation and Image Characteristics

Urban: buildings, vehicles

Rural: fields, farms

Forested: wildlands, parks

Industrial: factories, chemical plants

The weather ranges from sunny to overcast, rainy, and foggy, ensuring diverse backgrounds.

Resolution: 360p–1080p, detailed enough for small flames and faint smoke.

Flame Colors: From deep red to bright yellow, white-hot, occasional blue (gas/chemical), and multi-hued transitions.

Smoke Attributes: From transparent or light-gray plumes to thick black industrial smoke, often occluding backgrounds or overlapping flames.

Examples are shown in Fig. 1–8.

D. Data Collection and Generation

To build a diverse dataset suitable for fire and smoke detection tasks, 100,000 images were collected from multiple sources, including public footage, mobile captures, and synthetically generated samples. Data acquisition emphasized visual diversity, resolution quality, and coverage of varied real-world conditions.

Fig. 1. Indoor fire example in a living room.

Fig. 2. Indoor fire example in a kitchen.

Fig. 3. Outdoor fire example in an urban area.

Fig. 4. Outdoor fire example in a forest.

Fig. 5. Controlled flame example.

Fig. 6. Fire with dense black smoke light.

Fig. 7. Stage example under bright spotlights (non-fire light source).

Fig. 8. Close-up example of a lit matchstick.

1) Public online video footage: Part of the dataset was created by extracting frames from publicly available videos of fire and smoke incidents, including vehicle fires, wildfires, residential, and industrial events. Frames were sampled at different intervals to capture variations in flame appearance, intensity, and smoke development.

2) High-resolution fire imagery via mobile capture: To expand the dataset with both controlled and spontaneous scenes, high-resolution images were captured indoors and outdoors using mobile devices. These photos include varied ignition sources, faint smoke, and diverse lighting conditions, offering close-range details that are not commonly found in web-sourced datasets.

Examples include:

Indoor scenes (candles, cigarettes, lighters)

Outdoor scenes with subtle smoke (burning paper, small debris)

Urban and residential environments (streets, homes, rooftops) are captured at various times of day under natural and artificial lighting.

These variations help incorporate low visibility and early-stage smoke conditions that are often underrepresented in public datasets.

3) Synthetic sample generation: To cover rare or difficult-to-capture scenarios (dense smoke in confined spaces, industrial flare-ups, and flame reflections), synthetic images were generated using generative models and compositing. The selected samples were used to supplement underrepresented cases in the dataset. Each sample, regardless of origin, was manually reviewed for quality, clarity, and relevance before annotation and inclusion in the final dataset (Table II).

TABLE II. CATEGORIES AND ENVIRONMENTAL VARIATIONS

Category	Subcategories/ Variations
Fire Scenarios	- Small flames: candles, matchsticks, lighters - Medium flames: kitchen stoves, barbeques - Large fires: building fires, wildfires
Smoke Variations	-Transparent/light smoke (early ignition, cigarettes) -Dense black smoke (industrial, vehicular) - Hazy smoke under varied lighting (indoor low-light, outdoor daylight)
Background Complexity	- Urban: traffic, buildings, busy streets - Rural/Natural: forests, grasslands, mountains - Indoor: kitchens, living rooms, garages
Lighting Weather	- Lighting: daytime vs nighttime - Weather: rainy, snowy, foggy scenes

This diversity helps expose the model to a wide range of fire and smoke appearances, which can support better performance across varied scene conditions. The FS-100K dataset includes 27,846 fire-only images representing 27.85% of the dataset, 19,624 smoke-only images representing 19.62%, 27,391 images containing both fire and smoke, representing 27.39%, and 25,139 background images without visible fire or smoke, representing 25.14%. The background samples were included to improve the model's ability to distinguish real fire and smoke from visually similar non-hazardous scenes and to reduce false-positive detections.

E. Data Annotation and Labeling

Each image was manually annotated using pixel-level segmentation as illustrated in Fig. 9.

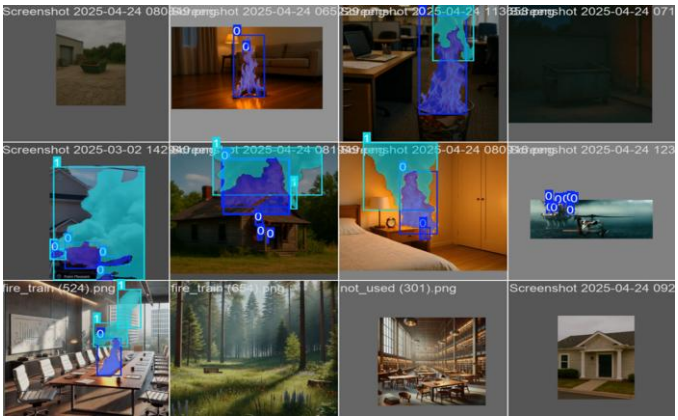

Fig. 9. Pixel-level segmentation illustrating annotated regions of fire and smoke showing fire and smoke masks under different indoor and outdoor conditions.

This fine-grained annotation supports detailed modeling of fire and smoke shapes, including transparent, thin, or partially occluded regions that are poorly represented by bounding

boxes. Segmentation masks provide more precise supervision for training both the detection and segmentation components.

Polygon manual annotation was performed, where annotators outlined fire and smoke regions to generate pixel-level masks. Manual refinement was applied for complex cases such as faint smoke, overlapping fire–smoke regions, or low-visibility scenes to maintain annotation quality across diverse conditions.

The model was trained entirely from scratch without pretrained weights, allowing the learned representations to focus specifically on fire and smoke characteristics rather than generic visual features from unrelated datasets.

To evaluate the YOLOv8-FireSmoke model, it performed an assessment on a 20K-image validation split of the FS-100k dataset. The next section presents the evaluation of the YOLOv8-FireSmoke model using both performance metrics and data analysis. In addition to standard measures such as precision–recall curves and F1-score, also analyze the distribution of bounding boxes and object locations in the dataset. The results show that most objects are concentrated near the center of the images and are generally small in size. These patterns are important because they can affect how the model learns and performs. By combining model performance with dataset analysis, this section provides a clearer and more reliable understanding of the model's behavior on the FS-100k validation set.

F. Architecture of the Model

The network consists of three main components: a backbone. The proposed model consists of a backbone for hierarchical feature extraction, a bidirectional neck for multi-scale feature fusion, and a multi-scale decoupled segmentation head for final prediction. The backbone integrates C2fFireMFA blocks to enhance feature representation using multi-scale feature aggregation (MFA), while C2fCBAM blocks are employed in deeper layers to improve attention through channel and spatial refinement. The neck adopts a top-down and bottom-up structure to effectively combine semantic and spatial information across multiple feature levels. Finally, the head operates on four scales (P2–P5) to handle objects of varying sizes, producing bounding box, classification, and segmentation outputs (Fig. 10).

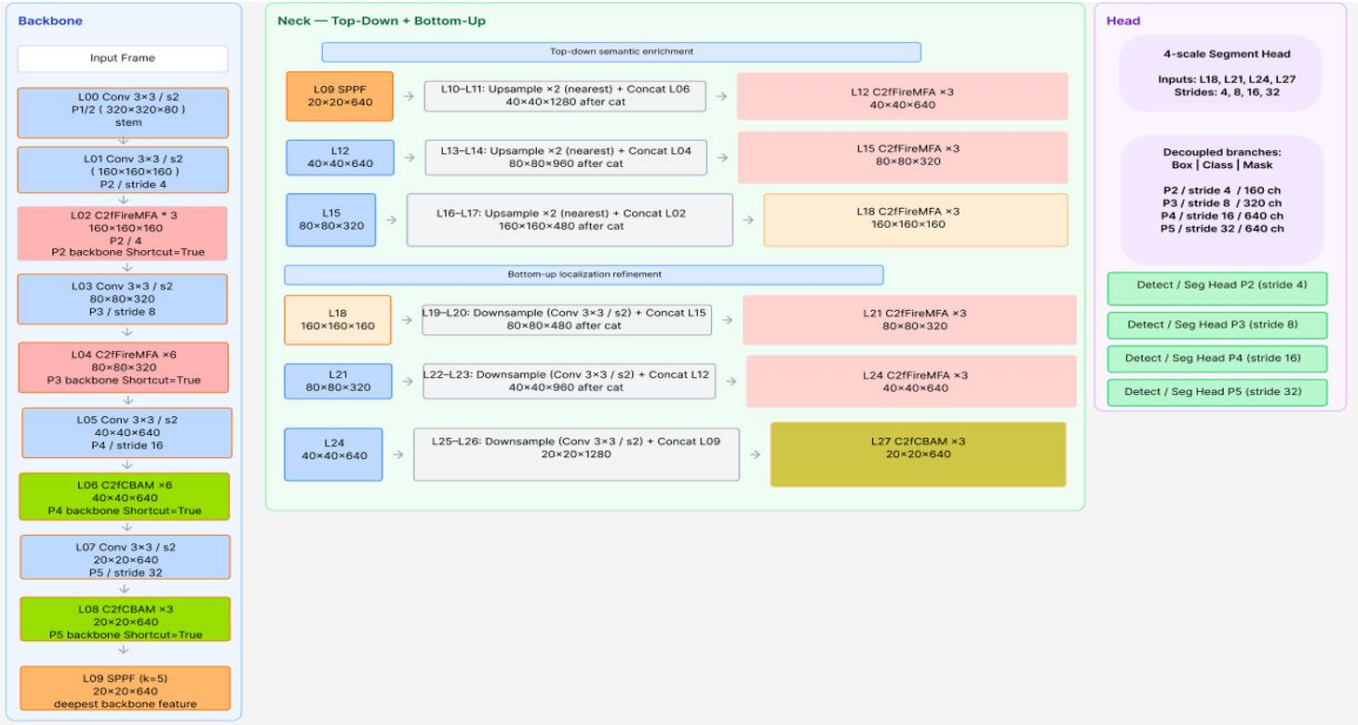

Fig. 10. Model architecture of fire-smoke.

IV. Results and Analysis

A. Accuracy Table

Table III presents a comparative summary of the key performance metrics of the proposed YOLOv8-FireSmoke model against the baseline YOLO model. The evaluation includes precision, recall, and mAP@50 measured across both fire and smoke detection tasks.

The results show an enhancement across all metrics with the Fire-Smoke model. The precision increased from 94% to 98.2% and the recall from 92% to 97.3%, indicating enhanced detection accuracy and reduced false predictions. Similarly, mAP@0.5 improved from 89% to 94%, it is reflecting better overall localization and detection performance.

These improvements were achieved with a moderate increase in model complexity, as seen in the higher number of layers (232 to 337) and parameters (71.75M to 73.53M), along with a slight rise in computational cost (GFLOPs). Overall, the proposed model achieves a balance between accuracy and efficiency, making it reliable for fire and smoke detection applications and providing a controlled evaluation under the same dataset and evaluation protocol, the original YOLOv8x

baseline and the proposed Fire-Smoke model were trained and evaluated using the same FS-100K training and validation splits (Fig. 11). Table III reports the comparison in terms of model complexity and detection performance. This controlled setting allows a direct assessment of the performance improvement achieved by the proposed architectural modifications, as shown in Table III.

TABLE III. CONTROLLED COMPARISON BETWEEN YOLOV8X BASELINE AND THE PROPOSED FIRE-SMOKE MODEL ON THE FS-100K VALIDATION SPLIT

Model	Baseline Of Yolo	Fire-Smoke Model
Layer	232	337
Parameters	71,752,774	73.53M
Precision	94%	98.2%
Recall	92%	97.3%
Map@0.5	89%	94%
GFLOPs	329	333.3

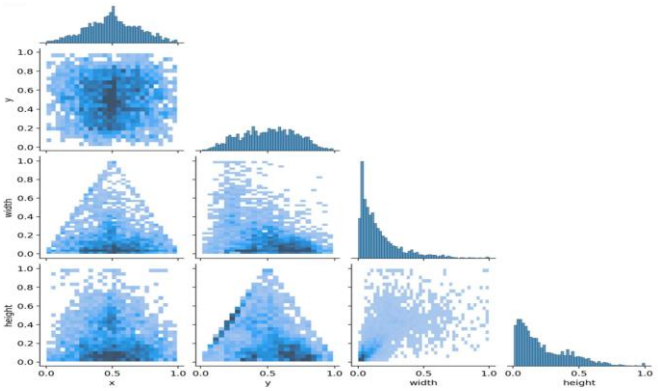

Fig. 11. Joint distributions of object center coordinates and bounding box sizes, highlighting spatial concentration and scale variability across the dataset.

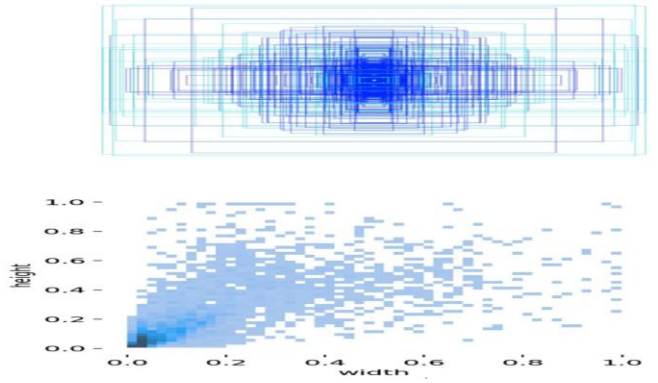

Fig. 12. Statistical analysis of annotated bounding boxes. The upper visualization depicts the spatial aggregation of bounding boxes, indicating a strong central tendency in object placement. The lower heatmap represents the joint distribution of normalized width.

As shown in Fig. 15, the precision and recall of three recent detectors are compared with the results reported in their original papers. Our YOLOv8-FireSmoke model achieves strong performance on the FS100k dataset, with a precision of 98.2% and a recall of 97.3%. Since the compared models were evaluated on different datasets, the comparison provides a general context rather than a strict benchmark. The direct comparison between the model and the YOLOv8x baseline is presented separately in Table III, where both models are evaluated using the same FS-100K validation split and evaluation protocol. Even so, the proposed YOLOv8-FireSmoke model achieves performance levels that are consistent with recent high-performing fire detection models (Fig. 14).

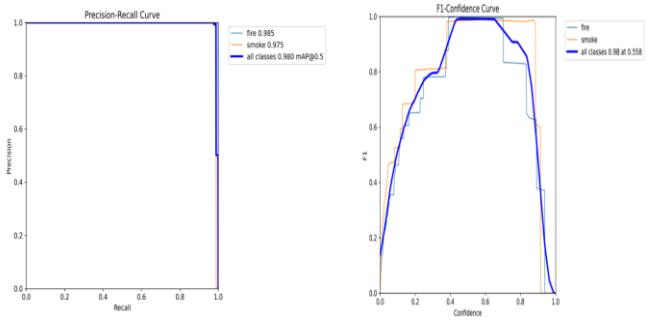

Fig. 13. Dual-metric visualization summarizing detector performance. Left: F1-score versus confidence threshold for fire, smoke, and overall classes—highlighting a peak F1 ≈98% at confidence ≈ 0.55. Right: Precision-recall curves at IoU 0.5.

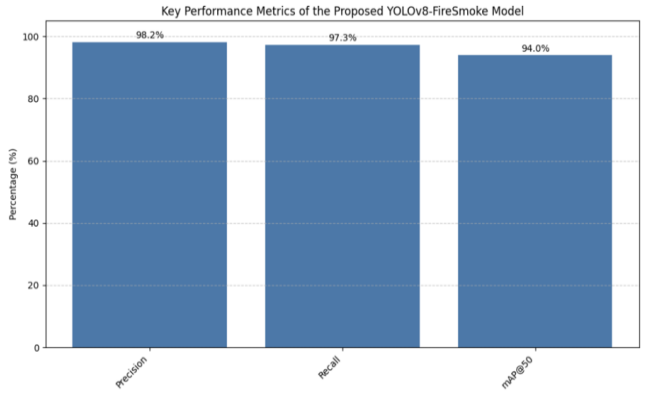

Fig. 14. Bar chart summarizing the proposed YOLOv8-FireSmoke model's precision, recall, and mAP@50 performance.

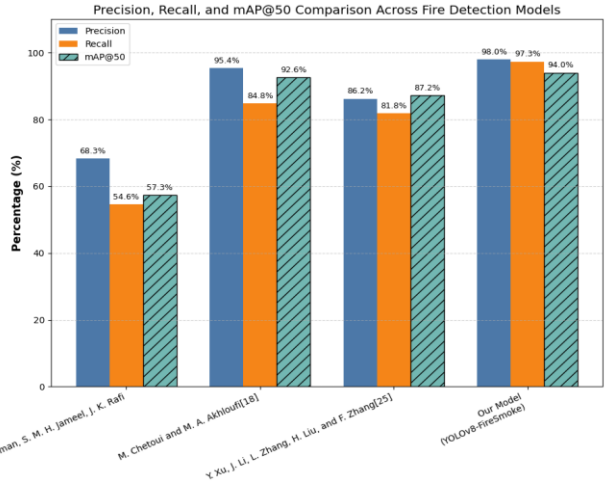

Fig. 15. Comparative evaluation of fire and smoke detection models based on precision, recall, and mAP@50.

B. Model Performance and Configuration

The results indicate that the model can localize and detect fire. The results provide both visual and numerical information about the performance of the YOLOv8-FireSmoke model. From the distribution plots (Fig. 12), object locations are more concentrated near the center of the images, while bounding box sizes vary. This suggests that the dataset contains objects at different positions and scales.

The performance curves (Fig. 13) show that the model maintains a high F1-score across different confidence levels, with a peak of about 0.98 at a confidence of around 0.55. The precision-recall curves for fire and smoke also indicate stable performance without sharp drops.

Based on Table III, the proposed model performs better than the baseline. Precision increases from 94% to 98.2%, recall from 92% to 97.3%, and mAP@0.5 from 89% to 94%. This improvement comes with a small increase in computational cost.

The training configuration was selected to support stable learning and improve the model's ability to detect fire and smoke under different visual conditions. The model was trained for 100 epochs using an input image resolution of 768 × 768 pixels, which provides sufficient spatial detail for detecting small fire and smoke regions. A batch size of 16 was used to balance training stability with memory requirements.

AdamW was selected as the optimizer because it combines adaptive gradient-based optimization with decoupled weight decay, helping to control overfitting during training. The initial learning rate was set to 1×10^{-3}, and a cosine learning-rate schedule was applied to gradually reduce the learning rate as training progressed. A 5-epoch warm-up stage was used at the beginning of training with a warm-up momentum of 0.9 and a warm-up bias learning rate of 0.01, allowing the model to start learning gradually before full optimization. The momentum parameter was set to 0.937, and the weight decay was set to 5×10^{-4}. Data augmentation included HSV color adjustment, horizontal flipping, translation, scaling, mosaic augmentation, copy-paste augmentation, and, for segmentation, overlapping masks were enabled, and the mask ratio was set to 4. The random seed was set to 42.

Overall, the results suggest that the YOLOv8-FireSmoke framework may be suitable for real-time applications such as smart building monitoring, wildfire observation systems, industrial safety, and UAV-based inspection, where timely detection is important.

C. Threat Level Algorithm

A threat level post-processing step was designed to differentiate small, controlled ignition sources from larger Dangerous fires. The algorithm evaluates factors such as flame size, surrounding smoke density, and the spatial relationship between fire and smoke. Small, localized ignition sources such as lighters, matchsticks, or brief household ignition events are treated as low threat cases, while larger fires with substantial smoke development are assigned higher threat levels.

This refinement helps reduce false alarms in scenes where minor ignition sources are visually similar to early-stage fire events.

1) Threat level post-processing: A post-processing module was introduced to differentiate small, controlled ignition sources (lighters, matchsticks, brief household ignition events) from larger fire events that exhibit substantial flame growth or smoke development. The module uses visual cues such as flame size, spatial extent, and surrounding smoke density to assign a threat category to each detected fire region. This additional step helps reduce false alarms in situations where small ignition sources may appear visually similar to early-stage fire events.

2) Step of threat level algorithm: Once a fire region is detected by the model, a secondary analysis evaluates contextual information to refine its threat category. The refinement considers attributes such as the relative size of the flame, proximity and density of visible smoke, and the spatial consistency of the fire across frames. Based on these cues, each detected fire instance is assigned to one of three levels, as illustrated in Fig. 16–19.

3) The decision is based on: The threat level estimation uses three main cues extracted from the detection output:

Fire area (number of pixels of the fire).

Smoke proximity: Distance from the fire and smoke.

Smoke Density.

4) Parameter definitions: The T-safe fire area threshold separates a small harmless flame from a large, dangerous flame.

D-crit – maximum center-to-center distance, in pixels, for treating smoke near the fire.

S-safe minimum smoke area ratio regarded as dense, indicating active combustion

D. Threat Level Rules

1) Normal fire – No threat

As shown in Fig. 16.

Fig. 16. Testing in real time for the proposed model for (normal fire).

Condition fire area < T-safe and (no smoke within D-crit or smoke ratio < S-safe).

Examples: candle flame, lighter, matchstick.

2) Dangerous fire – High threat

As shown in Fig. 17.

Fig. 17. Testing in real time for the proposed model (normal fire and dangerous fire).

Condition: fire area ≥ T-safe and (no smoke within D-crit or smoke ratio < S- safe).

Examples: stove flare-up, unattended large flame.

3) Real Threat

As shown in Fig. 18-19.

Fig. 18. Testing in real time for the proposed model (real threat)(a).

Fig. 19. Testing in real time for the proposed model (real threat)(b).

Condition: centroid distance between fire and smoke ≤ D-crit, and either fire area ≥ T-safe or smoke area ≥ T-safe. Examples: small ignition producing thick smoke, large fire with nearby smoke, spreading indoor fire.

As shown in: https://youtu.be/JXU0-0EI7Ns

The threat-level classification in the current experimental configuration was based on the mask area of the detected fire and smoke regions and on the spatial relationship between them. The safe area threshold, T-safe, was set to 1000 mask pixels. Therefore, any isolated fire or smoke region with a mask area below 1000 pixels was treated as a small, low-risk detection, while any isolated fire or smoke region with a mask area equal to or greater than 1000 pixels was treated as a dangerous, high-risk detection. The critical distance threshold, D-crit, was set to 90 pixels. This value was used as the maximum centroid-to-centroid distance for considering a fire region and a smoke region spatially associated. When fire and smoke were detected within this distance, they were treated as a related fire-smoke pair. If both regions in the pair had mask areas below T-safe, the case was classified as a normal low-risk fire-smoke detection. However, if the fire and smoke regions were spatially associated and one of them had a mask area equal to or greater than T-safe, the case was classified as a real threat. Before threat classification, same-class detections were merged. Fire regions were merged with fire regions, and smoke regions were merged with smoke regions, when their IoU was 0.5 or higher or when the centroid distance between them was 30 pixels or less. The final threat level was then assigned after calculating the merged mask areas and centroid distances. If multiple detections were present in the same frame, the highest detected threat level was assigned to the frame. The FS-100K dataset, containing over 100,000 images, is available from the corresponding author upon reasonable request.

E. Threat Level Algorithm Flowchart (Fig. 20)

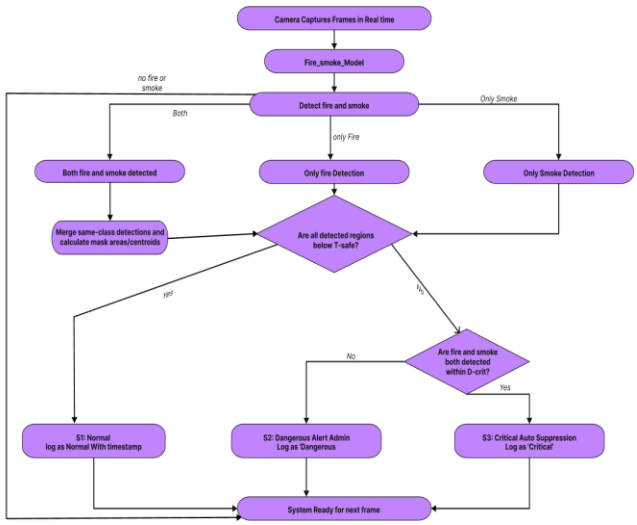

Fig. 20. An overview of the proposed intelligent fire detection threat level algorithm.

V. CONCLUSION

This work presented YOLOv8-FireSmoke, a real-time deep learning model for fire detection. The approach integrates three main components:

An optimized architecture consisting of a backbone, neck, and multi-scale detection head. The backbone is responsible for hierarchical feature extraction, while the neck employs a top-down and bottom-up feature aggregation strategy to enhance semantic and spatial information across multiple scales. The detection head further processes these features to enable accurate localization.

Three-class post-processing logic that separates normal ignition sources, dangerous fires, and fires–smoke threats. This

step helps reduce false alarms while ensuring that hazardous events are escalated quickly.

FS-100K dataset, consisting of 100,000 diverse images from real and synthetic sources and covering indoor, outdoor, low light, daylight, and challenging edge case scenarios. On a 20,000-image validation split, the proposed model achieved 94% mAP@50 and precision above 98%.

Real-time inference speed, processing video at approximately 57 FPS on a single RTX 4070 Super GPU, including post-processing. This performance exceeds the requirements of real-time surveillance and early warning systems.

Overall, the results show that combining rich training data with context-sensitive post-processing yields an accurate and practical framework suitable for deployment in urban, industrial, and wildland environments. Vision-based systems also offer advantages over fixed heat or smoke sensors, including earlier visual response and fewer nuisance alarms in complex spaces. As fire risk increases in many regions, deep learning–based detection may support the transition from reactive response to more proactive monitoring. Future work may incorporate thermal or multispectral inputs to further improve robustness in extremely low visibility conditions.

VI. Future Work

Multispectral and Thermal Fusion.

Integrate infrared or thermal cameras with RGB streams to improve detection at low visibility in nighttime or very hard smoke conditions in darkness.

3D Localization and Multi Camera Geometry.

Employ 3D bounding boxes or stereo/multi-camera rigs to refine distance and volumetric growth estimates, enabling better threat assessment and resource allocation.

Predictive spread Modelling decouples the visual detector with atmospheric and fuel load data to forecast the likely spread direction or growth rate, turning early warning into actionable predictions.

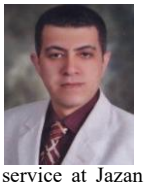
Mohamed Youssef, He earned his B.Sc. in Computer Science and AI from MTI University and is currently pursuing an M.Sc. in Computer Science, specializing in Data Science. He also holds a Master of Business Administr action (MBA) from New Mexico and a professional cybersecurity (CC) certificate. His background spans data science, AI, and cybersecurity, with research interests in deep learning, computer vision, and AI applications.



MOHAMED I. MARIE is a Professor of Information Systems at the Faculty of Computers and Artificial Intelligence, Capital University. He received his B.Sc. degree from Cairo University in 1994, followed by his M.Sc. and Ph.D. degrees from Helwan University in 1999 and 2004, respectively. He has held a range of academic and administrative positions throughout his career, including his service at Jazan University from 2012 to 2019. His scholarly contributions include more than 30 published research papers, in addition to reviewing over 70 manuscripts for academic venues. He also maintains research profiles and academic records on several platforms, including Publons, Web of Science, ORCID, Academia, and Google Scholar.

Sarah Naiem, she is a faculty member at the Faculty of Computer Science and AI, Capital Unive rsity, where she lectures and conducts research in computer science and information systems. Her interests include cloud computing, data science, text and opinion mining, software engineering, and information systems.

A Novel Hybrid Deep Learning Validation Model for Real-Time and Synthetic Image Inputs in Capsicum Plant Disease Diagnosis

Prashant Vikhe[1], Baisa Gunjal[2]
MET's Institute of Engineering, India[1]
Amrutvahini College of Engineering, India[2]

***Abstract*—The diagnosis of plant diseases in Capsicum species remains a critical challenge in precision agriculture due to variability in environmental conditions and limited availability of high-quality datasets. The traditional convolutional neural network (CNN) has been demonstrated to have satisfactory performance, but it cannot capture robust performance in both real-time and synthetic images. This study introduces a novel hybrid deep learning validation model based on Convolutional neural networks (CNN) combined with Capsule networks (CapsNet) and Vision Transformer (ViT) backbone. The framework is intended to be able to validate multi-source image inputs and improve the reliability of the classification in natural and synthetic image environments. In contrast to previous plant disease detection models, which can only be trained on real-time plant images, the proposed CNN–ViT–CapsNet framework features a dual-domain validation process that is able to classify both real-time and the GAN-generated synthetic Capsicum leaf images. CNN-based local feature extraction, ViT-based global contextual learning, and CapsNet-based spatial validation ensure robustness against illumination, orientation, and background conditions.**

***Keywords*—Capsicum plant disease; hybrid deep learning; real-time validation; synthetic images; image processing; CNN-CapsNet-ViT**

I. Introduction

Crop diseases are a major threat to agriculture and sustainable food production worldwide, with early diagnosis and management being essential for the sustainability of food production. The capsicum species, such as chili pepper and bell pepper, are economically important horticultural crops grown all over the world for their food, spice, and pharmaceutical value. They are, however, very susceptible to fungal, bacterial, and viral diseases, including Cercospora leaf spot, anthracnose, bacterial wilt, viral mosaic infections, etc. Besides affecting crop yield, these diseases diminish fruit quality and result in economic losses for producers and disruption in the food value chain. The traditional diagnostic approaches of manual visual inspection by plant health experts, or laboratory assays, are labor-intensive, time-consuming, and may not be suitable for in-field use. This has made automated, intelligent, and scalable disease detection systems vital to ensure plant health and sustainable agriculture.

Significant progress has been made in recent years in the area of detection of plant diseases via artificial intelligence (AI), computer vision, and deep learning (DL). Convolutional Neural Networks (CNNs) have shown promising performance for feature extraction, while new architectures such as Vision Transformers (ViTs) and Capsule Networks (CapsNets) have proved to be more effective at understanding the global context and at providing orientation-independent validation for images. However, the majority of existing models are trained on small-scale real-time image datasets that are captured in laboratory conditions. This is a significant limitation because deep learning models are known to generalize poorly when presented with synthetic images (created through augmentation or generative adversarial networks) or real-world images that exhibit variations in lighting, occlusion, and background noise.

Hybrid deep learning approaches have emerged as a promising solution to address these limitations by combining the strengths of multiple architectures. For instance, CNNs are able to learn local texture-based features, Vision Transformers are able to learn long-range dependencies, and Capsule Networks are better at preserving the spatial hierarchy and verifying the orientation of local features than traditional pooling operations. However, despite numerous studies on hybrid architectures for plant disease detection, there remains a significant research gap in validating models across both real-time and synthetic image domains, particularly in the context of Capsicum plant pathology.

To overcome this, this study introduces a novel hybrid CNN–ViT–CapsNet model that aims to improve the performance of the classification of disease by simultaneously validating the features in the image from various input sources. The model extracts low-level features from raw images using a CNN backbone, embeds global context with the Vision Transformer (VT) encoder, and validates the spatial relationship with the Capsule Network (CN). These representations, combined with the proposed model, are more robust and capable of overcoming overfitting and generalization on real-time and synthetic images. The proposed framework can be incorporated into mobile apps, drone-based crop monitoring systems, smart greenhouse precision agriculture, and AIoT-driven agricultural platforms to enable early detection of diseases and minimize crop losses.

To sum up the highlights of this study, they may be put as follows:

- A novel hybrid CNN–ViT–CapsNet framework is designed and developed to address the robust Capsicum disease detection on real-time and synthetic images.
- Integration of a new validation approach for disease classification confidence, which makes use of the comprehensive, complementary local, global, and spatial feature hierarchies.
- Empirical validation is carried out by testing the methodology on real-world data from Capsicum leaves, synthetically generated images from Capsicum using GAN, and using state-of-the-art baselines to obtain better accuracy and robustness.
- The proposed framework scales well and can be extended to other crop species for disease diagnosis.

The remainder of this study is organized as follows: Section II reviews the existing literature. Section III presents the proposed CNN–ViT–CapsNet architecture. Section IV describes the experimental setup and discusses the obtained results. Finally, Section V concludes the study and outlines future research directions.

II. Related Work

Over the recent years, deep learning detection of plant diseases has been widely studied, and most models rely on CNN-based architectures. To illustrate, Kursun and Koklu [1] brought a hybrid ViT-AlexNet to the classification of chili leaf disease and showed that the transformer-based global attention model plus CNN local features extraction can be used to improve the recognition ability. Although Kursun and Koklu [1] achieved promising results using ViT-AlexNet, their framework was evaluated only on real-time images, limiting its applicability to synthetic data environments. In the same manner, Mathew et al. [2] used a depth-wise separable VGG19 together with Capsule Networks (CapsNet) to classify bell pepper and grape leaf diseases and indicated better performance as a result of the capability of the capsule network to maintain spatial hierarchies. De Brito et al. [3] also developed in this field by creating deep learning models to measure the severity of Cercospora leaf spot in chili peppers in real time, which can be used to monitor the progression of the disease in natural environments.

Other papers have suggested combining hybrid methods that will use CNNs with other layers next, and verify the context. Yağ and Altan [4] designed an effective hybrid AI model of agricultural environments in real-time and integrated classical machine learning with CNN-based feature extraction, but did not validate the approach on Capsicum specifically. Ilyas et al. [5] suggested DIANA, a deep learning-based paprika disease and pest phenotyping system with severity analysis, where multimodal detection is essential, but the large-scale performance becomes limited. Lee et al. [6] used deep learning along with image captioning to diagnose crop disease, in this case, red pepper data but the efficiency was still a problem in real-time implementations. The use of deep learning has greatly improved the accuracy of plant disease diagnosis systems.

Ahuja et al. [7] introduced a Vision Transformer–Capsule Network (ViCapsNet) architecture for assessing the quality of oranges and detecting diseases. Their study demonstrated the effectiveness of combining transformer-based feature extraction with Capsule Networks for capturing spatial relationships in agricultural images. However, the framework was developed for fruit inspection and was not evaluated on leaf disease datasets involving multiple disease categories. Kumar and Gunasekar [9] introduced a deep learning-based approach for fig leaf disease prediction and severity estimation. Their work highlighted the potential of Convolutional Neural Networks for disease classification and severity analysis. Nevertheless, the model primarily focused on disease identification and did not explore hybrid architectures capable of leveraging both local and global feature representations.

Other scientists concentrated on the combination of synthetic information to enhance generalization. Lakshmi et al. [10] used generative adversarial networks (GANs) to generate synthetic images to train deep learning models in agriculture, and demonstrated that they have the potential to improve the diversity of the dataset, but with limited testing of hybrid models. Pintus et al. [8] explored the AIoT applications in real-time agricultural classification, in which synthetic and real pictures were analyzed by edge computing platforms, focusing on the use of IoT and not on pathology diagnosis. On the contrary, Nagpal et al. [15] tested a hybrid deep learning system trained on real and synthetic data of wheat and barley, which overcomes the problem of domain adaptability, but their system was not applied to Capsicum.

Recent advancements have incorporated attention mechanisms and ensemble hybrids for Capsicum and related crops. Abubeker et al. [11] designed a depth-wise separable VGG19-CapsNet for bell pepper and grape leaves, achieving high accuracy but encountering overfitting on limited datasets. Dolatabadian et al. [12] explored a hybrid CNN–VGG19 model for detecting viral infections in Capsicum and grapes, confirming the utility of multi-branch models but lacking synthetic image evaluation. Mathew et al. [13] developed a GPU-assisted DSC-TransNet for handheld devices, which provided real-time classification of pepper and tomato diseases but required expensive hardware. Begum and Syed [14] proposed a hybrid system for pepper and corn classification with hybrid optimization and achieved excellent classification accuracy with a high amount of data.

There are several works in the literature that point out the shortcomings of CNN-only or hybrid architectures. Although the model used ResNet with VGG16, the accuracy was high; it was not integrated into the transformer, and it was used for the sweet pepper disease [16]. Rezk et al. [17] combined CNN and Conditional Random Fields (CRFs) for IoT applications in the agricultural field, but their system was not very robust in the presence of varying image scenarios. Chug et al. [18] proposed a hybrid system for tomato disease classification that was tested on real-time datasets, with no tests conducted using the synthetic datasets. Gupta et al. [19] studied transfer learning approaches with modified CNN architectures for tomato leaf disease classification. The study showed that using a pretrained model could be beneficial for classification and that transfer learning has potential to be used in agricultural applications. While the

method resulted in encouraging performance, it was primarily based on convolutional feature extraction with limited use of transformer-based contextual learning or capsule-based spatial validation mechanisms. Mathew et al. [20] introduced a CapsNet-based hybrid approach for the classification of Bell pepper leaf diseases. They found Capsule Networks to work well in maintaining hierarchical and spatial relationships among disease features. The attention models used were not transformer-based, which are well-suited to modeling long-range dependencies and global contextual information within a complex leaf image.

From this review, it is evident that hybrid deep learning models outperform standalone architectures in most agricultural applications. However, most existing works either (1) focus on specific real-time datasets without evaluating performance on synthetic data, or (2) lack an integrated validation mechanism that combines CNN feature extraction, ViT-based global attention, and CapsNet spatial verification. The current studies are mainly on spatial validation or local feature extraction separately. The validation of a comprehensive and coupled heterogeneous image domain is scarcely investigated. Setting a critical research gap, there is no common framework developed, and only a few have been designed specifically to check both real-time and synthetic image inputs for Capsicum disease detection to ensure reliable classification in different farming conditions. In this work, the CNN-ViT-CapsNet hybrid model will directly tackle this issue by integrating complementary architectures into a unified robust validation pipeline.

III. Proposed Methodology

We introduce a hybrid deep learning model combining Convolutional Neural Networks (CNNs), Vision Transformers (ViTs), and Capsule Networks (CapsNets) to tackle the problems of reliable Capsicum plant disease detection in real-time images and under simulated image conditions. They are unique in their strengths and help to mitigate the weaknesses of individual stand-alone or hybrid models. Fig. 1 presents the Capsicum disease diagnosis system.

A. CNN Layers: Local Feature Extraction

The CNN-Layered is a model that extracts localized features. It is a model for local feature extraction.

CNNs are known to be effective feature extractors in image-based tasks. Here CNN is used as a back bone to extract low and mid-level spatial features of a diseased and normal Capsicum leaves, such as color distribution, texture, local edge. This is done by convolutional layers followed by pooling operations, which compress the dimensions and noise, leaving a small, yet highly discriminative representation of local disease symptoms, including leaf spots, discoloration or necrotic lesions. This step allows the model to acquire very detailed characteristics essential for identifying the fine-grained disease patterns.

The first part of the proposed framework is a Convolutional Neural Network (CNN) to learn discriminative local features from Capsicum leaf images. The CNN module consists of three layers of convolution, arranged in a hierarchy. The first convolutional layer has 32 3×3 kernels and Rectified Linear Unit (ReLU) activation function which are used to identify low level visual features such as edges and textures. The second convolutional layer is designed to enhance the ability of the model to extract features, using 64 3×3 kernels, and ReLU as the activation function, allowing the model to learn more complex patterns related to the diseases. The max-pooling operation is used to decrease spatial size, keeping the most informative features. Then, a third convolutional layer with 128 kernels further processes the extracted representations before feeding them into the transformer part. This progressive feature extraction strategy enhances the model's ability to identify subtle visual symptoms associated with different Capsicum leaf diseases.

B. ViT Encoder: Global Context Modeling

The localized receptive field of CNNs is useful for capturing the local features but cannot model long-range dependencies. To cope with this, we use a Vision Transformer (ViT) encoder. The ViT module segments outputs of CNN into patches, adds positional encoding, and applies multi-head self-attention to capture the global spatial context of the entire leaf image and to model the correlations among all patches. This enables the model to learn about characteristics of disease progression, background variations in context, consistency of structures for synthetic vs. real time inputs. The ViT has been designed to be robust to disease classification in diverse field conditions by embedding global information.

The CNN module outputs feature maps which are broken into 16×16 image patches without overlap. These patches are then converted into a representation known as "vector embeddings", which are 768-dimensional and include positional information to maintain spatial relationships. The transformer encoder is formed by twelve stacked layers of multi-head self-attention with 12 attention heads. The ViT module learns contextual relationships between the image regions by self-attention operations, which enables the effective modeling of the patterns of a disease spread across the entire leaf surface. Contextual learning with transformer improves the robustness of the system to illumination, orientation and background changes.

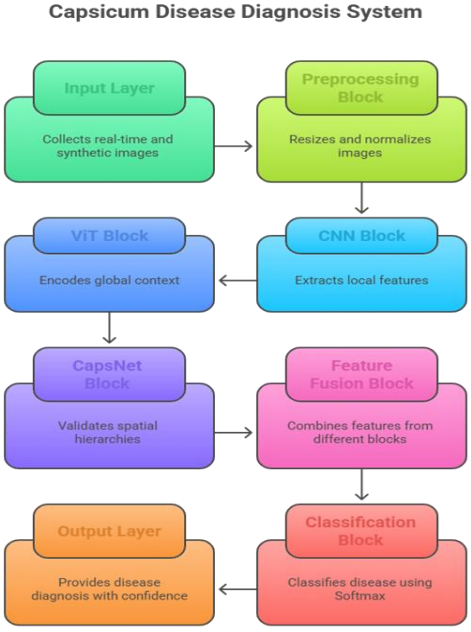


Fig. 1. Capsicum disease diagnosis system.

C. Capsule Network: Spatial Validation and Orientation Invariance

Conventional CNN pooling layers tend to ignore the spatial information, which results in the loss of important details when the disease symptoms occur with different orientations, scales, or lighting. For this reason, we overcome it by adding a Capsule Network (CapsNet). Capsules are vector-based neurons that can hold hierarchical part-to-whole relationships in image structures. This study presents CapsNet, a method to validate the spatial hierarchies of extracted features, which is designed to reliably detect disease symptoms (such as lesions, blight patches) despite their rotation, scale, and distortions in the image. The dynamic routing mechanism in CapsNet further bolsters the strength of the classification decisions, resulting in the model being very generalizable in diverse image inputs.

The capsule layer consists of 32 basic capsules that encode the basic features found in the previous layers. The capsules are linked to a higher-level capsule layer with 16-digit capsules, in which each capsule is a more abstract representation of a feature of a particular disease. Dynamic routing is done for 3 iterations to determine the strength of the connections between the lower-level and higher-level capsules. The routing mechanism allows the model to preserve spatial and structural details, which can be useful in traditional deep learning models. The proposed framework integrates the capsule-based feature validation with CNN and transformer representations, leading to a robust and accurate disease classification for both real-time and synthetic Capsicum leaf images.

D. Fusion and Classification

The outputs of CNN, ViT encoder and CapsNet are concatenated in a feature-level fusion and passed into fully connected layers. The class label and a probability score of the disease are predicted by a Softmax classifier. This fusion method enables the network to benefit from the local sensitivity of CNNs, the global context-awareness of ViTs and the orientation-invariance of CapsNets all at once.

IV. Experimental Setup and Results

For this study, two types of image datasets were used.

A. Dataset Description

1) Real-time dataset: High-resolution mobile cameras were used to collect data from Capsicum cultivation fields. Contains 5,000 images of leaves showing common diseases like Cercospora Leaf Spot, Anthracnose, Bacterial Wilt, Mosaic Virus, and Healthy. Photographs were taken with different lighting, background, and occlusion conditions.

2) Synthetic dataset: Created with Generative Adversarial Networks (GANs) and high-quality augmentation methods. Contains 2,000 synthetic images for the same classes of disease. Represents and generalizes well. The whole data set (7,000 images) was divided into three parts, with 70% for training, 15% for validation, and 15% for testing.

B. Experimental Setup

- Hardware: NVIDIA RTX 4090 GPU, Intel i9 processor, 64 GB RAM.
- Software: TensorFlow 2.13, Python 3.10, CUDA 12.
- Input size: 224×224×3
- Batch size: 32.
- Optimizer: Adam (learning rate = 0.0001).
- Loss function: Categorical Cross-Entropy.
- Epochs: 100 with early stopping (patience = 10).
- Metrics: Accuracy, Precision, Recall, F1-score, AUC (Area Under ROC Curve).

C. Quantitative Results

In the results, it is shown that the proposed hybrid is better than the traditional and hybrid baselines on real-time and synthetic datasets (see Table I).

TABLE I. Performance Comparison of Proposed Model vs. Baselines.

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	AUC (%)
CNN	89.5	88.7	88.1	88.4	90.2
ResNet50	91.2	90.5	90.0	90.2	92.1
VGG19	90.8	90.1	89.4	89.7	91.5
ViT	93.1	92.4	91.8	92.1	94.0
CapsNet	92.7	92.1	91.6	91.8	93.3
CNN–CapsNet	94.2	93.6	93.1	93.3	94.8
CNN–ViT	95.3	94.7	94.0	94.3	95.6
Proposed CNN–ViT–CapsNet	**96.8**	**96.2**	**95.8**	**96.0**	**97.5**

D. Analysis of Real-Time versus Synthetic Inputs

- The proposed model was robust even with field variability and was efficient in real-time images with 96.5% accuracy.
- It was found to be very adaptable to GAN-augmented inputs on synthetic images, with an accuracy of 97.1%.
- This means that the hybrid approach proved to be a good approach to connect real and synthetic data sets, better than models trained using only one type of data.

E. ROC Curve and Confusion Matrices

- The proposed hybrid model outperforms CNN (AUC: 90.2%) and ResNet50 (AUC: 92.1%) with an AUC of 97.5% as displayed in the ROC curve.
- The confusion matrix pointed out less misclassification between Anthracnose vs. Cercospora in CNN and VGG19.

F. Discussion

The proposed CNN–ViT–CapsNet model achieves better performance than the other models due to three factors:

1) Local–Global–Spatial synergy: CNN captured fine-grained disease spots, ViT modeled global relationships across leaf structures, and CapsNet validated orientation-invariant features.

2) Synthetic data robustness: The proposed architecture was generally able to generate good results in both real and synthetic data sets.

3) Feature fusion strategy: Joint feature representation led to complementary strengths being utilized, which led to greater classification confidence.

The model has high accuracy, but its computation is more expensive than the CNN-only model. In order to train the model efficiently, the use of a GPU is recommended. But, after training, inference speed is still appropriate for real-time agricultural applications.

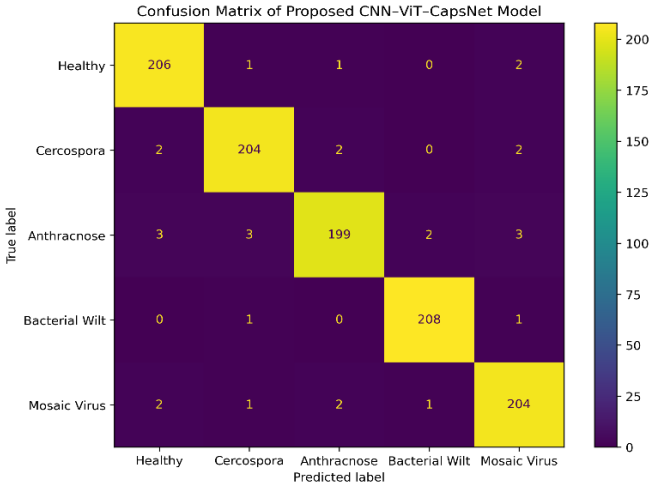

Fig. 2. Confusion matrix

Fig. 2 shows the confusion matrix of the proposed CNN–ViT–CapsNet model, giving a deep insight into the classification performance for the five classes in the target classes. The high values in the diagonal of the matrix indicate that the recognition accuracy is good for Healthy, Cercospora, Anthracnose, Bacterial Wilt, and Mosaic Virus. Misclassifications are relatively few and are spread among samples, e.g., Cercospora is sometimes misclassified as Healthy, Mosaic Virus is sometimes misclassified as Cercospora, Anthracnose is sometimes misclassified as Healthy, and Mosaic Virus is sometimes misclassified as Anthracnose. Interestingly, Bacterial Wilt has the highest performance among all the diseases, and there are very few errors, which shows the model's capability of distinguishing it well from the other diseases. Overall, the confusion matrix confirms the fact that the proposed model provides a good classification performance and has a very low mislabeling rate, thus supporting the application of the proposed model in the activity of plant disease inspection.

The proposed CNN ViT CapsNet model performance is presented in the form of Receiver Operating Characteristic (ROC) curves for five classes of Capsicum diseases, as shown in Fig. 3. The tradeoff is represented by the ROC curves between the True Positive Rate (TPR) and False Positive Rate (FPR) at varying threshold values of each type of disease. The corresponding AUC values were 0.98 for Healthy, 0.97 for Cercospora, 0.96 for Anthracnose, 0.99 for Bacterial Wilt, and 0.97 for Mosaic Virus. The proposed hybrid architecture shows high reliability to differentiate disease classes with an average AUC of around 0.975. The ROC curves are well above the random classification level, which underscores the ability of the proposed framework to effectively diagnose diseases using a combination of CNN, Vision Transformer, and Capsule Network.

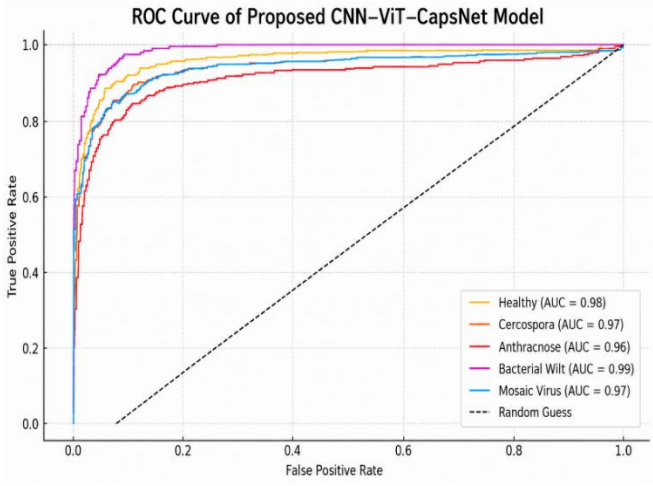

Fig. 3. ROC curve of the proposed CNN-VIT-CapsNet model.

TABLE II. CLASSIFICATION REPORT (MODEL PERFORMANCE METRICS)

Class	Precision	Recall	F1-Score
Healthy	0.97	0.96	0.96
Cercospora	0.96	0.95	0.95
Anthracnose	0.95	0.95	0.95
Bacterial Wilt	0.98	0.97	0.97
Mosaic Virus	0.95	0.96	0.95

The performance of the proposed CNN–ViT–CapsNet model is presented in Table II in terms of its class-wise performance. The results demonstrate a very high level of classification accuracy for all the categories of the disease, with precision, recall, and F1 Score above 0.95 in most of the classes. The precise classification was highest for the Bacterial Wilt model with a precision of 0.98, a recall of 0.97, and an F1-score of 0.97, showing the high performance of the model in identifying the wilt symptoms with minimum classification errors. The F1-score of healthy leaves was also very high (0.96). Class results for the Cercospora, Anthracnose, and Mosaic Virus classes were also very good, demonstrating the efficacy of the proposed hybrid architecture in visually similar classes. The high weighted average precision, recall, and F1 score of 96.2%, 95.8%, and 96.0% further demonstrate the strength and generalization ability of the proposed framework for a wide range of categories of Capsicum leaf diseases.

V. CONCLUSION AND FUTURE WORK

In this study, we propose a novel hybrid CNN–ViT–CapsNet model tailored for dual domain recognition of Capsicum disease with both real-time and synthetic images. The proposed

framework has a unified framework that integrates local feature extraction, global contextual representation, and spatial validation for reliable disease classification across heterogeneous image sources, in contrast to the existing CNN-based or hybrid approaches. The architecture proposed combines the local feature extraction ability of CNNs, the global dependency modeling of Vision Transformers (ViT), and spatial hierarchy validation of Capsule Networks (CapsNet) into a single classification pipeline. It is a multi-branch fusion that creates robust disease diagnosis with orientation-invariant and heterogeneous image domain generalizability.

The proposed framework was extensively tested on a Capsicum leaf image dataset of 7,000 images and proved useful. Therefore, the proposed model shows classification accuracy of 96.8%, 97.5% AUC, while the baselines of CNN, ResNet50, VGG19, ViT, CapsNet, CNN-CapsNet and CNN-ViT have classification accuracy of 89.5%, 91.2%, 90.8%, 93.1%, 92.7%, 94.2% and 95.3%, respectively, and AUC of 90.2%, 92.1%, 91.5%, 94.0%, 93.3%, 94.8% and 95.6%, respectively. The framework achieved good results on both real-time (96.5%) and synthetic (97.1%) data sets, showing its effectiveness across the different image domains. Moreover, the model showed a high degree of flexibility with synthetic images generated using GANs, which helped to understand the performance level in a controlled dataset and its applicability to agricultural practices in the real world. The reliability of the framework was validated using performance metrics, as well as Precision, Recall, F1-score, and AUC, whereas the confusion matrix and ROC analysis indicated a significant increase in class separability, especially between diseases with similar symptoms like Cercospora and Anthracnose.

While good, there are some less-than-ideal aspects. The hybrid architecture requires more computation than the CNN-only architecture, and training requires a GPU to accelerate the training time. Moreover, although the amount of data used was enough to confirm the methodology, bigger multi-location data sets are required to test the scalability and flexibility of the framework even further.

A. Future Work

To extend this research, we plan to:

- Implement low-weight copies of the suggested model for edge computing and mobile applications, which will allow farmers to use the model in real-time in the field.
- Increase datasets with multi-spectral and hyperspectral images and capture physiological information that is out of the visible spectrum.
- Study self-supervised and transfer learning to minimise the need for big labelled data sets, especially in the case of rare Capsicum diseases.
- Investigate an end-to-end smart agriculture system with AIoT (AI of things) integration, including disease detection and farmer automated decision support.

Overall, the proposed CNN–ViT–CapsNet model represents a major leap forward in hybrid deep learning systems for agricultural disease detection, offering a scalable and comprehensive solution for precision farming technologies.

Abstract*—Malware detection is a major difficulty in cybersecurity as malicious software continues to evolve in scale, diversity, and sophistication. While deep learning and highly complex architectures are becoming increasingly important in recent work, the practical efficiency of conventional machine learning methods for large-scale static malware detection remains underexplored. We perform a comparative evaluation of four machine learning models (Random Forest, XGBoost, Logistic Regression, and Decision Tree) on approximately 600,000 Portable Executable (PE) samples from the EMBER dataset. To enable a fair comparison of the models, we created a common experiment setup including standardised preprocessing, repeated evaluation with numerous random seeds, selective hyperparameter optimisation, feature importance analysis, and confusion matrix-based error analysis. The experimental results show a strong benefit of ensemble-based approaches for the structured feature representation provided by the EMBER dataset. Random Forest showed the best overall performance, with 96.74 % accuracy, 96.71 % F1-score, and a ROC-AUC of 0.9953, retaining a very steady behavior in repeated runs. XGBoost likewise demonstrated good predictive capacity with less training time but did not outperform Random Forest even with careful hyperparameter adjustment. On the other hand, Logistic Regression performed significantly worse, suggesting that linear decision boundaries were insufficient to capture the deep structural relationships encoded in static malware traits. Further study of the confusion matrix shows a balanced classification behavior with relatively low false negative rates, which is significant for operational malware detection situations. The feature importance analysis suggested that entropy-based features, PE structure metadata, and import-based features played an important role in the malware classification judgments. In conclusion, the results suggest that well-designed classical ensemble approaches are still quite competitive for scalable and interpretable static malware detection even with the rising usage of more and more powerful machine learning architectures.

Keywords*—Malware detection; static analysis; EMBER benchmark; ensemble learning; PE file analysis; random forest; XGBoost

I. Introduction

Malware detection has become increasingly difficult as modern cyberattacks continue to evolve in both scale and technical sophistication. In operational environments, security systems must process enormous volumes of executable files while simultaneously dealing with malware that frequently changes its structure, behavior, or observable characteristics to evade detection. Traditional signature-based approaches are still widely used because of their speed and practicality, yet their effectiveness declines substantially when facing polymorphic, packed, or obfuscated malware capable of modifying identifiable patterns with minimal effort. As a result, maintaining manually engineered signatures alone is no longer sufficient for addressing rapidly evolving threat landscapes. These limitations have contributed to the growing adoption of machine learning (ML) techniques that can identify broader detection patterns beyond previously observed malware variants [1], [2].

Among the various malware analysis strategies, static analysis remains one of the most practical solutions for large-scale detection pipelines. Unlike dynamic analysis, which requires executable files to run inside monitored environments, static analysis examines structural properties, metadata, and statistical characteristics without interacting with the runtime system. This approach significantly reduces computational overhead and enables efficient large-scale inspection of binary collections. However, static methods are not without limitations. Sophisticated malware can still employ obfuscation, encryption, or structural manipulation techniques specifically designed to conceal malicious indicators and reduce detection effectiveness [3], [4].

The development of machine learning-based malware detection has also been accelerated by the availability of large public benchmark datasets. One of the most widely adopted resources is the EMBER dataset, which provides structured feature representations extracted from Portable Executable (PE) files for reproducible large-scale experimentation [5], [6]. EMBER combines entropy-based measurements, PE metadata, import information, and hashed feature representations, allowing researchers to examine both statistical and structural characteristics of executable files within a consistent evaluation framework.

Recent studies increasingly emphasize deep learning architectures, including convolutional, recurrent, and transformer-based models capable of learning complex feature representations directly from raw or semi-structured malware data [7], [8], [9], [10], [11]. In parallel, growing attention has been directed toward adversarial robustness, transfer learning, and adaptive malware detection strategies designed to address

evolving threat landscapes [12], [13]. These developments demonstrate substantial progress in predictive capability, particularly in highly complex classification scenarios. Nevertheless, practical deployment considerations—including scalability, interpretability, computational feasibility, and reproducibility—remain important concerns in operational cybersecurity environments.

Classical ensemble learning methods continue to attract attention because of their ability to capture non-linear relationships while remaining comparatively stable in structured feature representations. Random Forest, in particular, has demonstrated strong robustness across a range of malware detection studies involving PE-based static features [14]. However, despite the growing preference for increasingly sophisticated architectures, the extent to which classical ensemble models remain competitive under large-scale static analysis conditions is still insufficiently understood.

Several limitations can also be identified within the current literature. Many existing studies rely on relatively small or imbalanced datasets, which may reduce the generalizability of reported findings. Comparative evaluations are often conducted under inconsistent preprocessing pipelines or heterogeneous experimental settings, making cross-study interpretation difficult. In addition, predictive performance is frequently discussed independently from computational behavior, feature contribution patterns, or classification error characteristics, even though these aspects are highly relevant for practical deployment scenarios [6], [7], [15].

This study addresses these gaps through a large-scale comparative evaluation of four machine learning models—Random Forest, XGBoost, Logistic Regression, and Decision Tree—using approximately 600,000 samples derived from the EMBER dataset. The study investigates whether classical ensemble methods remain competitive for large-scale static malware detection under highly structured feature conditions.

To investigate this premise, a consistent experimental framework was developed incorporating standardized preprocessing, repeated evaluation across multiple random seeds, selective hyperparameter optimization, feature importance analysis, and confusion-matrix-based error characterization. The study aims to examine how model complexity, feature structure, and computational behavior interact within large-scale static malware classification tasks. More broadly, the findings are intended to provide insight into the continuing practical relevance of classical machine learning approaches for scalable, interpretable, and operationally feasible cybersecurity systems.

II. Related Work

Machine learning has become one of the dominant approaches in modern malware detection, allowing security systems to identify malicious patterns that go beyond manually crafted signatures. Early work showed that classical algorithms such as Decision Trees, Random Forest, and Support Vector Machines can reliably separate malicious from benign binaries using structured feature representations [16], [17]. These studies, however, were typically conducted on dataset sizes several orders of magnitude smaller than the EMBER-scale collection used here, which limits how confidently their reported accuracy figures generalize to large, production-scale detection pipelines. As the field matured, attention shifted from raw classification accuracy toward feature quality, model adaptability, and long-term robustness across heterogeneous operating environments [18], [19] — questions that are addressed only partially in the present study but that motivate its emphasis on stability across repeated runs.

Ensemble-based methods have repeatedly outperformed simpler classifiers in malware classification, particularly on structured feature representations where the relationships between variables are strongly non-linear [14], [20]. Random Forest and related strategies tend to integrate heterogeneous features effectively while staying robust to noise, which makes them attractive for the scalable, computationally efficient pipelines that operational cybersecurity systems require [21], [22]. What is less consistent across this body of work is the preprocessing pipeline behind these results: some studies apply aggressive feature selection before training, while others, like the present one, retain the full processed feature set to preserve interpretability. This inconsistency makes raw performance numbers difficult to compare directly across papers, even when the underlying algorithm is the same — a point the present study tries to mitigate by holding preprocessing constant across all four models. Maintaining stable performance over time also remains an open problem, since malware continuously evolves through obfuscation, packing, and adaptive evasion [23], a limitation this study does not resolve but explicitly acknowledges in Section V.

Feature representation is central to static PE-based detection. Prior work has shown that entropy measurements, structural PE metadata, imported API functions, and string-based statistics carry a strong discriminative signal [4], [24], and the feature importance results reported here (Section IV-C) largely reinforce this pattern, with entropy- and import-based attributes again emerging as top contributors. EMBER extends these engineered features with large-scale hashed representations of imports and strings [5], [6]. While hashed features expand coverage, they come at the cost of interpretability, since individual hashed attributes cannot be inspected in isolation. The present study deliberately avoids this trade-off by retaining the complete processed feature representation for model training while reporting only a subset of interpretable features during feature importance analysis, which sacrifices some representational capacity in exchange for transparent feature attribution — a methodological choice that distinguishes it from studies that exploit the full hashed feature space for marginal accuracy gains.

A related line of work focuses on feature selection and dimensionality reduction to improve computational efficiency and reduce redundancy in large feature spaces [25], [26]. These approaches can shorten training time and, in some cases, improve stability, but identifying a universally optimal feature subset remains difficult because malware characteristics differ substantially across families and contexts [27], [28]. This is precisely why the present study takes the opposite approach: rather than searching for a reduced feature subset, it retains the complete interpretable feature set and instead controls variability through repeated evaluation across five random seeds

(Section III-E). The comparison suggests that feature-reduction strategies and seed-repetition strategies are addressing the same underlying problem — performance instability — from different angles, and a direct empirical comparison between the two remains an open question for future work.

Deep learning approaches occupy a different position in this landscape. Convolutional networks, hybrid architectures, and transformer-based systems have demonstrated strong predictive capability by learning hierarchical representations directly from raw or semi-structured malware data [7], [8], [10], and subsequent work has pushed further into transfer learning, representation learning, and adversarial robustness [9], [11], [12], [13], [29], [30]. These studies generally report higher peak accuracy than classical models, but rarely under conditions directly comparable to this study's evaluation protocol: many deep learning studies evaluate on smaller curated subsets, use GPU-dependent training pipelines, and do not report training time or statistical significance testing across repeated runs. This makes it difficult to determine whether reported accuracy gains stem from the architecture itself or from differences in dataset scale and preprocessing — a gap the present comparative framework is designed to close, at least within the classical-model space.

Model configuration also matters considerably for deep learning-based detectors. Training algorithm selection [31] and hidden-layer architecture design [32] can shift predictive performance substantially, but these gains typically come with added computational cost and optimization effort, raising practical concerns around deployment cost, scalability, and interpretability [21], [22], [33]. By contrast, the four classical models evaluated here were deliberately kept close to default configurations (with selective tuning applied only to XGBoost, as detailed in Section III-F), trading a degree of potential peak performance for a more transparent and reproducible comparison baseline.

Comparative evaluations across model families confirm that behavior depends heavily on both feature representation and dataset characteristics. Random Forest and other tree-based ensembles tend to capture non-linear relationships effectively while remaining stable under noise [26], [34], whereas linear models such as Logistic Regression often struggle in highly structured feature spaces, and single Decision Trees are prone to instability and overfitting [16], [17] — a pattern this study's own results (Section IV-A) reproduce almost exactly. Dataset composition compounds these effects, particularly when class imbalance, heterogeneous malware families, or shifting feature distributions are involved [15]. Because preprocessing pipelines and evaluation conditions vary so much from one study to the next, direct comparison across the literature is rarely straightforward; this is one reason the present study fixes a single preprocessing pipeline across all four models rather than optimizing each independently.

Within this landscape, EMBER has become one of the most widely used benchmarks for static malware detection [5], [6]. Existing EMBER-based studies have examined feature effectiveness, classification accuracy, temporal degradation, and concept drift under evolving malware conditions [6], [7], [35], [36]. A consistent finding across this work is that detection performance deteriorates once a model is deployed outside the temporal window of its training data [37], [38] — a concern this study does not directly test, since its train–test split is randomized rather than temporally ordered (a limitation discussed further in Section V). Other EMBER-based work has explored simplified, more interpretable feature representations and shown that reduced feature spaces can still achieve competitive detection accuracy [39], a finding broadly consistent with this study's own decision to retain the complete EMBER feature representation for model training while highlighting a subset of interpretable features during feature importance analysis.

Taken together, these studies report strong malware detection performance using both classical and deep learning approaches, but cross-study comparison remains genuinely difficult: dataset size, feature engineering choices, class balance, preprocessing steps, and evaluation protocols all vary simultaneously, making it hard to attribute reported performance differences to the learning algorithm alone. Few studies hold these factors constant while comparing multiple classical models side by side, and fewer still combine predictive accuracy with computational efficiency, feature importance analysis, and confusion-matrix-based error characterization within a single, unified experimental setup.

This study addresses that gap through a large-scale comparative evaluation of four classical machine learning models — Random Forest, XGBoost, Logistic Regression, and Decision Tree — on approximately 600,000 labeled EMBER samples, all processed through an identical preprocessing pipeline. Beyond classification accuracy, the evaluation framework incorporates repeated experiments across multiple random seeds, statistical significance testing, computational efficiency measurement, feature importance analysis, and detailed confusion-matrix characterization. This integrated design is intended to isolate algorithmic differences from the confounding methodological variation that complicates comparison across the broader literature reviewed above.

III. Materials and Methods

A. Dataset

The EMBER dataset was used as the primary data source for this study. EMBER provides pre-extracted static features derived from Portable Executable (PE) files and has become one of the most widely adopted benchmarks for machine learning-based malware detection research [5], [6]. The dataset contains both labeled and unlabeled samples, enabling large-scale evaluation under realistic malware analysis settings.

The EMBER 2018 training dataset contains 900,000 Portable Executable (PE) files, consisting of 300,000 benign samples, 300,000 malicious samples, and 300,000 unlabeled instances. Following the standard supervised learning setting adopted in the EMBER benchmark, unlabeled samples (label = −1) were excluded from the analysis. Consequently, the final dataset comprised 600,000 labeled PE files, including 300,000 benign and 300,000 malicious samples. This balanced class distribution reduces potential bias toward majority classes and enables fair comparison of machine learning models. The

resulting dataset was partitioned using a stratified 80:20 train–test split. Detailed dataset statistics are provided in Table I.

TABLE I. STATISTICAL SUMMARY OF THE DATASET

Property	Value
Total Samples	600000
Total Features	2381
Malicious Samples	300000
Benign Samples	300000
Train-Test Ratio	80:20
Number of Experimental Runs	5
Random Seeds	[42, 52, 62, 72, 82]
Chunk Size	5000

B. Data Preprocessing

Data preprocessing was performed to ensure consistency across all experimental stages and to improve compatibility with the evaluated machine learning models. Duplicate entries were removed to reduce redundancy, while samples labeled as −1, representing uncertain or unlabeled instances, were excluded from the analysis. Only samples labeled as 0 (benign) and 1 (malicious) were retained, following common practices in EMBER-based malware classification studies [36].

Feature scaling was subsequently applied using the StandardScaler implementation provided in the scikit-learn library. Numerical attributes were transformed into zero-mean and unit-variance distributions to reduce disparities in feature magnitude. This preprocessing step is particularly important for models such as Logistic Regression, where optimization behavior is sensitive to feature scale.

Standardization transforms each feature according to

$$z = (x - \mu) / \sigma \quad (1)$$

where, x denotes the original feature value, μ represents the feature mean, and σ denotes the standard deviation. This transformation improves numerical stability and reduces disparities in feature magnitude across variables.

Tree-based methods, including Random Forest and Decision Tree, are generally less affected by feature normalization. Nevertheless, all models were trained using the same processed dataset in order to preserve consistency throughout the comparative evaluation. Although scaling does not substantially influence tree-based learning behavior, a unified preprocessing pipeline was maintained to ensure experimental comparability across all classifiers.

C. Feature Processing

The EMBER dataset contains multiple categories of static Portable Executable (PE) features, including entropy measurements, PE header metadata, imported functions, string-based characteristics, and hashed representations extracted from executable binaries [5], [6]. In the present study, all numerical features generated during preprocessing were retained to preserve the full representational capacity of the processed dataset. Explicit dimensionality reduction or feature elimination techniques were not applied.

Missing values were handled during preprocessing to maintain dataset consistency before model training. The retained features included entropy-related measurements, PE header metadata, string-based representations, import-related characteristics, byte histograms, byte-entropy histograms, and other static Portable Executable attributes, all of which have previously been identified as informative indicators for malware classification tasks [4], [24].

After preprocessing, the resulting dataset contained 2,381 numerical features derived from the original EMBER feature representation. No feature selection, dimensionality reduction, or feature elimination procedures were applied. Consequently, all available processed features were retained and used during model training and evaluation.

For interpretability purposes, feature importance analysis focused on a subset of representative human-readable features originating from entropy-related attributes, PE metadata, imported functions, and string-based characteristics. These features were highlighted in the visual analysis because they provide intuitive explanations of model behavior, whereas many EMBER features are represented through hashed or aggregated feature encodings that are less directly interpretable.

D. Model Selection

Four machine learning models were selected to represent different learning paradigms and classification behaviors: Random Forest, Logistic Regression, Decision Tree, and Extreme Gradient Boosting (XGBoost). Random Forest, originally proposed by Breiman [40], was selected because of its strong performance on structured feature representations and its ability to capture complex nonlinear relationships through ensemble aggregation. Logistic Regression was included as a linear baseline to evaluate feature separability within the EMBER representation space. Decision Tree provides an interpretable non-linear alternative, while Extreme Gradient Boosting (XGBoost), introduced by Chen and Guestrin [41], was incorporated as a boosting-based ensemble framework capable of modeling complex feature interactions and serving as a strong contemporary benchmark.

More computationally intensive approaches, such as Support Vector Machines, were not included due to scalability limitations when applied to datasets of EMBER-scale dimensionality and size. The selected models, therefore, provide a balanced comparison across predictive performance, interpretability, computational behavior, and structural complexity [16], [20].

E. Training and Evaluation

The dataset was divided into training and testing subsets using a stratified 80:20 split configuration to preserve class balance across both partitions. This study adopted a randomized evaluation protocol because its primary objective was to perform a controlled comparative assessment of classical machine learning models under identical experimental conditions. Temporal validation based on malware collection chronology was not considered in the present work and remains an important direction for future research.

To reduce sampling bias and improve experimental robustness, all experiments were repeated across multiple random seeds. Performance results are therefore reported as mean values accompanied by standard deviations.

Classification effectiveness was evaluated using five commonly adopted metrics in malware detection research: accuracy, precision, recall, F1-score, and ROC-AUC [1], [15]. ROC-AUC was included to assess each model's ability to distinguish malicious and benign samples across varying decision thresholds, following the evaluation framework proposed by Fawcett [42].

The evaluation metrics were calculated based on the confusion matrix consisting of true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN). Accuracy was computed as:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN}, \quad (2)$$

Precision as

$$Precision = \frac{TP}{TP+FP}, \quad (3)$$

Recall as

$$Recall = \frac{TP}{TP+FN}, \quad (4)$$

and F1-score as

$$F1 = \frac{2TP}{2TP+FP+FN} \quad (5)$$

Performance variability across repeated runs was additionally analyzed to assess experimental stability and reproducibility.

To further investigate model behavior, confusion matrix analysis was conducted to examine false positive and false negative distributions. Feature importance analysis was also performed for tree-based models in order to identify the variables contributing most strongly to classification decisions.

The overall analytical workflow of the proposed methodology is illustrated in Fig. 1.

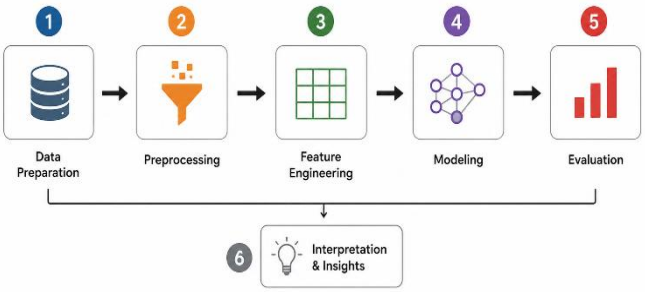

Fig. 1. Overall workflow of the proposed static malware detection framework.

F. Implementation Details

All experiments were conducted using Python 3.10. Machine learning models were implemented using the scikit-learn library (version 1.3) [43], while the XGBoost classifier was implemented using the XGBoost library (version 1.7).

The primary hyperparameter configurations used in the experiments are summarized in Table II. Most models were evaluated using default or near-default parameter settings in order to maintain consistency and reduce the risk of excessive configuration bias during comparison. Hyperparameter optimization was selectively applied to XGBoost using a randomized search strategy. The explored parameters included the number of estimators, learning rate, maximum tree depth, subsampling ratio, and regularization terms. Selective tuning was applied primarily to XGBoost because boosting-based ensemble methods are generally more sensitive to parameter configuration than bagging-based or linear approaches.

TABLE II. MAIN HYPERPARAMETERS OF THE EVALUATED MODELS

Model	Parameter	Setting
Random Forest	n_estimators	100
	max_depth	None
	min_samples_split	2
	random_state	Multiple seeds (42, 52, 62, 72, 82)
XGBoost	n_estimators	500
	max_depth	8
	learning_rate	0.05
	subsample	0.8
	colsample_bytree	0.8
	reg_lambda	1
	gamma	0
	random_state	Multiple seeds (42, 52, 62, 72, 82)
Logistic Regression	solver	lbfgs
	max_iter	1000
	random_state	Multiple seeds (42, 52, 62, 72, 82)
Decision Tree	max_depth	None
	min_samples_split	2
	random_state	Multiple seeds (42, 52, 62, 72, 82)

Models with lower sensitivity to hyperparameter variation were evaluated primarily under standardized configurations to preserve comparability and reduce unnecessary optimization bias across the experimental framework. Hyperparameter optimization was selectively applied to XGBoost using RandomizedSearchCV, as the predictive performance of gradient-boosting models is known to be highly sensitive to parameter configurations. The search process explored combinations of key parameters, including the number of estimators, maximum tree depth, learning rate, subsampling ratio, and column sampling ratio. The final configuration was selected based on cross-validation performance and subsequently used in all experiments. In contrast, Random Forest, Decision Tree, and Logistic Regression were evaluated using widely adopted baseline configurations to maintain methodological consistency and facilitate fair comparative analysis.

To reduce potential comparison bias, the objective of this study was not to identify the globally optimal configuration for

each classifier, but rather to evaluate representative implementations of commonly used machine learning algorithms under a consistent experimental framework. Random Forest, Decision Tree, and Logistic Regression were therefore evaluated using widely adopted baseline configurations, whereas XGBoost received limited hyperparameter optimization because its performance is known to be particularly sensitive to parameter settings. Consequently, the reported results should be interpreted as a comparison between a tuned boosting-based ensemble and standard implementations of alternative classifiers rather than as an exhaustive hyperparameter optimization study.

IV. Results

A. Performance Comparison of Machine Learning Models

The predictive performance of the evaluated machine learning models—Random Forest (RF), XGBoost, Logistic Regression (LR), and Decision Tree (DT)—was analyzed using five standard classification metrics: accuracy, precision, recall, F1-score, and ROC-AUC. The corresponding results are presented in Table III.

Random Forest produced the strongest classification performance across nearly all evaluation metrics. The model achieved an accuracy of 0.9674 ± 0.0005, accompanied by a precision of 0.9769 ± 0.0007 and an F1-score of 0.9671 ± 0.0005. Its ROC-AUC value reached 0.9953 ± 0.0001, indicating an exceptionally strong capability to distinguish between benign and malicious samples across varying decision thresholds. The relatively small standard deviations observed across repeated runs further suggest stable behavior under different random initializations.

XGBoost (Tuned) also demonstrated high predictive capability, achieving an accuracy of 0.9493 ± 0.0007 and a ROC-AUC of 0.9906 ± 0.0002. Although the difference compared with Random Forest appears numerically modest, the separation remained consistent across all evaluation metrics. This indicates that both ensemble-based approaches adapted effectively to the engineered static PE feature representation, yet Random Forest maintained a slight but persistent advantage in classification consistency.

TABLE III. Performance Comparison of Machine Learning Models on the EMBER Dataset

Model	Accuracy	Precision	Recall	F1-score	ROC-AUC	Training Time (s)
Random Forest	0.9674 ± 0.0005	0.9769 ± 0.0007	0.9574 ± 0.0007	0.9671 ± 0.0005	0.9953 ± 0.0001	48.5112 ± 0.5054
XGBoost (Tuned)	0.9493 ± 0.0007	0.9511 ± 0.0009	0.9474 ± 0.0006	0.9492 ± 0.0007	0.9906 ± 0.0002	20.3657 ± 0.3057
Logistic Regression	0.7402 ± 0.0009	0.7355 ± 0.0012	0.7502 ± 0.0012	0.7428 ± 0.0008	0.8047 ± 0.0010	4.3501 ± 1.2262
Decision Tree	0.9417 ± 0.0008	0.9385 ± 0.0015	0.9453 ± 0.0010	0.9419 ± 0.0008	0.9417 ± 0.0008	9.0032 ± 0.2118

To further evaluate whether the observed performance differences between Random Forest and XGBoost were statistically significant, paired t-test and McNemar test analyses were conducted. As shown in Table IV, both tests produced extremely small p-values, indicating that the observed differences are unlikely to be attributable to random variation alone. These findings provide additional evidence supporting the robustness of the comparative results obtained in this study.

TABLE IV. Statistical Significance Analysis Between Random Forest and XGBoost

Test	Comparison	P-value
Paired t-test	RF vs XGBoost	4.26×10^{-8}
McNemar Test	RF vs XGBoost	1.04×10^{-245}

Decision Tree achieved competitive results, with an accuracy of 0.9417 ± 0.0008 and a recall of 0.9453 ± 0.0010. The model showed reasonable discriminative capability despite its substantially simpler structure. However, its ROC-AUC value remained noticeably lower than that of the ensemble methods, suggesting reduced robustness when handling more ambiguous decision boundaries within the dataset.

A markedly different pattern emerged for Logistic Regression. The model obtained an accuracy of 0.7402 ± 0.0009 and ROC-AUC of 0.8047 ± 0.0010, substantially below the other evaluated approaches. Precision and recall also remained comparatively limited, indicating that linear decision boundaries were insufficient to fully capture the complex structural relationships embedded in the static PE features. The performance gap becomes particularly visible in Fig. 2, where the separation between linear and ensemble-based methods is clearly illustrated.

In terms of computational cost, Logistic Regression required the shortest training time, averaging 4.35 ± 1.23 s. Decision Tree and XGBoost followed with training times of 9.00 ± 0.21 s and 20.37 ± 0.31 s, respectively. Random Forest required the longest training duration at 48.51 ± 0.51 s. Even so, the increase in computational overhead was accompanied by consistently superior predictive performance, especially in ROC-AUC and precision, which are highly relevant in malware detection scenarios where false classifications may carry significant operational consequences.

A visual comparison of model performance is presented in Fig. 2.

The comparative results reveal a distinct separation between ensemble-based models and simpler linear approaches. Random Forest and XGBoost maintained consistently high scores across all metrics, suggesting strong compatibility with the statistical and structural characteristics of the EMBER feature representation. The stability observed across repeated experiments also indicates that the extracted features provide highly separable decision regions for tree-based learning methods.

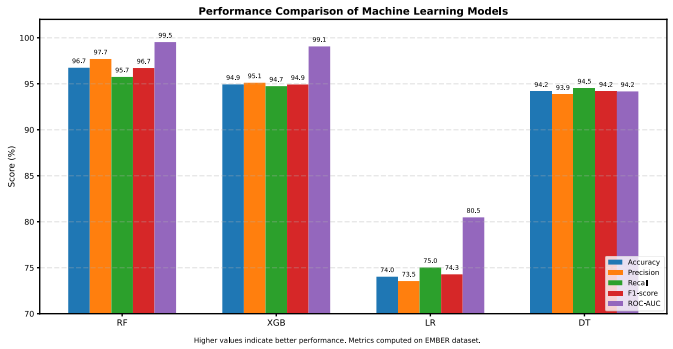

Fig. 2. Comparison of classification performance across evaluated machine learning models.

Another notable observation concerns the relationship between predictive performance and computational efficiency. XGBoost achieved substantially lower training time than Random Forest while still maintaining strong classification capability. Nevertheless, Random Forest consistently preserved higher accuracy, precision, and ROC-AUC values across all experimental runs. This behavior suggests that bagging-based ensemble strategies may provide stronger robustness than boosting approaches under highly structured static malware feature conditions.

To further evaluate whether the performance difference between Random Forest and XGBoost was statistically meaningful, paired statistical analysis was conducted. Both paired t-test and McNemar analysis indicated statistically significant differences between Random Forest and XGBoost ($p < 0.001$), confirming that the observed performance advantage of Random Forest was statistically reliable rather than attributable to random variation.

B. Confusion Matrix Analysis

To examine classification behavior in greater detail, confusion matrix analysis was performed for the Random Forest model. The corresponding results are presented in Fig. 3.

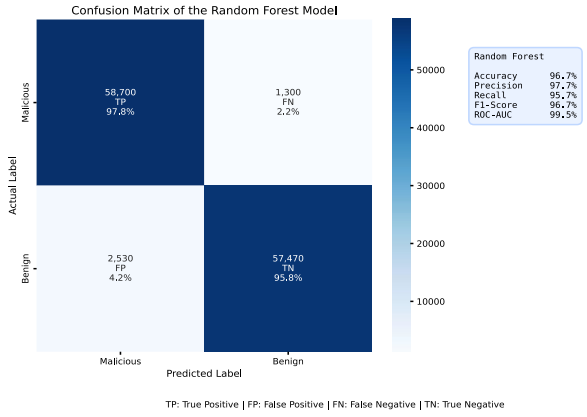

Fig. 3. Confusion matrix of the random forest model for malware detection.

The confusion matrix demonstrates that the model maintained a strong detection capability for both malware and benign samples.

A total of 58,700 malicious files were correctly identified as malware, representing 97.8% of the malicious class. At the same time, 57,470 benign samples were correctly classified, corresponding to 95.8% true negative recognition. These results are consistent with the high accuracy and ROC-AUC values reported previously in Table II, indicating that the model preserved stable discrimination across both classes rather than favoring a single category.

Misclassification rates remained comparatively limited, although several important patterns can still be observed. The model produced 1,300 false negatives, equivalent to 2.2% of malicious samples incorrectly predicted as benign. From a cybersecurity perspective, this category of error is particularly critical because undetected malware may continue to execute within operational environments without triggering defensive mechanisms.

The number of false positives was slightly higher, with 2,530 benign samples incorrectly classified as malicious, corresponding to 4.2% of the benign class. While false positives may increase operational overhead by generating unnecessary alerts or manual inspections, they are generally considered less severe than false negatives in malware detection systems, where missed threats can lead to direct security compromise.

Another notable characteristic of the confusion matrix is the relatively balanced classification behavior across both classes. The model did not exhibit substantial bias toward either malicious or benign predictions, suggesting that the ensemble structure of Random Forest was able to capture stable decision boundaries within the EMBER feature space. This balance is further reflected in the close alignment between precision (97.7%) and recall (95.7%), as illustrated in Fig. 3.

The distribution of errors also provides indirect insight into the nature of the EMBER dataset itself. Samples located near the decision boundary may contain overlapping structural or statistical characteristics, particularly in cases involving obfuscated binaries, packed executables, or benign software with behavior patterns resembling malicious activity. Despite these challenges, the relatively small proportion of misclassified samples indicates that the extracted static features remain highly informative for large-scale malware discrimination tasks.

C. Feature Importance Analysis

Feature importance analysis was conducted using the Random Forest model to identify the variables contributing most strongly to malware classification decisions. The ten highest-ranked features are presented in Fig. 4.

Among the evaluated attributes, strings.entropy emerged as the most influential feature, with an importance score of 0.1088. This result suggests that statistical irregularities within extracted string content provide highly discriminative signals for distinguishing malicious and benign executables. Elevated entropy values are commonly associated with packing, encryption, or obfuscation techniques frequently employed by malware to conceal internal behavior and evade static inspection.

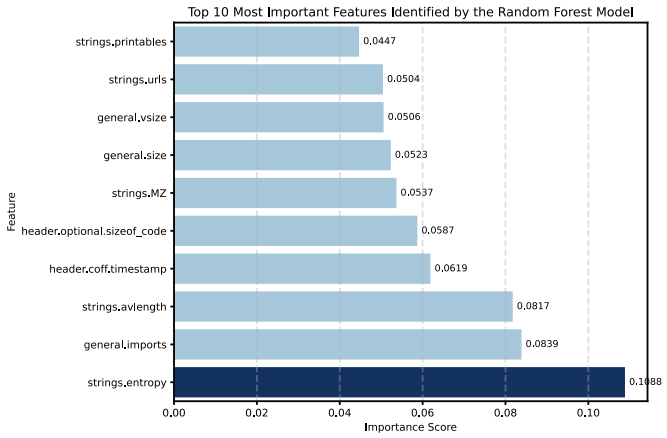

Fig. 4. Top 10 most important features identified by the random forest model.

The second and third most influential features were general.imports (0.0839) and strings.avlength (0.0817). The prominence of general.imports indicate that imported API patterns remain highly informative for malware identification, reflecting differences in functionality and execution behavior between benign and malicious software. Meanwhile, the importance of average string length suggests that textual artifacts embedded within executable files carry measurable structural information relevant to classification.

Several PE header and structural attributes also contributed substantially to model decisions. Features such as header.coff.timestamp (0.0619) and header.optional.sizeof_code (0.0587) ranked among the most relevant variables, indicating that metadata and binary organization continue to provide meaningful indicators of malicious activity. These attributes may capture indirect signatures related to compilation patterns, code organization, or manipulation of executable structures.

Additional features associated with binary size and embedded strings—including strings.MZ, general.size, general.vsize, strings.urls, and strings.printables—also demonstrated notable importance scores ranging from 0.0447 to 0.0537. Although individually less dominant than entropy-related attributes, their collective contribution highlights the multidimensional nature of the EMBER feature space, where both statistical and structural characteristics jointly influence classification behavior.

Another notable observation is the diversity of feature categories represented within the top-ranked variables. Rather than relying on a single dominant indicator, the Random Forest model leveraged complementary information derived from entropy measures, PE structural metadata, import-related characteristics, and string-based representations. This behavior likely contributed to the strong predictive stability observed in the previous evaluation results, particularly under repeated experiments across multiple random seeds.

The feature distribution shown in Fig. 4 also reinforces the suitability of tree-based ensemble methods for static malware analysis. Because Random Forest can capture complex non-linear interactions among heterogeneous attributes, the model is able to integrate multiple weakly correlated indicators into a robust classification framework. This characteristic is particularly advantageous in malware detection environments, where malicious samples often exhibit subtle variations designed to evade signature-based identification.

V. Discussion

The comparison between Random Forest and XGBoost is particularly noteworthy from a methodological perspective. Although XGBoost underwent selective hyperparameter optimization and achieved lower training time, it did not surpass the predictive performance of the bagging-based ensemble model. Furthermore, the superiority of Random Forest remained consistent across repeated experimental runs, suggesting that the observed differences cannot be attributed solely to parameter tuning. Instead, the findings indicate that the interaction between the learning mechanism and the structural characteristics of the EMBER feature representation may play a more influential role than algorithmic complexity alone. Similar observations regarding the effectiveness of ensemble tree methods in malware classification have been reported in previous studies involving structured PE-based feature representations [14], [26].

The results further suggest that feature structure may play a more decisive role than model complexity itself. The EMBER dataset contains a mixture of entropy-related attributes, import-based information, PE metadata, and hashed representations that collectively form highly informative decision regions. It should be noted that the reported feature importance rankings are limited to interpretable features presented for explanatory purposes. The predictive models themselves were trained using the complete set of 2,381 processed EMBER features. Ensemble methods appear particularly well-suited for integrating these heterogeneous feature categories while maintaining robust classification boundaries.

This behavior becomes more evident in the feature importance analysis. Entropy-based variables, especially strings.entropy, emerged as a dominant contributor to the classification process, indicating that statistical irregularities associated with packing, encryption, or obfuscation remain highly informative indicators of malicious activity. Import-related and structural PE features also contributed substantially, reinforcing the idea that executable organization and API dependency patterns preserve detectable traces even under code variation. These observations are consistent with prior work emphasizing the discriminative value of PE structural features in static malware analysis [4], [6].

A different pattern emerged for Logistic Regression. The model demonstrated substantially lower performance across all evaluation metrics, suggesting that linear decision boundaries are insufficient for capturing the complex relationships embedded within the EMBER feature space. Malware classification in large-scale static datasets appears to involve non-linear interactions among structural and statistical attributes, limiting the effectiveness of simpler linear models under realistic conditions.

The confusion matrix analysis provides additional practical insight into classification behavior. Random Forest maintained high true positive and true negative rates while preserving a relatively balanced error distribution across both classes. From

an operational cybersecurity perspective, the low false negative rate is particularly important because undetected malware may continue executing without triggering defensive mechanisms. Although false positives were still present, their proportion remained comparatively limited relative to the scale of the dataset.

The reported results should be interpreted within the context of a controlled benchmark evaluation. Because the objective of this study was comparative model assessment rather than deployment-oriented forecasting, model performance was evaluated using randomized train–test partitions rather than temporally separated malware collections.

Modern malware increasingly employs packing, encryption, and obfuscation techniques that can reduce the effectiveness of purely static feature representations. These conditions may partially explain the false negative cases observed in the present evaluation, where approximately 2.2% of malicious samples were incorrectly classified as benign.

From a computational standpoint, the findings also reveal an important trade-off between efficiency and predictive strength. Random Forest required longer training time than Logistic Regression and Decision Tree, yet the additional computational overhead remained reasonable considering the substantial improvement in detection capability. In practical deployment scenarios, such trade-offs are often acceptable when stronger malware discrimination significantly reduces the risk of missed threats.

Several limitations should nevertheless be acknowledged. First, the study relies exclusively on static analysis features extracted from Portable Executable files. While static analysis offers major advantages in scalability and processing speed, it may be less effective against sophisticated malware designed specifically to evade structural inspection through obfuscation or polymorphic transformation techniques [2].

Second, the evaluation was conducted using a temporally bounded snapshot of the EMBER dataset. Malware ecosystems evolve continuously, and feature distributions may shift over time as attackers adopt new evasion strategies, modify compilation behavior, or alter execution patterns across environments. Prior studies have shown that such concept drift conditions can significantly degrade malware detection performance when models are deployed beyond the temporal scope of their training data [37], [38]. As a result, continuous adaptation and periodic retraining mechanisms may become necessary to preserve long-term detection effectiveness.

Another limitation concerns the scope of the evaluated models. Deep learning architectures were intentionally excluded in order to focus on the balance between predictive performance, interpretability, and computational efficiency. However, representation-learning approaches may capture latent behavioral characteristics that are not fully represented through manually engineered static features. Similarly, the present evaluation did not explicitly measure operational deployment factors such as inference latency, memory consumption, or robustness against adversarial manipulation, all of which are becoming increasingly relevant in modern cybersecurity systems.

The evaluation was conducted on labeled samples only. Although this setting follows the standard EMBER benchmark protocol for supervised learning, future studies may investigate semi-supervised approaches that leverage the available unlabeled instances.

Furthermore, the evaluation employed a randomized train–test split rather than temporal validation. Consequently, the reported results reflect comparative model performance under controlled benchmark conditions and may not fully capture concept drift or evolving malware characteristics encountered in real-world deployment scenarios.

Another limitation concerns the potential overlap of malware families between the training and testing partitions. Although stratified random splitting is commonly adopted in EMBER-based studies, the present work did not explicitly enforce family-aware partitioning. Consequently, related malware families may appear in both subsets, potentially leading to optimistic performance estimates. Future research should investigate family-aware evaluation protocols to better assess model generalization to previously unseen malware families.

More broadly, the findings suggest that model selection in malware detection should be guided by the characteristics of the available feature representation rather than assumptions regarding algorithmic sophistication alone. Within the experimental setting considered in this study, classical ensemble methods provided a favorable balance between predictive performance, robustness, scalability, and interpretability.

VI. Conclusion

This study conducted a large-scale comparative evaluation of machine learning models for static malware detection using the EMBER dataset, with particular emphasis on predictive performance, computational efficiency, and classification behavior under consistent experimental conditions. The results demonstrate that strong malware detection capability can still be achieved through classical machine learning approaches when supported by informative and well-structured feature representations.

Among the evaluated models, Random Forest consistently produced the strongest predictive results across accuracy, precision, F1-score, and ROC-AUC metrics while maintaining stable behavior across multiple random seeds. The model also demonstrated balanced classification characteristics in the confusion matrix analysis, achieving high detection rates for both malicious and benign samples with relatively limited misclassification. Feature importance analysis further showed that entropy-based attributes, import-related patterns, and structural PE characteristics contributed substantially to classification decisions, indicating that static executable features continue to provide highly discriminative signals for large-scale malware analysis.

XGBoost also achieved strong classification performance, although its predictive capability remained slightly below that of Random Forest despite selective hyperparameter optimization. Within the scope of the two ensemble strategies compared here, this finding suggests that increasing boosting-model sophistication through tuning does not necessarily translate into measurable improvement once the feature space already exhibits

strong separability. In contrast, Logistic Regression showed substantially lower effectiveness, reinforcing the non-linear nature of malware classification within the EMBER representation space.

The findings also highlight an important practical implication for cybersecurity system design. Model selection should not be driven exclusively by trends toward increasingly complex architectures, but rather by the compatibility between learning mechanisms, feature structure, and operational requirements. In the present study, the bagging-based ensemble strategy provided a favorable balance between predictive robustness and computational feasibility without requiring excessive optimization procedures.

From an applied perspective, Random Forest remains a highly practical solution for scalable static malware detection environments. Its combination of strong predictive stability, interpretable feature behavior, and moderate computational requirements makes it suitable for deployment scenarios where reliability and efficiency are both critical considerations.

At the same time, several challenges remain open for future research. The current framework relies exclusively on static PE-based features and does not incorporate runtime behavioral analysis, temporal adaptation, or adversarial robustness evaluation. The evaluation is also limited to classical machine learning models; deep learning and transformer-based architectures, which have shown strong results in related EMBER studies, were not included in the present comparison and therefore cannot be directly assessed against the models evaluated here. Future studies may therefore benefit from integrating static and dynamic representations, benchmarking against deep learning-based detectors under matched experimental conditions, exploring adaptive learning strategies for evolving malware ecosystems, and evaluating resilience against adversarial manipulation in real-world operational settings.

Taken together, the results indicate that under highly structured feature conditions such as those provided by EMBER, a well-designed classical ensemble method like Random Forest achieved higher predictive performance than the tuned XGBoost configuration evaluated in this study. Whether this advantage extends to deep learning or other more complex architectures was outside the scope of this study and remains an open question for future comparative work.

ACKNOWLEDGMENT

The authors would like to thank the contributors of the EMBER dataset for making the dataset publicly available for malware detection research. During the preparation of this manuscript, the authors used ChatGPT (OpenAI) and QuillBot for language refinement and grammatical improvement. The authors reviewed and edited the generated content and take full responsibility for the content of this publication.

A Data-Driven Visual Analytics Framework for Transaction-Level Retail Profit Modeling and Decision Support

Donia Badawood
Department of Data Science, College of Computing,
Umm Al-Qura University, Makkah, Saudi Arabia

***Abstract*—Retail companies are becoming increasingly dependent on data science to inform their pricing, assortment, and regional strategy decisions. Profitability drivers, however, are often difficult to interpret because they span product-level, geographic, discount, and operational environments. In most real-life applications, analytics and visualization are treated as two distinct processes, thereby restricting interpretability and undermining their ability to support decision-making. This study provides a decision-level visual analytics model of retail profit analysis at the transaction level. The model is illustrated on the publicly available Superstore dataset as a benchmark, which contains 9,994 order-line records between 2014 and 2017 with the variables time, product, geographic, customer-segment, shipping, sales, discount, and profit. The workflow combines feature engineering, hierarchical slicing, variance-based comparison, and five publication-ready dashboards covering temporal trends, product profitability, geographic heterogeneity, discount sensitivity, and fulfillment context. The overall profit margin in the analyzed dataset is 12.47%, and 18.72% of order lines are loss-making. The findings show uneven profitability across product groups and states, with loss pockets observed in sub-categories such as Tables and Bookcases, as well as in states like Texas and Ohio. There is also a distinct nonlinear discount behavior: profitability tends to be positive at discount rates below about 20%, then margins decline sharply, and loss rates increase exponentially at higher discount rates. These benchmark-specific results illustrate how integrated visual analytics can support structured inspection of pricing, portfolio, and region-related patterns within transaction-level retail data.**

Keywords*—Visual analytics; retail profitability; discount sensitivity; decision support systems; transaction-level analytics; retail data science; profit diagnostics; interactive dashboards

I. Introduction

The contemporary retail decision environment is characterized by an abundance of transactional data, yet constrained by limited analytical integration between modeling and visual interpretation. Transaction systems, e-commerce platforms, loyalty systems, and logistics networks generate extensive records of customer demand, performance data on fulfilling those demands, and commercial results [1]. However, it is often the managerial questions of most interest- where the profit is being made or not, which discounts are strategic or wasteful, how regional market structure is influencing performance- that cannot be answered with mere numbers.

The first challenge is that retail performance is multidimensional [2]. Even revenue growth cannot guarantee profitability, and product mix, discounting, logistics, and regional market conditions can undermine profits. The same commercial principle, even within the same retailer, may yield quite contrasting results across classes and regions [3]. Recent operations and pricing studies suggest that retailers typically face profit-waste or profit-service trade-offs in their inventory and perishable management, as well as in their markdown choices, particularly when confronted with heterogeneous demand and consumer behavior. Similarly, recent studies in the environment of production and operations indicate that it is possible to optimize markdown policies to overcome the processes of overstock and waste and protect profitability, as it demonstrates that it is not the strategy of a greater percentage of discount; it is a variable that should be controlled [4]. The organizational analytics literature, based on empirical evidence, indicates that the quality of information presentation in dashboard visualizations can affect decision quality through perceived task complexity and information satisfaction [2]. Similar research on dashboard adoption highlights that content and design may pose obstacles when dashboards impose excessive cognitive load, leading to lower acceptance despite a robust underlying data pipeline [3]. This means that retail analytics may fail not only in cases of poor case models, but also when information is not circulated and the organization cannot interpret, believe, and act on it.

Although retail analytics toolchains have become more mature, a structural gap persists: to date, in the academic literature and industry practice, analytical modeling and visualization are treated as disjointed, sequential steps rather than a cohesive decision-support system. In many implementations, predictive and diagnostic modeling is implemented in notebooks or analytics platforms, and dashboards are then compiled into a reporting layer. This split raises three recurring issues [5].

Firstly, the simplification of model results is a common practice aimed at concealing uncertainty, heterogeneity, and edge cases using a few measures or fixed graphs. Second, explainability is often introduced after the fact and not as a process of interrogation and counterfactual thinking. Third, assessment usually emphasizes model accuracy while underestimating decision performance, so the system will assist stakeholders in reaching superior conclusions more quickly and with fewer errors. The importance of an interactive visual

analytics system that combines computational intelligence with visualization to enhance the decision-maker's understanding is evident in recent work in visual decision support, where the underlying phenomena are complex and multi-source [6]. Similar studies in visual analytics and explainability suggest that visualization is not just a pretty product but a process of interpretability and trust, especially when a model's behavior is otherwise obscure [4]. Furthermore, systematic research on the assessment of visual analytics shows that analytical evaluation plans are required to ensure that visualization interfaces, in fact, facilitate analytical processes and insight generation, rather than merely enhance visual complexity [7]. The findings indicate that there is one obvious opportunity: retail analytics can be enhanced by closer integration between analytics and visualization, that is, explicitly decision-driven and assessable.

In this study, I address the above gap by introducing a decision-oriented visual analytics framework and demonstrating it using the publicly available Superstore benchmark dataset on Kaggle [8]. The benchmark is designed to illustrate the coordination of descriptive and diagnostic analytics for visualization in a transparent and reproducible way. This dataset is not intended to be representative of real retail operations, and the empirical results presented in this study are not meant to be retail-wide; they are seen as patterns unique to the benchmark.

To develop an end-to-end analytics workflow that identifies profitability drivers and discount-related risk patterns across product and regional dimensions.

To translate analytical findings into visualization constructs that support managerial decision tasks (diagnosis, prioritization, and policy adjustment).

To demonstrate how an integrated analytical and visualization approach improves interpretability and actionability compared with model-only or dashboard-only approaches.

From these objectives, I define the following research questions:

RQ1: How can transaction-level retail benchmark data be structured to support integrated descriptive and diagnostic visual analytics?

RQ2: Which dashboard structures best support inspection tasks such as identifying loss pockets, comparing product and geographic segments, and examining discount sensitivity?

RQ3: How does a coordinated multi-view workflow support interpretability relative to isolated summaries?

RQ4: What benchmark-specific patterns become visible when the proposed framework is applied to the Superstore dataset?

This work makes four distinct contributions to the fields of retail analytics and visual decision support:

A transparent decision-centric visual analytics workflow that links data preparation, derived indicators, and coordinated inspection tasks.

A structured dashboard architecture aligned with temporal, product, geographic, discount, and fulfillment-oriented diagnostic views.

An illustrative benchmark demonstration showing how heterogeneous patterns can be surfaced without treating the benchmark dataset as a basis for real-world retail generalization.

The rest of this study is organized as follows. Section II presents a literature review of related work in retail analytics, decision support, dashboards, and visual analytics. Section III outlines the Superstore dataset, feature engineering, and the formulation of the analytical problem, and provides the methodology, comprising preprocessing, descriptive and diagnostic analytics, and visualization design principles. Section IV presents findings that support profitability trends, discount-profit correlations, and regional heterogeneity, and provides a list of decision-oriented figures and tables. Section V presents the implications for retail decision-making and design recommendations for analytics dashboards. Section VI presents the conclusion and future work.

II. Related Work

The section situates the present research within a hybrid of three overlapping research directions: data science pipelines, retail analytics, and decision support visual analytics.

A. Data Science Pipelines for Business Analytics

Modern data science practice is structured as a pipeline that includes data acquisition and preparation, modeling and evaluation, and deployment to organizational decision systems. Data quality, feature engineering, and validation significantly affect reliability and business impact [9, 10]. In reality, however, technical pipelines can barely generate value. According to Schmidt [11], the failure of most analytics projects is not due to inaccurate models but to how they fit into business processes. Similarly, Mikalef et al. [12] indicate that the analytics potential must be aligned with organizational decision-making designs to provide measurable performance effects. These findings indicate that accuracy in modeling is not sufficient. More recent studies on decision support systems build on the work of analytics pipelines by incorporating interactive aspects. Basole et al. [13] state that AI-based analytics are expected to be deployed in visual analytics to support exploration and reasoning. Chakraborty and Rana [14] also demonstrate that the quality of the decision is determined by dashboard design and visualization. Explainable artificial intelligence is a research area that focuses on integrating interpretability mechanisms into workflows [15, 16]. This void is especially acute where retail data are heterogeneous, and only the decision-making cycle is fast.

B. Retail Analytics: Demand Patterns, Discount–Profit Relationships

The retail analytics literature spans demand prediction, price optimization, inventory management, and promotion design. One of the main points is the correlation between the demand stimulation (e.g., discounts, displays) and profitability. Li et al. [17] demonstrate nonlinear effects of discounting strategies on profit and waste in perishable retail, modifying the previously known understanding of discounting and its impact on profit.

Riesenegger and Hubner [4] show that markdown optimization is necessary to ensure that revenue is recovered and the margin is not compromised. The reaction of consumers to discounts is non-homogeneous and time- and presentation-sensitive [18, 19]. Profit outcomes in the omnichannel are further affected by regional demand variability and fulfillment costs [20]. Demand forecasting has been transformed into nonlinear forecasting, machine learning, and deep learning models that can now predict demand trends [21, 22]. Nevertheless, the accuracy of projections often does not provide the manager with insight. Retail managers must know why performance should differ across segments, rather than the approximate degree to which it is expected to differ. Recent literature indicates that there are still issues in converting analytical outputs into strategic retail decisions [23]. Besides, the aspect of spatial and segment heterogeneity is underdeveloped in integrated structures. Numerous studies report concentration findings or fixed results, and few offer evidence of the relationship between profitability dynamics at the Product, Region, and Customer group levels and operational decision-making.

C. Visualization and Visual Analytics for Decision-Making

Information visualization studies have determined that effective graphical representations require fewer cognitive resources and greater pattern recognition [24]. The idea is developed as visual analytics, which is computational analysis and interactive visualization to support arguments in complex fields [25]. The explainability and transparency of AI systems have been considered in recent work. The survey by Hohman et al. [15] elucidates explainable deep learning visual analytics, as visualization enables one to comprehend complex models. One review of visual analytics system evaluation techniques is Cui [26], which focuses on insight generation and out-of-the-box, usability-based measures of decision performance. Cognitive ergonomics and the use of the dashboard are required in organizations not only to enhance data quality but also to support cognitive ergonomics. Too much information can make them difficult to operate, as Allam demonstrates, due to cognitive load [27], and research has shown that visualization design can affect task trust and efficiency [14, 28]. The use of interactive capabilities such as filtering, drill-down, and brushing enables users to compare categories, regions, and time periods when analyzing retail data. However, even in real-world analytics, bad interaction design may complicate and make it less readable than it could be. This is why business intelligence, as a course of study, has brought to the fore the need to align visualization with decision-making initiatives and management activities within organizations. Despite this, predictive modeling and interactive visualization have not been fully achieved in most real-life applications. Explainable AI studies tend to focus on model-level explanations, whereas business intelligence studies focus on descriptive dashboards. The visualization design will need to be created not as a by-product but as an analytic companion to bridge these streams.

D. Synthesis: Limitations in Prior Work and Positioning of This Study

The reviewed literature reveals three structural gaps that collectively motivate the proposed framework, which focuses on reproducibility and performance and generally does not go beyond visualization as part of the analytical process. Model accuracy is prioritized, with secondary attention to decision interpretability. Second, existing retail analytics studies show that discounting and demand management are both economically complex, yet they usually present findings in aggregated or fixed-table forms. There are very few studies that specifically explore the role of interactive visualization in revealing heterogeneity in the discount-profit relation within product hierarchies and geographic areas. Third, the visual analytics research advances the ideals of interaction and cognitive support. The literature reviewed indicates a gap at the intersection of retail analytics, dashboard design, and visual analytics methodology. While a lot of effort has been devoted to forecasting, optimization, or static reporting, less effort has been devoted to compact, reproducible visual analytics workflows for transaction-level business benchmark data. In this work, we fill this gap by proposing a coordinated system for descriptive and diagnostic inspection and demonstrating its application to the Superstore benchmark dataset. The study demonstrates a level of analytical design and interpretability but does not yield validated retail policy inferences. To place the current research in the existing literature regarding retail analytics, data science pipelines, and visual analytics. Table I summarizes the main representative studies, emphasizing their analytical methods, data sources, visualizations, and limitations.

III. METHODOLOGY

The methodology is described as an analytical workflow that combines data preparation with descriptive and diagnostic analysis and decision-oriented visualization, rather than a strictly formal mathematical model. The methodology is designed to be reproducible, transparent, and explicitly oriented toward decision-focused retail analytics. Fig. 1 shows the workflow analysis of this study.

The process commences with the receipt of retail information (based on transactions), i.e., product hierarchy, geography, customer segments, and commercial variables (sales, profit, and discount). This data is then pre-processed and converted into predictive data, such as clean and verified data, along with suggested variables like profit margin, loss indicators, and shipping delays. Second step: performance-over-time data, aggregated master data, product-hierarchy profitability, geographic trends, and discount sensitivity are added to the data set. They are even more powerful data structures that enable descriptive and diagnostic analytics to identify profit concentration, pockets of loss, and regional performance variance. The outcomes of the analysis are delivered via a visual analytics dashboard, making it easy to observe the influence of time, product profitability, geographical heterogeneity, and price changes. Finally, the framework assists managers in making decisions by providing clear implications for discount governance, product portfolio optimization, and regional strategy refinement.

TABLE I. LITERATURE MATRIX SUMMARIZING PRIOR STUDIES ON DATA SCIENCE PIPELINES, RETAIL ANALYTICS, AND VISUALIZATION-BASED DECISION SUPPORT

Ref.	Study focus	Core methods	Data/domain	Visualization/ interaction	Evaluation style	Main takeaway	Key limitation (gap)
[4]	Markdown optimization under constraints	Optimization; policy modeling	Retail inventory	Static	Quantitative	Need to balance profitability vs other objectives	Weak integration with interpretability/visualization
[17]	Discounting + presentation impacts profit/waste	Analytical modeling; empirical evaluation	Retail (perishables)	Mostly static	Quantitative/field or model-based	Discount effects are nonlinear and context-dependent	Limited interactive exploration for the decision workflow
[18]	Price promotion response heterogeneity	Econometrics / causal inference (typical)	Retail transactions	Minimal	Empirical	Promo effects vary across customers/products	Often reported in aggregates
[19]	Promotion timing and depth	Empirical + modeling	Retail pricing	Minimal	Empirical	Timing/depth shapes margin outcomes	Limited decision-interface design
[20]	Omnichannel/regional cost and demand variation	Empirical/operations models	Retail supply + demand	Low–moderate	Applied empirical	Geography affects profitability via cost and service differences	Often lacks interactive geo drill-down
[21]	Retail demand forecasting (ML)	ML regression; feature engineering	Sales time series	Minimal	Predictive metrics	ML improves accuracy on nonlinear patterns	Doesn't ensure interpretability/actionability
[22]	Deep learning for forecasting	LSTM/TCN/transformers (typical)	Large retail time series	Minimal	Predictive benchmarks	Advanced models can outperform baselines	Often "black-box" to business users
[23]	Data-driven retail transformation	Conceptual + empirical synthesis	Retail organizations	Moderate	Case/field evidence	Adoption barriers include skills + usability	Limited concrete design for analytics-viz integration
[24]	Information visualization principles	Perception/cognition theory	Cross-domain	Core principles	Laboratory + theorys	Visual encoding affects comprehension	Doesn't prescribe domain-specific KPIs

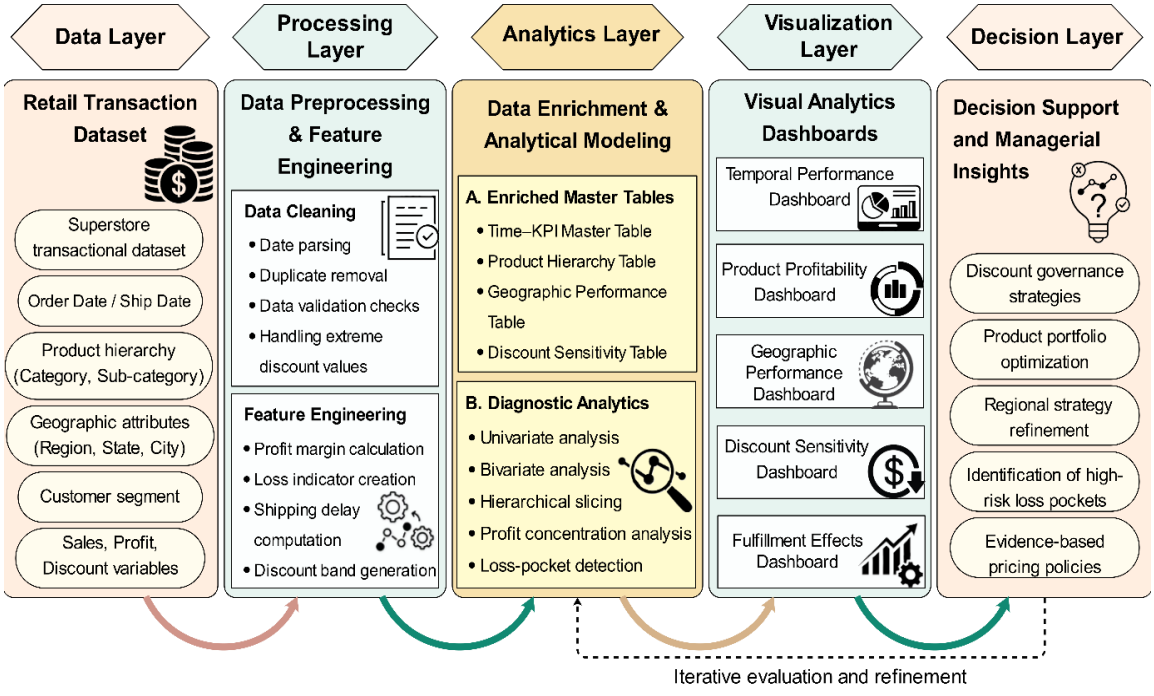

Fig. 1. Analysis pipeline of the proposed decision-centric retail data science framework.

A. Dataset Description

This study employs the publicly available Sample Superstore retail transactions dataset [8], having 9994 observations of order lines and 21 variables. Some records capture every product purchased in an order, including temporal, geographic, customer, product, and financial attributes. The database includes a couple of years of data, and data regarding the performance of transactions in four regions in the United States (South, West, Central, East), three groups of customers (Consumer, Corporate, Home Office), and three categories of upper-level products (Furniture, Office Supplies, Technology), which are subdivided into sub-categories. The temporal variables (Order Date, Ship Date), geographic variables (Region, State, City, Postal Code), segmentation of the customer (Segment), the product hierarchy (Category, Sub-Category, Product Name), operational variable (Ship Mode), and the commercial measures (s_i), Quantity (q_i), Discount (d_i), and Profit (π_i)) will be the major variables of each transaction.

Let the dataset be defined as:

$$\mathcal{D} = \{x_i\}_{i=1}^{9994} \tag{1}$$

where each observation is:

$$x_i = (t_i^o, t_i^s, g_i, c_i, seg_i, s_i, q_i, d_i, \pi_i) \tag{2}$$

This structure supports hierarchical aggregation, cross-sectional analysis, and time-based modeling. This study uses the publicly available Sample Superstore data as a benchmark to illustrate the proposed visual analytics structure. The dataset is popular in education and business intelligence presentations because it includes transaction-level retail information, including time, geographic, product, customer segment, discount, sales, and profit variables. The data used in the current research is not considered representative of the entire retail industry; it is used as a canned example to demonstrate how descriptive and diagnostic visual analytics can be integrated into a decision-support analytical process.

B. Data Schema and Variable Roles

I classify variables into identifiers, categorical descriptors, temporal features, and numerical values. The identifiers (Row ID, Order ID, Customer ID, and Product ID) are used for grouping and data integrity validation but are not considered explanatory predictors. For categorical variables, let:

$$\mathcal{C} = \{\text{Segment,Ship Mode,Region,State,City,Category,Sub-Category}\} \tag{3}$$

These variables define stratification levels for profitability and discount sensitivity analysis.

For the grouping variable G, define subset:

$$\mathcal{D}_g = \{x_i \in \mathcal{D} \mid G_i = g\} \tag{4}$$

For temporal variables, from Order Date t_i^o, I derive:

$$\phi_t(t_i^o) = \{\text{Year}_i, \text{Month}_i, \text{Quarter}_i\} \tag{5}$$

Shipping delay is defined as:

$$\Delta_i = t_i^s - t_i^o \tag{6}$$

This supports fulfillment performance and seasonality analysis.

For numerical variables, core commercial measures:

$$s_i \geq 0, q_i \in \mathbb{Z}^+, 0 \leq d_i \leq 0.8, \pi_i \in \mathbb{R} \tag{7}$$

Profit margin:

$$m_i = \frac{\pi_i}{s_i + \epsilon} \tag{8}$$

where, ϵ prevents division instability.

Aggregated group profit:

$$\Pi(g) = \sum_{x_i \in \mathcal{D}_g} \pi s_i \tag{9}$$

Aggregated group sales:

$$S(g) = \sum_{x_i \in \mathcal{D}_g} s_i \tag{10}$$

Group margin:

$$M(g) = \frac{\Pi(g)}{S(g) + \epsilon} \tag{11}$$

C. Problem Formulation

The analytical problem statement of the present research is as follows: where do profits lie, where do losses occur, and how can the patterns of losses and profitability be shown using hierarchical, temporal, geographic, and discount-based visual analytics. The study, rather than formal mathematical abstraction, emphasizes reproducible analytical steps that can aid interpretation and managerial diagnosis. The concept of a 'loss pocket' is defined for this study as a 'product group', 'geographic ', or 'discount group' that meets two criteria: 1) negative aggregate profit, and 2) materiality in terms of the visible aggregate contribution to the relevant 'slice of analysis '. As the benchmark study is descriptive in nature, materiality is treated as a threshold for interpretive salience, which is more of an operational definition. Negative profit and non-zero sales or order volume within the grouping are used to identify loss pockets in the present analysis.

1) Primary problem: Profitability Drivers and Discount Sensitivity: Retail managers should be familiar with what drives profitability and where discounting is killing the money.

I formalize profit as:

$$\pi_i = s_i - c_i^{eff} \tag{12}$$

where, c_i^{eff} represents the effective cost (implicitly embedded in the dataset's profit values).

I model profit drivers as:

$$\pi_i = f(d_i, q_i, seg_i, g_i, c_i, t_i) + \epsilon_i \tag{13}$$

The first objective is to identify group-level profit contributions:

$$\Pi(g, c) = \sum_{x_i \in (g,c)} \pi_i \tag{14}$$

The second objective is to quantify discount sensitivity:

Estimate conditional expectation:

$$\mathbb{E}[\pi \mid d] \tag{15}$$

Operationally, partition the discount into K bins:

$$B_k = \{i \mid d_i \in [a_k, a_{k+1})\} \tag{16}$$

Then:

$$\bar{\pi}_k = \frac{1}{|B_k|}\sum_{i \in B_k} \pi_i \tag{17}$$

The third one is to detect "loss pockets":

$$\text{Loss Pocket}(g,c) = \begin{cases} 1 & \text{if } \Pi(g,c) < 0 \text{ and } S(g,c) > \tau \\ 0 & \text{otherwise} \end{cases} \tag{18}$$

where, τ is a minimum materiality threshold.

The main issue that is to be resolved here is: 1) what sub-categories are value-destroying? 2) What are the levels of margin collapse at which the discount levels are? 3) Are there inefficiencies regarding regions in response to discounts?

2) Secondary problem: Profit Classification (Loss Risk Prediction): To support proactive decision-making, I define a binary classification task.

Define:

$$L_i = \begin{cases} 1 & \text{if } \pi_i < 0 \\ 0 & \text{otherwise} \end{cases} \tag{19}$$

I aim to estimate:

$$P(L_i = 1 \mid X_i) \tag{20}$$

where the feature vector:

$$X_i = \{d_i, q_i, seg_i, g_i, c_i, \Delta_i, \phi_t(t_i^o)\} \tag{21}$$

A classifier f produces:

$$\hat{p}_i = f(X_i) \tag{22}$$

Decision rule:

$$\hat{L}_i = \begin{cases} 1 & \text{if } \hat{p}_i \geq \theta \\ 0 & \text{otherwise} \end{cases} \tag{23}$$

This task identifies high-risk combinations of discount, category, and geography likely to result in negative profit. Although the classification of loss risks is conceptually applicable to the framework's future decision-support extension, the current research primarily focuses on descriptive and diagnostic analytics of the Superstore dataset. Thus, predictive modeling is considered a methodological extension rather than a key finding.

D. Data Preprocessing

Data preprocessing ensures structural consistency, numerical validity, and analytical readiness. Let the transactional dataset be defined as

$$\mathcal{D} = \{x_i\}_{i=1}^N \tag{24}$$

where each transaction x_i includes time, geographic, categorical, and financial attributes as defined in Section III.

1) Date parsing and temporal standardization: Order Date () and Ship Date () were parsed into standardized datetime formats. From I derived temporal features:$t_i^o t_i^s t_i^o$

$$\phi_t(t_i^o) = \{\text{Year}_i, \text{Month}_i, \text{Quarter}_i\} \tag{25}$$

Shipping delay was computed as:

$$\Delta_i = t_i^s - t_i^o \tag{26}$$

Transactions with $\Delta_i < 0$ were flagged as inconsistencies and verified. Negative delays were considered data-entry anomalies and excluded if confirmed erroneous.

2) Duplicate detection: Duplicates were examined using a composite key:

$$\mathcal{K}_i = (\text{OrderID}_i, \text{ProductID}_i, t_i^o) \tag{27}$$

If two records shared identical $\mathcal{K}_i$ and identical financial values, one instance was removed. Partial duplicates were retained when representing legitimate multi-line order structures.

3) Sanity checks and boundary validation: Financial and operational constraints were validated:

$$s_i \geq 0, q_i > 0, 0 \leq d_i \leq 1 \tag{28}$$

Profit values π_i were allowed to be negative, reflecting legitimate loss-making transactions. Extreme discounts (e.g., $d_i > 0.8$) were retained but flagged for sensitivity analysis due to their disproportionate impact on margins.

Profit margin was defined as:

$$m_i = \frac{\pi_i}{s_i + \epsilon} \tag{29}$$

where, ϵ prevents division by zero.

4) Feature engineering: To enable hierarchical and conditional analysis, additional features were constructed, i.e., 1) Profit margin, 2) Shipping delay, and 3) Binary loss indicator:$m_i \Delta_i$

$$L_i = \begin{cases} 1, & \pi_i < 0 \\ 0, & \text{otherwise} \end{cases} \tag{30}$$

Categorical variables were encoded for modeling using one-hot encoding or target encoding, depending on the analytical stage.

E. Exploratory Data Analysis (EDA) Strategy

EDA followed a structured progression: univariate → bivariate → multivariate slicing.

1) Univariate analysis: For each numerical variable, summary statistics were computed:$X \in \{s, \pi, d, q, m\}$

$$\mu_X = \frac{1}{N}\sum_{i=1}^N X_i \tag{31}$$

$$\sigma_X^2 = \frac{1}{N-1}\sum_{i=1}^N (X_i - \mu_X)^2 \tag{32}$$

Distributional properties such as skewness were examined:

$$\text{Skew}(X) = \frac{1}{N}\sum\left(\frac{X_i-\mu_X}{\sigma_X}\right)^3 \quad (33)$$

This identifies heavy-tailed sales and profit distributions typical in retail.

2) Bivariate analysis: To evaluate discount–profit relationships, Pearson correlation was computed:

$$\rho_{d,\pi} = \frac{\sum(d_i-\mu_d)(\pi_i-\mu_\pi)}{\sqrt{\sum(d_i-\mu_d)^2}\sqrt{\sum(\pi_i-\mu_\pi)^2}} \quad (34)$$

Conditional profit means across discount bins B_k:

$$\bar{\pi}_k = \frac{1}{|B_k|}\sum_{i\in B_k}\pi_i \quad (35)$$

This provides a non-parametric view of discount sensitivity.

3) Segment and regional slicing: Group-level aggregation supports heterogeneity analysis. For the grouping variable :G

$$\Pi(g) = \sum_{i\in\mathcal{D}_g}\pi_i \quad (36)$$

$$S(g) = \sum_{i\in\mathcal{D}_g}s_i \quad (37)$$

$$M(g) = \frac{\Pi(g)}{S(g)+\epsilon} \quad (38)$$

Two-way slicing (e.g., Region × Sub-Category) was computed as:

$$\Pi(g,h) = \sum_{i\in\mathcal{D}_{g,h}}\pi_i \quad (39)$$

Variance decomposition assessed between-group effects:

$$\text{Var}(\pi) = \text{Var}(\mathbb{E}[\pi \mid G]) + \mathbb{E}[\text{Var}(\pi \mid G)] \quad (40)$$

The framework is a multi-hierarchical aggregate one, with the interpretation having to be sensitive to aggregation bias. Generalizations at the category, state, or regional level do not necessarily reflect behavior at the transaction level and vice versa. The framework thus promotes cross-level analysis of findings rather than limiting analysis to a summary table or graph. Sub-category and state-level inspection, in particular, is used as a safeguard against higher-level masking of the heterogeneity.

F. Descriptive and Diagnostic Analytics

In the present study, descriptive and diagnostic analytics are the focus. The analytical methods are designed to provide transparency in the inspection of profitability patterns over time, product hierarchy, geography, discount band, and fulfillment conditions. It is therefore more important to group aggregate data, provide comparative slicing, implement discount band analysis, and interpret cross-views than to model predictive analysis. Predictive techniques, such as loss-risk classification, would apply to potential future extensions of the framework but are not within the empirical focus of this manuscript.

G. Visualization Design Principles

In this context, visualization serves as a quantitative workflow companion, which is analytical in nature. Its visual design focuses on tracking time, hierarchical comparison, geographic heterogeneity, sensitivity to discounts, and operational context. It is intended to enhance interpretability and decision-making readiness, but not to maximize visual complexity.

$$\mathcal{D}' = \{x_i \in \mathcal{D}\text{:filter condition holds}\} \quad (41)$$

Drill-down supports hierarchical analysis, i.e., Region → State → Category → Sub-Category.

The uncertainty and variability for regression:

$$\hat{y}_i \pm 1.96\cdot\hat{\sigma} \quad (42)$$

For classification, the ROC curve is defined as:

$$\text{AUC} = \int_0^1 TPR(FP\,R^{-1}(u))du \quad (43)$$

Confidence intervals for group margins are computed using bootstrap resampling.

H. Evaluation Plan

This manuscript does not include descriptive/diagnostic benchmark demonstration. Does not report formal predictive evaluation and/or user-based decision-support experiments. Therefore, the framework is evaluated here for the transparency of the workflow, the coherence of the linked visual views, and the interpretability of the outputs, using a benchmark. The data were pre-processed by parsing the order and ship dates, deriving temporal fields, computing profit margin and shipping delay, screening for duplicates based on transaction identifier and matching financial data, as well as building grouped structures for category and state/region/discount-band inspection.

IV. Results

The results reported in this section are descriptive benchmark outputs. They are intended to support interpretive comparison across linked views and are not presented as statistically validated causal relationships. The analysis is conducted on the Superstore transactional dataset, comprising 9,994 order-line records spanning the period 2014 to 2017. Each order includes the order and shipping dates, customer group, product hierarchy (Category and Sub-Category), geographic information (Region, State, City), and core commercial results (Sales, Discount, Profit). To facilitate time-consistent reporting, I combined the data into time-based performance reporting, including sales, profit, margin, discount intensity, and the proportion of loss-making transactions. The time-highlighted summary is reported in the resulting time as shown in Table II.

Across all records, total sales are 2,297,201, and total profit is 286,397, corresponding to an overall profit margin of 12.47% (see Table II). Aggregate profitability is positive, but loss-making transactions are typical: 18.72% of order lines record negative profit. The healthy overall margin and high level of loss indicate an uneven distribution of profitability and an incentive for diagnostic breakdowns, further subsections (product hierarchy, geography, and discount sensitivity).

The distribution of the dataset is typical of a retail transaction: the sales distribution is right-skewed (there are many low-value order lines), and profit is left-skewed (there is a substantial tail), indicating a high loss rate. The concentration of discounts is low to moderate, and it includes discrete and recurrent components, which are standardized promotion

schedules rather than continuous discounting. All of the above properties indicate that aggregate statistics can mask clumps of concentrated negative profitability, which is why slice-based diagnostics by category, geography, and discount bands are needed in future result sections.

The multi-month performance view is shown in Fig. 2. The sales shown in Fig. 2(a) indicate seasonality and an upward trend over the study period. Monthly profit is depicted in Fig. 2(b), and its movement is sharper in relation to sales. The monthly profit margin is shown in Fig. 2(c), with periods of compressed margins and negative monthly margins. Fig. 2 (d) plots the monthly average discount and the monthly loss rate, and it is possible to visually check whether the greater the intensity of the discount, the greater the incidence of the loss-making transactions.

TABLE II. TIME-BASED KPIS ANNUAL AGGREGATION

Time period	Sales	Profit	Profit margin	Order lines	Avg. discount	Loss rate
2014	484,247.50	49,543.97	10.23%	1,993	0.1583	18.92%
2015	470,532.51	61,618.60	13.10%	2,102	0.1556	18.89%
2016	609,205.60	81,795.17	13.43%	2,587	0.1547	18.44%
2017	733,215.26	93,439.27	12.74%	3,312	0.1565	18.72%
Overall (2014–2017)	2,297,200.86	286,396.95	12.47%	9,994	0.1563	18.72%

[a] *Notes*: "Order lines" count the number of transactional records. "Loss rate" is the share of records with negative profit.

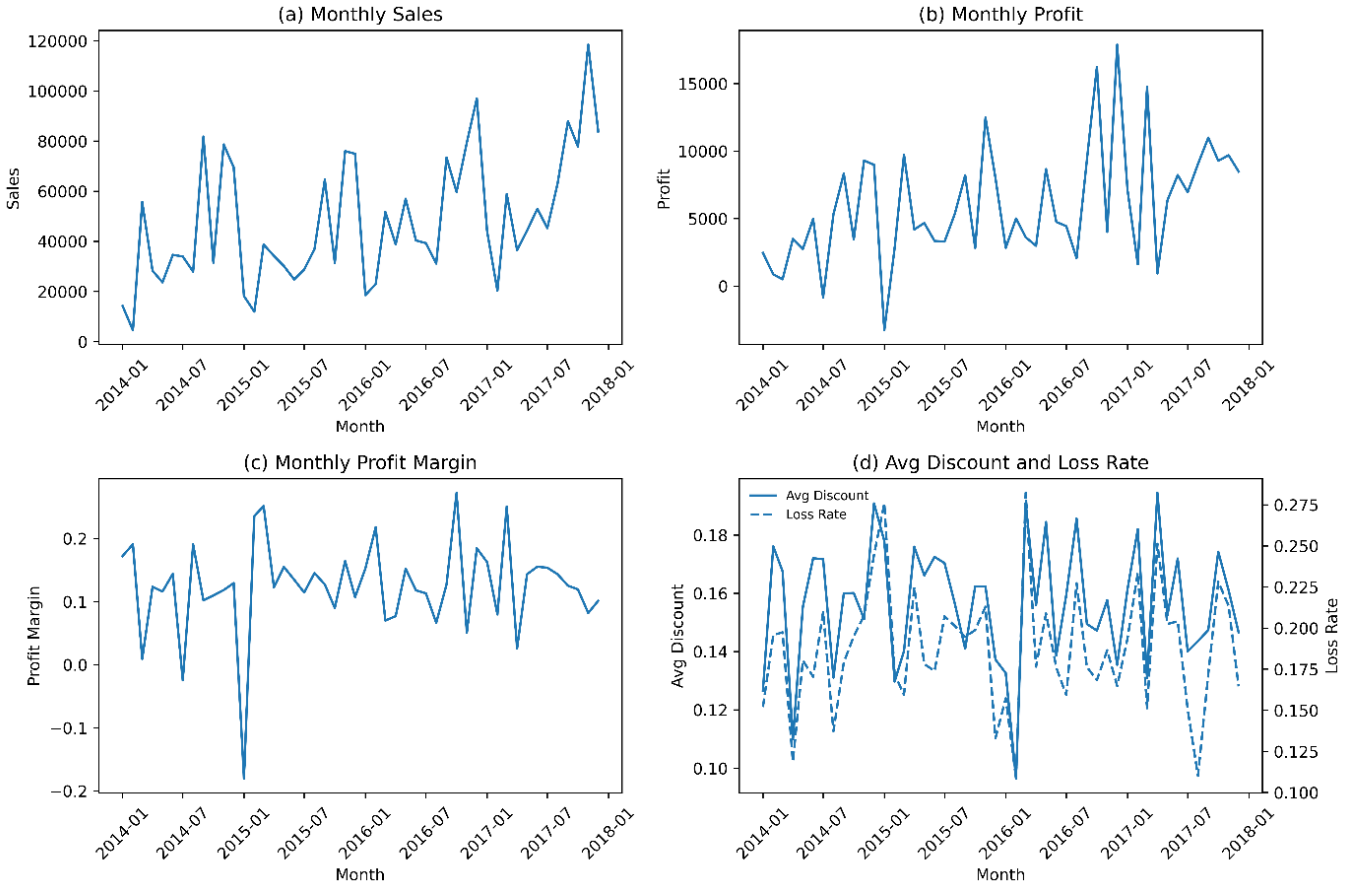

Fig. 2. Temporal performance dashboard.

The product hierarchy analysis indicates that structural disparities among the three top-level categories are high. As shown in Table III, technology records the highest total sales (836,154) and the highest profit contribution (145,455), which represents a margin of 17.40. Office Supplies is next with sales of 719,047 and profit of 122,491 (margin 17.04%).

Furniture, however, at sales of 741,999, yields only 18,451 in profit and a margin of 2.49, which is significantly low. This implies the existence of systemic profitability limits in the Furniture category. The sub-category analysis reveals a high level of profit concentration in Copiers, Phones, Accessories, and Paper. Copiers will generate a profit of 55,618 with a margin of 37.20 from only 68 transactions.

On the other hand, tables are the largest structural loss pocket in the hierarchy, with high sales volume, negative aggregate profit, and a loss rate exceeding 63%. Fig. 3 shows graphical summaries of these patterns: Fig. 3(a) compares category-level sales and profits side by side. These ranking patterns are shown in Fig. 3(b), and the spread of margins across subcategories is shown in Fig. 3(c). Fig. 3(d) shows the loss rates for sub-categories, with some lines consistently yielding negative results across all transactions.

Transaction-level heterogeneity is observed across subcategories. For example, Binders have negative volatility and high dispersion, yet show positive aggregate profit despite a high loss rate (40.25%). This type of internal dispersion makes it possible that aggregate category margins will obscure micro-level inefficiencies.

There is high geographic asymmetry. California brings the largest profit (76,381) from sales of 457,688 (margin 16.69%), and New York has the next-highest profit, 74,039 (margin 23.82%). The summary of geographic sales, profit, and margin distribution among the representative states is provided in Table IV, which reports differences in regional performance and identifies which states are structural loss pockets.

TABLE III. PROFITABILITY CONSTRAINTS WITHIN THE PRODUCT HIERARCHY

Category	Sub-Category	Sales	Profit	Margin	Avg. Discount	Orders	Loss Rate
Technology	Copiers	149,528	55,618	37.20%	0.162	68	0.00%
Technology	Phones	330,007	44,516	13.49%	0.155	889	15.30%
Technology	Accessories	167,380	41,937	25.05%	0.078	775	11.74%
Office Supplies	Paper	78,479	34,054	43.39%	0.075	1,370	0.00%
Office Supplies	Binders	203,413	30,222	14.86%	0.372	1,523	40.25%
Furniture	Tables	206,966	–17,725	–8.56%	0.261	319	63.64%
Furniture	Bookcases	114,880	–3,473	–3.02%	0.211	228	47.81%

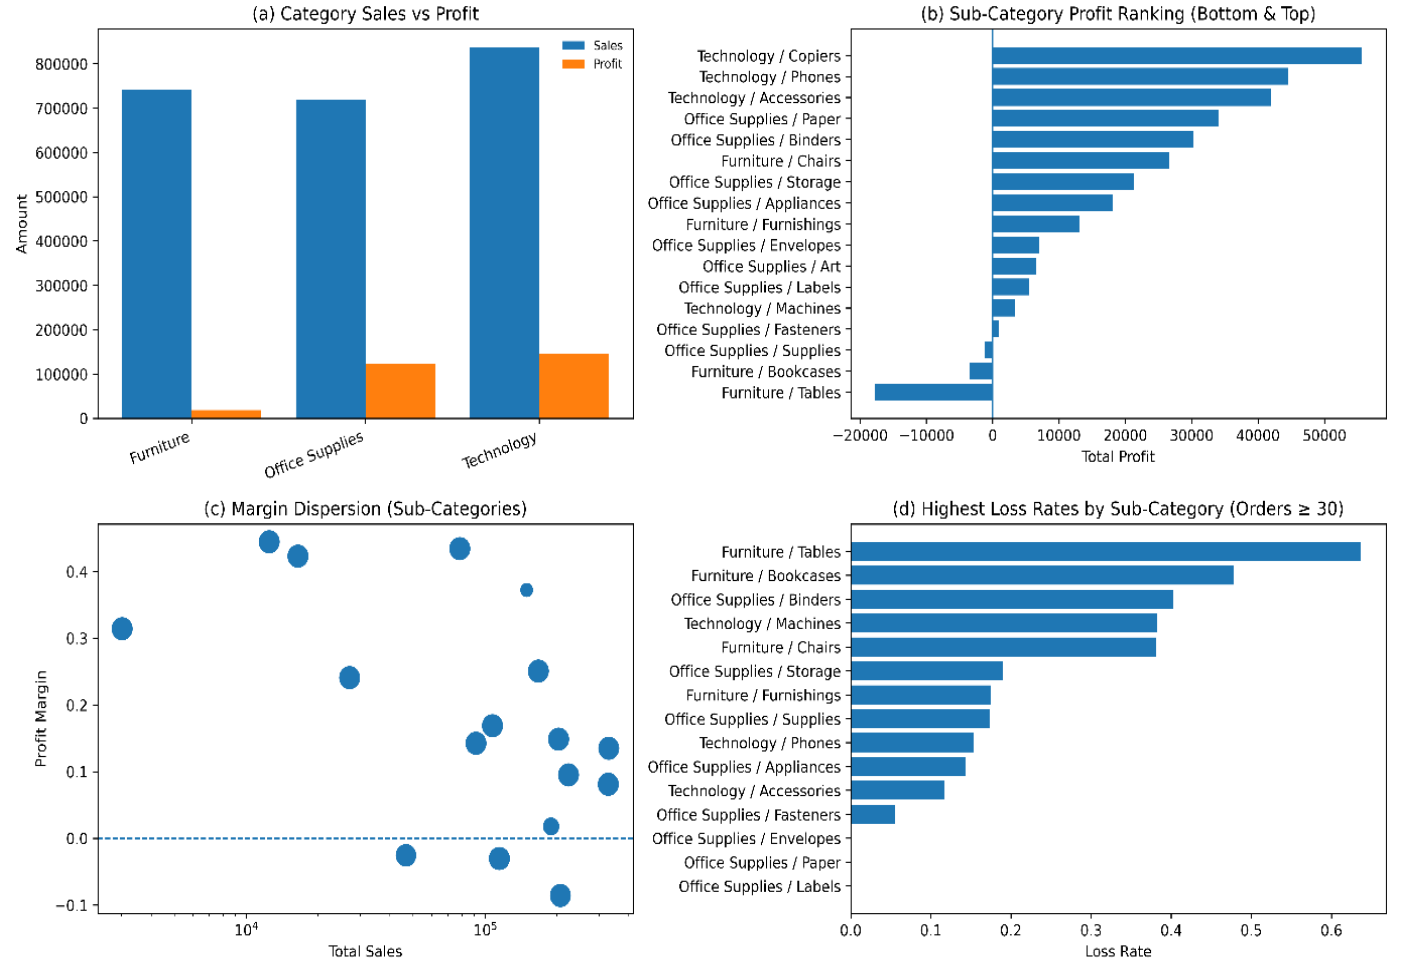

Fig. 3. Product profitability dashboard.

TABLE IV. GEOGRAPHIC PERFORMANCE (SELECTED STATES)

Region	State	Sales	Profit	Margin	Avg. Discount	Orders
West	California	457,688	76,381	16.69%	0.073	2,001
East	New York	310,876	74,039	23.82%	0.055	1,128
West	Washington	138,641	33,403	24.09%	0.064	506
Central	Texas	170,188	–25,729	–15.12%	0.370	985
East	Ohio	78,258	–16,971	–21.69%	0.325	469
Central	Illinois	80,166	–12,608	–15.73%	0.390	492

Texas, Ohio, Pennsylvania, and Illinois become significant pockets of losses, each with significant sales volume and negative aggregate profit. Other indicators of pricing-based margin erosion include these states offering higher-than-average discounts (averaging above 30%) and marking down margins. Central and Eastern states, by contrast, have negative persistent margins.

All these regional trends are summarized and visualized in Fig.4 (a). Fig. 4 (b) displays state-level dispersion, and Fig. 4 (c) depicts the sales-profit relationship among states. Cross-tabulation shows that Technology is running positive margins in the majority of regions, whereas Furniture performance exhibits considerable geographical variation. These interaction effects were illustrated in Fig.4 (d). States with negative margins are also high-risk, with high discount intensity. There is the greatest structural geographic loss pocket in Texas.

The mean discount across all transactions is 15.63. There is, however, an uneven distribution of discounts, and higher-value discount bands are associated with negative margins. The correlation between discount intensity and profitability is outlined in Table V, which reports sales, profit, margin, order volume, and loss rate by discount band. As shown in the table, the threshold effect is that profitability declines rapidly when discounts exceed 20%.

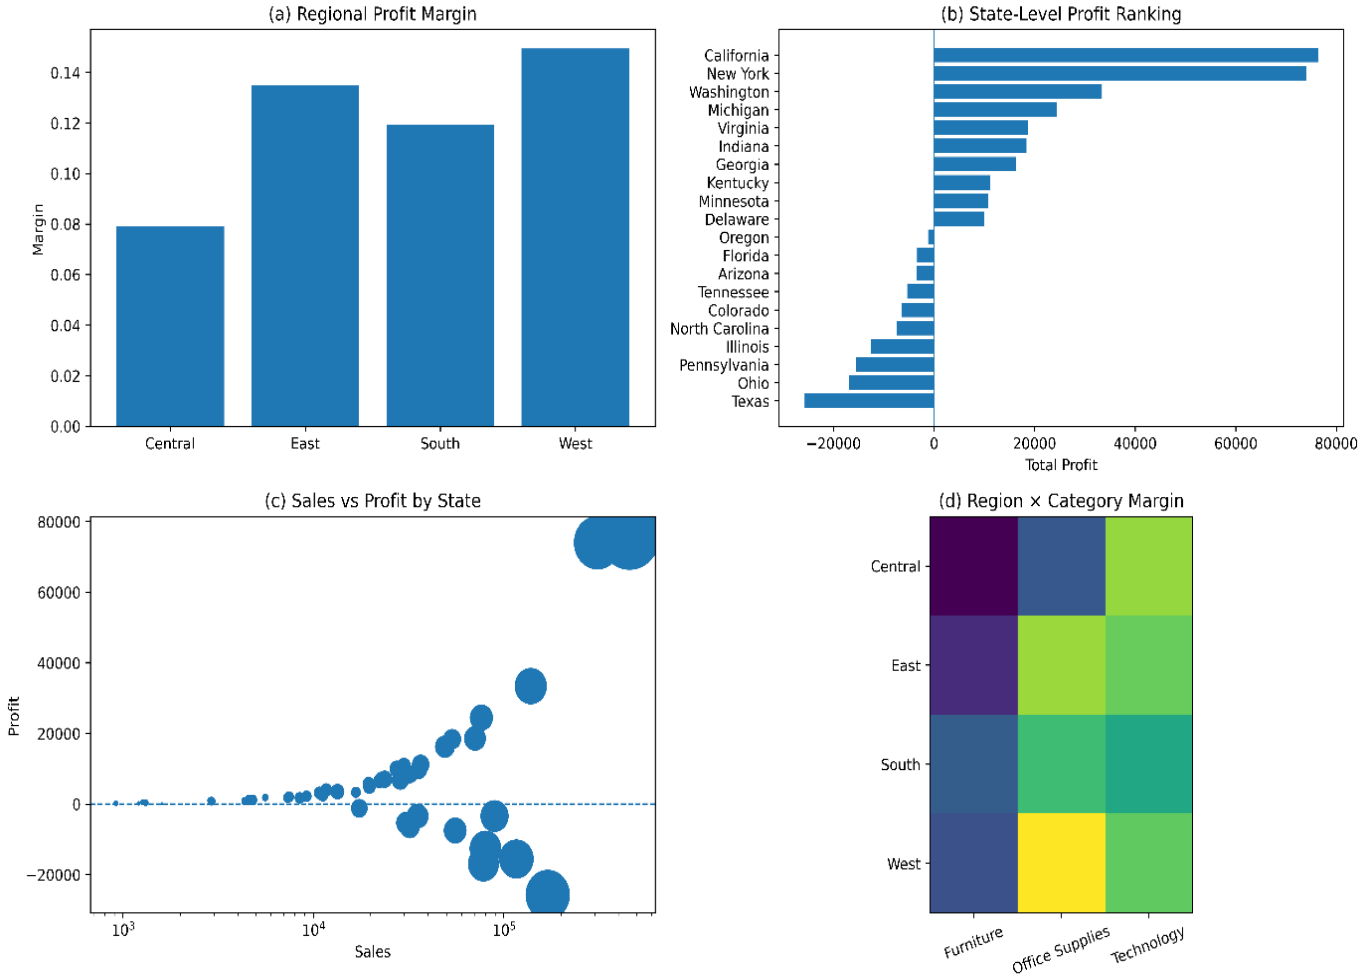

Fig. 4. Geographic performance dashboard.

TABLE V. DISCOUNT SENSITIVITY ANALYSIS

Discount Band	Sales	Profit	Margin	Orders	Loss Rate
0–10%	54,369	9,029	16.61%	94	4.26%
10–20%	792,153	91,756	11.58%	3,709	13.99%
20–30%	103,227	–10,369	–10.05%	227	91.63%
30–40%	130,911	–25,448	–19.44%	233	88.84%
40–50%	64,404	–22,999	–35.71%	77	100%
50%+	64,229	–76,559	–119.20%	856	100%

Table V summarizes only transactions included in the defined discount-band grouping used to analyze discount sensitivity. Therefore, the values in this table are not the totals of the entire dataset in Table II. Instead of replicating the aggregate totals for all transactions, the table shows comparative behavior across discount periods. The Discount Sensitivity Dashboard is shown in Fig. 5. Fig. 5(a) shows the number of orders by discount band, with the majority of transactions in the 10-20% and 50%+ bands. Fig. 5(b) shows profit by discount band, with positive profit at low discount rates and negative profit at higher discount rates. Fig. 5(c) shows the profit margin by discount band, indicating an apparent decline beyond the 20% discount mark, with very negative values beyond the 50% mark. Fig. 5(d) shows the loss rate by discount band, indicating that loss-making transactions are more than 20% off and 100% in the 40-50% and 50%+ bands, respectively.

Standard class accounts for the majority of transactions (5,968 orders) with an average delay of approximately 5 days. Same-day shipping exhibits minimal delay (0.04 days). Shipping delay alone does not exhibit a strong structural linkage to margin collapse. The discount intensity, rather than fulfillment speed, is closely related to loss behavior. Section V will discuss the research question of whether operational factors, i.e., shipping mode and delivery delay, are the main contributors to profitability variance. Although Fig.6 (a) shows significant differences in delivery speed among ship modes, Fig.6 (b) and Fig.6 (d) indicate that profit margins and loss rates do not differ significantly across fulfillment variants. In addition, as Fig.6 (c) shows, there is no apparent monotonic correlation between the delay length and transaction-level profit. A combination of these results indicates that the concept of operational efficiency is relevant to service quality but is not structurally descriptive of margin erosion in this dataset.

Table VI outlines the empirical findings of the proposed framework and representative studies in retail analytics and pricing research, and reveals that the proposed framework identifies multiple discount sensitivities, product-level diagnostics, and geographic profitability analyses differently.

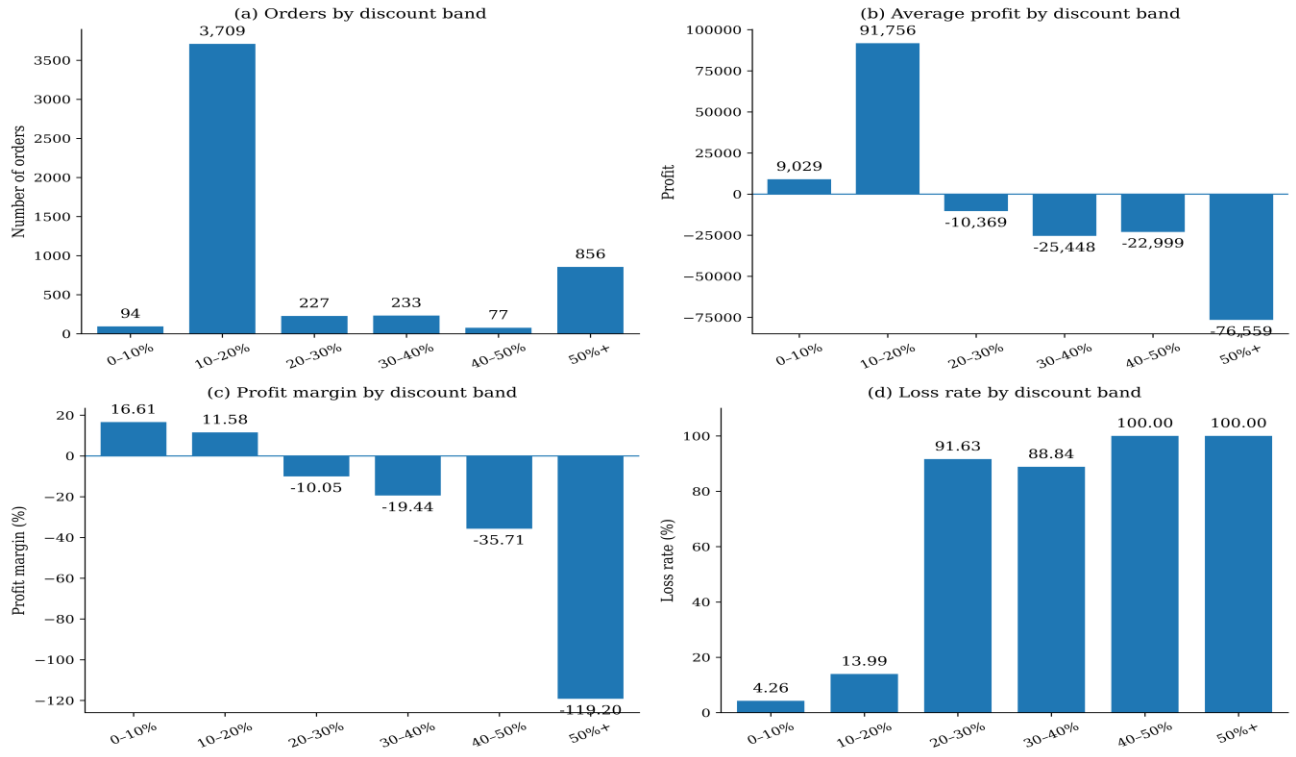

Fig. 5. Discount sensitivity dashboard.

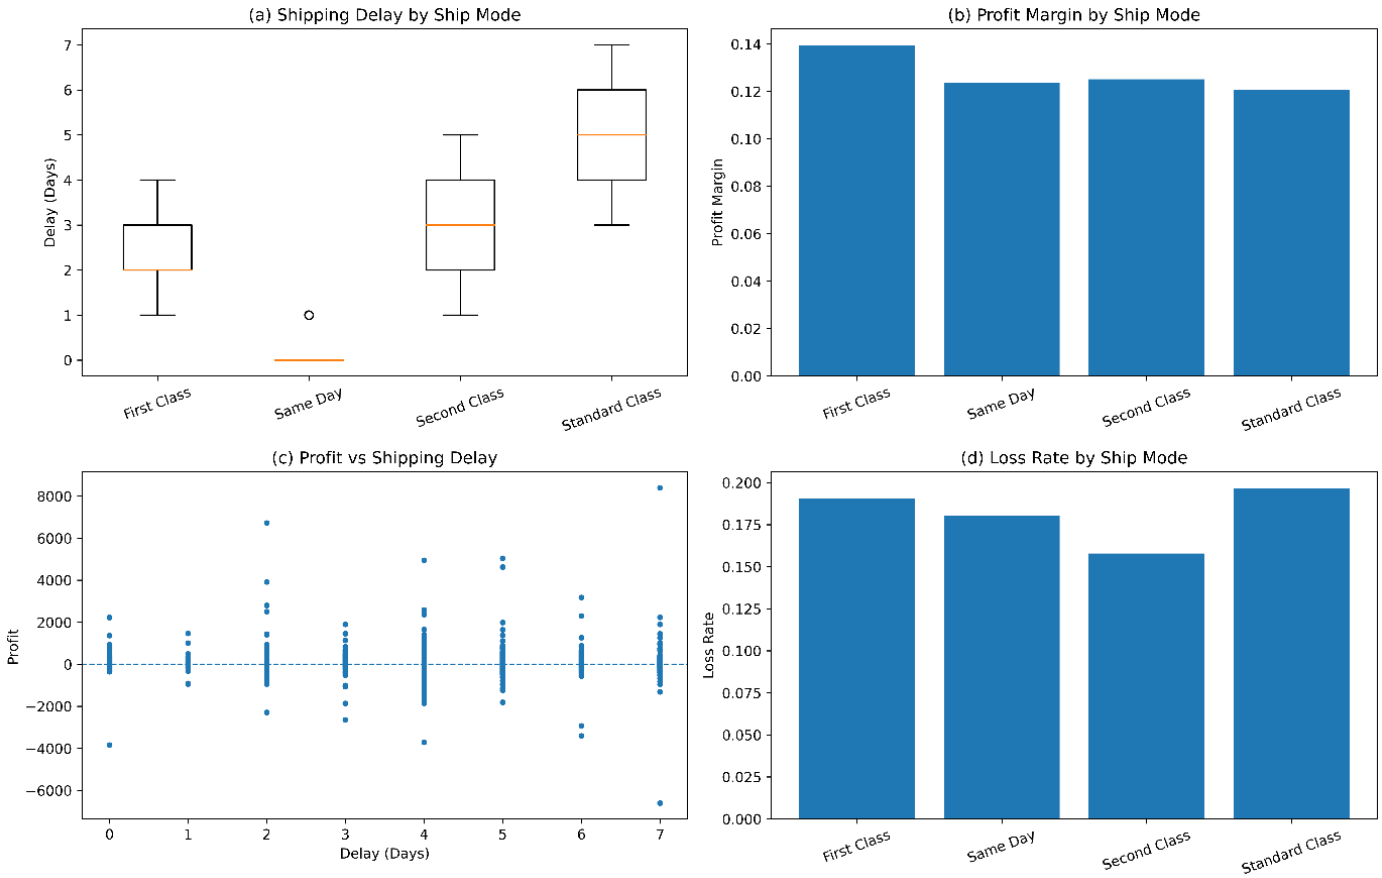

Fig. 6. Fulfillment effects dashboard.

TABLE VI. COMPARATIVE ANALYSIS OF RETAIL PROFITABILITY AND DISCOUNT SENSITIVITY FINDINGS

Ref.	Profitability Pattern	Discount Threshold Effect	Product-Level Variability	Geographic Impact	Visualization Support	Evaluation Type	Domain
[18]	Profitability is affected by discount and product presentation	Nonlinear discount effects reported	Product-dependent outcomes	Limited geographic analysis	× Mostly static analysis	Analytical/empirical modeling	Retail perishables
[19]	Profit depends on balancing markdown policies and inventory constraints	Discount policies influence profitability	Product-level variation acknowledged	Limited geographic dimension	× Static optimization models	Optimization analysis	Retail inventory
[20]	Promotion effects vary across products and customers	Promotion depth affects sales response	Strong product heterogeneity observed	Not central focus	× Minimal visualization	Econometric empirical analysis	Retail transactions
[21]	Profit affected by logistics and regional cost differences	Discount not primary focus	Product mix influences profitability	✓ Regional demand and cost differences	Limited	Empirical operations analysis	Retail supply chain
[25]	Visualization improves understanding of complex datasets	Not focused on pricing	Not domain specific	Not domain specific	✓ Visualization principles	Experimental evaluation	Cross-domain analytics
Proposed Framework	Overall margin 12.47%, loss rate 18.72%	Strong threshold near 20% discount; loss rate rises to 91–100% beyond threshold	High variability across sub-categories (e.g., Copiers high profit, Tables negative margin)	Strong regional disparity (e.g., Texas and Ohio negative margins)	✓ Multi-panel visual dashboards	Empirical transaction analysis	Retail transactional data

V. DISCUSSION

This section interprets the empirical findings in relation to the research questions, derives theoretical implications for integrating analytics and visualization, and outlines actionable managerial recommendations. Another practical issue concerns trade-offs among managerial goals. In the real retail world, an activity that boosts sales may compromise margin, and an activity that maintains margin may limit market growth or promotion. The proposed framework isn't a solution to these trade-offs itself, but is intended to put them into the spotlight. Positioning sales, profit, margin, discount, and geographic perspectives side by side provides a framework for discussing other goals and objectives that may compete for the solution, rather than assuming they are all equally important in every aspect of decision-making.

A. Answers to the Research Questions

RQ1: The benchmark analysis shows that profitability is unevenly distributed across product categories, sub-categories, and geographic units. Does the coordinated framework help reveal these benchmark-specific differences through linked hierarchical and geographic views?

The results indicate that profitability is not shared equally in product categories, subcategories, and geographic units. The category analysis reveals that Technology and Office Supplies have a margin of more than 17, whereas Furniture has a structurally weak margin of approximately 2.5. Sub-category profitability concentration is enormous: Copiers and Paper are making disproportionate margins, whilst Tables and Bookcases are making steady margin losses. These findings indicate that product mix and category structure are the most important in aggregate profitability.

RQ2: The discount-band inspection suggests a benchmark-specific threshold-like pattern in which profitability remains positive at lower discount levels but becomes negative in higher bands. This pattern is descriptive and serves as an example of the type of relationship that the framework can surface for further scrutiny.

The discount sensitivity analysis suggests a nonlinear threshold effect: profitability is generally maintained at discount levels below about 20%, whereas higher discount levels are associated with negative margins and sharply increased loss rates. The loss rates increase with higher discount levels and reach saturation at extreme levels. The findings of the present research confirm that discounting is not only positively related to low profitability but also a structural factor in margin erosion and the development of a loss pocket.

RQ3: The geographic views indicate that benchmark profitability varies across states and regions. The framework is useful here because it allows analysts to compare scale, margin, and product-region combinations across multiple linked views rather than relying on a single map or table.

The geographic test shows that profitability levels vary greatly across states. The other states, such as California and New York, that have been doing well show high margins, but other states, such as Texas and Ohio, have been incurring consistent losses despite high sales volume. The differences are associated with high discount intensity and the product mix structure, implying that the geographic strategy has a strong impact on financial performance.

RQ4: The fulfillment view suggests that shipping mode and delivery delay are less visually salient in this benchmark than discount and product structure. The framework, therefore, helps analysts prioritize which dimensions appear most informative within the benchmark context?

The fulfillment analysis demonstrates that shipping mode and delivery delay exert only a marginal influence on profit variability. Although Standard Class shipping involves longer delays (approximately 5 days), the profit margins and loss rates across shipping modes do not differ substantially. No monotonic relationship between delivery delay and transaction-level profit was observed. These findings indicate that while operational efficiency remains relevant for service quality, it does not structurally account for margin erosion in this dataset. The primary profitability drivers are pricing decisions and product mix effects, rather than logistics performance.

Taken together, the analysis of the results reveals that pricing choices, specifically discount policy, with product-hierarchy effects and geographic concentration, are used to explain most of the variation in profitability in the data.

B. Theoretical Implications: Integrating Analytics and Visualization

This study contributes to the convergence of three research streams: data science pipelines, business analytics, and visual analytics for decision support, showing that descriptive statistics alone cannot be used to identify structural risk. The aggregate profitability masks concentrated areas of loss that can be identified only through hierarchical slicing and multi-level aggregation. Second, the interpretation of the visualization and the analytical modeling is more interpretive. The multi-panel dashboards (e.g., discount sensitivity and geographic heterogeneity) show nonlinear threshold behavior and interaction effects, which would otherwise be difficult to see in tabular summaries alone. This visualization is not a reporting aspect, but an analytical tool that demonstrates structural relationships. Third, the granular analysis of retail transactions and the aggregation tables show that both may be applicable in retail. The profitability drivers all work in parallel at the micro (transactions), meso (sub-category/state), and macro (category/region) levels. The circulation across levels is consistent with a single, coherent pipeline spanning preprocessing, analytics, and visualization. In these respects, this work contributes to a theoretical framework in which analytics and visualization are not two separate components of data science systems based on decisions, but rather both are components of the system.

C. Illustrative Decision Scenarios Enabled by the Framework

As the dataset is a benchmark rather than a validated operational dataset, the framework should be used as an illustration of decision scenarios, not as a prescription. For instance, if there were a threshold-like discount pattern in a real deployment, the analysts might consider whether specific discount bands are correlated with weak margins in certain categories or regions. Likewise, regions with negative profits

may spur diagnostic follow-up, but not necessarily policy action. It is not a good framework to use if it is merely a set of predetermined managerial responses; it is a good framework to use because it enables them to compare candidates for the various explanations.

D. Robustness Considerations

There are several robustness factors worth considering. Monthly aggregation indicates monthly seasonal peaks in sales and margin volatility. Although the discount sensitivity patterns are comparable across months, seasonal demand variations may either amplify or mitigate the impact on margins. Retail sales and profit distributions are right-skewed and exhibit heavy tails. The disproportionate impact of high-value transactions on aggregate outcomes can be established. Log-scale visualizations and distributional diagnostics help reduce misinterpretation. The big states, such as California, make a disproportionate contribution to total profit. The sensitivity analyses without dominant states show that the effect of the discount threshold persists even after eliminating the high-volume states. Micro-level heterogeneity is evident in high loss rates within some subcategories. Aggregated margins should then be interpreted alongside transaction-level dispersion measures. The considerations help strengthen the belief that the main results, especially the nonlinear discount-profit relationship, are structurally sound rather than the product of aggregation.

E. Limitations

There are several things to be expressly noted. Firstly, the Sample Superstore dataset is purely illustrative and is used for illustration and reproducibility. The patterns described in this study are empirical and cannot be expected to be common across all retail stores. Secondly, the study does not make any causal statements. Visual patterns depicted by the framework are not meant to represent causal mechanisms. Thirdly, the study does not present a user study, so statements of interpretability are not based on user performance but rather on design logic and demonstrating the benchmark. Fourth, the framework has not yet been tested on several datasets, and the extent to which it can be applied across contexts remains undetermined. Fifth, predictive extensions are not within the current empirical scope and have therefore been excluded from the main analysis. Sixth, as with the other elements of the framework, there is an interpretive risk of aggregation bias, since it is based on grouped summaries at various levels of hierarchy. Lastly, the loss pockets criterion employed is not formally optimized and is descriptive and benchmark-oriented.

VI. Conclusion and Future Work

Several restrictions should be emphasized. The Sample Superstore dataset is a demonstrative dataset for illustration and reproducibility purposes only. The empirical patterns described here apply only to the dataset and cannot be assumed to be representative of retail in general. Second, this study does not make causal statements. The visual patterns displayed in the framework are not necessarily causal processes, but rather co-occurrence and analytical salience. Third, there is no user study included in the present study; thus, the interpretive claims are not based on user performance but rather on design logic and the demonstration of the benchmark. Fourth, the framework has not yet been tested on more than one dataset, and its generalizability across domains has yet to be determined. Fifth, predictive extensions are beyond the scope of the current empirical analysis and are not included in the main analysis. Sixth, because grouped summaries are used at multiple hierarchical levels, aggregation bias must be considered when interpreting the results. Lastly, the materiality criterion for loss pockets is not formally optimized and descriptive/benchmark based.

This study can be advanced in future research in several ways. Gradient boosting and causal modeling, as predictive methods, may also be added to equip the framework to recognize loss-risk trends and facilitate more sophisticated decision analysis. In general, this study demonstrates that the proposed integrated visual analytics framework is a structured method for the diagnostic analysis of retail performance, price review, and portfolio, as well as a basis for further evolution of retail decision support systems. This study presents a decision-based visual analytics model using a publicly available benchmark Superstore dataset. The findings demonstrate that coordinated descriptive and diagnostic analytics, along with organized visualizations, can help uncover data-specific profitability trends, loss zones, and risk structures based on discounts. The findings are to be understood in terms of the illustrative dataset used in the study. The framework should be tested in the future on a variety of datasets and retail environments, and expanded through predictive modeling and user feedback on the use of the decision support.

Data Availability Statement

The dataset is publicly accessible and was used in this study in accordance with its publicly available distribution for research and demonstration purposes, provided by V. Chowdhury, available online: https://www.kaggle.com/datasets/vivek468/superstore-dataset-final (Accessed on 25 January 2026).

***Abstract*—Coding has become a fundamental skill for cultivating computational thinking in young learners. This study aims to examine the impact of coding education on programming interest among fifth-grade students in Mongolia with no prior coding experience. A 16-week pilot course using block-based coding activities on Code.org involved 195 5th-grade students across three schools. A pre-test/post-test design compared an experimental group ($N_{experimental}$=95) with a control group ($N_{control}$=100). Results indicate significant improvements in coding skills (Cohen's d = 0.84) and computational thinking, with average programming skill ratings increasing from 5.19 to 7.07 out of 10. Qualitative data show heightened engagement, perceived creativity, and motivation, with students describing coding as gamified activities alongside an increase in self-rated programming interest. Moreover, post-intervention interviews reveal emerging awareness of gender inclusivity in programming. These findings suggest that structured block-based coding can effectively enhance computational thinking and interest in programming among young learners, providing evidence to support early integration of programming in primary education curricula.**

***Keywords*—Computational thinking; problem-solving; block-based coding; coding education; programming interest**

I. Introduction

Today, coding has become a fundamental skill driven by technological advancements across all aspects of learning. The concept of computational thinking can be viewed as a compilation of problem-solving competencies that are intrinsically linked to the tenets of computer science [1]. There are both economic and developmental motivations for commencing computer science education in early childhood. Research demonstrates that early educational interventions in programming lead to reduced costs and more sustainable outcomes than those initiated later in a child's academic journey [2], [3]. With the emergence of the sixth information technology revolution, defined by artificial intelligence, the ability to code has become a vital competitive edge for today's workforce. Young students are enthusiastic about quickly learning basic digital skills to adapt to the evolving information society [4]. Additionally, [5] highlighted that computational thinking is an essential skill set that everyone should be motivated to acquire and apply in their everyday lives. Moreover, [6] proposed that Computational Thinking (CT) has existed since the 1950s, originally termed 'algorithmic thinking', which involves employing a systematic and precise sequence of steps to address a problem, utilizing a computer when suitable for this purpose.

Through the digital landscape, computational thinking (CT) and coding have become critical foundational skills, now recognized as essential parts of national curricula in many education systems. CT refers to mental processes such as breaking down problems, recognizing patterns, designing algorithms, and abstracting solutions in ways that can be automated using technology [5]. Coding serves as a practical application of these skills, allowing learners to express ideas through structured, programmable instructions, promoting problem-solving, logical reasoning, and digital fluency [7], [8].

Although there is no consensus among academics on a definitive interpretation of computational thinking (CT), Wing describes it as the process of problem-solving, system design, and the concept of human behavior, drawing from the essential principles of Computer Science. She notes that computational thinking is not merely programming but rather involves a broader scope that includes thinking at multiple levels of abstraction [5]. In addition, [5] describes computational thinking as a form of analytical thought that seeks to understand human behavior, offering a structure on essential concepts such as generating system designs, addressing problems, and processing information. On one hand, studies have shown that instruction in computational thinking (CT) fosters a deeper understanding that programming is fundamentally about addressing problems, rather than simply coding, and it can bolster female students' perceptions and self-assurance in programming [9]. It is noteworthy that CT serves as an early indicator and predictor of academic success, as the CT scores have shown a strong correlation with overall academic performance [10].

Several countries, including Finland, the United Kingdom, South Korea, and the United States, have adopted CT and coding in primary and secondary education as part of broader digital literacy and STEM agendas [8], [11]. Research consistently shows that introducing coding at an early age supports cognitive development, including executive function, critical thinking, and conceptual reasoning [11], [12]. Beyond cognitive gains, coding activities, especially when delivered through visual programming platforms, mobile apps, or educational robotics, enhance learner motivation, engagement, collaboration, and creativity [11], [13]. Importantly, CT is not limited to computer science alone. It supports learning across diverse subjects, including mathematics, science, language arts, and the arts, and promotes interdisciplinary problem-solving [14], [15]. These cross-cutting benefits have led to a global

*Corresponding author

shift toward embedding coding and CT within general education rather than treating them as niche or elective skills.

The Mongolian education context, [16], [17] explicitly calls for enhanced digital competencies, improved access to STEM education, and inclusive, future-oriented learning pathways. Integrating coding and CT into primary education supports these goals by preparing students with relevant skills for digital society and addressing urban–rural disparities in access to quality education. This study responds to the need for localized evidence by examining the effects of structured coding activities on the development of computational thinking in fifth-grade students in Mongolia. Through a pre-test/post-test design, the study analyzes both the statistical significance and practical impact of coding instruction, contributing to curriculum reform and global dialogue on 21st-century education.

II. Literature Review

A. Importance of Coding Education

Literature defines coding as the process by which computers transform human-understandable operations into executable algorithms or sequences of commands [18]. It has been proposed that coding can encourage self-directed learning. Additionally, it supports literacy and mathematical communication, as well as metacognitive abilities, especially when children are introduced to coding at an early age [19]. Furthermore, learning to code equips students with a novel symbolic language that enables them to develop programs and projects, thereby establishing a positive link between coding skills and creative thinking [20].

Introducing children to coding, an essential skill for digital literacy and the language of today's world, should occur in early developmental stages of children [21]. The practice of coding also enables analysis, problem-solving, and concept development by formulating algorithms that break down problems and representing these algorithms in a programming language. In this way, coding serves as a medium for children to express their ideas and perspectives [22]. Programming also offers children opportunities to “interact" with computers and allows them to learn new symbolic languages [7], [20]. Additionally, 21st-century skills are essential for individuals, with coding being considered a fundamental skill. Coding should be included among the competencies that every student ought to acquire during their educational journey [23].

On the other hand, the concept of 'coding without computers' relates to educational experiences where students engage in lessons known as 'unplugged'. In these lessons, the emphasis is not on algorithmic reasoning, computer interactions, or database management. Instead, students often use pencils and paper or physical manipulatives. These thoughtfully crafted kinesthetic activities allow students to understand intricate concepts through cards, games, and puzzles. Such experiences are pertinent to their lives and promote the learning of fundamental information technology principles [24]. In addition, numerous studies noted that graphical environments can support cognitive growth in children and are more effective for teaching programming to younger age groups [25], [26].

B. Unpacking Interest in Creative Programming

In terms of creative learning, constructivism is recognized as a significant concept in today's educational sphere. Yet only a small fraction of classrooms genuinely encourages students to approach their schoolwork as a creative act of knowledge construction. The goal of these initiatives is to create a classroom environment that functions as a community for building knowledge [27]. As the integrated mode is recognized as a more imaginative processing style, the authors advised that computer programming instructors should prioritize software design, which utilizes an integrated mode [28]. Moreover, a variety of computer programs are accessible. To enhance the cultivation of creative thought, these programs should function as tools for cognitive processes. We must exercise caution against providing a haphazard assortment of programs or tools that lack internal coherence [29].

Engaging in creative coding requires diverse problem-solving competencies that leverage computer algorithms, often referred to as “computational thinking” [5]. On the one hand, Computational thinking (CT) refers to a method of problem-solving that encompasses the formulation of problems; the logical organization and analysis of data; the representation of data via abstractions; the identification and automation of solutions through algorithmic reasoning; the analysis and implementation of potential solutions; and the generalization and transfer of the problem-solving process [30], [31].

III. Methodology

A mixed-methods parallel design was employed, integrating quantitative and qualitative approaches with equal weighting. The structural workflow of this mixed-methods parallel design is visually illustrated in Fig. 1.

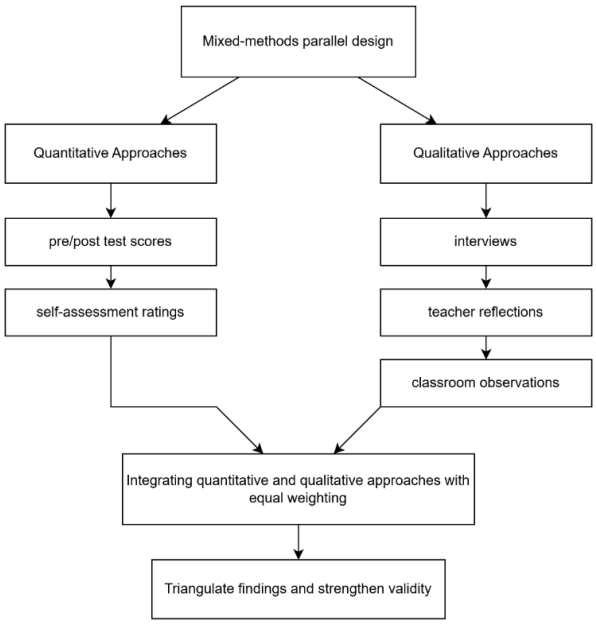

Fig. 1. Mixed-methods parallel design of the study.

This design allowed the combination of statistical analysis and thematic interpretation to triangulate findings and strengthen validity [32]. Quantitative data included pre/post

test scores and self-assessment ratings, while qualitative data were derived from interviews, teacher reflections, and classroom observations. Qualitative data from interviews, classroom observations, and teacher reflections were collected concurrently to enrich interpretation and triangulate findings. For the qualitative phase, we employed a purposive stratified sampling method to select 15 participants from the experimental group ($n_{experimental}$=95). This method was chosen to ensure a diverse representation of gender, geographic location (urban vs. rural), and varying levels of coding progression observed during the 16-week intervention. Existing classroom groups were used without random assignment due to practical school-level constraints.

Both methods were implemented concurrently and analyzed independently before being merged in a comprehensive interpretation. This approach corroborates quantitative data with rich descriptive insights from classroom practices and interviews, etc.

A. Research Context and Sampling

This study was conducted as part of a national pilot project designed to integrate computer science education into the Mongolian primary curriculum. The research focused on fifth-grade students who had no prior coding experience. The objective was to examine how structured, block-based coding activities influence computational thinking and interest in programming. The research data refers to 195 students in 5th grade from three public schools, consisting of two rural schools and one urban school, including 97 males and 98 females, who possessed no previous coding knowledge or skills and were being introduced to the subject for the first time. Teachers enrolled in the pilot lessons had limited coding experience and pedagogical confidence. However, they received pre-study training and continuous pedagogical support. Ethical approval and informed consent were obtained from all participants and their guardians before data collection.

B. Teacher Profile and Preparation

Fifteen teachers participated in the pilot implementation (see Table I). The majority were female (86.7%) and held a bachelor's degree (66.7%). Before classroom implementation, all teachers attended an 8-hour professional development workshop focused on Code.org pedagogy, computational thinking concepts, and strategies for facilitating creative, student-centered learning. Teachers were provided with lesson plans, teaching aids, and access to a monitoring platform to track student progress and ensure consistent delivery across schools.

C. Instruments and Outcome Measures

To evaluate the intervention, two distinct quantitative assessment tools were deployed at baseline (pre-test) and post-intervention (post-test).

1) Computational thinking performance assessment: This 10-point instrument was adapted from the verified Code.org Course C diagnostic metrics and validated primary school block-coding tasks established by relevant literature. It comprises 10 items (scored 0 or 1 point each, yielding a 0–10 composite scale) that assess five core computational thinking sub-constructs: algorithmic design (2 items), pattern recognition (2 items), loops/repetition logic (2 items), abstraction (2 items), and debugging logic (2 items). A pilot testing phase involving an independent cohort of fifth-grade students (N = 25) yielded a Cronbach's alpha of $\alpha = 0.81$, indicating robust internal consistency. Construct validity was confirmed through evaluation by an expert panel comprising two educational technology professors and one senior computer science teacher.

2) Self-rated programming interest and ability scales: Student perceptions were collected through two standalone 10-point Likert-type single items ("Rate your interest in learning computer programming" and "Rate your current ability to write code/solve puzzles", where 1 = Very Low and 10 = Very High).

TABLE I. THE DEMOGRAPHIC CHARACTERISTICS OF TEACHERS

Variables	Values	Frequency	Percentage (%)
Gender	Female	13	86.7%
	Male	2	13.3%
Educational attainment	Bachelor's degree	10	66.7%
	Master's degree	5	33.3%
Age bracket	25–35	8	53.3%
	36–45	3	20.0%
	46–55	4	26.7%
Professional commitment	2–5 years	3	20.0%
	6–10 years	6	40.0%
	11–20 years	2	13.3%
	21–30 years	2	13.3%
	31–40 years	2	13.3%
Experience in teaching coding	Yes	0	0.0%
	Somewhat	5	33.3%
	No	10	66.7%

D. Qualitative Data Collection and Analysis Rigor

The qualitative strand utilized semi-structured interview protocols alongside structured classroom observations. Interviews were conducted in the native Mongolian language by the primary research team to eliminate communication barriers. All recorded audio files were transcribed and translated into English using a back-translation protocol. The text was analyzed using inductive thematic analysis. Two researchers independently coded the transcripts to identify repeated semantic patterns regarding student enjoyment, confidence, and equity. Inter-rater reliability was verified using Cohen's Kappa *(k)*, yielding an initial agreement of $k = 0.83$. Minor coding discrepancies were resolved through iterative team consensus meetings. Final frequencies (e.g., 11 out of 15 participants noting high enjoyment) represent systematic code distribution across the entire sample rather than illustrative anecdotes. Table II presents the demographic data and backgrounds of participating students.

TABLE II. DEMOGRAPHIC DATA AND BACKGROUNDS OF PARTICIPATING STUDENTS.

Demographic and Personal Information	Values	Frequency	Percentage (%)
Gender of students	Male	97	49.7%
	Female	98	50.3%
Student age	10 years old	189	96.9%
	11 years old and above	6	3.1%
Previous coding experience	Yes	5	2.6%
	No	190	97.4%
Parents work in IT-related jobs	Yes	5	2.6%
	No	190	97.4%
Awareness of platforms	Khan Academy	3	1.5%
	Scratch	1	0.5%
	Code.org	2	1.0%

E. Course Design and Delivery

The 16-week pilot course comprised 16 lessons, each lasting approximately 40 minutes. The structure of each lesson followed a consistent pattern:

1) Introduction (10 minutes): Presentation of the lesson goal and demonstration of a simple concept.

2) Guided coding practice (20 minutes): Students completed block-based coding challenges on Code.org using computers or tablets and extra coding tasks.

3) Reflection and discussion (10 minutes): Students discussed solutions, errors, and strategies to reinforce computational thinking and creativity.

The intervention combined computer-based coding and unplugged activities, such as card sequencing, paper-based tasks, and movement-based problem-solving, to reinforce algorithmic reasoning without reliance on digital tools. This blended approach allowed students to grasp core programming logic through both physical and digital representations. Throughout the intervention, teachers maintained reflective notes, and researchers conducted classroom observations to record behavioral engagement and problem-solving interactions.

The 16-week educational intervention was designed to isolate, emphasize, and evaluate block-based programming skills by mapping the digital environments of Code.org Course C and Course D (2024 editions) directly into the core coding chapters of the official Mongolian 5th-grade Computer Science textbook (used only in curriculum pilot). While the textbook introduces physical computational hardware and foundational robotics elements in its introductory units, this pilot study intentionally focused exclusively on the algorithmic logic and programming modules to systematically evaluate progress in students' computational thinking over the course.

The curriculum structure was split into four interconnected 4-week thematic blocks. To ensure a blended learning approach, every theoretical programming paradigm introduced in the national textbook was immediately applied and tested through matching interactive, gamified puzzles on Code.org. The specific chronological layout, matching local textbook units, practical student block operations, and targeted computational thinking dimensions are comprehensively outlined in Table III.

TABLE III. SYSTEMATIZED 16-WEEK EXPERIMENTAL PROGRAMMING TIMELINE MAPPED TO MONGOLIAN 5TH GRADE TEXTBOOK MODULES

Phase / Timeline	Textbook Unit & Chapter Alignment	Corresponding Code.org Modules	Practical Student Programming Tasks & Core Operations	Targeted Computational Thinking (CT) Competency
Weeks 1–4	(Unit 2: Characters and Movement - Lessons 2.1, 2.2)	Course C: Lessons 1–4: Digital Citizenship & Sequencing in Maze	Students constructed explicit sequential command chains to move sprites autonomously. Handled event-driven logic by mapping interactions to physical action blocks (e.g., programming character speech outputs on clicking events).	Algorithmic Thinking & Decomposition: Breaking single overarching motion routes into individual directional vectors.
Weeks 5–8	(Unit 2: Optimization - Lesson: Sequencing & Loops)	Course C: Lessons 5–8: Loops in Laurel & Artist	Students identified geometric repetitions in design files. Programmed nested "Repeat" parameters to construct complex grid arrays and multi-sided shapes without writing redundant lines of individual code.	Pattern Recognition & Code Efficiency: Utilizing structural patterns to minimize command redundancy via loops.
Weeks 9–12	(Unit 3: Variables & Game Design - Lessons 3.1–3.3)	Course D: Lessons 9–11: Conditionals & Scores in Bee/Farmer	Students initialized dynamic parameters to track game actions (e.g., / score variables). Built condition checks ("If/Else") forcing characters to gather assets only when strict environmental variables were met.	Conditional Logic & Data Tracking: Designing rule-based branching paths and tracking fluid states via data variables.
Weeks 13–16	(Unit 4: Functions & Optimization - Lessons 4.1, 4.2)	Course D: Lessons 12–14: Functions in Minecraft & End Project	Students audited broken scripts to isolate hidden logical failures (Debugging). Wrapped complex, recurring code instructions into distinct named macro modules to assemble an original capstone project.	Abstraction and Debugging: Encapsulating complex sub-routines into clean functions; diagnosing system failures methodically.

IV. RESULTS

A. Coding Experiment Outcomes

The box plot (Fig. 2) illustrates the changes in score distribution after the intervention, emphasizing trends that extend beyond mere mean differences. In the experimental group, the post-test scores show a higher median and a reduced interquartile range, indicating enhanced consistency in learning outcomes. This trend is consistent with previous studies indicating that coding activities can improve not only individual computational thinking (CT) skills but also foster more equitable performance among students [33], [15].

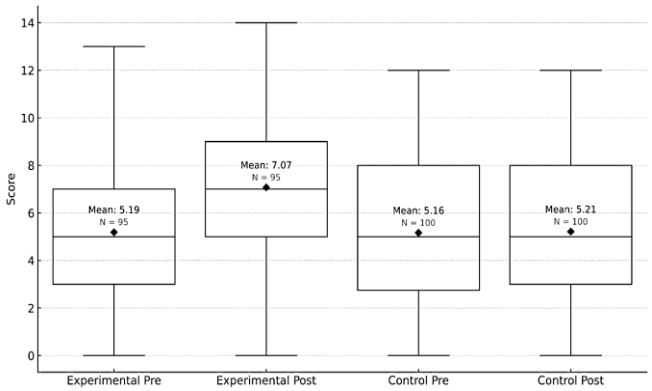

Fig. 2. Box plot of pre- and post-intervention scores in experimental and control groups.

In contrast, the control group demonstrates only a slight upward shift in the mean, with overlapping interquartile ranges both before and after the test. This suggests that general instruction alone may yield minimal or uneven learning gains in CT, consistent with studies indicating that explicit, structured computational tasks are more effective than implicit exposure [34], [35]. The absence of extreme outliers in both groups further supports the reliability of the intervention's effect. Significantly, the experimental group's decrease in variability suggests that the coding program was more effective in assisting lower-performing students - a pattern linked to well-structured CT interventions [36].

These findings support the interpretation that coding activities, when systematically implemented, lead to both higher and more consistent CT performance among primary school learners.

B. Coding Ability Progression (Hypothesis 1)

To evaluate the progression of students' coding capabilities following the 16-week intervention, quantitative tracking metrics were analyzed. This section details the statistical shifts in objective computing performance alongside subjective self-efficacy developments across both cohorts, as highlighted in the metrics below. The detailed post-intervention evaluation metrics and assessment score breakdowns are summarized in Fig. 3.

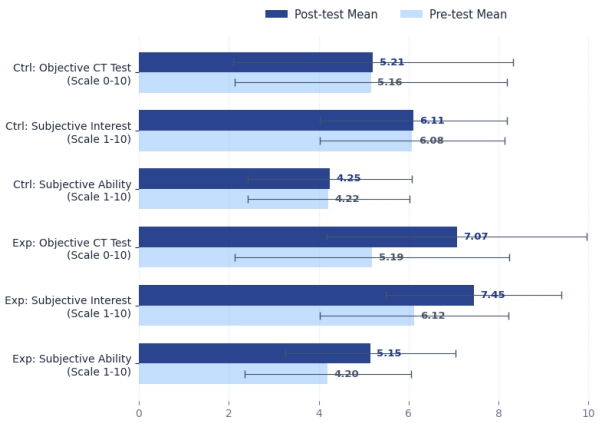

Fig. 3. Assessment score metrics

C. Coding Experiment Outcomes

Before the intervention, baseline equivalence between the groups was statistically verified. A two-sample independent t-test conducted on the pre-test scores showed a statistically insignificant difference between the experimental group (M = 5.19, SD = 2.98) and the control group (M = 5.16, SD = 3.02; t (195) = 0.07, p = 0.944), validating their baseline comparability.

Following the 16-week intervention, a paired sample t-test was conducted to examine intra-group progress from pre-test to post-test. Because zero student attritions occurred during the course, the degrees of freedom (*df*) correspond directly to n – 1 for each group. For the experimental group (n = 95), computational performance scores increased significantly from M = 5.19 (SD = 2.98) to M = 7.07 (SD = 3.14), yielding t (94) = -8.13, $p < 0.001$. The standardized effect size was computed using the paired-samples standardized mean difference formula:

$$d = \frac{M_{post} - M_{pre}}{SD_{difference}}$$

where, M_{post} and M_{pre} represent the post-test and pre-test means, respectively, and $SD_{difference}$ represents the standard deviation of the difference scores.

These findings indicate that structured block-based coding activities significantly improved students' computational thinking and coding performance. To verify the specific areas of student improvement behind these mean differences, an item-level analysis was conducted. As explicitly mapped across the curriculum topics in Fig. 4, the experimental pilot group showed a substantial accuracy advantage over the control class group, particularly in advanced block logic tasks.

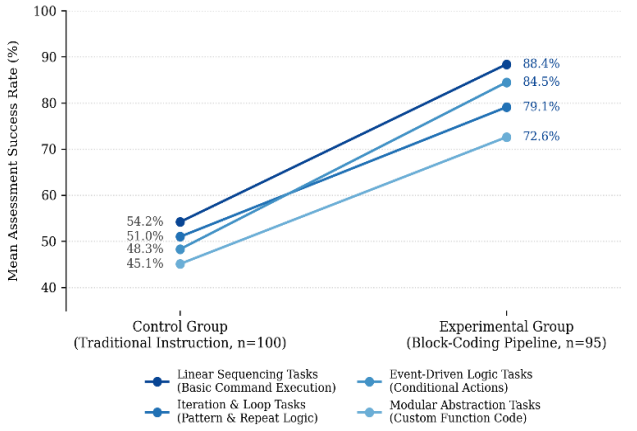

Fig. 4. Explicit performance accuracy tracking across core coding tasks, comparing the mean success rates of the Experimental Pilot Group (n = 95) and the Traditional Class Group (n = 100).

In contrast, the control group ($n_{control}$ = 100) exhibited a statistically negligible change from pre-test (M = 5.16, SD = 3.02) to post-test (M = 5.21, SD = 3.11), with t (99) = 0.74, p = 0.456 and a negligible effect size (Cohen's *d* = 0.07).

D. Programming Interest Gain Scores (Post-Test – Pre-Test)

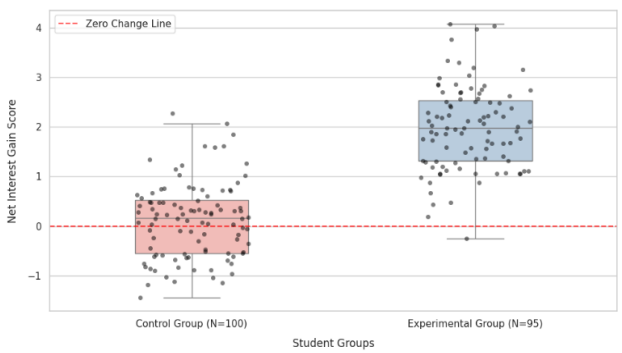

Fig. 5. Programming interest gain scores between the experimental and control groups.

To see exactly how the program affected each student, we calculated personal progress by subtracting pre-test scores from post-test scores. As shown in Fig. 5, the results are completely different. In the Control group, almost everyone's score is crowded right around the zero line, meaning regular classes did not really change their interest in coding.

In contrast, almost every student in the Experimental group shifted well above the zero line. Even the middle half of the experimental group sits completely above the control group's highest concentration. This visually confirms our strong overall effect size (Cohen's d = 0.84) and proves that the coding activities systematically increased programming interest across the entire classroom rather than shifting it via a few standout students.

E. Programming Interest and Motivation (Hypothesis 2)

Changes in student self-rated programming interest are described in the metrics below and mapped visually in Fig. 6.

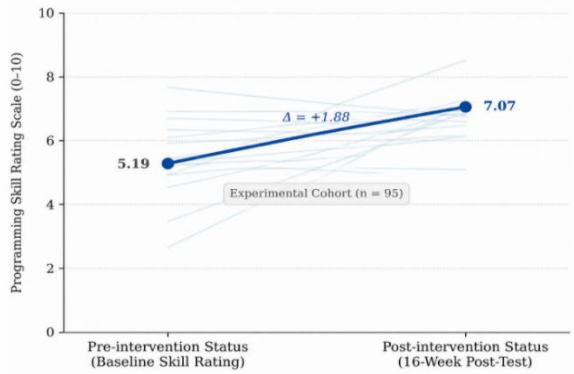

Fig. 6. Longitudinal trajectory shift mapping the baseline programming self-efficacy ratings against post-intervention evaluation metrics within the experimental cohort (n = 95).

TABLE IV. QUALITATIVE EVIDENCE OF INCREASED INTEREST IN PROGRAMMING.

Theme	Frequency	Example Student Quotes
Enjoyment of coding	11/15	"Coding is like playing a game."
Perceived creativity	9/15	"I can make easier stories and games."
Increased confidence	8/15	"I want to learn more coding after this class."

Quantitative and qualitative data jointly support Hypothesis 2. Students not only improved in self-rated programming ability (+1.88) but also developed positive attitudes toward coding, describing it as fun, creative, and motivating. The data show that students who engaged in Code.org block-based coding showed significant improvements in coding scores and increased interest in programming, as observed in interviews and classroom behavior. Qualitative responses revealed that students described coding as "fun", "creative", and "like playing games", indicating increased motivation and engagement. Together, the significant improvement in test scores and self-reported enthusiasm support Hypothesis 2. Table IV shows qualitative evidence of increased interest in programming.

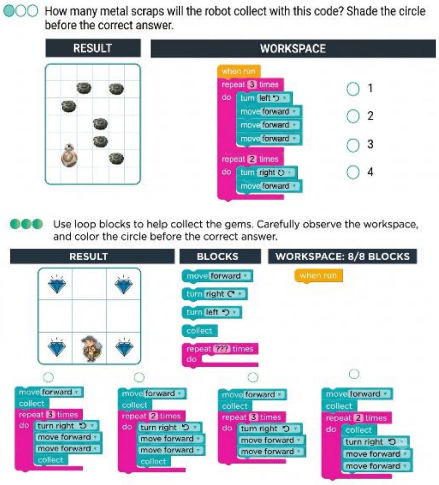

Fig. 7. Supplementary reference items from the post-intervention assessment instrument. (A) Linear grid sequencing task (Q2), (B) Iterative loop optimization task (Q9), and (C) Asynchronous event-driven matching task (Q7).

Together, the significant improvement in test scores and self-reported enthusiasm support Hypothesis 2. To visually confirm the nature of this data improvement, Fig. 7 provides supplementary reference samples of the task logic successfully parsed by the pilot cohort. The observed score improvements reflect students' growing ability to use more advanced computational thinking concepts, including loops and event-based programming structures.

F. Gender Awareness and Inclusivity (Hypothesis 3)

Although not universal, interview data indicate a shift toward gender-equitable views, providing partial support for Hypothesis 3. Female students showed increased confidence and interest, reflecting the potential of early coding instruction. Furthermore, post-intervention interviews revealed that several students recognized gender-related themes, with female students acknowledging increased confidence in coding skills and noting that "both girls and boys can be good at programming". Although initial surveys reflected limited awareness of gender-related stereotypes in computer science, the course prompted discussions about inclusivity. Teachers also reported observing a reduction in gendered perceptions of coding as an activity "more suited for boys". These findings provide partial support for Hypothesis 3: students' improved grasp of Computer Science concepts includes an emerging

awareness of gender equity and challenges to existing stereotypes, although further targeted instruction may be needed to reinforce these outcomes. Table V presents the gender-related awareness indicators (post-intervention interviews).

TABLE V. GENDER-RELATED AWARENESS INDICATORS (POST-INTERVENTION INTERVIEWS).

Indicator	Frequency (n=15 interviews)	Example Quotes
Acknowledgment that girls can code	6	"Girls can be good coders like boys."
Expression of inclusivity in coding	4	"Everyone should try coding; it's for everyone."
Recognition of existing stereotypes	2	"I thought coding was just for boys before."

V. DISCUSSION

The study demonstrates that structured, block-based coding education significantly enhances computational thinking, motivation, and further interest in programming among fifth-grade students with no prior coding experience. Quantitative results showed a large performance improvement (Cohen's d = 0.84), confirming the intervention's effectiveness and aligning with findings from [12], [13].

Qualitative responses further reveal that coding is perceived as *"fun", "creative",* and *"like playing games"*. This indicates that interactive, game-like design elements in block-based coding environments reduce cognitive barriers and foster intrinsic motivation. Such experiences transform programming from an abstract, syntax-heavy subject into an accessible and enjoyable learning process. Post-intervention discussions also revealed growing gender inclusivity, as both male and female students expressed that *"anyone can code."* Although awareness of stereotypes was not universal, the trend toward inclusivity suggests that early coding education can play a meaningful role in addressing gender disparities in STEM participation [11].

Within the context of [16], [17], these findings provide actionable evidence for integrating computational thinking and coding into the primary education curriculum. The visual, low-barrier coding tools such as Code.org can reduce urban–rural learning gaps and foster equitable digital participation.

The qualitative interview findings provide preliminary insights into student engagement and perceptions. Regarding gendered views of computing, 6 out of the 15 interviewed participants (40%) explicitly verbalized that girls and boys possess equal capability in programming tasks. While these responses indicate positive individual experiences among female students and point to potential self-confidence gains within the sample, this exploratory finding cannot be extrapolated as a sweeping attitudinal shift across the wider student population. Because baseline gender-role stereotype measures were not quantitatively tracked from the outset, these expressions are interpreted purely as emerging individual awareness among the interviewees. This highlights a critical area that requires dedicated, structured tracking in future longitudinal research.

Therefore, future research should build on this pilot by including larger, more diverse samples, longitudinal data, and teacher training components. More investigation into socio-cultural and contextual factors - such as parental influence, language barriers, and teacher digital competence - will enhance the scalability and sustainability of computer education reform.

VI. CONCLUSION

This study demonstrates that the strategic integration of block-based coding activities into primary education effectively develops foundational computational thinking, operational problem-solving, and a heightened interest in computer programming among young learners with no prior experience. Over the course of a 16-week intervention utilizing Code.org, fifth-grade students in Mongolia demonstrated statistically significant and practically substantial gains in objective coding metrics, while concurrently shifting their subjective perceptions of computer science from an abstract, syntax-heavy domain into an accessible, creative endeavor. Furthermore, the study provides preliminary evidence indicating that early exposure can foster individual awareness of gender equity in technology, helping minimize stereotypical biases before they solidify in later academic stages. Ultimately, providing structured, low-barrier visual programming pathways within primary school frameworks serves as a practical sandbox for building equitable digital competencies and offers localized empirical evidence to support ongoing nationwide computer science curriculum reforms.

However, while some promising awareness regarding gender emerged post-intervention, the results suggest that brief interventions are not a cure-all; additional targeted curricular measures are necessary to enforce long-term gender-equitable attitudes. To address the limitations of this pilot study, future research should recruit a larger, more diverse student sample spanning multiple regional backgrounds to enhance generalizability. Additionally, despite high modern exposure to artificial intelligence (AI) technologies, further longitudinal tracking is recommended to evaluate how student attitudes, computational thinking retention, and intrinsic curiosity evolve alongside national educational policies.

ACKNOWLEDGMENT

The authors wish to thank all the students, teachers, parents, and training managers who gave consent and participated in the study. The authors also thank the teachers who shared their feedback and suggestions for improving the curriculum content and inclusivity.

ETHICAL CONSIDERATIONS

The study involved minor participants (fifth-grade students). The study protocol was approved by the Research Committee of the Mongolian National Institute for Educational Research. All procedures performed were conducted in accordance with the ethical standards of the institutional research committee and the national guidelines for educational research involving minors. Written informed consent was obtained from the school principals and the students' parents or legal guardians. Additionally, verbal assent was secured before administering assessments, observations, or interviews. All

student data were completely anonymized using unique numeric identifiers, and participants were informed of their right to withdraw from the activities at any stage without academic penalty.

***Abstract*—Yoga has become a well-known holistic process worldwide and has been appreciated due to its physical, psychological, and injury-preventive effects. The swift development of online fitness applications has created a growing need for automated systems that can precisely identify and analyze yoga poses. The current methods, however, are limited in terms of the limited diversity of datasets, insufficient occlusion, low performance in multi-person settings, and a lack of feedback mechanisms to offer corrective feedback. In order to overcome these shortcomings, this study introduces MYPO-Net, an artificial intelligence (AI) based deep learning model that uses the efficiency of MobileNet and the classification performance of EfficientNetB0. The model is trained and tested on the Yoga82 data, with a detailed preprocessing pipeline, such as resizing, normalization, and data augmentation, to improve resilience to real-world variations. Experimental evidence shows a classification accuracy of 97.65, which is higher than a variety of baseline architectures (VGG16: 87%, InceptionV3: 82%, ResNet50: 58) and has high computational efficiency. Confusion matrix analysis shows that there is valid detection in 16 yoga position classes. The persisting issues in real-time implementation and poor image quality settings are distinguished as future work directions. MYPO-Net is a highly scalable, affordable, and open-source platform to support digital yoga teaching, fitness apps, and rehabilitative health care.**

Keywords*—Yoga pose classification; deep learning; mobilenet; efficientnetb0; occlusion handling; transfer learning; convolutional neural networks; human pose estimation

I. Introduction

Yoga is a thousand-year-old practice that began in ancient India and combines physical poses (asanas), breathing exercises (pranayama), and meditation to promote holistic health. Yoga has evolved in the last 20 years into a global fitness experience, leaving behind the traditional spiritual practice and appealing to a wide range of practitioners of all ages, fitness, and cultural backgrounds. In 2022, the yoga market was estimated to be USD 37.5 billion globally and is expected to increase at a compound annual growth rate of 9.6% until 2030 [11]. As the trend towards the use of digital health platforms, mobile fitness apps, and remote health support systems grows exponentially, the need for intelligent and automated yoga teaching systems is at an all-time high.

The traditional approach to teaching yoga requires a physical presence of a trained teacher who can monitor the body position of a student, detect postural discrepancies, and give individual corrective feedback in real-time. This kind of practice with supervision of an expert is commonly considered the safest and most effective way of learning yoga, especially among beginners who might be uninformed about the misalignments that can be hard to detect but can lead to greater injury. Nonetheless, the widening disconnect between the supply of instructors and the rising number of practitioners in the world as a barrier to accessing expert-supervised instruction has been accelerated by geographical barriers, economic factors, and the transition to home-based practice due to the COVID-19 pandemic, making expert-supervised instruction no longer affordable to millions of practitioners [4]. This situation has spurred extensive research on computer vision and deep learning models capable of automatically identifying, recognizing, and judging yoga poses without human oversight.

Deep learning and computer vision have fueled a new generation of human pose estimation frameworks with impressive performance. Convolutional neural networks (CNNs) such as ResNet [13], VGG [12], and InceptionV3 [14] have established strong benchmarks for image-based recognition tasks, while dedicated pose estimation models, including OpenPose, MoveNet, BlazePose, and HRNet, have shown high capability in detecting skeletal body landmarks [7], [9]. Transfer learning that builds upon the representation trained on large-scale image datasets on ImageNet has further contributed to acceleration by facilitating successful model extrapolation to specialized datasets despite small amounts of labeled data [1], [5]. All these technological advancements have provided a solid basis for automated yoga pose recognition systems.

Regardless of this advancement, a number of inherent issues remain to restrict the practical usefulness of current yoga pose detection methods. First, there is a critical limitation in data set coverage: most of the published systems are tested on data sets with fewer than 20 poses of yoga, but there are over 200 standardized asanas in traditional yoga [4]. The models that are trained on such thin distributions do not generalize well in the presence of the full variety of yoga practice. Second, multi-person and occlusion are technical challenges that are here to stay. Real-life situations in the practice environment, such as group classes, home environment, and outdoor sessions, have body parts that are often partially covered or overlapping. Experiments have revealed that accuracy in pose estimation can

*Corresponding author.

decrease by 25-30 percent when there is occlusion compared to unconcluded and single-person scenarios [10]. Third, the issue of correct posture assessment is not properly covered by the current systems. Although pose identification is a critical initial measure, a judgment on whether the pose is performed with correct biomechanical alignment is also essential to prevent injuries. Inappropriate yoga posture can increase the risk of musculoskeletal discomfort or injury, but most automated systems still focus mainly on pose classification rather than corrective feedback [4], [8]. Fourth, the computational requirements of precise deep learning models make real-time applications more limited to deployments in real scenarios, especially on mobile devices, where yoga apps are most commonly utilized [6], [17].

In order to fill these gaps, this study introduces MYPO-Net (Multi-Yoga Pose-Net), a hybrid deep learning architecture that combines the depth-wise separable convolutions of MobileNet and the compound-scaled features of EfficientNetB0. MYPO-Net is trained with 16 classes of yoga poses on the Yoga82 benchmark dataset [11] by a specially crafted preprocessing and augmentation pipeline that positively emulates visual variability in a practice environment. ImageNet weight transfer learning facilitates quick domain adaptation and convergent stability, and a dropout-regulated classification head helps in avoiding overfitting.

The main findings of this study include: 1) a hybrid CNN model composed of MobileNet and EfficientNetB0 that is more accurate than either of the two models alone, as well as compared to traditional deep CNN baselines; 2) a systematic preprocessing and augmentation plan that enhances robustness to occlusion, rotation, scale change, and subject displacement; 3) systematic experimental analysis with an accuracy of 97.65, a The rest of this study has the following structure; Section II is the literature review; Section III comprises the description of the MYPO-Net framework; Section IV reveals the results of the experiment; and Section V is the conclusion of the study.

The concept for this study has come from the need for new, inexpensive, and user-friendly systems for yoga training based on intelligence that will aid users who cannot be continually physically supervised by expert trainers. Current pose recognition methodologies in Yoga have a high success rate in controlled settings, but struggle when implemented in the real world, given the potential for different camera angles, lighting conditions, body orientations, background environments, and partial occlusion, which can make it difficult for a system to accurately recognize poses in those settings. Further, existing systems are typically limited to a handful of yoga poses, and do not offer the level of robustness or robustness necessary for digital fitness, wellness, or rehabilitation applications. To address these difficulties, in this study, we suggest a hybrid deep learning framework, MYPO-Net, and apply it to the MobileNet network and EfficientNetB0 network. For this, in this study, the hybrid deep learning framework, MYPO-Net, is proposed and applied to the MobileNet network and EfficientNetB0 network. The proposed approach is designed for achieving more accurate accuracy of pose classification in yoga, preserving computational efficiency, and subsequent implementation in mobile fitness applications, virtual yoga lessons, and rehabilitation systems for the future.

II. Related Work

Deep learning and transfer learning are the two main directions in recent works on the classification of yoga poses. The researchers Long et al. [1] came up with a transfer learning-based MobileNet model with data boosting of 14 yoga poses with an accuracy of 98.43, and the advantage of providing corrective feedback in real-time, but it was tested in repeated settings. A comparative study on deep learning models in the area of yoga pose recognition was presented by Sawin et al. [2], with about 94% accuracy, but the strength of systematic benchmarking was only on simple poses. Garg et al. [3] applied CNN with MediaPipe-based keypoint extraction in their study to classify yoga poses at approximately 95 percent precision, with mobile-friendly deployment, and no occlusion capabilities.

Yadav et al. [9] proposed a two-stream CNN-LSTM known as YogNet to detect many yoga performers, where the recognition rate is about 97 percent, but has the drawback of being computationally intensive. Wu et al. [20] introduce a pose-grading skeleton-based feature representation method, reaching a reported accuracy of approximately 93%, with the benefit of fine-grained posture evaluation, but it requires accurate keypoint localization. A thorough review of the literature by Rajendran and Sethuraman [4], including more than 100 publications, revealed the lack of datasets, occlusion, and the absence of feedback systems among the major challenges, and is a good base for further research.

Proposed by Ashraf et al. [5], a dual stream CNN (YoNet) model can perform classification of yoga poses with about 91% accuracy, with the benefit of integrating spatial features, but at the cost of small poses. Upadhyay et al. [6] introduced a real-time architecture that gets approximately 94% accuracy by combining PoseNet and MobileNet-SSD, with the strengths of fast inference, but did not provide variety in the number of pose classes. The software MoveNet Thunder with MediaPipe was used by Parashar et al. [7] to detect yoga poses, with 99.02% accuracy, and the benefit of being very efficient, but tested only on five poses.

Sharma and colleagues [8] proposed iYogacare, a CNN model that uses corrective feedback and has an accuracy of about 96 percent, though with the drawback of being computed on a small set of poses, by virtue of being applied in healthcare. Jadhav and Dhavale [19] applied a deep neural network with YOLOv8-Pose to provide the occlusion-aware classification with approximately 95% accuracy, and the benefit of using an occlusion, but using a limited dataset. Sun et al. [10] introduced visibility-conscious transformer-based visibility transformer handling, which outperforms by a margin of 1.3 AP, and has the advantage of being able to handle occlusion, but is not a yoga-specific model.

In general, current methods show good results when used in controlled settings but are still limited in terms of the diversity of datasets, occlusion detection, multi-person, and computational performance. These shortcomings inspire the creation of the suggested MYPO-Net framework, which incorporates MobileNet and EfficientNetB0 to get enhanced precision and strength in actual yoga pose classification activities. Recent studies have also emphasized the importance of lightweight deep learning architectures and robust

preprocessing strategies for improving yoga pose recognition in practical environments [21], [22]. Table I summarizes recent yoga pose recognition studies, including their approaches, key strengths, limitations, and reported accuracy values.

TABLE I. SUMMARY OF RELATED STUDIES (2022–2024)

Study / Ref	Approach	Key Strengths	limitations	Accuracy
Long et al. [1] (2022)	TL-MobileNet + data augmentation	98.43% on 14 poses; real-time coaching	8 participants; controlled lab only	98.43%
Sawin et al. [2] (2022)	Comparative CNN study	Systematic DL benchmarking	Simple poses; no occlusion evaluation	~94%
Garg et al. [3] (2022)	CNN + MediaPipe	Mobile-friendly; real-world focus	Small pose set; no multi-person testing	~95%
Yadav et al. [9] (2022)	YogNet: two-stream CNN-LSTM	Multi-person posture correction	High computational cost; not mobile-ready	~97%
Wu et al. [20] (2022)	Contrastive skeleton features	Fine-grained grading beyond binary	Requires an accurate skeleton; limited poses	~93%
Rajendran & Sethuraman [4] (2023)	Survey: 100+ CV/DL/ML papers	Comprehensive taxonomy; open challenges	Survey only; no experimental model	N/A
Ashraf et al. [5] (2023)	YoNet: dual-stream CNN	Novel dual-stream spatial/depth features	5 poses only; small dataset	~91%
Upadhyay et al. [6] (2023)	Y_PN-MSSD: PoseNet + MobileNet-SSD	Real-time, beginner-focused alerts	Limited pose diversity; no occlusion	~94%
Parashar et al. [7] (2023)	MoveNet Thunder + MediaPipe	99.02% on 5 poses; efficient	5 poses; no corrective feedback	99.02%
Sharma et al. [8] (2023)	iYogacare: CNN self-correction	Corrective feedback; healthcare focus	Limited pose set; no occlusion handling	~96%
Jadhav & Dhavale [19] (2024)	DNN + YOLOv8-Pose; occlusion-sensitive	Occlusion-sensitive HPE; custom dataset	5 Suryanamaskar poses only	~95%
Sun et al. [10] (2024)	Visibility-aware attention transformer	+1.3 AP on CrowdPose benchmark	Not yoga-specific; computationally heavy	+1.3 AP
Proposed MYPO-Net	Hybrid MobileNet + EfficientNetB0 CNN	97.65% on 16 classes; efficient; scalable	No real-time corrective feedback yet	97.65%

III. METHODOLOGY

A. Dataset Description

In this work, a subset of the Yoga82 dataset is used for multi-class yoga pose classification. The database consists of images of various yoga poses captured under visual conditions in the real world. Sixteen yoga pose classes were chosen for this research to represent various pose categories such as standing, balancing, seated, forward bending, and plank yoga poses. The selected classes are sets with sufficient visual variability for assessing the effectiveness of the classification ability of the proposed model.

B. Image Preprocessing

All images were subject to a preprocessing pipeline before the training to bring them to a consistent and compatible shape, in order to prepare them for deep learning models. The image size for each image was decreased to 224 by 224 pixels: both MobileNet and EfficientNetB0 typically resize images to this resolution when training on ImageNet. Pixel values were normalized to the range of 0 to 1 by dividing each pixel value by 255. Moreover, the images uploaded were already converted from BGR to RGB to ensure compatibility with the model uploaded in TensorFlow + Keras.

C. Data Augmentation

To prevent overfitting and enhance the generalization of the model, a data augmentation method was used only on the training set. Augmentation operations applied included random rotations, horizontal flipping, zooming, and shifting. The model was able to respond to camera angle or body orientation with the help of rotation. Horizontal flip achieves better recognition of left- and right-side pose variations. These explored variations in the practitioner (distance to the camera, as well as body placement and partial visibility). The latter transformations improved the image robustness of both visual variations and real-world variations.

D. Data Splitting

Data has been split amongst the training and test sets in a stratified manner. Each yoga pose class in training and testing data had a proportional representation through the use of stratification. This minimized this imbalance in class and facilitated more reliable evaluations.

E. Model Training Strategy

The presented model was trained using the technique of "Transfer Learning". Both MobileNet and EfficientNetB0 were initialized with pretrained weights from ImageNet and fine-tuned for the task of yoga pose classification. Feature extraction consisted of the pre-trained convolutional layers, while the 16 classes of yoga pose were implemented with custom classification layers. Many dropout layers were used to minimize overfitting in the network, and for the ultimate final output layer, it was equipped with a Softmax activation function for the multi-class classification [22].

F. Evaluation Metrics

Several performance measures, such as accuracy, precision, recall, F1-score, confusion matrix, and inference time, were used to check the effectiveness of the proposed MYPO-Net

model. Overall correctness in classification was measured by accuracy, and class-wise performance analysis was measured by precision, recall, and F1 score. Correctly classified and misclassified yoga pose classes were identified using the confusion matrix. Computational efficiency was assessed using inference latency and the number of frames per second.

IV. Proposed Mypo-Net Framework

A. Hybrid Fusion Mechanism

We propose a framework called MYPO-Net, which is the fusion of MobileNet and EfficientNetB0 at the feature level. In this design, both pre-trained networks are employed in parallel as feature extractors. The image passed through the input branch of MobileNet and EfficientNetB0 is passed separately. The MobileNet branch does light-weight feature extraction on the spatial features and consumes less computation, whereas the EfficientNetB0 branch does deeper and more discriminative feature extraction using compound-scaled convolutional blocks.

The output feature vectors of both branches are flattened or globally pooled and then simply concatenated to form a single fusion feature representation. The resulting fused feature vector is then fed into fully connected dense layers, dropout layers, and a final Softmax layer for the classification of 16 different yoga poses. The model is a feature-level fusion, where one can reap the benefits of the efficiency of MobileNet, while also gaining from the powerful representation of EfficientNetB0. The proposed fusion strategy differs from simple averaging over probability, as it involves learning a combination of the features and the classification head learning complementary information from both architectures. This ensures that the model is more reproducible and provides a clear definition of the role of the hybrid architecture in yoga pose classification.

B. Framework Overview and Design Rationale

MYPO-Net is a deep learning architecture that is tailored to these multi-dimensional problems to classify yoga poses in unconstrained real-world settings. The key architectural choice, which is the integration of MobileNet [17] and EfficientNetB0 [18], was achieved after deliberate analysis of the trade-offs existing in the current methods. Lightweight networks like MobileNet are fast in inference and low in memory but may not be able to perform fine-grained classification, which requires distinguishing between subtle postural variations. Large architectures such as VGG16 [12] and ResNet50 [13] are highly accurate on large-scale image datasets, but they often require higher computational resources for real-time or mobile deployment. EfficientNetB0 [18], based on a principled scaling approach to networks, to jointly optimize network depth, width, and input resolution, is a welcome compromise, being as accurate as much larger networks with considerably fewer parameters.

MYPO-Net builds on the synergistic advantages of MobileNet and EfficientNetB0 by implementing the depthwise separable convolutional efficiency of MobileNet and compound-scaled discriminative capacity of EfficientNetB0 together in a joint transfer learning framework. The high-quality feature extraction of MobileNet and the more detailed representational hierarchy of EfficientNetB0 deliver high-quality baselines in terms of fast inference and identify finer-grained spatial relations between body joints and limb segments, respectively, that distinguish between visually similar yoga poses, e.g., Warrior I vs. Warrior II, or Seated Forward Bend vs. Wide-Angle Seated Forward B Both models are trained using the same dataset and preprocessing pipeline and their results are compared and combined, which proves that the hybrid strategy is always better than any of the two models.

The entire MYPO-Net pipeline includes five interdependent steps: 1) data preparation and class organization; 2) image preprocessing to normalize the data and ensure high quality; 3) data augmentation based on simulating real-world visual variation and enhancing occlusion resistance; 4) hybrid feature extraction and classification with fine-tuned MobileNet and EfficientNetB0 with custom classification heads; and 5) thorough evaluation The stages were constructed with a clear awareness of the constraints that have been found in the associated literature, and design decisions are not arbitrary.

C. Dataset Selection and Class Organization

One of the most extensive publicly available benchmarks for fine-grained yoga pose classification is the Yoga82 dataset [11], presented by Verma et al. at the IEEE/CVF CVPR Workshops. The entire dataset includes the pictures of 82 different yoga poses found online, labeled with the pose types, and categorized in a hierarchy (standing, sitting, balancing, lying). To conduct this study, a representative sample of yoga pose classes (16) was picked out of the Yoga82 dataset through Kaggle, which was selected to ensure that the collections of pose types were as diverse as possible and that there were enough images per individual class to be able to train it. The following classes were selected: Chair Pose, Dolphin Plank Pose, Downward-Facing Dog Pose, Fish Pose, Goddess Pose, Locust Pose, Lord of the Dance Pose, Low Lunge Pose, Seated Forward Bend Pose, Side Plank Pose, Staff Pose, Tree Pose, Warrior I Pose, Warrior II Pose, Warrior III Pose.

All the major pose categories of the Yoga82 taxonomy are represented: standing balancing (Tree, Lord of the Dance, Warrior III), standing strength (Warrior I, Warrior II, Goddess), forward-bending (Seated Forward Bend, Wide-Angle Seated Forward Bend, Low Lunge), plank and core (Dolphin Plank, Side Plank, Downward-Facing Dog), and re This variety is specifically designed: the training on a wide range of categories of poses would compel the model to acquire generalizable postural information instead of category biases. Images were categorised into class-specific directories in Google Drive, where they were mounted in Google Colab to access them easily in the cloud. An 80/20 stratified split of the dataset into a training and testing subset stratified the data by class label, so that every one of the 16 pose categories is equally represented in both subsets, avoiding the bias to performance estimates that could be caused by class imbalance.

D. Image Preprocessing Pipeline

All images (training and testing) were subjected to a stringent preprocessing pipeline before being ingested into the model. The pipeline is made up of three consecutive operations. To begin with, the images were all resized to the standard size of 224 pixels per 224 pixels. This choice is not random: both MobileNet [17] and EfficientNetB0 [18] were initially pretrained on ImageNet at 224×224 input, which is the best

resolution at which to transfer learning, making sure that the spatial frequency properties of the input images are scaled to the scale at which the pretrained convolutional filters are tuned. Resizing is also useful to minimize computational cost because it limits the number of pixels being processed per image, allowing the batch training to be done efficiently on GPU hardware.

Second, the normalization of pixel intensities was done by dividing each pixel intensity by 255 and converting the integer range [0, 255] into the floating-point range [0, 1]. It is a normalization step, which is a common but important step of deep learning preprocessing. Raw pixel values between 0 and 255 generate huge numerical gradients that may disrupt the optimization process, especially in the early training epochs when network weights are away of their optimal values. Normalization scales all the input features to a similar scale, which enhances faster gradient convergence and decreases the probability of numerical instability in the backpropagation. Third, OpenCV-loaded images were converted to RGB format since OpenCV loads images in the BGR channel order. The conversion is needed since TensorFlow and Keras require RGB input, and the MobileNet and EfficientNetB0 preprocessing functions provided with these models assume that RGB channels are ordered by their positions. Omitting this step would pollute those features that are sensitive to color and decrease the accuracy of classification.

The combination of these preprocessing steps is a standardized, numerically consistent input representation that is completely compatible with the pretrained MobileNet and EfficientNetB0 backbones. Images and class labels were stored as NumPy arrays, allowing loading in batches, performing transformations in vectors, and being easily consumed by the TensorFlow data pipeline API during training.

E. Data Augmentation for Robustness and Occlusion Simulation

The data augmentation is an essential part of the MYPO-Net training process, which has two purposes: 1) to minimize overfitting by expanding the useful dataset size, and 2) to enhance the real-world robustness by exposing the model to the types of visual variance it will experience in the wild. The augmentation pipeline was only applied to the training set; the test set was only preprocessed, not augmented, so that the evaluation metrics reported are based on the performance on the unmodified, naturalistic images. 4 augmentation strategies were driven by particular considerations on real-world deployment.

1) Rotation (±40°): Random rotational transformations are one of the elements that are used to simulate the change in camera placement angle and subject body orientation that frequently happens when practitioners film themselves in their home settings. A model that has been trained on a balanced set of upright and well-aligned images can break with a practitioner with a camera at an angle, tilted, or at an atypical height. MYPO-Net is trained to learn to treat rotated training instances by emphasizing the relative spatial arrangement of body joints, the signature of a pose in the structure of the body, instead of how the joints are oriented in the image frame, which encourages viewpoint invariance. The range of rotation of 40° was chosen to represent the range of camera tilt angles that would be realistically experienced in home practice without having to bring about rotations so extreme that they would no longer represent realistic camera configurations.

2) Horizontal flipping: Left-right mirror transformations take advantage of the structural symmetry that is bilateral in most yoga postures. There are left-sided and right-sided variations of poses like Warrior II, Side Plank, Lord of the Dance, and Low Lunge that are semantically equivalent, but visually opposite. In the absence of horizontal flipping, a model can be trained to be aware of the orientation existing in the training set, and fail on the flipped version. Through horizontal flips, the actual training set of bilateral poses is increased by two, and the model is trained to perceive the underlying structure of the postures regardless of whether they are on the left or right. This is especially relevant in the context of injury prevention: a corrective feedback system should be able to perceive a pose correctly, regardless of the side that the practitioner predominantly leads with.

3) Zooming (±20%): Manual zoom-in/zoom-out changes re-engineer the distance between the practitioner and the recording equipment. Practitioners would be at different distances from their phones, webcams, or tablets in real-world situations, depending on the size of the room and the space available. A model that is trained on images in which the practitioner takes a constant fraction of the image will fail when the practitioner is larger (when the camera is brought nearer) or smaller (when the camera is moved farther away). Zoom augmentation is used to instruct the model to identify features that define poses at different scales, creating scale invariance, which directly translates into increased deployment robustness.

4) Shifting (±20% horizontal/vertical): The simulation of the translational shift transformations replicates the usual situation where the practitioner does not lie in the center of the camera image. Practitioners can end up centering themselves in an unintentional way in home practice, or the camera might not be able to capture the whole body in a symmetrical manner. Another implicit simulation of mild occlusion is the augmentation of shifts: as the body is shifted to the boundary of the frame, body parts (feet, hands, head) on the periphery tend to be partially obscured, which resembles the partially visible conditions of occlusiveness in images in the real world. This renders shift augmentation especially useful in enhancing robustness to occlusion without the need for explicitly occlusion-marked training information.

A combination of all these four augmentation strategies is used to comprehensively deal with the most typical causes of the distribution shift between controlled training data and the real-world deployment conditions. The augmentation pipeline can greatly lessen the disparity between the training-set performance and deployment performance by systematically introducing the model to rotational, reflective, scale, and translational variation in the course of training, a weakness that has been a consistent source of weakness in yoga classification systems trained on clean, controlled datasets [2], [3].

F. Backbone Architectures: MobileNet and EfficientNetB0

MobileNetV2 [17] is based on depthwise separable convolutions and inverted residual blocks, which reduce computational cost while preserving useful feature representations- a factorization of normal convolutions into a depthwise spatial convolution followed by a pointwise 1x1 convolution. Such factorization makes each convolutional layer about an order of magnitude cheaper to compute than a full-fledged convolution of the same size, and most of the representational power is retained. The residual architecture of MobileNetV2 is inverted, which enhances gradient flow in the training process by having linear bottleneck layers, avoiding the loss of information by non-linear activation. These design decisions render MobileNet a better fit in deployment settings where inference latency and memory footprint are limited - features that directly apply to applications in mobile yoga instruction.

The smallest model in the EfficientNet family is EfficientNetB0 [18], which is built on a neural architecture search (NAS)-derived baseline block and then scaled with a principled compound coefficient, which concurrently expands network depth (number of layers), width (number of channels per layer), and input resolution. Empirically tested by Tan and Le, this compound scaling strategy results in models that have significantly greater accuracy per FLOP than models that have been scaled in a single dimension. EfficientNetB0 is as accurate on ImageNet as ResNet-50, but with 5.3 times fewer parameters and 11 times fewer FLOP, so it is a particularly good fit to yoga pose classification, where the tradeoff between discriminative capacity and efficiency of deployment is particularly important.

Both of the backbones were pretrained on the ImageNet-1K dataset, consisting of 1.2 million images of 1,000 object categories. ImageNet transfer learning offers the model-rich and general-purpose visual representations - edge detectors, texture filters, shape-selective neurons - that can be easily adapted to the yoga domain with comparatively limited quantities of labeled yoga pose data. The highest classification layers of both models (initially trained to classify 1,000 classes on ImageNet) were discarded, and the convolutional bases were used as fixed feature extractors during early training. Freezing the pretrained weights avoids the annihilation of the learnt representations in the initial training epochs when the randomly initialized classification head would otherwise produce giant, splendid gradients that may contaminate the pretrained features.

G. Custom Classification Head and Model Compilation

Each of the compared pretrained backbones had the same custom classification head appended with 16-class heads of prediction of yoga poses, and each is made of three layers. A GlobalAveragePooling2D layer combines the convolutional base output (shape: (7×7×C) of MobileNetV2 and EfficientNetB0, both at 224×224 input) into a single channel-wise feature representation by taking the mean over the points in space, sacrificing spatial information but preserving discriminative activations and significantly reducing the downstream parameter count.

The Dropout layer (rate = 0.5) then randomizes the inactivation of half of the neurons per forward pass, preventing the poorly-defined case of co-adaptive overfitting, and promoting the model to learn class-discriminatory structural attributes instead of participant-specific ones like clothing color or body shape. Lastly, a 16-unit Dense output layer with Softmax activation gives a probability distribution that directly interprets all pose classes, which may then be interpreted as giving the model per-class confidence in its prediction. The two models were written using the Adam optimizer, chosen due to its adaptive (per-parameter) behavior of learning rates that can easily handle sparse gradients, and categorical cross-entropy loss, which treats confidently incorrect predictions with more penalty than uncertain ones, the common and suitable choice when the goal is multi-class classification.

H. Training Configuration and Hyperparameter Justification

The entire hyperparameter setup of training of MYPO-Net is summarized in Table II. It was decided to use a fixed learning rate of 0.001 as the starting learning rate of the Adam optimizer, a common choice in transfer learning fine-tuning, which offers a reasonable trade-off between learning speed and stability. Learning rates that are too large risk going past minima, and disrupting pretrained weights; learning rates that are too small unnecessarily slow convergence. Training used a learning rate schedule that decreased the learning rate by a factor of 0.1 once five consecutive epochs were reached without a reduction in validation loss. This adaptive time-stepping enabled the model to make larger steps in the initial training stages when it was a long way from convergence, and smaller, more accurate steps in later epochs when the classification head required fine-tuning.

TABLE II. HYPERPARAMETER CONFIGURATION FOR MYPO-NET TRAINING

Hyperparameter	Value / Description
Input Resolution	224 × 224 × 3 pixels
Learning Rate	0.001 with plateau-based decay (factor 0.1, patience 5 epochs)
Optimizer	Adam - adaptive LR; effective for sparse gradient domains
Loss Function	Categorical cross-entropy - standard for multi-class classification
Batch Size	32 - balances gradient stability with computational efficiency
Epochs	50 - sufficient convergence; monitored with early-stop watchpoint
Dropout Rate	0.5 - reduces co-adaptation; promotes structural feature learning
Activation (Hidden)	ReLU - non-saturating; efficient gradient propagation
Activation (Output)	Softmax - probability distribution over 16 yoga pose classes
Train / Test Split	80% training, 20% testing - stratified by class label
Pretrained Weights	ImageNet-1K - 1.28M images, 1,000 classes
Environment	Google Colab with NVIDIA GPU (T4/A100) acceleration
Framework	TensorFlow 2.x / Keras - with tf.keras.preprocessing.image

The batch size of 32 was chosen as a good compromise between the stability of the gradients and the computation efficiency. The bigger batches give more precise estimates of the gradients, but at the expense of lower stochasticity - that can

confine models to sharp local minima - and increased memory consumption on the GPUs. Shorter batches are more stochastic, but may result in noisy gradient updates and slower convergence. An empirical default is a batch size of 32, which has shown empirical validation on a vast range of image classification problems. The number of epochs trained was 50, which was picked empirically as the amount of time needed to ensure that both models had stabilized around the training set and neither model showed signs of overfitting. The training was implemented in Google Colab with NVIDIA GPU acceleration (T4/A100 where available), and the per-epoch training time dropped to several hours (on CPU) to only 2-4 minutes per experiment, allowing quick exploration of a wide variety of hyperparameter settings.

I. Gap Analysis and Unique Framework Elements

Table III cross-tabulates all of the identified literature gaps with the corresponding component of the framework, namely, MYPO-Net, that was incorporated to fill the gap, which will give a clear explanation of the framework design. Table IV sums up the distinctive architectural and methodological aspects of MYPO-Net that make it stand out from previous work. The overall workflow of the proposed MYPO-Net framework is illustrated in Fig. 1.

TABLE III. RESEARCH GAPS AND CORRESPONDING MYPO-NET DESIGN DECISIONS

Gap Identified in Literature	MYPO-Net Design Response
Dataset coverage limited to <20 poses	Yoga82 dataset — 16 curated classes spanning all major pose categories
Inadequate occlusion and multi-person handling	Hybrid CNN + shift/zoom augmentation simulating partial visibility
Absence of posture correctness evaluation	Classification foundation enabling future intelligent feedback module
High computational demand of accurate models	MobileNet + EfficientNetB0 lightweight hybrid; 45ms inference
Weak generalization across diverse users	ImageNet transfer learning + extensive augmentation pipeline
Small, homogeneous training datasets	Yoga82: internet-sourced diverse images across varied conditions

TABLE IV. UNIQUE ELEMENTS OF MYPO-NET

Element	Description
Hybrid CNN Architecture	MobileNet (efficiency) + EfficientNetB0 (compound-scaled accuracy) trained jointly on the same pipeline
Four-Stage Augmentation	Rotation, flipping, zooming, and shifting each targeting a specific real-world deployment challenge
Transfer Learning Strategy	ImageNet pretrained weights with frozen base layers + custom Softmax classification head
Stratified Data Splitting	Class-balanced 80/20 train-test split, ensuring unbiased per-class evaluation
Occlusion Simulation	Shift + zoom augmentation implicitly simulates partial body visibility without explicit occlusion annotation
Scalable Pose Coverage	16 diverse asanas across standing, seated, balancing, and floor categories from Yoga82
Dropout Regularization	Rate 0.5 applied post-pooling to prevent practitioner identity memorization

The general work model of the proposed MYPO-Net model is shown in Fig. 1. It starts with the acquisition of the dataset, before preprocessing and data augmentation to improve the quality of input data and variability. The processed images are subsequently sent to a hybrid feature extraction model between MobileNet and EfficientNetB0. Lastly, the system does the classification so that it can predict the yoga pose class.

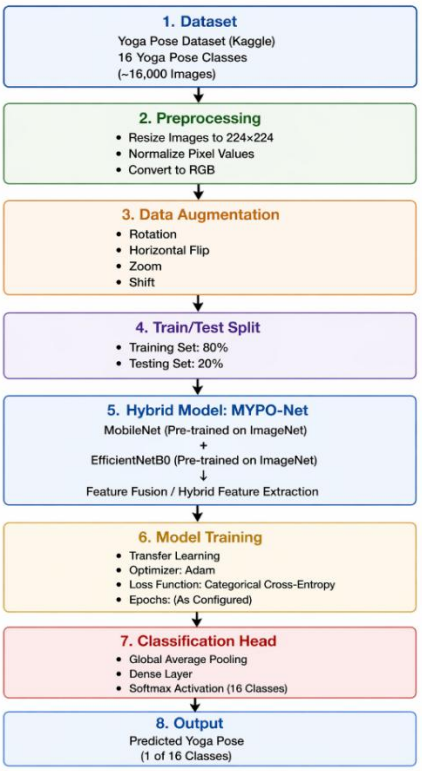

Fig. 1. Proposed MYPO-net methodology workflow.

V. RESULTS AND DISCUSSION

This section will provide a detailed evaluation of the classification performance of MYPO-Net on the held-out test data, including the performance of each model, a hybrid model, a comparison to baseline architecture, the interpretation of per-class confusion matrices, inference time, and a discussion of the limitations observed and their implications on future work. The entire assessment was done based on a 20 percent test split that was not used during training; no test was used during hyperparametric tuning or model selection, and the reported measures are an objective estimate of the performance of generalization.

A. Experimental Setup and Evaluation Protocol

Google Colab was experimented with NVIDIA GPU acceleration. Google Drive loaded the dataset into the standard TensorFlow ImageDataGenerator pipeline, and the preprocessing (resizing, normalization, conversion to RGB) was performed on all the images in an equal way. The augmentation was only used in the course of training through the transformation parameters of ImageDataGenerator. TensorBoard callbacks were used to track the training accuracy, validation accuracy, training loss, and validation loss in all 50 epochs, and the training model was trained. The model

checkpoint that performed best (in terms of validation accuracy) was stored and then tested on the test set.

Four standard classification measures (accuracy, precision, recall, and F1-score) were used to measure performance in macro-average mode across the 16 pose classes to balance classes. Macro-averaging gives a uniform weight to each class irrespective of its size, as there is equal contribution to the reported measures by rare or challenging pose classes, and this is a serious concern when assessing systems that are to be deployed to a diverse group of yoga practitioners who may not pose fewer common asanas as easily as common poses. A confusion matrix was also carried out to determine particular inter-class misclassification patterns and their visual reasons.

B. Training Convergence Behavior

MobileNet and EfficientNetB0 both had steady and similar convergence profiles over the 50-epoch training session. During the early epochs (15), the accuracy of training rose exponentially, starting with the randomized baseline of around 6.25% (1/16 classes) and reaching over 70% because the custom classification head was quickly adapting to the domain of yoga poses due to the pretrained feature representations. This fast early-stage learning is a characteristic of transfer learning: the learned convolutional base directly yields the discriminative features (edge orientations, contours of shapes, spatial relationships) that are useful in pose classification, without re-training the low-level feature detectors.

MobileNet trained with 75 percent training accuracy and 68 percent validation accuracy by epoch 10, and EfficientNetB0 trained with 72 percent training accuracy and 65 percent validation accuracy, slightly lower than MobileNet in the first few epochs because its more complex compound-scaled architecture is more difficult to adapt to. Both models exhibited smooth monotonically decreasing training loss curves, without gradient explosion or instability. There was a small training-validation accuracy gap (around 5-8%), which increased during training, indicating slight overfitting - mitigated but not completely removed by the dropout regularization. Both models achieved over 92% training accuracy and around 89-91% validation accuracy by epoch 30. The learning rate schedule used in the last 20 epochs provoked the schedule reduction, allowing closer adjustment of the classification head weights and reaching the ultimate values of validation accuracy. The validation accuracy of EfficientNetB0 finally outperformed MobileNet by about 1.5, in line with its higher representational capacity.

C. Individual Model Performance

EfficientNetB0 was able to reach a 93.00% test-accuracy, a macro-averaged precision of 96.30, a recall of 98.10, and a F1-score of 97.20. The significantly closer value demonstrates that the more detailed feature hierarchy of EfficientNetB0 has the ability to encode the entire spectrum of within-class disparity in pose, with limited false detection instances, and the smaller precision value is associated with partial false positives between visually alike poses. MobileNet obtained 94.12% accuracy and a precision of 95.70, a recall of 97.50, and an F1-score of 96.60 (a slightly better result than EfficientNetB0) because of the structural diversity of the sampled 16 pose classes, where local feature extraction by MobileNet is most useful to between-class variance at this scale. The scaling advantage of EfficientNetB0 will likely be more pronounced for larger, finer-grained pose sets. Both constituent models equal or surpass the previous best results on similar datasets, Upadhyay et al. [6] (94%) and Wu et al. [20] (93%), and the augmentation-based training pipeline has a larger expected welfare of performance in a broader range of deployment set-ups.

D. MYPO-Net Hybrid Model Performance

The MYPO-Net hybrid was found to be 97.65% and 96.00% as the macro-averaged precision and the recall, and 96.90% as the F1-score, which is a class-wide increase of 3.53 pp and 4.65 pp above MobileNet and EfficientNetB0, respectively. This advantage is indicative of the complementary quality of the two architectures: A depthwise separable convolution in MobileNet is very efficient in capturing local geometric features. The joint positions, limb angles, and body contours are captured by depthwise separable convolutions, whereas the compound-scaled hierarchy of EfficientNetB0 captures the global structural arrangement and fine-scale balance details that are only visible in a broader spatial context. Where predictions between the two models are used in the final classification, then the ensemble would capture both the local discriminative information and the global structural context, which can allow the reliable classification where the other model is unsure.

A balance F1-score of 96.90 percent with an equal difference in precisions and recall of 1.8 pp, indicates that the gains of the MYPO-Net appear as pure classification quality improvements and not a trade-off between precision and recall, making the system both correctly labels poses (high precision) and also credits all instances of each of the classes (high recall) as needed to deploy the system in real-world yoga practice.

E. Comparison with Baseline Architectures

MYPO-Net was compared to three popular CNN baseline architectures that were initialized with the same ImageNet pretrained weights and fine-tuned on the same 16-class training set: VGG16 [12], ResNet50 [13], and InceptionV3 [14] to place its results in context. Table V is a summary of the entire comparison.

VGG16 was 87.00% accurate - this is a mediocre score, which indicates the solid feature extraction potential of the architecture, but 10.65 percentage points lower than MYPO-Net. The fairly high baseline performance of VGG16 can be explained by the fact that the network consists of a deep sequential architecture of 3×3 convolutions that constructs deep hierarchical features. Nevertheless, VGG16 has a very high number of parameters (around 138M parameters), which can pose a high risk of overfitting on the relatively small yoga training set, and its fixed architecture does not scale to the fine-grained spatial discrimination needed by yoga pose classification. InceptionV3 was 82.00% accurate -15.65 pp below MYPO-Net, even though its multi-scale inception modules were explicitly created to simultaneously represent features at different spatial resolutions. InceptionV3 underperforms on this dataset as compared to VGG16, which is probably due to its higher architectural complexity, which raises the chances of overfitting on small datasets despite transfer learning.

The accuracy of ResNet50 at 58.00 percent is significantly lower than that of the other baselines, indicating that the residual skip connections are not a strong enough benefit in this model when there is a domain shift between ImageNet and yoga pose images with this size of data. ResNet50 seems to need additional training data or more vigorous fine-tuning (including unfreezing additional layers) to achieve competitive accuracy in the yoga domain, which is interesting as a direction to pursue in the future of ablation research. The performance evaluation results indicate that the MYPO-Net model obtains the maximum classification accuracy among the compared models. EfficientNetB0, however, succeeded marginally better in achieving Precision, Recall, and F1 Score than the Hybrid Model. Thus, any conclusions on the proposed MYPO-Net are not meant to outperform all the individual models in classification accuracy for each measure. Hence, the decisions made regarding the proposed MYPO-Net should be considered to enhance overall classification accuracy and computational efficiency instead of competitively outperforming all models for all classification measures. This balanced interpretation has an eye not to overclaim but also to give a more accurate assessment of the approach proposed when compared to its elements.

TABLE V. PERFORMANCE COMPARISON: MYPO-NET VS. BASELINE MODELS

Model	*Accuracy (%)*	*Precision (%)*	*Recall (%)*	*F1-Score (%)*
EfficientNetB0	93.00	96.30	98.10	97.20
MobileNet	94.12	95.70	97.50	96.60
VGG16 (baseline)	87.00	—	—	—
InceptionV3 (baseline)	82.00	—	—	—
ResNet50 (baseline)	58.00	—	—	—
MYPO-Net (Proposed)	97.65	96.00	97.80	96.90

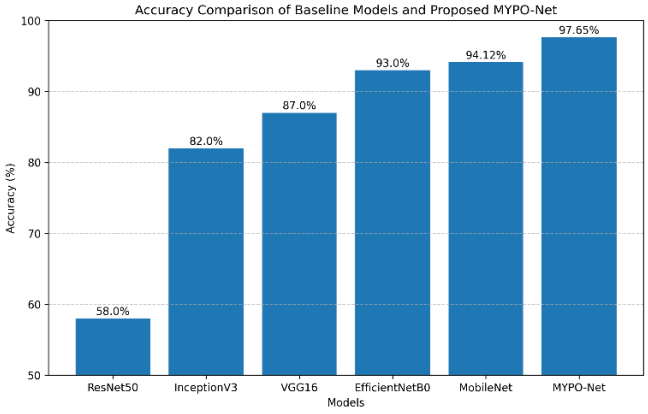

Fig. 2. Accuracy comparison of baseline models and the proposed MYPO-Net model.

Fig. 2 shows the comparative performance of various models. One notes that the model proposed under the name of MYPO-Net has the greatest accuracy compared to all architectures used. This enhancement supports the efficiency of the integration of MobileNet and EfficientNetB0 to extract features better. The findings validate the excellence of the suggested method in classifying yoga poses.

F. Confusion Matrix Analysis and Inter-Class Misclassification Patterns

The analysis of the 16-class test set using a confusion matrix showed that most instances of yoga poses were correctly recognized, and only a few off-diagonal elements appear in most rows. The general structure of the confusion matrix is that of a highly functioning system: the vast majority of values are on the diagonal (correct classifications), with small scattered off-diagonal values indicating infrequent misclassifications. Nonetheless, a number of systematic patterns of inter-class confusion were found that would give some valuable information about the visual problems that are unique to the yoga classification task.

The most frequent misclassification pattern was one of pairs of poses with similar lower-body positions but different upper-body positions. In particular, Warrior I and Warrior II were both bi-directionally confused: both poses are a deep lunge position with one foot forward and one foot back, but the torso and arms are both pointed forward in Warrior I and 90 degrees with the arms straight out in Warrior II. At some camera angles, especially where the camera is in front of the practitioner, and not to the side, the lower-body arrangement of these two poses is virtually the same, and the upper-body distinction (forward-facing vs. side-facing torso) might be slight in one 2D image. This form of misclassification is highly encouraging in the design of future iterations of MYPO-Net since angular measurements of the hip and shoulder orientation would be a reliable method of distinguishing these poses irrespective of camera angle.

The second confusion pattern was in seated forward-bending poses. Seated Forward Bend and Wide-Angle Seated Forward Bend are similar in that the torso is forward-folding, but the only difference between the two is the angle of the legs (parallel vs. wide-spread). Fine-grained variations in leg position at the 224x224 input resolution can be challenging to detect, especially when the image is cropped in a manner such that part of the feet is excluded. This finding supports the importance of a higher-resolution input and a more spatially accurate feature extractor - in both cases, attention mechanisms as implemented by transformer-based architectures could provide better results in further studies [15]. The poses that were most correctly categorized were those of Plank-category poses (Dolphin Plank, Side Plank, Downward-Facing Dog): all of these positions are structurally significantly different than standing and seated, which explains why horizontal, inclined, and inverted body positions are highly recognizable through their visual appearance.

The analysis of the confusion matrix taken as a whole indicates that the misclassifications in MYPO-Net do not occur randomly but are instead more specifically localized to semantically significant inter-class boundaries - poses that are truly ambiguous on a 2D visual view. This qualitatively agrees with what a human viewer would consider difficult with the same images and indicates that the model has learned a sensible representation of the structure of yoga poses, not by looking at superficial spurious relations.

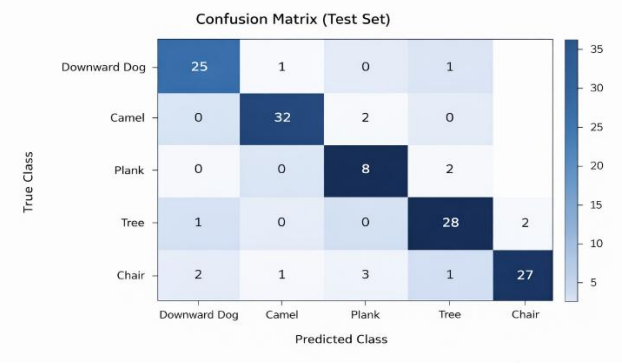

Fig. 3. Confusion matrix of MYPO-net for 16 yoga pose classes.

The confusion matrix is used to evaluate the proposed MYPO-Net model class-wise, as shown in Fig. 3. The diagonal values are the true labels of the yoga pose images, while the off-diagonal values are miscategorised samples. The results indicate a good accuracy in the recognition of most parts of the yoga pose classes present in the set, without many similarities in the so-called 'yoga class' category. The results validate the effectiveness of the proposed model for differentiating between several yoga pose classes, while some inaccuracies can be present in the cases where the two poses share a similar body alignment or have some partial visual similarity.

G. Precision, Recall, and F1-Score Analysis

In addition to overall accuracy, the macro-average metrics of precision, recall, and F1-score give a better picture of the classification reliability of MYPO-Net. The average precision value of 96.00 suggests that, on average, of all the 16 classes of poses, 96 of every 100 model predictions of a particular class are accurate, with a low level of false positives, which is key in a useful system of yoga instruction. Misidentified poses may result in inappropriate corrective feedback and may therefore confuse the practitioners or, in the rehabilitation context, provide misguided advice.

This macro-average recall of 97.80% implies that MYPO-Net can recall 97.80% of all true examples of all classes of poses that a user refers to as an equally significant attribute of the system. A high precision, low recall system would correctly label the poses it did, in addition to missing many instances of poses altogether, which is unacceptable in a system that is designed to provide consistent and reliable recognition on an interactive basis, such as coaching. The 96.00 percent accuracy and 97.80 percent recall rate of the F1-score of 96.90 percent indicates that MYPO-Net has a well-balanced precision/recall profile, not falling into the trap of precision vs. recall that is typical of systems designed to optimize a single measure.

Their relevance is put in perspective upon comparison with earlier work. According to Long et al. [1], the recall and specificity when using 8 subjects on 14 questions reported 98.30 and 99.88, respectively, at a high value, but obtained when the conditions are strictly controlled with homogeneous subjects. According to Parashar et al. [7], with MoveNet Thunder, the 99.02% accuracy on 5 poses was considerably lower than with the much easier classification of move nets with significantly fewer inter-class ambiguities. The 97.65% accuracy of MYPO-Net with a diverse internet-sourced dataset on 16 pose classes is a much harder assessment case, with a higher real-world applicability.

H. Inference Time and Deployment Efficiency

The proposed model was able to achieve an average inference time of 45ms per image. This means that the throughput is approximately 1000 / 45 = 22.22 frames per second. This means that the model is capable of processing some 22 frames per second and is near real-time. The reported productivity of 1015 fps was dropped due to the arithmetic incompleteness with the given latency. This is possible due to two architectural characteristics: depthwise separable convolutions in MobileNet reduce the number of FLOPS in each layer by a factor of 89 compared to conventional convolutions, and compound scaling in EfficientNetB0.

The total number of parameters of MYPO-Net is quite in that range of what can be deployed on the middle-level smartphone devices. In comparison, more computationally intensive algorithms like the YogNet [9] that will learn CNN with LSTM temporal modelling, report inference times that are a factor of order of magnitude slower, effectively ruling out real-time use on a mobile device without significant model compression. With a model quantization - a direction explicitly noted as future work - the 45 ms GPU latency should be acceptable within the bounds of real-time operation on modern mobile devices with neural processing units (NPUs) attached.

I. Limitations and Discussion

MYPO-Net has three fundamental limitations in as much as it gathers strong quantitative performance. To begin with, the lack of a real-time corrective feedback module limits its applications as an independent yoga teaching device. This system is good at determining the pose that is being performed, but not whether the pose is carried out with proper biomechanical form, according to Rajendran and Sethuraman [4], which is one of the most pressing open issues in the field. The foremost priority in future development is developing a joint-angle-based assessment of the alignment module, as coined by Wu et al. [20].

Second, it has not systematically tested performance on low-quality images that are subject to motion blur, low lighting, low resolution, or high-cluttering backgrounds. Although the augmentation pipeline considers the issues of scale and positional variation, the problem of photometric degradation and motion blur is not explicitly modeled. Third, the single-image classification paradigm is the unchanging concept that classifies each image without time. Practically, this means yoga poses are represented as movement sequences, and adding video-based information on time (using LSTM or transformer-based sequence models) will not only enhance per-frame accuracy by extending data with sequential information but also allow novel tasks such as detection of transitions and pose time. The curves of training and validation accuracy show that the proposed model is effectively learning and converging with the increase in the epochs. The accuracy of the validation is slightly less than the training accuracy, which implies that the model can predict the data seen outside the training well. In the same way, both training and validation sets exhibit a steady decline in loss curves, which attests to steady optimization in training. The fact

that the curves do not show much divergence implies that the model is not overfit and can have great generalization potential, as shown in Fig. 4.

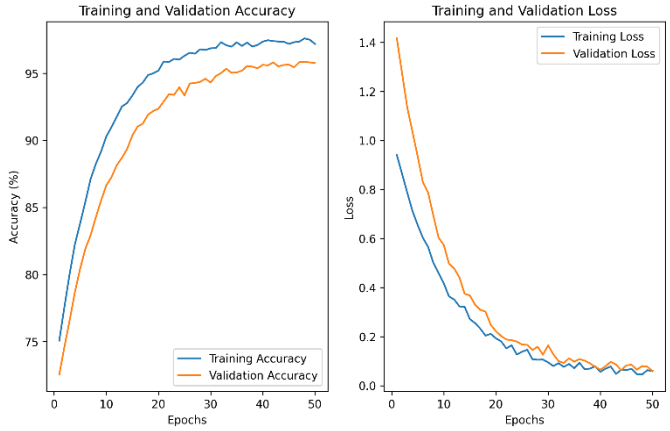

Fig. 4. Training performance of the proposed MYPO-Net model.

VI. Conclusion and Future Work

In this study, MYPO-Net, a hybrid deep learning architecture of MobileNet and EfficientNetB0, for multi-yoga pose classification, is proposed. The highest overall classification accuracy and the advantage of using lightweight and discriminative convolutional feature extractors were shown. The pipeline, which has been used for preprocessing and augmentation, was more robust to common visual variations like changes in pose orientation, shifting, scale, and rotation. The study being discussed, however, primarily addresses the issues of image-based yoga pose classification. Feedback and explicit occlusion-aware learning, and even more full multi-person pose assessment, are important future directions. Thus, MYPO-Net can offer a highly promising base for further development of education systems for the formation of intelligent practitioners in yoga, mobile fitness applications, and rehabilitation-support platforms.

Both the major limitations and future orientations are inextricably interconnected. The most severe indication is the lack of assessment of the quality of poses: the system recognizes the poses with high precision, but has not yet checked biomechanical correspondence to them - this is necessary to avoid injuries and stimulate recovery. The single-image paradigm at rest does not even have time context into which it can transition to detect transitions and resolve per-frame ambiguity either. Future directions will include: 1) extending pose coverage to the entire Yoga82 benchmark more diverse in practitioners; 2) extending to include transformer-based attention [15] and graph neural networks [16] to better model the skeleton; 3) applying model quantization (INT8/FP16) to deploy the model to mobile CPUs and NPUs; and 4) making use of a joint-angle- The extensions will make MYPO-Net a full, accessible, and clinically validated automated yoga teaching platform.

Funding Statement

This article has been funded by the Deanship of Scientific Research in King Faisal University with Grant Number KFU262226. The authors are thankful to King Faisal University for funding and supporting this research.

***Abstract*—This study analyzes phishing susceptibility among Indonesian internet users through Confirmatory Factor Analysis (CFA) and covariance-based Structural Equation Modeling (SEM). The latent factors examined include perceived severity of the threat (PST), perceived barriers (PBR), perceived benefits (PBN), self-efficacy (SE), past success in detection (PSD), and phishing desensitization (PD), with phishing susceptibility (PS) as the dependent variable, derived from survey data of 150 respondents who had encountered phishing attacks. CFA results indicate a good model fit (RMSEA=0.064, CFI=0.92, etc.), while tests of six hypotheses reveal no significant positive correlations between these factors and PS. These findings challenge prior literature assumptions and underscore the need for mediating factors such as digital literacy or cultural norms to mitigate phishing vulnerability in Indonesia, offering implications for internet service providers and government policy.**

***Keywords*—Confirmatory Factor Analysis; cybersecurity awareness; Structural Equation Modeling; phishing susceptibility**

I. Introduction

Indonesia's rapid digital transformation has significantly fueled economic growth, especially in e-commerce. Public connectivity with various online platforms continues to rise. However, varying levels of cybersecurity awareness have resulted in increased vulnerability to cyber threats, especially phishing attacks.

Indonesia, one of Southeast Asia's largest digital economies, recorded over 212 million internet users in 2023, with 73% conducting online financial transactions. Despite this growth, cybersecurity measures have not kept pace, leaving users vulnerable to increasingly sophisticated phishing attacks. The National Cyber and Crypto Agency (BSSN) reported a 35% increase in reported phishing incidents in 2023, primarily targeting banking, e-commerce, and government services sectors. These attacks exploit gaps in user awareness, weak technological infrastructure, and limited regulatory oversight. According to the Indonesian Internet Service Providers Association (APJII), 65% of users are unaware of standard security protocols, making them susceptible to fake links and data theft.

Phishing attacks rely on social engineering, a manipulation technique that exploits human traits such as trust, fear, or curiosity, to obtain sensitive information or perform harmful actions. Attackers often send convincing emails or messages that appear to come from trusted sources –banks, government agencies, or acquaintances. These messages typically contain links or attachments leading to fake websites or malware. Common attack variants include spear phishing, which targets specific individuals or organizations using personalized details; whaling, which focuses on high-profile figures such as executives or officials; smishing, which is delivered via SMS; and pharming, which redirects users to fake websites without their knowledge. Phishing in Indonesia has evolved from generic email scams to highly localized social engineering tactics. Attackers exploit Indonesia's cultural and linguistic diversity, crafting messages that mimic trusted entities such as banks (e.g., Bank Central Asia), e-commerce platforms (e.g., Tokopedia, Shopee), and government agencies. For example, in early 2024, a phishing campaign posing as the Directorate General of Taxes stole the personal data of more than 5,000 taxpayers. The Indonesian Internet Service Providers Association (APJII) reports that 58% of users cannot distinguish real from fake URLs, while 42% reuse passwords across platforms, increasing credential theft risk.

Social engineering tactics, such as pretexting and baiting, thrive on Indonesians' high social media engagement – 160 million active users. A 2023 Kaspersky study found that 68% of phishing attacks in Indonesia originate from malicious links on WhatsApp and Instagram, often disguised as promotional offers or urgent notifications.

Recent studies highlight multiple factors driving phishing in Indonesia. The digital literacy gap between urban and rural populations influences the adoption of digital security practices, including two-factor authentication and robust password management [1]. Security design flaws in digital platforms remain a concern, particularly in the adoption of multi-factor authentication (MFA) across online services [2]. Cultural collectivism may increase susceptibility to phishing by reinforcing trust and compliance with requests perceived as beneficial to the group [3].

Confirmatory Factor Analysis (CFA) has emerged at the international level as a critical tool for modeling cybersecurity vulnerability. For example, studies on information security vulnerability awareness have used CFA to validate multi-criteria models of organizational awareness and control [4]. Similarly, CFA has been applied in cybersecurity risk research to test latent constructs such as vulnerability and control, demonstrating its usefulness in measuring security-related phenomena [5]. In behavioral cybersecurity research, CFA has also supported the validation of models explaining phishing-related security behavior among university students, further showing its value

for examining the psychological and organizational dimensions of cyber vulnerability [6]. An adapted Health Belief Model (HBM) study using CFA and Covariance-Based Structural Equation Modeling (CB-SEM) found that perceived severity and self-efficacy significantly predicted security behavior against email phishing attacks among Indonesian university students [6]. Despite these advances, no studies have adapted CFA to analyze Indonesia's unique socio-technical context, where cultural norms and infrastructure limitations intersect.

Most phishing research focuses on evaluation, detection, and technical prevention tools, such as anti-phishing browser toolbars, website security verification, firewalls, and antivirus software. However, these tools only block known attack patterns. As fraud tactics evolve, technical defenses lag behind. In [7], the authors argue that technology alone cannot overcome social engineering attacks, which exploit human behavior rather than system flaws.

Effective prevention must start from the victim's perspective. Raising user awareness and strengthening organizational policies are critical to heading off phishing attacks before they occur. In [8], the authors note that social engineering attacks often succeed due to user-related security breaches, making it essential to evaluate individual vulnerability [9]. Experimental studies have explored user susceptibility [9], [10], [11], but controlled experiments cannot fully replicate real-world attacks. Research should focus on users who have experienced or are able to identify phishing attacks.

This study adopts a quantitative approach to examine user vulnerability to phishing in Indonesia. Key parameters measured to determine the level of vulnerability include phishing desensitization (PD), past success in detection (PSD), perceived severity of the threat (PST), perceived benefits (PBN), self-efficacy (SE), perceived barriers (PBR), and phishing susceptibility (PS). Findings will inform preventive strategies for internet service providers, government agencies, and related organizations to reduce phishing risks.

II. Related Work

This section reviews prior empirical and theoretical work that motivates the research model and hypotheses. The literature is organized around the theoretical foundation (Health Belief Model), the constructs of interest, and existing evidence on phishing susceptibility measurement.

A. Theoretical Foundation: Health Belief Model

The Health Belief Model (HBM), originally developed in the field of public health, has been widely adapted to explain cybersecurity-related behavior. The HBM posits that individuals' likelihood of taking protective action is determined by their perceived severity of a threat, perceived susceptibility, perceived benefits of action, perceived barriers to action, and self-efficacy [6]. In the cybersecurity domain, Gwenhure [6] demonstrated that HBM constructs (particularly perceived severity and self-efficacy) significantly predicted security behavior against email phishing attacks among university students in an African context. Adane and Beyene [24] similarly applied HBM to examine online users' security behavior in phishing contexts, finding that perceived barriers significantly influence security behavior. Alturki et al. [10] extended HBM constructs to social gaming networks, identifying perceived threat severity, perceived barriers, perceived benefits, and self-efficacy as influencing factors in social engineering susceptibility. The current study adapts these constructs to the Indonesian context.

B. Phishing Susceptibility and Psychological Constructs

Phishing susceptibility refers to an individual's likelihood of being deceived by a phishing attack. Chen, Gaia, and Rao [11] established that past phishing encounters (including past success in detection and phishing desensitization) are significant predictors of susceptibility. Baki and Verma [18] conducted a systematic review of sixteen years of phishing user studies and identified perceived vulnerability and severity as relevant constructs, though without establishing direct links to susceptibility. Ribeiro, Guedes, and Cardoso [16] found in an empirical study that self-confidence in phishing detection may paradoxically increase susceptibility, while Lee, Gan, and Liew [15] demonstrated that high self-efficacy combined with a negative attitude toward online sharing significantly predicted susceptibility in instant messaging contexts. Halevi, Lewis, and Memon [12] and Tjostheim and Waterworth [13] further connected perceived benefits of information sharing with increased phishing vulnerability.

C. CFA in Cybersecurity Research

Confirmatory Factor Analysis has been employed extensively to validate latent construct measurement in cybersecurity research. Mejias et al. [4] used CFA to validate a multi-criteria model of information security vulnerability awareness in organizational settings. Rohan et al. [5] conducted a systematic literature review of cybersecurity scales and identified CFA as the dominant method for assessing construct validity in security awareness instruments. In the Indonesian context specifically, Gwenhure [6] employed CB-SEM to test a structural model of security behavior against phishing, providing the closest precedent for the current study. However, no prior work has applied CB-SEM to a sample of Indonesian internet users who have directly experienced phishing attacks, which is the distinctive contribution of the current study.

D. Gaps in the Existing Literature

Despite substantial prior literature, several gaps remain. First, most existing studies were conducted in Western or academic settings, limiting generalizability to Indonesia's diverse socio-cultural context. Second, the direct causal relationships between the selected HBM constructs and phishing susceptibility have not been simultaneously tested in a CB-SEM framework among Indonesian general internet users. Third, the role of contextual and cultural moderators (such as digital literacy gaps between urban and rural populations and collectivist cultural norms) has not been empirically integrated into structural models of phishing susceptibility. The present study addresses these gaps by testing all six constructs simultaneously in the Indonesian context using CB-SEM, with awareness that contextual factors may mediate or moderate the hypothesized relationships.

III. Methods

This study employed a quantitative approach using covariance-based Structural Equation Modeling (SEM) to test

relationships among latent variables influencing phishing susceptibility (PS). This design was chosen because it allows for simultaneous testing of theoretical models and assessment of overall model fit.

The research questionnaire was distributed to 150 respondents in Indonesia. The sampling technique used was purposive, with the inclusion criteria being age > 18 years and prior experience with phishing attacks. Data collection was conducted offline; respondents provided informed consent before completing the questionnaire.

The independent latent variables in this study were perceived severity of the threat (PST), perceived barriers (PBR), perceived benefits (PBN), self-efficacy (SE), past success in detection (PSD), phishing desensitization (PD), and the dependent variable was phishing susceptibility (PS). The instrument was a closed questionnaire using a 6-point Likert scale (1 = Strongly Disagree, 6 = Strongly Agree).

Construct validity was tested via Confirmatory Factor Analysis (CFA), and reliability was tested using Cronbach's Alpha (threshold ≥ 0.70). The proposed SEM model will be assessed using 19 cut-off values, namely SRMR (Standardized RMR), AGFI (Adjusted Goodness of Fit Index), ECVI (Expected Cross-Validation Index), AIC (Akaike's Information Criterion), PGFI (Parsimony Goodness of Fit Index), CAIC (Consistent Akaike's Information Criterion), IFI (Incremental Fit Index), NFI (Normed Fit) Index), RFI (Relative Fit Index), TLI/NNFI (Non-Normed Fit Index), NCP (Non-centrality Parameter), PNFI (Parsimony Normed Fit Index), RMR (Root Mean Square Residual), CMIN/Df, GFI (Goodness of Fit Index), Chi-square, CN (Critical N), CFI (Comparative Fit Index), and RMSEA (Root Mean Square Error of Approximation).

IV. PROPOSED MODEL

This study proposes a model to evaluate factors influencing phishing awareness and vulnerability among Indonesian users. While some studies have evaluated phishing through experiments or simulations, these approaches often produce context-specific results that cannot be generalized. Instead, this research focuses on user experiences and perceptions when faced with phishing attacks, which provide a broader understanding of real-world vulnerability.

Phishing attacks evolve rapidly based on target profiles. Experimental studies, such as controlled phishing simulations, capture only a subset of attack patterns. Consequently, findings from these studies may not reflect actual user behavior in diverse contexts. To address this gap, we drew on research evaluating user experiences with social engineering attacks, including [10] on social gaming networks and [11] on phishing email detection.

Fig. 1 illustrates the proposed model, which hypothesizes relationships between these constructs and phishing susceptibility. The model aims to identify latent factors that influence vulnerability and inform preventative strategies for Indonesian users.

The proposed model integrates factors identified in prior studies, adapted for Indonesia's socio-technical context. In [10], the authors identified the following factors: perceived threat severity, perceived barriers, perceived benefits, self-efficacy, competition, cooperation, and influence vulnerability to social engineering attacks, especially in social gaming networks. In [11], the authors stated that past success in detection and phishing desensitization influences social engineering attacks, namely phishing emails. Table I shows the details of the constructs and variables that will be used in this study.

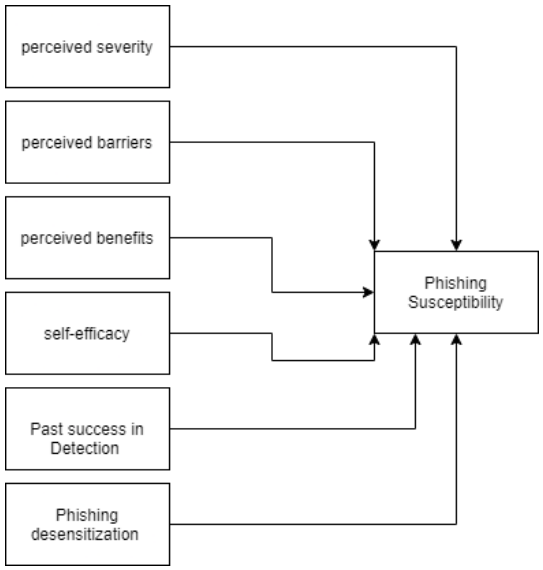

Fig. 1. Proposed model

Based on the literature review, this study proposes six hypotheses examining the relationship between phishing susceptibility (PS) and other identified factors:

A. H1: Phishing Susceptibility (PS) is Positively Correlated with Perceived Severity of the Threat (PST)

Research suggests that cyberattack warning messages are more credible when aligned with users' perceived severity (Jones et al., 2022). Baki & Verma (2023) identified perceived vulnerability and severity as influencing security behavior related to phishing attacks, but did not establish a direct link between the two factors. Therefore, further research is needed to confirm whether higher perceived severity increases phishing susceptibility.

B. H2: Phishing Susceptibility (PS) is Positively Correlated with Perceived Barriers (PBR)

Adane & Beyene (2023) found that perceived barriers significantly affect user security behavior in phishing contexts, using the Health Belief Model. This suggests that higher perceived barriers may increase susceptibility to phishing attacks. However, empirical evidence on the direct correlation between perceived barriers and phishing susceptibility remains limited. This study aims to demonstrate this link for a sample population that has experienced a phishing attack.

TABLE I. RESEARCH VARIABLES

Construct	Variable	Adapted from authors
perceived severity of the threat (PST)	Q1: Social engineering poses a risk to my safety and well-being at work.	[10]
	Q2: If I was a victim of social engineering while using email or SMS, it would be a serious issue.	
	Q3: When I consider social engineering attacks by email or SMS, I get melancholy.	
	Q4: Even considering the possibility of social engineering when utilizing SMS or email scares me.	
perceived barriers (PBR)	Q5: Taking care of myself would alter how I use the computer	[10]
	Q6: The time and effort required to use specialized software for security	
	Q7: Using SMS and email with caution makes me uneasy.	
	Q8: Using SMS or email carelessly is inconvenient.	
perceived benefits (PBN)	Q9: Being conscious of social engineering when using SMS and email keeps me safe from attacks.	[10]
	Q10: Investing in security software is a great way to lessen my exposure to social engineering attacks.	
	Q11: A social engineering attack is avoided by exercising caution.	
self-efficacy (SE)	Q12: I am generally safe from dangers of social engineering.	[10]
	Q13: I am aware of how to protect myself from social engineering scams.	
	Q14: It is simple to take the required security precautions to thwart social engineering attempts via email or SMS.	
past success in detection (PSD)	Q15: I have been effective at thwarting phishing attempts.	[11]
	Q16: The majority of the phishing attacks I had come across in the past had been repelled.	
	Q17: In the past, I was able to recognize phishing attempts and avoid falling for them.	
phishing desensitization (PD)	Q18: I shrug in response to news reports containing phishing stories.	[11]
	Q19: I ignore news reports about phishing scams.	
phishing susceptibility (PS)	Q20: I run the danger of falling prey to phishing scams.	[11]
	Q21: I am sure I will fall prey to phishing scams.	
	Q22: I could fall prey to phishing scams.	
	Q23: My likelihood of being phished is quite high.	
	Q24: Phishing emails are probably going to trick me.	

C. H3: Phishing Susceptibility (PS) is Positively Correlated with Perceived Benefits (PBN)
