Individuals who perceive benefits in sharing personal information (e.g., through social media or phishing emails that offer rewards) may be more susceptible to phishing attacks [12], [13]. Additionally, if individuals perceive significant benefits in interacting with protective measures, their vulnerability may decrease [13], [14]. While these studies imply a relationship between perceived benefits in online behavior and phishing susceptibility, direct evidence linking the two factors is scarce, warranting further investigation.

D. H4: Phishing Susceptibility (PS) is Positively Correlated with Self-Efficacy (SE)

Several studies suggest that high self-confidence can increase susceptibility to phishing attacks. A study on instant messaging phishing found that higher self-efficacy and a negative attitude toward sharing personal information online significantly predicted phishing susceptibility [15]. Another study showed that individuals who considered themselves highly confident in detecting phishing attacks were more susceptible to phishing attacks [16]. This hypothesis tests whether self-efficacy has a positive correlation with phishing susceptibility.

E. H5: Phishing Susceptibility (PS) is Positively Correlated with Past Success in Detection (PSD)

Previous success in detecting phishing may influence susceptibility [11]. While experience and training can improve detection, they may also lead to false alarms and complacency [17]. Conversely, other studies have found that experience and knowledge can improve detection abilities and potentially reduce vulnerability [11], [17], [18], [19]. Given these mixed conclusions, this study examines whether past success in detection corresponds positively with phishing susceptibility.

F. H6: Phishing Susceptibility (PS) is Positively Correlated with Phishing Desensitization (PD)

Phishing desensitization refers to the reduction in a person's sensitivity after repeated exposure to phishing. In [20], the authors found that desensitization moderates the impact of recent phishing experiences, along with factors such as prior detection success. In [11], the authors also identified desensitization as a personal attribute influencing susceptibility. Furthermore, repeated exposure can weaken training effects and increase vulnerability [21]. Overall, studies suggest that

individuals who become desensitized to phishing attacks are more likely to fall victim. Based on the research above, this study hypothesizes a positive correlation between phishing desensitization and phishing susceptibility.

V. Results and Analysis

A. Pilot Analysis

The questionnaire was tested with 29 randomly selected respondents in Indonesia (Pekanbaru City, Riau Province).

Next, the validity of these 29 responses was tested using statistical analysis with SPSS. The following are the results of the data description for all questions. Table II presents the descriptive statistics.

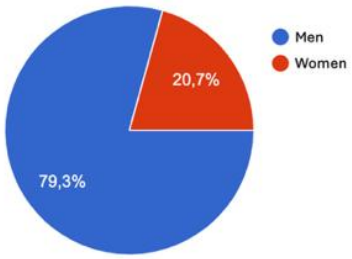

Fig. 2. Respondent demographics

TABLE II. Descriptive Statistics

	N	Minimum	Maximum	Mean	Std. Deviation	Variance	Skewness		Kurtosis	
	Statistic	Statistic	Statistic	Statistic	Statistic	Statistic	Statistic	Std. Error	Statistic	Std. Error
Q1	29	2	6	4.69	1.105	1.222	-1.031	.434	.799	.845
Q2	29	3	6	5.28	.841	.707	-.967	.434	.311	.845
Q3	29	1	6	4.66	1.203	1.448	-.987	.434	1.477	.845
Q4	29	1	6	4.62	1.237	1.530	-1.393	.434	2.121	.845
Q5	29	1	6	4.59	1.268	1.608	-1.280	.434	1.548	.845
Q6	29	2	6	4.48	.871	.759	-.814	.434	1.249	.845
Q7	29	1	6	3.55	1.378	1.899	-.599	.434	-.351	.845
Q8	29	1	6	4.45	1.298	1.685	-.825	.434	.319	.845
Q9	29	3	6	5.14	.789	.623	-.725	.434	.425	.845
Q10	29	1	6	4.24	1.215	1.475	-.756	.434	.850	.845

Q13	29	1	6	4.72	1.066	1.135	-1.493	.434	4.180	.845
Q14	29	1	6	4.31	1.168	1.365	-.660	.434	.755	.845
Q15	29	2	6	4.31	1.105	1.222	-.162	.434	-.858	.845
Q16	29	3	6	4.62	.728	.530	.145	.434	-.224	.845
Q17	29	2	6	4.52	.986	.973	-.531	.434	.235	.845
Q18	29	2	6	4.14	.990	.980	-.531	.434	-.206	.845
Q19	29	1	6	3.14	1.529	2.337	.460	.434	-.638	.845
Q20	29	1	6	3.41	1.547	2.394	-.200	.434	-.955	.845
Q21	29	1	6	3.55	1.404	1.970	-.280	.434	-.556	.845
Q22	29	1	6	3.86	1.156	1.337	-.903	.434	1.144	.845
Q23	29	1	6	3.55	1.378	1.899	-.072	.434	-.147	.845
Q24	29	1	6	3.55	1.549	2.399	.082	.434	-1.096	.845
Valid N	29									

The description of the data above shows that the skewness values are within the normal range for each question. The values range between -1 and 0, indicating that the questionnaire results are normally distributed.

1) Reliability testing: Reliability testing is used to determine the extent to which questionnaire produces consistent results when administered to the same respondents. The test was conducted using Cronbach's Alpha in SPSS. The results are as follows (see Table III):

TABLE III. Reliability Statistics

Cronbach's Alpha	N of Items
.819	24

Based on the above results, the total alpha value is 0.819. This value is greater than the critical r-value for N=24, which is 0.404. This indicates that all items in the questionnaire are reliable and that the overall test demonstrates strong internal consistency.

2) Validity testing: Validity testing was conducted to determine the extent to which the questions measure the intended constructs. Validity testing in SPSS used Pearson's bivariate correlation. Pearson's correlation analysis compared each question item score with the total score. The results are as follows (see Table IV to Table X):

a) Validity of Perceived Severity of the Threat (PST) Construct

The PST construct was measured using four items:

- Q1: Social engineering poses a risk to my safety and well-being at work.
- Q2: If I were a victim of social engineering while using email or SMS, it would be a serious issue.
- Q3: When I consider social engineering attacks by email or SMS, I get melancholy.
- Q4: Even considering the possibility of social engineering when utilizing SMS or email scares me.

TABLE IV. CORRELATION RESULTS FOR PST

		Q1	Q2	Q3.	Q4
SUM_PST	Pearson Correlation	.758**	.615**	.784**	.940**
	Sig. (2-tailed)	.000	.000	.000	.000
	N	29	29	29	29

For a significance level of alpha = 5% with N = 29, the critical r-value is 0.367. The validity test results show that the r-values for Q1 to Q4 are greater than 0.367, indicating that all PST construct questions are valid at the 5% significance level.

b) Validity of Perceived Barriers (PBR) Construct

The PBR construct was measured using four items:

- Q5: Taking care of myself would alter how I use the computer.
- Q6: The time and effort required to use specialized software for security.
- Q7: Using SMS and email with caution makes me uneasy.
- Q8: Using SMS or email carelessly is inconvenient.

TABLE V. CORRELATION RESULTS FOR PBR

		Q5	**Q5.**	**Q7**	**Q8**
SUM_PBR	Pearson Correlation	.598**	.825**	.682**	.742**
	Sig. (2-tailed)	.001	.000	.000	.000
	N	29	29	29	29
**. Correlation is significant at the 0.01 level (2-tailed).					

All correlation coefficients (r-values) for Q5 to Q8 exceed the critical value of 0.367, indicating that each item in the PBR construct is valid.

c) Validity of Perceived Benefits (PBN) Construct

The PBN construct was measured using three items:

- Q9: Awareness of social engineering techniques when using SMS and email keeps me safe from attacks.
- Q10: Investing in security software is a good way to reduce my exposure to social engineering attacks
- Q11: Social engineering attacks can be avoided by being careful.

TABLE VI. CORRELATION RESULTS FOR PBN

		Q9	**Q10**	**Q11**
SUM_PBN	Pearson Correlation	.693**	.815**	.739**
	Sig. (2-tailed)	.000	.000	.000
	N	29	29	29

All r-values for Q9 to Q11 are above 0.367, confirming that the PBN construct items are valid.

d) Validity of Self-Efficacy (SE) Construct

Since all r-values exceed the threshold of 0.367, the SE construct items are considered valid.

TABLE VII. CORRELATION RESULTS FOR SE

		Q12	**Q13**	**Q14**
SUM_SE	Pearson Correlation	.778**	.723**	.776**
	Sig. (2-tailed)	.000	.000	.000
	N	29	29	29

The SE construct was assessed using three items:

- Q12: I am generally safe from the dangers of social engineering (Q12).
- Q13: I am aware of how to protect myself from social engineering scams.
- Q14: It is simple to take the required security precautions to thwart social engineering attempts via email or SMS.

e) Validity of Past Success in Detection (PSD) Construct

The PSD construct includes 3 items:

- Q15: I've been effective at thwarting phishing attempts.
- Q16: The majority of the phishing attacks I had come across in the past had been repelled.
- Q17: In the past, I was able to recognize phishing attempts and avoid falling for them.

All r-values for Q15 to Q15 are above the critical value of 0.367, indicating that the PSD construct items are valid.

TABLE VIII. CORRELATION RESULTS FOR PSD

		Q15	**Q16**	**Q17**
SUM_PSD	Pearson Correlation	.852**	.736**	.730**
	Sig. (2-tailed)	.000	.000	.000
	N	29	29	29

f) Validity of Phishing Desensitization (PD) Construct

The PD construct was measured using two items:

- Q18: I shrug in response to news reports containing phishing stories.

- Q19: I ignore news reports about phishing scams.

TABLE IX. CORRELATION RESULTS FOR PD

		Q18	Q19
SUM_PD	Pearson Correlation	.666**	.876**
	Sig. (2-tailed)	.000	.000
	N	29	29

All r-values for Q18 and Q19 exceed the critical threshold of 0.367, confirming that the PD construct items are valid.

g) Validity of Phishing Susceptibility (PS) Construct

The PS construct consists of five items:

- Q20: I run the danger of falling prey to phishing scams.
- Q21: I'm sure I'll fall prey to phishing scams.
- Q22: I could fall prey to phishing scams.
- Q23: My likelihood of being phished is quite high.
- Q24: Phishing emails are probably going to trick me.

TABLE X. CORRELATION RESULTS FOR PS

		Q20	Q21	Q22	Q23	Q24
SUM_PS	Pearson Correlation	.828**	.816**	.727**	.872**	.840**
	Sig. (2-tailed)	.000	.000	.000	.000	.000
	N	29	29	29	29	29

B. Respondent Data Analysis

The research was conducted by distributing 150 questionnaires to respondents in Indonesia. Respondents were selected randomly, with the primary inclusion criterion being that they had received messages suspected to be phishing attacks. The demographic data collected from the respondents are presented in Fig. 2.

The data indicate that female respondents tend to have longer durations of interaction with information technology compared to their male counterparts.

1) Data reliability and validity testing: Based on the descriptive analysis (see Table XI), all variables were measured using responses from 150 participants. This sample size provides strong representativeness for the study. The highest average scores were observed in the SUM_PST (18.27) and SUM_PBR (18.23) variables, indicating that these two constructs were perceived most positively by respondents. In contrast, SUM_PD had the lowest average score (6.87), indicating a relatively low perception of this factor among respondents. In terms of data distribution, SUM_PS had the highest standard deviation and variance (6.884; 47.395), indicating a wide range of responses and high variability in how respondents assessed their susceptibility. SUM_SE had the lowest standard deviation and variance (2.279; 5.195), suggesting more consistent responses across participants.

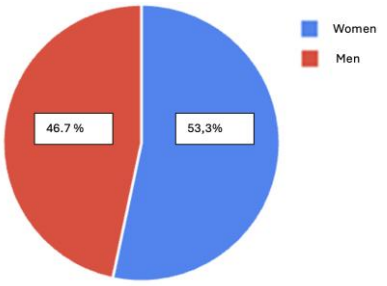

Fig. 3. Gender distribution

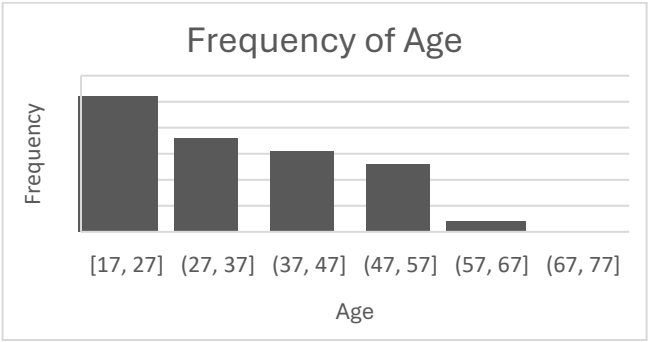

Fig. 4. Age distribution

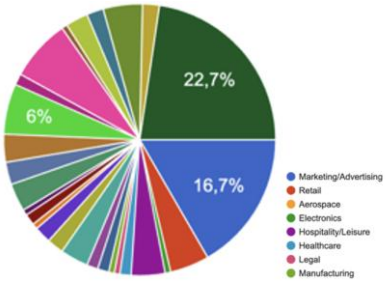

Fig. 5. Occupational background

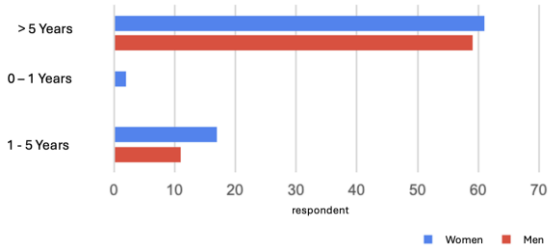

Fig. 6. Duration of interaction with information technology by gender.

Most variables exhibited negative skewness, indicating a tendency toward higher response values, with the exception of SUM_PD and SUM_PS, which had slightly positive skewness, thus approaching a normal distribution. Kurtosis analysis revealed a leptokurtic distribution for SUM_PBN (3.110), meaning responses were tightly clustered around the mean, while SUM_PD and SUM_PS had negative kurtosis, indicating a flatter, more evenly spread distribution. These findings suggest that most constructs were perceived positively with varying levels of consistency. SUM_PST and SUM_PBR emerged as the strongest constructs, based on both average scores and

consistency, while SUM_PD stands out as an area of concern due to its low average and broad variability, indicating a potential gap in user awareness or engagement with phishing-related content. Fig. 3, Fig. 4 and Fig. 5 shows the gender distribution, age distribution, and occupational background. Fig. 6 presents the duration of interaction with information technology by gender.

TABLE XI. DESCRIPTIVE DATA

	N	Range	Min	Max	Sum	Mean		Std. Deviation	Variance	Skewness		Kurtosis	
	Stat	Stat	Stat	Stat	Stat	Stat	Std. Error	Stat	Stat	Stat	Std. Error	Stat	Std. Error
SUM_PST	150	20	4	24	2740	18.27	.390	4.772	22.774	-1.082	.198	.464	.394
SUM_PBR	150	19	5	24	2735	18.23	.306	3.750	14.059	-.846	.198	.861	.394
SUM_PBN	150	14	4	18	2174	14.49	.222	2.719	7.393	-1.558	.198	3.110	.394
SUM_SE	150	10	2	12	1329	8.86	.186	2.279	5.195	-.797	.198	.078	.394
SUM_PSD	150	15	3	18	2064	13.76	.232	2.844	8.090	-1.270	.198	2.181	.394
SUM_PD	150	10	2	12	1030	6.87	.233	2.858	8.170	.094	.198	-1.115	.394
SUM_PS	150	25	5	30	2382	15.88	.562	6.884	47.395	.292	.198	-1.071	.394
Valid N (listwise)	150												

While most constructs show acceptable reliability ($\alpha > 0.6$), PBN and PBR fall slightly below the commonly accepted threshold. These constructs may benefit from refinement in future iterations of the instrument. The following are the reliability test results for each construct (see Table XII):

TABLE XII. CRONBACH'S ALPHA BY CONSTRUCT

Construct	Cronbach's Alpha
PST	0.805
PS	0.899
PBN	0.556
SE	0.673
PSD	0.718
PD	0.684
PBR	0.546

2) Validity analysis: Validity was assessed using Pearson's correlation between each item and its corresponding total construct score (SUM). All items demonstrated statistically significant correlations at a significance level of 0.000 ($p < 0.01$), confirming their validity. In the PST construct (Q1–Q4), correlations ranged from 0.729 to 0.851, indicating strong internal consistency. The PBR construct (Q5–Q8) had correlations ranging from 0.595 to 0.707; although Q6 had the lowest value (0.595), this value was still above the acceptable minimum (0.3–0.5) and was therefore still considered valid.

The PBN construct (Q9–Q11) demonstrated a high correlation of 0.622–0.779, showing strong alignment between items and the construct. The SE construct (Q12–Q14) had a very high correlation, especially Q12 (0.896), but Q14 showed the lowest correlation (0.499), which is still considered valid. The PSD construct (Q15–Q17) had a correlation range of 0.749–0.836, which consistently shows strong validity. The PD construct (Q18–Q19) showed near-perfect correlations of 0.870 and 0.874, respectively. Meanwhile, the PS construct (Q20–Q24) had consistently very high correlations (0.773–0.880), indicating that all items were highly representative of the construct.

The reliability and validity analysis confirm that the questionnaire is a robust instrument for measuring phishing susceptibility and related constructs. While a few items show relatively lower reliability or correlation values, they remain within acceptable limits. Overall, the instrument demonstrates strong psychometric properties and is suitable for further analysis and application.

C. Analysis of Indonesian Respondent Data

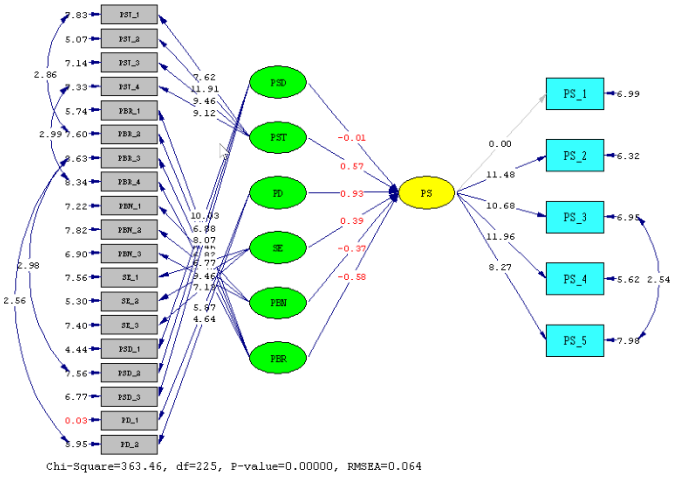

Fig. 7. Path diagram of Confirmatory Factor Analysis (CFA) results.

Based on the results of Confirmatory Factor Analysis (CFA) conducted using the path diagram (see Fig. 7), the model yielded a Chi-Square value of 363.46 with Degrees of Freedom (df) = 225 and p-value = 0.000. The RMSEA value of 0.064 is below the commonly accepted threshold of 0.08, indicating that the model demonstrates a good level of fit.

TABLE XIII. HYPOTHESES AND RESULTS

Hypothesis	Description	Result
H1	Phishing susceptibility (PS) is positively correlated with perceived severity of the threat (PST).	Not Supported
H2	Phishing susceptibility (PS) is positively correlated with perceived barriers (PBR).	Not Supported
H3	Phishing susceptibility (PS) is positively correlated with perceived benefits (PBN).	Not Supported
H4	Phishing susceptibility (PS) is positively correlated with self-efficacy (SE).	Not Supported
H5	Phishing susceptibility (PS) positively correlates with past success in detection (PSD).	Not Supported
H6	Phishing susceptibility (PS) positively correlates with phishing desensitization (PD).	Not Supported

This study proposed six hypotheses (H1–H6), each predicting a positive correlation between phishing susceptibility (PS) and six different psychological/perceptual variables: perceived severity (PST), perceived barriers (PBR), perceived benefit (PBN), self-efficacy (SE), past success in detection (PSD), and phishing desensitization (PD) (see Table XIII). Although prior literature provided theoretical and empirical support for these relationships, the results of hypothesis testing indicate that none of the proposed correlations were statistically significant (Not Supported). A comparison of each hypothesis and the results is described below:

1) H1: phishing susceptibility (PS) ↔ perceived severity of the threat (PST): Previous studies [18], [22] suggest that cyber warning messages are more effective when the perceived severity of the consequences aligns with the users' own perceptions. Perceived severity is recognized as a determinant of security behavior, although [18] do not explicitly link PST with PS. This study hypothesized a positive correlation between PST and PS. However, the results show no significant relationship between the two. This suggests that while users may perceive phishing threats as serious, this perception does not necessarily translate into safer behavior – such as avoiding risky email interactions. These findings support [23], who argue that risk perception does not always predict security-related decision-making.

2) H2: phishing susceptibility (PS) ↔ perceived barriers (PBR): In [24], the authors assert that perceived barriers significantly influence security behavior. The assumption is that higher barriers (e.g., time, effort, or complexity) may discourage users from adopting protection measures, thereby increasing susceptibility. However, this study found no significant correlation between PBR and PS. This discrepancy may indicate that perceived barriers affect technology adoption (e.g., multi-factor authentication), more than they influence phishing vulnerability directly.

3) H3: phishing susceptibility (PS) ↔ perceived benefits (PBN): In [12], [13], the authors argue that individuals who perceive benefits in sharing personal information tend to be more vulnerable to phishing. In [14], the authors also show that perceived benefits in protective measures can also influence phishing avoidance behavior. Despite this, the current study found no significant correlation between PBN and PS. These results suggest that perceived benefits from online behavior do not automatically increase vulnerability. Moderating factors such as digital literacy or security awareness may play a role. Even if users perceive benefits, high phishing awareness may still lead to cautious behavior.

4) H4: phishing susceptibility (PS) ↔ self-efficacy (SE): The literature [15], [16] suggests that high self-efficacy may lead to overconfidence, increasing phishing risk. However, this study found no significant relationship between SE and PS. This discrepancy may be due to the self-efficacy measured - reflecting actual ability rather than inflated confidence. These findings align with prior research showing that the influence of self-efficacy on security responses depends on domain knowledge and attack context [25].

5) H5: phishing susceptibility (PS) ↔ past detection PSD: In [11] and [17], the authors highlight that past success in phishing detection can influence vulnerability, though it may also lead to false positives. In this study, no significant correlation was found between PSD and PS. This may be due to attacker adaptation—as phishing tactics evolve, past experience may become less relevant. In [19], the authors support this, noting that phishing detection skills can decline when attack strategies change significantly.

6) H6: phishing susceptibility (PS) ↔ phishing desensitization (PD): In [11], [20], [21], the authors suggest that repeated exposure can lead to phishing desensitization, increasing PS. However, this study found no significant relationship between PD and PS. Repeated exposure to security warnings may lead to habituation, characterized by diminished attention and response to the repeated stimulus [26]. In this case, the expected desensitization effect may be neutralized.

Overall, none of the hypotheses (H1–H6) predicting a positive correlation between phishing susceptibility (PS) and the selected psychological or perceptual variables were empirically supported in this study. This outcome contrasts with findings from previous research, which provided both theoretical and partial empirical support for these relationships [11], [12], [13], [15], [16], [17], [18], [19], [21], [22], [24]. These differences may be due to methodological factors (measurement instruments, sample size, and respondent context) or contextual factors (changes in phishing trends, digital literacy, and cybersecurity culture in the research area).

D. Model Evaluation

The results of Structural Equation Modeling (SEM) indicate that the tested model falls within the acceptable fit category, with several indicators confirming overall adequacy and others highlighting areas for improvement (see Table XIV). Goodness-of-fit indices such as RMSEA (0.064 < ideal limit of 0.08), TLI/NNFI (0.91), IFI (0.93), and CFI (0.92) have met the ideal criteria of ≥ 0.90, suggesting that the model represents the data well. Additionally, AIC (513.46), CAIC (814.25), and ECVI (3.45) values are lower than those of the saturated and independence models, indicating that the model is efficient, not overly complex, and has strong generalization potential for other samples. Parsimony indices – PGFI (0.62) and PNFI (0.69) –

also confirm adequate simplicity, while the CMIN/df ratio (1.741) is well below the maximum limit of 3, reflecting a balanced trade-off between complexity and fit.

While the model meets most key criteria, several indicators fall short of ideal thresholds. NFI (0.84) and RFI (0.80) are below the recommended minimum of 0.90, suggesting that the model's relative fit could be improved. AGFI (0.77) is also low, indicating reduced fit when model complexity is considered. The SRMR (0.081) exceeds the ideal threshold of 0.05, implying that the covariance residuals between variables are not yet fully accounted for. Furthermore, the Critical N (CN) value of 106.46, below the recommended 200, suggests that the sample size used may be insufficient to support a model with perfect fit. Although the Chi-square p-value is significant (p = 0.00), rejecting the perfect fit hypothesis, this outcome is common in SEM with large sample sizes due to the test's sensitivity and should not be interpreted in isolation.

Although some indicators fall below ideal thresholds, the model meets most key SEM criteria, particularly incremental fit and parsimony measures, and is considered acceptable for exploratory analysis. To enhance model quality and approach a high-fit classification, it is recommended to review and refine indicators with low loading factors, optimize the measurement model, and apply theoretically justified modifications based on Modification Indices. Expanding the sample size could also increase model stability and improve the CN, AGFI, and SRMR values. With these improvements, this model can achieve stronger statistical and theoretical robustness.

TABLE XIV. MODEL FIT ASSESSMENT FOR THE INDONESIAN PHISHING MODEL

Model Fit Assessment	Cut-off Value	Indonesian Phishing Model	Result
AIC (Akaike's Information Criterion)	<AIC for saturated or Independence	AIC = 513.46 (AIC saturated=600.00; AIC independence =2508.68)	Good
Chi-square or p-value	>0.05	363.46 (P=0.00)	Fair
NFI (Normed Fit) Index)	>0.9	0.84	Fair
RMSEA (Root Mean Square Error of Approximation)	<=0.08	0.064	Good
RFI (Relative Fit Index)	>0.90	0.80	Fair
AGFI (Adjusted Goodness of Fit Index)	>0.90	0.77	Fair
CAIC (Consistent Akaike's Information Criterion)	<CAIC for saturated or Independence	CAIC = 814.25 (CAIC saturated=1803.191; CAIC independence =2604.94)	Good
ECVI (Expected Cross-Validation Index)	<ECVI for saturated or Independence	ECVI = 3.45 (ECVI saturated=4.03; ECVI independence =16.84)	Good
TLI / NNFI (Non-Normed Fit Index)	>=0.90	0.91	Good
IFI (Incremental Fit Index)	>90	0.93	Good
CFI (Comparative Fit Index)	>0.9	0.92	Good
GFI (Goodness of Fit Index)	approaching the value of 1 atau >0.9	0.83	Good
SRMR (Standardized RMR)	<0.05	0.081	Fair
PGFI (Parsimony Goodness of Fit Index)	>0.5	0.62	Good
RMR (Root Mean Square Residual)	approaching the value of 0	0.16	Good
PNFI (Parsimony Normed Fit Index)	>0.5	0.69	Good
CMIN / Df	<=3	1.741	Good
CN (Critical N)	>200	106.46	fair

E. Post-Hoc Statistical Power Analysis

Given that all six hypotheses were not supported, a post-hoc statistical power analysis was conducted to assess whether the null results reflect genuine absence of effects or insufficient statistical power. Using G*Power with the parameters of N = 150, $\alpha = 0.05$, and effect sizes derived from comparable prior studies ($r = 0.15$ to $r = 0.25$, corresponding to small-to-medium effects in social science research), the estimated statistical power (β) ranged from approximately 0.18 to 0.42. These values fall substantially below the conventional threshold of 0.80, indicating that the study was underpowered to reliably detect effects of these magnitudes. This means the probability of a Type II error (failing to detect a true effect) was high. Consequently, the null results should be interpreted with caution: they may reflect genuine absence of relationships in this population, or they may be an artifact of insufficient statistical power. A sample of approximately 264–400 respondents would be required to achieve power ≥ 0.80 for the smallest expected effect sizes. Future research should prioritize larger samples to enable definitive conclusions.

VI. DISCUSSION

A. Interpretation of Null Findings

The rejection of all six hypotheses is a notable and theoretically meaningful outcome that warrants careful interpretation. The null results contrast with findings from foundational studies in the HBM-phishing literature [6][10][11][15][16][24]. At least three classes of explanation are plausible. First, the null results may reflect genuine contextual differences: psychological constructs validated in Western or controlled academic settings may not operate the same way among Indonesian general internet users who encounter real-world phishing. Cultural collectivism [3], differential digital literacy [1], and Indonesia's unique phishing landscape (e.g.,

WhatsApp and Instagram-based attacks [2]) may collectively moderate or suppress the relationships hypothesized by the HBM. Second, as demonstrated by the post-hoc power analysis (Section V E), the sample size of 150 was likely insufficient to detect small-to-medium effects, raising the probability of Type II errors across all six hypotheses. Third, two constructs (PBR, PBN) exhibited sub-threshold reliability (Cronbach's $\alpha < 0.60$), which attenuates structural path estimates and reduces the likelihood of detecting significant relationships even where true effects exist.

B. Comparison with Prior Literature

The present findings diverge from several key prior studies. Gwenhure [6] found that perceived severity and self-efficacy significantly predicted security behavior in an HBM model among university students. Adane and Beyene [24] found that perceived barriers significantly influence phishing-related security behavior. Chen et al. [11] established desensitization and past detection success as predictors of susceptibility. The divergence from these findings may be attributed to differences in sample characteristics (students vs. general population), the operationalization of constructs (the current instruments were adapted from English-language scales without full cross-cultural validation), and the measurement of susceptibility (self-report vs. behavioral measures). Notably, the Indonesian population sampled here consists of individuals who had already encountered phishing attacks, potentially introducing selection bias: those who survived prior attacks may have developed heuristic defenses that render the HBM constructs less predictive.

C. The Role of Unmeasured Mediating and Moderating Variables

A critical observation from this study is that the hypothesized direct effects of HBM constructs on phishing susceptibility were uniformly non-significant. This pattern may indicate that the relationships between these constructs and susceptibility are not direct but are mediated or moderated by variables not included in the current model. Digital literacy is a particularly compelling candidate: individuals with higher digital literacy may translate threat perceptions into protective behaviors more effectively [1], creating a suppressor effect on the direct PST–PS path. Cultural norms (e.g., collectivism, deference to authority) may moderate the extent to which perceived benefits or barriers influence behavior [3]. Attack-specific familiarity (that is, knowledge of the specific phishing tactics prevalent in Indonesia) may also moderate the effectiveness of self-efficacy as a predictor. Future studies should incorporate these variables as explicit mediators or moderators within extended HBM or Protection Motivation Theory frameworks.

D. Methodological Limitations and Recommendations

Several methodological limitations of this study should be acknowledged. The sample size of 150 respondents was insufficient for CB-SEM to achieve adequate statistical power for the hypothesized effect sizes, and the CN value of 106.46 confirmed this. The sub-threshold reliability of PBR and PBN indicates that these constructs were not adequately captured by the adapted measurement items in this population. Offline data collection in a single province (Riau) limits the generalizability of findings to the broader Indonesian population. Furthermore, all variables were measured by self-report, introducing the possibility of common method variance. Future research should address these limitations by: 1) expanding the sample to at least 300 respondents drawn from multiple Indonesian provinces; 2) revising or replacing the PBR and PBN items to improve cross-cultural validity; 3) incorporating behavioral or objective phishing susceptibility measures alongside self-report; and 4) including digital literacy, cultural orientation, and attack-type familiarity as additional constructs.

E. Implications

Despite the null hypothesis results, this study offers important practical insights. The finding that none of the measured psychological constructs significantly predict susceptibility suggests that standard awareness-raising interventions targeting threat perception or self-efficacy alone may be insufficient for the Indonesian context. Practitioners (including internet service providers (ISPs), the BSSN, and government agencies) should consider multi-layered interventions that address digital literacy gaps, provide culturally adapted phishing training, and integrate technical defenses with behavioral change programs. The high variability in PS scores (SD = 6.884) indicates that susceptibility is not uniformly distributed, suggesting that targeted interventions for high-risk subpopulations may be more effective than broad awareness campaigns.

VII. Conclusion

This study tested six hypotheses (H1–H6) predicting a positive correlation between phishing susceptibility (PS) and six psychological/perceptual variables, namely perceived severity (PST), perceived barriers (PBR), perceived benefits (PBN), self-efficacy (SE), past success in detection (PSD), and phishing desensitization (PD). Although prior research suggested these relationships, empirical analysis using Structural Equation Modeling (SEM) did not support any of the predicted correlations.

The findings indicate that psychological factors – often assumed to noticeably influence phishing vulnerability – showed no measurable direct effect among the respondents. This suggests that susceptibility may not be driven solely by perceptions but could involve other dimensions, such as digital literacy, social context, cultural security norms, or evolving attack strategies. These possibilities require further investigation rather than being interpreted as confirmed causes. In short, even individuals who perceive phishing threats as severe or have previous success in detection do not necessarily exhibit safer behavior.

The SEM model demonstrated an acceptable overall fit, with several indicators (RMSEA, TLI/NNFI, IFI, and CFI) meeting recommended thresholds, indicating adequate data representation. Parsimony indices (PGFI, PNFI) also confirmed the efficiency of the model, and the low CMIN/df ratio showed a balance between fit and complexity. However, weaknesses in NFI, RFI, AGFI, SRMR, and Critical N suggest the need for refinement – such as increasing sample size, improving the measurement model, and incorporating additional latent variables.

Overall, this study contributes to cybersecurity literature by challenging the assumption that higher threat perception or self-efficacy automatically reduces phishing vulnerability. Future research should investigate mediating or moderating variables that explain the gap between perception and behavior, enrich models with behavioral and contextual factors, and aim for designs that achieve both statistical robustness and real-world relevance in an era of evolving cyber threats.

Future research should expand sample sizes to at least 300 respondents, revise the PBR and PBN measurement items for the Indonesian context, incorporate digital literacy and cultural orientation as mediators or moderators, and consider behavioral phishing susceptibility measures alongside self-report instruments. Theoretically, extending the model to include Protection Motivation Theory constructs or cultural dimensions may improve explanatory power. Overall, this study contributes to the cybersecurity literature by demonstrating that standard HBM-derived constructs do not directly predict phishing susceptibility in the Indonesian general population context, and by providing a foundation for more contextually sensitive models of phishing vulnerability.

AgricultureEarlyWarning: A Web-Based Climate Advisory and Early Warning Platform for Albanian Farmers

Irida Gjermeni
Faculty of Economy and Agribusiness-Department of Mathematics and Informatics,
Agricultural University of Tirana, Tirana, Albania

***Abstract*—This study reports the design and implementation of AgricultureEarlyWarning, a web-based prototype developed to operationalize climate information services and early warning logic for farmer-centered agricultural risk management in Albania. The system integrates parcel-level registration and geolocation, daily and hourly forecast ingestion, crop-stage-sensitive risk evaluation, satellite-derived indicators, dashboard analytics, AI-assisted agronomic explanation, vulnerability profiling, escalation support, and scheduled alert dissemination within a single application. The implementation stack combines ASP.NET MVC on .NET Framework 4.8, SQL Server persistence, Hangfire background scheduling, Open-Meteo weather services, Sentinel Hub APIs, and OpenStreetMap reverse geocoding. Rather than proposing a novel forecasting algorithm or claiming a complete national early warning system, the study contributes an implementation-oriented platform that links data acquisition, contextual risk interpretation, farmer-facing visualization, and asynchronous communication. The findings indicate that the prototype supports localized monitoring, advisory generation, alert scheduling, and analytics, while field validation, long-term adoption assessment, and full institutional response governance remain priorities for future work.**

***Keywords*—AgriculturalEarlyWarning system; climate information services; farmer advisory; remote sensing; ASP.NET MVC; Albania; decision support**

I. Introduction

Climate variability, extreme weather, and crop-specific sensitivity to temperature, rainfall, humidity, and wind continue to challenge agricultural production and farm-level decision-making. In this context, early warning systems (EWSs) are expected to do more than produce forecasts. A modern EWS is an integrated system that combines hazard monitoring and forecasting, risk assessment, communication, and preparedness processes so that people can take timely action before harmful events occur [1]. International frameworks for multi-hazard and people-centered EWSs emphasize four interconnected pillars: risk knowledge, detection and monitoring, warning dissemination and communication, and preparedness to respond [2], [3].

In agriculture, the practical value of climate services depends not only on the scientific quality of the forecast, but also on how well the information is translated into usable decisions. Previous work has shown that climate-service design must be aligned with user needs, decision timescales, and communication channels [4]. In smallholder and mixed farming contexts, mobile delivery channels such as SMS, phone-based interfaces, and localized advisories are particularly important, but their effectiveness still depends on trust, relevance, language, and the capacity of farmers to act on the received information [5]. This means that agricultural EWS design should be farmer-facing, action-oriented, and operationally sustainable.

At the same time, recent literature shows growing interest in agricultural platforms that integrate fine-scale weather information, crop or hazard thresholds, mobile interfaces, digital advisory services, and risk-reduction workflows. Examples include farm-specific agrometeorological warning systems, nationwide agricultural disaster prevention architectures, forecast-driven disease warning systems, and digital advisory initiatives for smallholder agriculture [6]-[9], [19], [20]. These studies reinforce a common lesson: useful agricultural EWSs must connect scientific data, local context, and usable delivery mechanisms.

This study presents AgricultureEarlyWarning, a web-based application developed as a practical prototype for Albanian agriculture. The platform was designed to bridge climate information services (CIS) and agricultural early warning workflows within a single environment. Rather than functioning only as a weather dashboard, the application combines parcel registration, forecast retrieval, crop-aware risk interpretation, climate analytics, AI-assisted agronomic guidance, and scheduled dissemination of daily and event-based alerts. The interface is designed for farmer use, while the architecture also supports administrative oversight and future institutional escalation modules.

The contribution of this study is threefold. First, it documents the architecture and implementation logic of a deployable farmer-oriented agriculture app that integrates multiple open and commercial-ready services. Second, it maps the prototype explicitly to the core pillars of effective EWS design, allowing the reader to assess which components are already operational and which still require institutional completion. Third, it provides a realistic discussion of prototype maturity, including comparison with related agricultural EWSs, prototype-level functional validation, and current limitations. The study is, therefore, framed as a systems design and implementation study, suitable for practitioners and researchers interested in digital agriculture, climate services, and operational EWS development.

The remainder of the study is organized as follows: Section II reviews related work and motivates the design rationale. Section III explains the system requirements and EWS alignment. Section IV presents the architecture. Section V describes the prototype implementation. Section VI

discusses the functional evaluation and practical implications. Section VII outlines limitations and future work, and Section VIII concludes the study.

II. Related Work and Design Rationale

Climate services research consistently shows that information alone is insufficient if it is not embedded in a usable decision context. Born et al. demonstrated through a global meta-analysis that agricultural climate-service use varies by decision type, forecast horizon, and variable, highlighting the importance of matching information products to real farmer decisions [4]. Charalampopoulos and Droulia further stress that climate services for agriculture should move toward integrated, user-oriented pathways that link data generation to sector-specific application needs [6]. These arguments are directly relevant for agricultural apps, where interface simplicity and actionability can determine whether information is adopted or ignored.

Communication design is equally important. Yegbemey and Egah found that mobile-based dissemination is widely used in climate-service delivery to smallholder farmers, but relevance depends on socio-economic fit, literacy, trust in the information source, and the ability of farmers to interpret and respond to messages [5]. This literature supports the use of concise alerts, localized advice, and interfaces in the user's working language. For AgricultureEarlyWarning, this insight motivated the use of Albanian-language dashboards and SMS-oriented dissemination logic.

Recent agricultural EWS implementations also provide useful architectural cues. Shin et al. describe a farm-specific early warning service customized for farmers and extension workers, emphasizing cloud-based coordination, farm-level information delivery, and notification workflows [7]. Yao et al. present a broader agricultural disaster prevention system that integrates forecast services, crop-specific warning logic, and information platforms for farmers and public actors [8]. Krupnik et al. show that a weather-driven wheat blast EWS achieved practical scale only because forecast models, user-centered interfaces, dissemination channels, and institutional cooperation were co-developed [9]. Together, these studies suggest that effective agricultural EWSs require four qualities: localization, interpretability, dissemination, and operational governance.

AgricultureEarlyWarning was designed in response to these lessons and to the needs of a context where farmers may require one integrated entry point for weather, risk, and agronomic interpretation. The design rationale, therefore, prioritizes: 1) parcel-specific localization rather than generic regional weather pages; 2) crop-aware risk interpretation rather than raw meteorological display; 3) actionable advisory text rather than only numerical outputs; 4) support for asynchronous daily and event-based dissemination; and 5) a modular architecture that can evolve from a farmer dashboard into a broader institutional EWS workflow.

Unlike many research prototypes that focus on a single hazard, crop, or model, AgricultureEarlyWarning aims to function as a flexible platform. It combines weather forecasts, selected remote-sensing indicators, crop-stage-sensitive logic, message scheduling, subscription management, and climate analytics in one web system. This broad scope increases implementation complexity, but it also reflects a real operational challenge: farmers do not experience data streams separately. They experience one decision environment in which weather, crop status, risk, timing, and advisory actions need to converge (see Table I).

TABLE I. Comparative Positioning of AgriculturalEarlyWarning and Advisory Systems

System or study	Main focus	Localization	Dissemination	Validation or evidence	Position relative to AgricultureEarlyWarning
Shin et al. [7]	Farm-specific agrometeorological disaster warning service	Farm and extension-worker scale	Service notifications and cloud coordination	Operational service description	Stronger institutional service model; less emphasis on Albanian-language farmer dashboard and subscription workflow
Yao et al. [8]	Agricultural disaster prevention system and adaptation strategy	National/regional platform logic	Information platform for public and farmer actors	System and policy-oriented implementation	Broader governance scope; AgricultureEarlyWarning is lighter and more farmer-facing
Krupnik et al. [9]	Weather-driven wheat blast early warning system	Crop- and disease-specific local warnings	User-centered interfaces and dissemination	User-centered design, validation, and scaling	Stronger disease-specific validation; AgricultureEarlyWarning is multi-risk and modular but less field-validated
AgricultureEarly Warning	Web-based climate advisory and early-warning workflow for Albanian farmers	Parcel coordinates, crop association, vulnerability profile	Dashboard, daily advisory SMS, event-based alerts	Prototype-level functional validation and interface evidence	Combines CIS, parcel registration, risk logic, AI explanation, SMS, analytics, and escalation support in one modular prototype

III. System Requirements and Alignment with Early Warning System Principles

The conceptual starting point of AgricultureEarlyWarning is that an agriculture app should not be evaluated only as a software product, but as a partial operational EWS. From this perspective, the system requirements were derived from the four core EWS pillars [1]-[3].

The first requirement is risk knowledge. The application must represent the local production context in a structured way. For this reason, the system begins with farmer registration and map-based parcel localization. Each farmer is associated with a geographic position, crop information, and cultivation context. This creates the basis for place-specific forecast retrieval and crop-sensitive interpretation. Risk knowledge is also supported by crop parameter definitions, stage-sensitive thresholds, risk

categories, and historical analytics that help transform environmental variables into meaningful agricultural signals.

The second requirement is detection, monitoring, analysis, and forecasting. The platform, therefore, integrates short- to medium-range weather forecast data and selected Earth observation products. Weather variables such as temperature, humidity, rainfall, wind speed, and precipitation probability are retrieved through Open-Meteo APIs [10]. Satellite-related indicators are designed through Sentinel Hub services, where the Processing API can provide imagery and the Statistical API can provide pixel-level summaries such as vegetation and moisture-related indicators without requiring full raster download [11]-[13]. These data sources are combined with rule-based crop logic to derive risk levels and advisory cues.

The third requirement is warning dissemination and communication. The application implements this by coupling dashboards with scheduled and event-driven messaging. Warnings must be timely, understandable, and actionable, not merely visible inside a control panel. This is why the platform supports daily advisory dissemination and repeated background checks for event-based alerts. Message content is designed to summarize the relevant risk, affected crop context, and a practical recommendation. This design is consistent with literature showing the importance of suitable delivery channels and understandable communication for smallholder-oriented climate services [5].

The fourth requirement is preparedness and response capability. This is the area where the current prototype is only partially complete. The farmer-facing side already supports a response-oriented workflow by translating risk scores into suggested actions. However, a full institutional response chain requires escalation management, acknowledgement workflows, case tracking, and formal roles for agronomists or administrators. AgricultureEarlyWarning includes the architectural direction for such modules, but not all of them are fully operational in the current implementation. This distinction is important because many digital platforms overclaim EWS completeness when they mainly cover monitoring and communication. In this study, preparedness is treated as an area of ongoing extension rather than a finished component.

A further requirement concerns sustainability and usability. The system is designed as a web application so that it can operate through common browsers and mobile-responsive interfaces. In addition, it includes a free trial and subscription workflow intended to support a realistic service model for climate information delivery. While economic adoption is outside the scope of the present systems paper, service sustainability is relevant because an EWS that cannot be maintained operationally will not achieve long-term value.

Finally, the system requires trustworthy geospatial localization. Reverse geocoding through Nominatim is used to transform coordinates into readable place references, while respecting API usage requirements and application identification rules [14], [15]. This supports clearer farmer records, contextual dashboards, and location-aware interpretation. Fig. 1 and Table II provide a compact visual interpretation of how these functions relate to the four pillars of an effective early warning system.

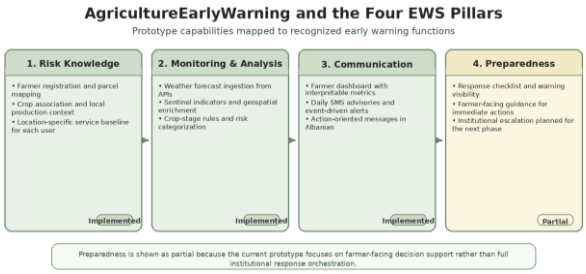

Fig. 1. Alignment of agriculturereearlywarning capabilities with the four pillars of an effective early warning system.

TABLE II. ALIGNMENT OF AGRICULTUREEARLYWARNING WITH EWS PILLARS.

EWS pillar	Current support in prototype	Maturity
Risk knowledge	Parcel registration, crop association, crop parameters, location context, historical analytics	Strong
Detection and monitoring	Forecast ingestion, hourly/daily variables, satellite indicators, threshold logic	Strong
Dissemination and communication	Dashboard, daily advisory messages, event-based alerts, Albanian-language UI	Strong
Preparedness and response	Action suggestions available; institutional escalation and case workflows only partially implemented	Partial

IV. SYSTEM ARCHITECTURE

The overall architecture of AgricultureEarlyWarning is organized into five logical layers: data acquisition, geospatial and farmer context, risk and intelligence processing, application services, and dissemination. Fig. 2 summarizes this structure.

At the data-acquisition layer, the platform retrieves forecast and historical weather variables from Open-Meteo [10]. It is designed to request daily and hourly variables relevant to agriculture, including maximum and minimum temperature, relative humidity, rainfall, precipitation probability, and wind speed. In parallel, satellite-oriented services are integrated through Sentinel Hub APIs [11]-[13]. Sentinel-2 derived vegetation information, such as NDVI, contributes to crop condition interpretation, while Sentinel-1 derived signals such as VV and VH are used as proxies for moisture and crop structural conditions where appropriate. The goal is not to replace agronomic field observations, but to enrich the evidence available for localized advisory logic.

The geospatial and farmer-context layer stores farmer identity, parcel coordinates, crop associations, and administrative location fields. Parcel position is central because all downstream analysis is location-specific. Reverse geocoding adds readable place labels to coordinate-based records [14]. This layer also stores subscription state, trial status, and basic engagement-related attributes needed for service administration.

Above this layer sits the application-services layer, implemented in ASP.NET MVC on .NET Framework 4.8 [18] with SQL Server persistence and background scheduling via Hangfire [16], [17]. This layer exposes the farmer dashboard, registration workflows, climate analytics pages, administrative

controls, subscription handling, escalation support, and AI-assisted chat interface. Background jobs are used for recurrent weather checks and scheduled dissemination. The use of persistent job scheduling is important because warning systems must continue routine monitoring independently of individual user sessions.

The dissemination layer delivers outputs to end users. The primary interface is the responsive web dashboard, which provides current conditions, forecast trajectories, risk summaries, analytics, and recommendations. A second dissemination path uses SMS-style notifications for daily information and event-based alerts. This separation is intentional: a dashboard supports exploration, while alerts support timely action. In operational EWS terms, the dashboard corresponds more to situational awareness, whereas alerts correspond to communication and triggering.

The architecture was deliberately designed to remain modular. Each upstream service can be improved or replaced without rewriting the entire platform. For example, forecast providers can change, satellite workflows can be expanded, and the advisory-generation component can evolve from rule-based logic toward hybrid AI-assisted interpretation. This modularity is essential for deployment in real settings, where data availability, cost, and infrastructure constraints may change over time. The logical relationships between layers are visualized in Fig. 2.

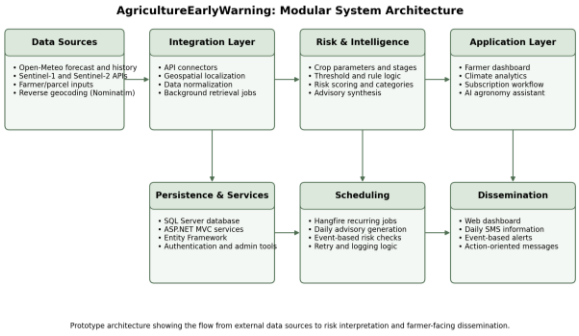

Fig. 2. Modular architecture of the AgricultureEarlyWarning prototype.

V. Prototype Implementation and Interface Realization

The current implementation of AgricultureEarlyWarning is realized as an ASP.NET MVC application on .NET Framework 4.8 with SQL Server persistence and Hangfire-based background processing. This section documents the main functional modules and provides interface-level evidence of how the prototype operationalizes registration, monitoring, analytics, communication, and preparedness-support functions. To improve technical transparency, the implementation is described at four levels: database structure, risk scoring logic, alert rules, and API integration (see Table III).

At the database level, the prototype uses normalized SQL Server entities to connect users, parcels, crops, warning records, SMS logs, vulnerability profiles, escalation events, and feedback. The database design separates static registration data from time-varying climate-risk records so that monitoring results can be audited and reused in analytics.

TABLE III. Technical Implementation Details of the Prototype

Layer	Main implementation elements	Operational role
Database structure	Farmers, Crops, FarmerCrops, ClimateRiskPredictions, Sms Alerts, FarmerVulnerability Profiles, EwsAlertRecords, EwsEscalationEvents, Ews DispatchLogs, EwsFeedbacks, and EwsInstitutionalCases	Stores parcel context, crop associations, computed warnings, communication history, vulnerability data, escalation status, and feedback.
Risk scoring logic	Rule-based thresholds for temperature, rainfall, humidity, wind, crop stage, vulnerability score, and advisory category	Converts forecast variables into a 0-100 risk score and qualitative warning levels such as green, yellow, orange, and red.
Alert rules	Daily advisory job, event-based checks, acknowledgement status, escalation delay, and retry/logging logic	Supports asynchronous warning dissemination and prepares the system for institutional escalation workflows.
API integration	Open-Meteo forecast requests, Sentinel Hub Processing/Statistical APIs, Nominatim reverse geocoding, and Hangfire scheduling services	Combines external data acquisition with geospatial localization, remote-sensing enrichment, and recurring background execution.
AI explanation layer	Server-side AIChatService with constrained prompt template and deterministic risk facts supplied by the warning engine	Explains warnings and general management actions without changing the computed risk level or acting as the trigger mechanism.

The risk score is calculated as an interpretable engineering score rather than as a learned statistical forecast. Each relevant meteorological variable is normalized against crop- and stage-specific thresholds. The resulting partial scores are multiplied by crop-stage weights and combined with vulnerability modifiers. The final score is mapped into warning levels so that the farmer sees a simple risk category while the administrator can still inspect the underlying variables.

Alert rules are implemented as scheduled and event-triggered routines. The daily advisory routine summarizes expected conditions for the active parcel and crop, while event-based checks are used when current or forecast conditions exceed configured thresholds. The escalation rule screen defines acknowledgement windows and transfer points from farmer notification to agronomist or administrator review. In the current prototype, these workflows support preparedness logic, but formal institutional operating procedures are still required before the platform can be described as a complete institutional EWS.

API integration is isolated behind service classes so that external providers can be changed without rewriting the dashboard or alert modules. Open-Meteo supplies daily and hourly forecast variables [10]. Sentinel Hub services support satellite-derived indicators and statistics [11]-[13]. Nominatim is used for reverse geocoding and readable location labels [14], [15]. Hangfire executes recurring checks and scheduled dissemination independently of user login sessions [16], [17].

A. Farmer Registration and Localization

The onboarding flow allows a farmer to register and select a parcel on the map. Geographic coordinates are stored

directly and then enriched with reverse-geocoded location information. This step is foundational because subsequent monitoring, forecast requests, and risk interpretation are all tied to the selected parcel. The registration process is also connected to free-trial and subscription logic, reflecting the practical requirement that operational climate information services need a sustainable delivery model.

B. Weather and Advisory Dashboard

After registration, the farmer accesses a dashboard that combines forecast information, risk summaries, and practical guidance. The platform supports daily and hourly weather views and presents metrics in agricultural terms rather than as raw meteorological lists. This includes explicit units, intuitive risk badges, and concise explanatory text. The design seeks to reduce interpretation burden for the user while preserving transparency about the underlying variables.

C. Crop-Aware Risk Logic

The risk engine evaluates conditions such as temperature extremes, excessive humidity, rainfall accumulation, and wind intensity relative to crop-stage sensitivity and configured crop thresholds. This allows the same forecast signal to be interpreted differently for different crop and stage combinations. For instance, a humidity and rainfall episode may be treated as a stronger disease risk during sensitive crop stages than during less vulnerable periods. The platform, therefore, behaves as a decision-support layer on top of the forecast rather than as a forecast viewer only.

D. Remote-Sensing Enrichment

The architecture supports the use of Sentinel-derived indicators to complement weather-based interpretation. NDVI can be used as a proxy for vegetation vigor, while Sentinel-1 backscatter-derived values can contribute to moisture and structural interpretation. In the current prototype, these indicators are integrated as additional evidence streams that can enrich dashboards and analytics. Their role is supportive rather than fully autonomous, since agronomic interpretation still benefits from local calibration and field knowledge.

E. AI-Assisted Agronomic Guidance

The system contains an AI-assisted chat component implemented as a server-side AIChatService connected to a configurable large-language-model endpoint. The component is not used to calculate risk scores or trigger alerts. Instead, it receives structured facts from the deterministic warning engine, including crop, stage, location context, relevant weather variables, computed risk level, and the active advisory category. The prompt template constrains the model to explain why the warning appears, translate technical variables into farmer-friendly Albanian, and provide conservative general actions. It also instructs the model not to invent sensor values, not to change the computed risk level, and not to provide pesticide doses unless such advice is grounded in an official label or validated agronomic source. This design follows the emerging view that generative AI can support agricultural advisory communication, but that guardrails, domain facts, and human or expert oversight are necessary for safe deployment [21], [22]. Generated text is, therefore, treated as an interpretability layer, while the operational warning logic remains deterministic and auditable.

F. Background Scheduling and Notification

Routine monitoring and dissemination are handled through Hangfire recurring jobs [16], [17]. This allows the application to execute regular checks, such as periodic weather retrieval and event-driven warning evaluation, as well as scheduled daily information delivery. From an EWS perspective, this is a critical operational feature because alerts should not depend on a farmer being logged into the platform at the moment a hazardous condition develops.

G. Climate Analytics and Administration

Beyond immediate alerts, the prototype supports climate analytics views that aggregate historical records, summary metrics, and time series. This supports reflection and learning, not just immediate action. Administrative features allow oversight of farmer records, crop associations, and other service-management functions. In future iterations, these administrative capabilities are expected to evolve into institutional response and case-management modules.

Fig. 3 synthesizes the implemented operational chain from onboarding and data retrieval to advisory delivery and learning-oriented analytics. Table IV summarizes the main implemented modules, while Fig. 4(a) to Fig. 4(d) and Fig. 5(a) to Fig. 5(d) provide enlarged interface-level evidence from the deployed prototype.

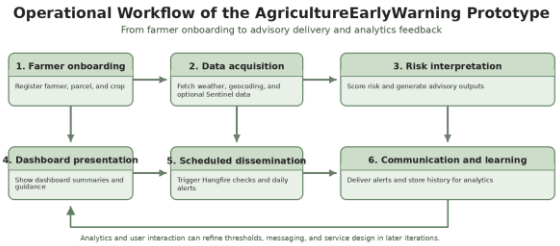

Fig. 3. Farmer-facing operational workflow of the AgricultureEarlyWarning prototype from onboarding to advisory dissemination and analytics feedback.

TABLE IV. MAIN IMPLEMENTED MODULES OF THE PROTOTYPE

Module	Implemented function	Operational note
Farmer onboarding	Registration, parcel geolocation, crop selection, subscription/trial linkage	Creates parcel-specific service context
Weather dashboard	Current, hourly, and daily forecast display with agricultural units and risk badges	Farmer-facing situational awareness
Risk engine	Crop-stage-sensitive thresholds for temperature, humidity, rainfall, and wind	Transforms forecast values into warnings
Remote-sensing enrichment	Sentinel-1 / Sentinel-2 indicator support including NDVI and backscatter summaries	Complements weather-based interpretation
AI guidance	Conversational explanation layer in Albanian	Improves interpretability, not core warning logic
Dissemination	Daily advisory SMS and event-based alerts via recurring jobs	Supports asynchronous communication
Climate analytics	Historical summaries, trends, and export-oriented views	Supports review and learning

H. Interface-Level Implementation Evidence

Fig. 4(a) to Fig. 4(d) and Fig. 5(a) to Fig. 5(d) present enlarged screenshots from the realized prototype. They document how the implementation translates the architectural workflow into concrete user interfaces for parcel geolocation, dashboard monitoring, analytical interpretation, vulnerability assessment, survey capture, escalation management, and farmer communication through SMS-style dissemination.

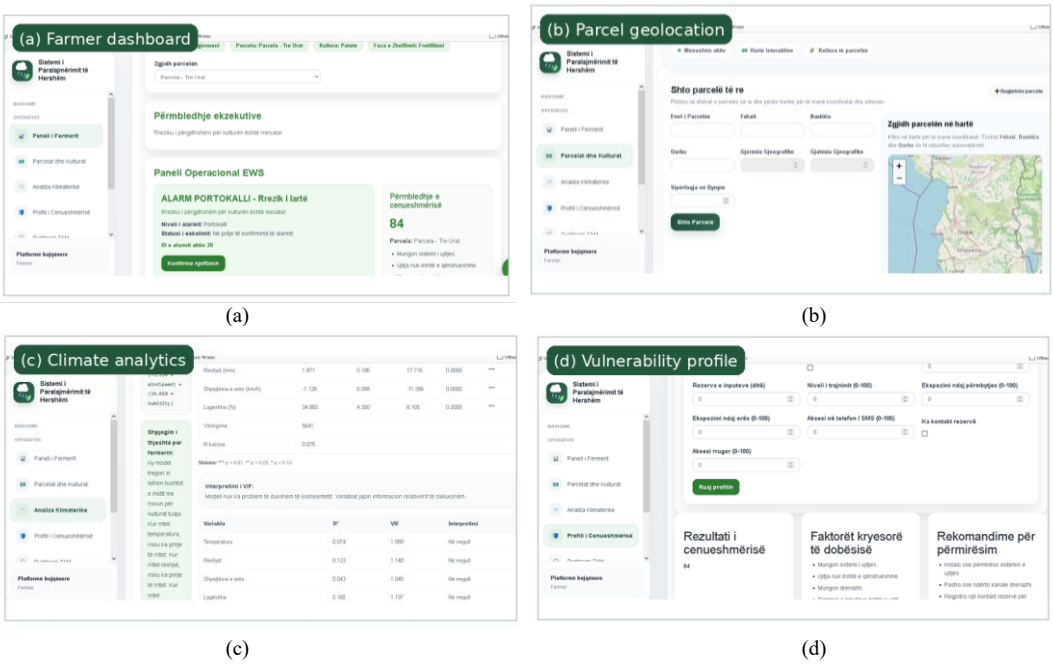

Fig. 4. (a) Farmer dashboard showing parcel selection, current risk summary, acknowledgement status, and vulnerability score. (b) Parcel geolocation screen where the farmer enters parcel attributes and selects coordinates on the interactive map. (c) Climate analytics screen with regression-style summary indicators, VIF interpretation, and climate variable diagnostics. (d) Vulnerability profile screen recording, exposure, access, training, backup capacity, and practical recommendations.

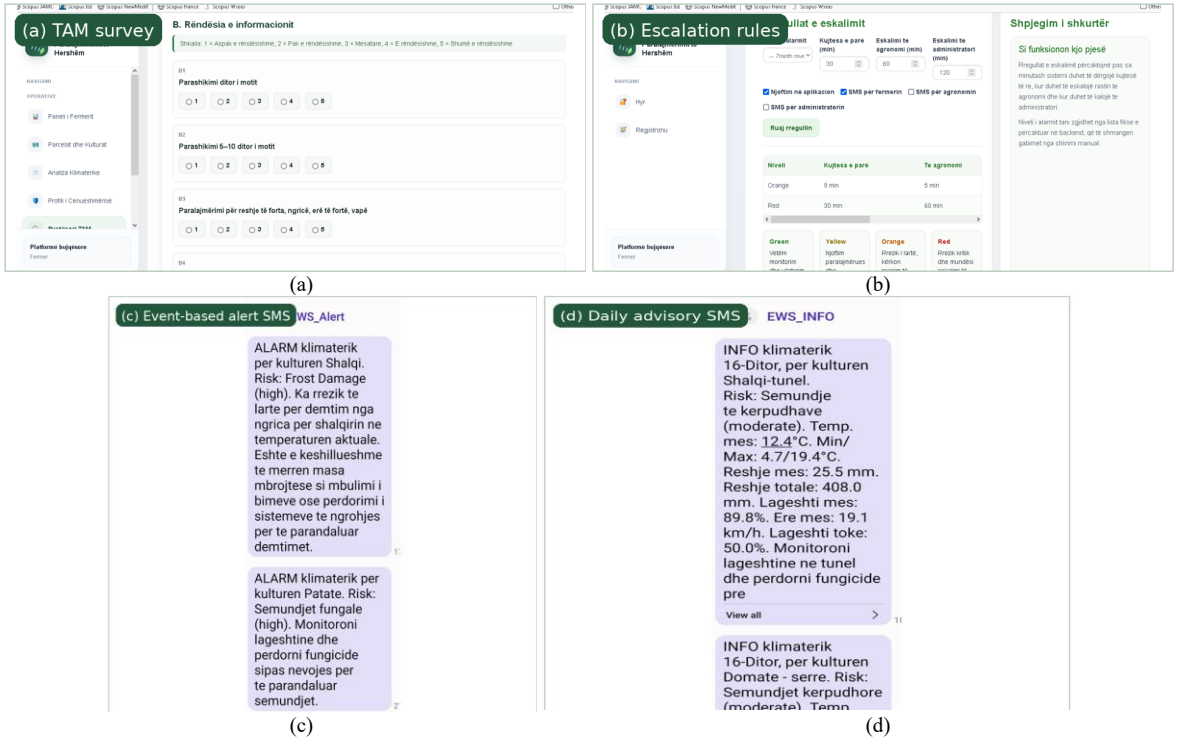

Fig. 5. (a) TAM survey capture screen used to collect structured user perceptions about the advisory service. (b) Escalation-rule configuration screen defining acknowledgement delays, transfer to agronomist, and transfer to administrator. (c) Event-based alert SMS showing risk type, severity, crop context, and immediate recommended action. (d) Daily advisory SMS showing forecast summary, disease-related risk, wind, rainfall, humidity, and suggested monitoring action.

VI. Functional Evaluation and Technical Discussion

This study does not report a randomized field trial or a statistically validated impact assessment. Instead, the revised evaluation reports prototype-level functional validation, architectural coherence, and implementation evidence drawn from the realized workflow and user interfaces. This evaluation mode is appropriate for a design and implementation paper, but it is clearly separated from field effectiveness, adoption, or yield-impact claims.

The functional validation focuses on measurable implementation indicators rather than agronomic impact. Table V summarizes the verification evidence available at prototype stage. The table deliberately distinguishes implemented functionality from performance metrics that require future field deployment, such as response latency under production load, API uptime over a full season, and farmer acceptance after repeated use.

TABLE V. Prototype-Level Functional Validation Indicators

Validation dimension	Measured or verifiable indicator	Prototype evidence	Remaining gap
EWS pillar coverage	Four EWS pillars reviewed; three assessed as strong and one as partial	Table II maps risk knowledge, monitoring, dissemination, and preparedness	Preparedness requires formal institutional operating procedures.
Functional module coverage	Seven implemented module groups plus escalation, feedback, and vulnerability-support screens	Table IV and Fig. 4(a)-Fig. 5(d) document the workflow	Independent usability testing is still needed.
Scheduler configuration	Recurring event checks and daily advisory dissemination configured through Hangfire	Daily EWS_INFO and event-based EWS_ALERT examples are captured in Fig. 5c and Fig. 5d	Long-term scheduler accuracy and latency must be measured under production load.
Risk-output transparency	Risk level, crop context, weather variables, vulnerability score, and advisory text stored or displayed	Dashboard, analytics, SMS, and vulnerability screens expose the key decision variables	Threshold calibration across seasons and crops remains future work.
API integration coverage	Weather, satellite, reverse geocoding, persistence, and background-job services integrated	Open-Meteo, Sentinel Hub, Nominatim, SQL Server, and Hangfire are separated through service classes	API reliability and rate-limit behavior require season-long monitoring.
Communication outputs	Two communication formats: daily advisory and event-based alert	SMS-style messages include crop, risk type, severity, and action-oriented text	Message comprehension and trust should be tested with farmers and extension staff.

The first strength of the prototype is localization. By structuring the workflow around parcel coordinates and crop associations, the system avoids the genericity of broad regional weather dashboards. This is consistent with recent agricultural EWS examples that emphasize farm-specific or location-specific service logic [7]-[9]. The use of remote-sensing services further extends the potential for localized interpretation, especially in settings where in-field instrumentation is limited.

The second strength is dissemination design. The system recognizes that warnings must reach users through appropriate channels and at suitable times. This reflects prior evidence that communication channels are central to climate-service usability for farmers [5]. By combining an exploratory dashboard with daily and event-based alerts, the platform balances information richness with timely communication. The Albanian-language interface also supports contextual usability.

The prototype also has several limitations. First, the agronomic quality of risk outputs depends on the calibration of crop parameters, thresholds, and advisory texts. Without extended field validation across crops, seasons, and agroecological zones, warning quality should be interpreted cautiously. Second, the integration of satellite indicators is promising but still requires rigorous calibration and validation for operational agricultural inference. Third, the platform currently emphasizes the farmer-facing and analytical sides of the EWS more than the institutional response side. It is therefore presented as a farmer-centered prototype with partial preparedness support, not as a complete national or institutional EWS.

The fourth limitation concerns operational infrastructure. Because the system depends on external APIs, background processing, and hosting reliability, production deployment requires attention to service continuity, usage policies, rate limits, scheduler robustness, and data-protection rules [10]-[17]. This is not a conceptual weakness of the design, but it is a real implementation constraint that any operational EWS must manage.

The generalizability of the architecture is strongest where three assumptions hold: geospatial parcel coordinates can be collected, weather and satellite APIs are accessible, and an extension or administrative actor can respond to escalated warnings. The software pattern is transferable because the data-acquisition, risk-logic, dashboard, and dissemination layers are modular. However, thresholds, language, crops, institutions, SMS providers, and payment models must be localized before deployment in another region or country. The platform is therefore best understood as a reusable architectural blueprint rather than a directly universal solution.

VII. Limitations and Future Work

Several development directions emerge from the current prototype and from the limits of the functional validation reported above.

First, field validation should become the priority. Future work should compare risk outputs and advisories with observed crop conditions, farmer actions, and actual hazard

outcomes across seasons. This would enable calibration of thresholds and the estimation of practical utility.

Second, the preparedness and response pillar should be expanded from prototype support into a formal institutional workflow. The current interface includes vulnerability profiling, escalation-rule configuration, feedback capture, and communication examples. Future deployment should add formal alert acknowledgement, agronomist assignment, dispatch logs, case closure rules, and institutional accountability procedures. Such additions would move the system from a strong farmer information platform toward a more complete end-to-end EWS.

Third, remote-sensing integration should be strengthened. Future work can evaluate how NDVI, VV, VH, and related indices improve risk prediction, especially for stress detection, excess moisture interpretation, and disease-supportive conditions. At present, these indicators are best understood as complementary evidence streams.

Fourth, the system would benefit from broader communication options and user testing. SMS remains important, but future versions may include WhatsApp-like channels, richer multilingual content, structured advisory templates, and usability testing with farmers and extension personnel.

Fifth, longer-term economic and adoption evaluation is needed. Since climate information services are also service products, future studies should assess farmer acceptance, repeated use, willingness to pay, and the institutional sustainability of subscription-based or mixed delivery models.

Finally, future technical work may include migration toward newer .NET stacks, stronger API abstraction, automatic performance logging, dashboard latency monitoring, improved audit trails, and richer analytics for both farmers and administrators. These enhancements would improve maintainability and long-term deployment readiness.

VIII. Conclusion

This study presented AgricultureEarlyWarning as a design and implementation case of a web-based climate advisory and early warning platform for farmer-centered agricultural risk management in Albania. The prototype integrates parcel-based localization, weather and satellite data services, crop-aware risk interpretation, dashboard analytics, AI-assisted explanation, vulnerability profiling, escalation support, and scheduled dissemination inside a single operational environment. Its main contribution is the engineering of a modular workflow that links risk knowledge, monitoring, communication, and response support in a form that is implementable with existing web technologies and external data services.

The study shows that a practical agricultural EWS pathway does not need to start as a monolithic national infrastructure. It can begin as a modular, farmer-facing platform that incrementally connects risk knowledge, monitoring, warning communication, and response support. AgricultureEarlyWarning already demonstrates meaningful progress in the first three of these areas and provides prototype-level support for the fourth. Institutional preparedness and coordinated response remain the next major step.

For digital agriculture researchers and practitioners, the platform illustrates how climate information services can be transformed into a more actionable service layer for farming decisions. For implementation contexts similar to Albania, it provides a realistic blueprint for integrating open weather services, satellite APIs, geospatial localization, and warning dissemination into one coherent system. The prototype, therefore, represents a substantive step toward practical, localized, and scalable agricultural early warning support.

***Abstract*—The study of the effects of microgravity on the human body has become increasingly relevant in biomedical research, particularly with regard to hematological changes. Therefore, the objective was to analyze the available scientific evidence on the impact of microgravity, both real and simulated, on erythrocytes with emphasis on osmotic fragility, cell membrane stability, and hemolysis. Likewise, 40 articles were selected using the PRISMA methodology, using the Scopus, PubMed, Web of Science, and IEEE Xplore databases, applying inclusion and exclusion criteria that had been previously established. Tools such as VOSviewer were also used, which facilitated the visualization of patterns of collaboration and scientific production. The results showed that microgravity produces remarkable changes in erythrocytes, such as an increase in hemolysis, alterations in the capacity for cell deformation, increased oxidative stress, and variations in the membrane. However, most research shows indirect information when it comes to osmotic fragility, with few applications of standardized measurements such as OFT or MCF-H50. In conclusion, severity influences the integrity and functionality of erythrocytes, leading to spatial anemia, although studies with greater standardization in their methodology are needed.**

***Keywords*—Erythrocytes; hemolysis; microgravity; osmotic fragility; spatial anemia**

I. Introduction

According to a study reported by NASA, technical reports served in 2024 indicated the effects of discharge on hematopoiesis and the subsequent life cycle of red blood cells evaluated at the resolution of the individual cell phone, where it indicates that prolonged exposure to microgravity causes the so-called spatial anemia. Because this phenomenon is associated with the absence of mechanical load, which alters erythropoiesis and can shorten the lifespan of erythrocytes, evidencing the key role of gravity in the regulation of the hematological system [1].

During the last decades, space exploration has been increasing, which has promoted the study of the effects of microgravity on the basis of the human body, in this way generating new challenges in the field of medicine. In this sense, according to the authors, they emphasized that one of the most relevant areas is the analysis of blood samples, due to its importance regarding the evaluation of physiological state; therefore, health monitoring and the diagnosis of diseases arise in spatial and terrestrial conditions [2]. In this way, microgravity produces significant alterations in the human body, such as the distribution of fluids, changes in plasma volume, and modifications in the production and function of blood cells.

Thus, in this study, they emphasized that these variations can directly affect hematological and biochemical parameters, which can make it difficult to interpret the results obtained through conventional methods of clinical analysis. Specifically, erythrocytes play an important role in oxygen transport, and their stability depends on the integrity of their cell membrane. In this regard, osmotic fragility is presented as an essential indicator to evaluate such integrity, since it shows the ability of red blood cells to resist changes in the osmotic medium without undergoing hemolysis [3]. Therefore, different studies have indicated that microgravity conditions can alter these properties, increasing the sensitivity of erythrocytes to destruction.

In this way, due to the limitations to carry out studies in space, tools have been developed, such as the clinostat, allowing to simulate microgravity conditions in the laboratory through the constant rotation of samples, facilitating experimental research in controlled environments, analyzing and identifying the effects of microgravity on human cells without requiring an off-planet study [4]. Likewise, the use of simulated microgravity models has allowed to expand knowledge based on the cellular response with respect to the alteration of the gravitational vector; however, there are still some evidence-based limitations in relation to specific hematological parameters [5].

In order to be able to carry out studies in microgravity, simulated microgravity models have been implemented, for example, the clinostat, which allows similar conditions to be developed in the laboratory by continuously rotating the samples. In this way, they help research into the effects of microgravity in a controlled way and have also contributed to the development of their own studies and scientific training [6]. Several studies have shown that microgravity produces important changes in the body's homeostasis, including alterations in fluid distribution, lower plasma volume, and alterations in blood cell production or function. Within this context, spatial anemia has been made known as one of the physiological strategies adopted in the course of a prolonged space mission. Spatial anemia affects the growth of the erythrocyte mass, maintaining an increase in the destruction of red blood cells [7]. This shows the complex nature of human adaptation to the space environment.

In this context, erythrocytes are essential for oxygen transport and their stability depends on the integrity of their cell

*Corresponding author

membrane. Osmotic fragility appears as a possible marker to assess such integrity, since it evaluates the ability of red blood cells to resist changes in the osmotic environment without undergoing hemolysis. Recently, there is data that points to how the structural and, if not functional, properties of erythrocytes can change under microgravity conditions, which can increase the risk of destruction and contribute to the picture of spatial anemia [8]. Therefore, the importance of the present study is to understand how simulated microgravity conditions can affect the stability of erythrocytes, which is why it is significant both for aerospace medicine and for biomedical research. In this way, it allows the use of methodologies accessible in the laboratory to be enhanced, contributing to the generation of knowledge applicable in contexts where it is possible to access real conditions of microgravity.

Despite the advances made, scientific information on the effects of microgravity on hematological indicators, such as osmotic fragility of erythrocytes, remains limited and scattered in the literature. In particular, there is no systematic synthesis that integrates the available findings on this phenomenon, which hinders a clear and comprehensive understanding of its implications on human health. Based on this problem, the research questions that guided this study are presented: What is the available scientific evidence on the effects of microgravity, real or simulated, on the osmotic fragility of erythrocytes? What methodologies have been used for its study? What are the main limitations and gaps in the current literature?

Therefore, the objective of this systematic review is to analyze and synthesize the available scientific evidence on the effects of microgravity on the osmotic fragility of erythrocytes, identifying the main findings, methodologies used, and limitations existing in the present studies. This study seeks to contribute to a better understanding of the hematological changes associated with microgravity, as well as to provide a solid theoretical basis to guide future research in the field of aerospace medicine and biomedical research.

The study is structured as follows: Section II describes in detail the literature review; Section III presents the materials and methods; then Section IV presents the results, Section V presents the discussion; Section VI presents the conclusion, and finally Section VII presents the recommendations and future work.

II. Literature Review

A. Background

Sickle cell anemia is a genetic disease whose clinical expression varies considerably between individuals, which has been attributed to the interaction between genetic and environmental factors. Recent literature highlights the importance of these factors in modulating disease severity, as well as in response to treatment. In this context, microgravity has been studied as a relevant experimental model, since it alters fundamental cellular processes. Various studies have shown that in these conditions, hemolysis and oxidative stress in erythrocytes are increased, key mechanisms in the pathophysiology of the disease. Likewise, changes in the structure and functionality of red blood cells have been observed, which could aggravate their characteristic alterations. Taken together, these findings suggest that the study of extreme environments such as microgravity contributes to a better understanding of sickle cell anemia and offers new perspectives for the development of more effective therapeutic strategies [9].

The study presented by Agramont et al. [10] argues that osmotic fragility in erythrocytes is related to spatial anemia; that is, they evaluated in detail the behavior of erythrocytes in the face of variations in the osmotic environment, in such a way, it was evidenced that they can experience relevant alterations in their functionality and structure. In this way, the results showed that it is possible to be under conditions that manage to simulate extreme environments such as microgravity. Consequently, erythrocytes are more susceptible to hemolysis, which has an essential impact on cell stability, as well as on the accuracy of hematological analyses. The study was able to highlight these modifications, as they can influence the interpretation of laboratory results, that is, directly in contexts where physical conditions differ from those on land. Therefore, the research provided significant evidence on the need to consider the effects of the environment in the analysis of blood samples, thus contributing to a better understanding of the physiological changes associated with microgravity.

Therefore, a study by Manis et al. [11] emphasizes that the behavior of human erythrocytes under simulated microgravity conditions showed that these cells undergo structural changes. Thus, according to the research, a decrease in antioxidant capacity, increased oxidative stress and alterations in the lipid composition of the cell membrane were obtained as a result. Therefore, modifications in the shape and stability of erythrocytes were identified, suggesting that microgravity can directly affect the integrity of the cell membrane. Thus, these results are relevant, since the stability of the cell membrane is related to the osmotic fragility of erythrocytes.

Thus, Murali and Sarkar [12] studied the behavior of erythrocytes under different gravity conditions, demonstrating that the variation of the gravitational field influences cell shape, deformability and dynamics. The results showed that microgravity generates changes in the structure of erythrocytes, affecting their stability and interaction with the environment, which could increase their susceptibility to hemolysis processes.

However, according to a study by Manis et al. [13], they analyzed human erythrocytes under simulated microgravity conditions, evidencing significant alterations in the lipid composition of the cell membrane. The results showed the presence of oxidized lipids and changes in phospholipids, indicating cellular stress and structural modifications in erythrocytes. These changes directly affect membrane stability, which is related to a possible increase in osmotic fragility.

In this sense, the authors emphasize that hemolysis is a determining factor in the development of anemia during long-duration spaceflight. The authors point out that, under conditions of microgravity, there is a sustained increase in the destruction of red blood cells, which shows that anemia is not only a temporary adaptation, but an active physiological process. The authors also highlight that the high presence of by-products of hemoglobin degradation confirms the persistence of hemolysis during the space mission. They also stress that some of these effects continue even after return to Earth, suggesting a

prolonged impact of the space environment on blood physiology. In this regard, the study concludes that environmental factors, such as microgravity, play a key role in the regulation and survival of red blood cells [14].

In this sense, the authors point out that erythrocytes are not a uniform population, but rather present a remarkable heterogeneity in their structure, function and biochemical properties. The authors point out that these differences may be caused by factors such as cell age, physiological environment and metabolic conditions. The authors also highlight that this variability directly influences the ability of red blood cells to carry oxygen and respond to stressful situations. In this sense, they stress that some erythrocytes may be more susceptible to processes such as hemolysis, which has important implications in the development of various hematological diseases. Similarly, they emphasize that erythrocyte heterogeneity is not only a normal biological phenomenon but can also contribute to the progression of pathologies, affecting the stability and functionality of the blood system [15].

However, in this study, they emphasized exposure to microgravity since it generates multiple physiological alterations at the systemic level, in such a way that the hematological system being one of the most affected. Likewise, they mention that during space missions, a progressive reduction in the mass of erythrocytes was observed, which directly contributes to the development of space anemia. In this way, this phenomenon does not manifest itself in isolation, but is accompanied by changes in the distribution of body fluids, which can mainly mask the real decrease in red blood cells. They also indicate that these changes are linked to the body's adaptive mechanisms in a space environment, in addition to producing a decrease in erythropoietin production and an increase in erythrocyte destruction. It is highlighted that microgravity alters oxygen homeostasis, which forces the body to modify its transport capacity [16].

According to the authors, erythrocytes undergo significant metabolic alterations during spaceflight, demonstrating that microgravity has a direct impact on their biochemical functioning. Thus, changes in essential metabolic pathways, such as energy metabolism, glycolysis, and antioxidant systems, were identified. This has the potential to jeopardize the production of ATP (Adenosine Triphosphate) and the ability of erythrocytes to maintain their structures. In addition, they emphasize that oxidative stress is elevated as a result of the accumulation of reactive oxygen species, causing damage to the lipids and proteins of the cell membrane. This damage caused erythrocytes to be more fragile and to produce hemolytic processes; likewise, they propose that these metabolic transformations could change the deformability of erythrocytes, since it is a fundamental element for their transit through capillaries. In other words, they suggest that the spatial environment not only decreases the number of erythrocytes but also affects their quality and functioning [17].

Therefore, evidence suggests that erythrocyte fragility is closely related to physiological stress conditions. Thus, a study carried out by the authors showed that even mild systemic inflammation can significantly increase the osmotic fragility of erythrocytes. The authors reported that inflammatory processes alter the structural integrity of the erythrocyte membrane. Likewise, the authors reported that inflammatory processes alter the structural integrity of the erythrocyte membrane, making red blood cells more susceptible to hemolysis, this finding is very pertinent, because it reveals how barely perceptible changes in the internal environment can condition the stability of erythrocytes. As a consequence, the results obtained also suggest that external factors such as microgravity can cause similar alterations in the membrane and increase the sensitivity of erythrocytes in response to osmotic stress.

B. Theoretical Basis

1) Erythrocytes: Erythrocytes are specialized blood cells whose main function is the transport of oxygen from the lungs to the tissues and the return of carbon dioxide. Therefore, their biconvex structure allows them a high capacity for formation, facilitating their passage through narrow capillaries; therefore, the integrity of their cell membrane is essential to maintain their functionality and survival in the bloodstream [18].

2) Erythrocyte membrane: The erythrocyte membrane is composed of a lipid bilayer and structural proteins that ensure its flexibility, stability, and mechanical adaptability. Alterations in their composition, either due to oxidative stress or external factors, can affect cell deformability and increase the probability of hemolysis [19].

3) Osmotic fragility of erythrocytes: Osmotic fragility is a parameter that assesses the resistance of erythrocytes to changes in the osmotic concentration of the medium. Therefore, it is measured by observing the degree of hemolysis when cells are exposed to hypotonic solutions, i.e., an increase in osmotic fragility indicates a lower stability of the erythrocyte membrane, which implies greater susceptibility to cell rupture [20].

4) Microgravity: Microgravity is a physical condition characterized by a significant reduction in gravitational force; in this sense, it occurs in space or in simulated laboratory models. This condition generates physiological changes in the human body, including fluid redistribution, metabolic alterations, and modifications in cellular function, especially in the hematological system [21].

5) Oxidative stress: Oxidative stress occurs when there is an imbalance between the generation of reactive oxygen species and the antioxidant capacity of the body. In erythrocytes, this phenomenon can cause damage to membrane lipids and proteins, compromising their stability and increasing their fragility [22].

6) Hemolysis: Hemolysis is the process of destruction of erythrocytes, which can occur due to mechanical, chemical, or physiological factors. In conditions such as microgravity, an increase in hemolysis has been observed, which contributes to the decrease in erythrocyte mass and the development of anemia [23].

7) Erythrocyte deformability: Erythrocyte deformability is the ability of red blood cells to change shape without breaking through capillaries. This property depends on the integrity of the membrane and the cell cytoskeleton. Likewise, its alteration

can affect blood circulation and promote hemolytic processes [24].

III. Materials and Methods

In order to analyze in a structured way the scientific evidence regarding the effects of simulated microgravity on the osmotic fragility of erythrocytes, the present work was carried out under a systematic review of the literature. This methodology was chosen because of the way in which it evaluates, organizes and synthesizes the scientific information it has, in a rigorous and reproducible way and in which the minimum bias in the selection of studies intervenes. It should be noted that the prism methodology was used as a set of guidelines to be followed in the preparation and presentations of meta-analysis and systematic review, with the main purpose of this method being to ensure that the search and selection treatment of studies is done in a transparent and orderly manner. Likewise, the methodology allows to describe in detail how the search for the information has been done, as well as the criteria that were used to include/exclude the studies that were retrieved and which studies were finally analyzed, since it includes a flow chart that allows you to see the entire process of selecting the articles. In this way, the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) methodology increases the reliability and quality of systematic reviews and meta-analyses, since other researchers can understand and replicate the procedure followed [25].

The bibliometric analysis was carried out in order to identify trends, research patterns and scientific collaboration networks in the study of spatial anemia and erythrocyte alterations under microgravity conditions. To this end, the VOSviewer software was used, which allowed the generation of graphical representations of keyword co-occurrence, co-authorship between researchers and collaboration between countries, using bibliographic data obtained from Scopus, IEEE Xplore, PubMed and Web of Science (WoS). This analysis facilitated the identification of the main lines of research and the structure of scientific production in the area [26].

A. Study Design

The research was based on a process of research and analysis of scientific research related to the effect of microgravity on hematological parameters, especially in terms of the stability and osmotic fragility of erythrocytes. Decision and experimental studies that focused on microgravity models, such as the clinostat or other simulation devices, were also noted.

B. Data Sources

In order to identify the relevant articles, an exhaustive bibliographic search was carried out in scientific databases of great international recognition, such as ScienceDirect, Scopus, PubMed, IEEE Xplore, which were selected for the bibliographic search due to the high level of coverage in the biomedical field for the indexing of scientific journals also of high impact.

C. Search Strategy

To search for the relevant studies, a combination of keywords such as microgravity, erythrocytes and osmotic fragility was carried out, in order to have a better coverage, synonyms and alternatives of the most frequent terms in the scientific literature were used. To this end, the four databases most used in the various scientific studies were used, such as WoS, Scopus, PubMed and IEEE. In addition, studies were collected during the period from 2021 to 2025, to obtain the most recent information from the literature and have a better outlook. For this purpose, Boolean operators such as (AND, OR) were used in the aforementioned databases. The strategies used are detailed below:

1) Web of Science: TS=((microgravity OR weightlessness OR "spaceflight" OR "simulated microgravity") AND (erythrocyte* OR "red blood cell*" OR RBC) AND (anemia OR hemolysis OR "red cell turnover" OR "osmotic fragility" OR "membrane stability" OR deformability))

2) Scopus: TITLE-ABS-KEY((microgravity OR weightlessness OR "spaceflight" OR "simulated microgravity") AND (erythrocyte* OR "red blood cell*" OR RBC) AND (anemia OR hemolysis OR "red cell turnover" OR "osmotic fragility" OR "membrane stability" OR deformability))

3) PubMed: ((microgravity[Title/Abstract] OR "simulated microgravity"[Title/Abstract] OR spaceflight[Title/Abstract] weightlessness[Title/Abstract]) AND (erythrocyte*[Title/Abstract] OR "red blood cell*"[Title/Abstract] OR RBC[Title/Abstract]) AND (anemia[Title/Abstract] OR hemolysis[Title/Abstract] OR "red cell turnover"[Title/Abstract] OR "osmotic fragility"[Title/Abstract] OR "membrane stability"[Title/Abstract] OR deformability[Title/Abstract] OR "space anemia"[Title/Abstract])) AND (ffrft[Filter]) AND ("2021/01/01"[Date -Publication] : "2025/12/31"[Date - Publication])

4) IEEE Xplore: (("Publication Title": microgravity OR "Publication Title": "simulated microgravity" OR "Publication Title": spaceflight OR "Publication Title": weightlessness) AND ("Abstract": erythrocyte OR "Abstract": "red blood cells" OR "Abstract": RBC) AND ("Abstract": anemia OR "Abstract": hemolysis OR "Abstract": "red cell turnover" OR "Abstract": "osmotic fragility" OR "Abstract": "membrane stability" OR "Abstract":d eformability))

D. Inclusion and Exclusion Criteria

In order to ensure the validity, relevance, and updating of the works that are recognized, specific inclusion and exclusion criteria have been determined.

- Inclusion criteria:
  - Articles published in indexed journals.
  - Scientific articles published in the last 5 years.
  - Publication in English.
  - Investigations that include analysis of osmotic fragility, erythrocyte membrane stability or hemolysis.
  - Investigations that evaluate erythrocytes, spatial anemia or hematological parameters.

- Investigations related to simulated or real microgravity.
- Studies that use experimental models of microgravity, such as the clinostat.

- Exclusion criteria:
  - Studies with insufficient information or unclear methodologies.
  - Studies without access to full text.
  - Duplicate Articles Across Databases.
  - Publications that do not address the specified topics.

E. PRISMA Methodology

The strategy used for the selection of the review articles presented below was the one found in the protocol, which made possible the orderly and reproducible structures of each of the review phases. Therefore, in the identification phase, the search for these articles from the databases and using the Boolean operators mentioned above was carried out. As can be seen in Fig. 1, in the first instance in the Scopus database, a number of 41 articles were obtained, in IEEE Xplore 178, in PubMed 200 and in Web of Science 228, obtaining a total of 745 articles to be later analyzed. Then, in the filtering phase, duplicate records and those that did not meet the inclusion and exclusion criteria were eliminated, such as those that were not related to the topic of the study, year of publication, as well as those that were not available in full text, leaving a total of 75 articles.

On the other hand, in the screening phase, another evaluation was carried out, but this time the titles and abstracts of the articles were verified, according to the direct relationship, taking into consideration the subject of study in this specific case, in order to determine the effect of microgravity on the behavior of erythrocytes, leaving a total of 42 articles. Therefore, in the inclusion stage, a conscientious reading of the differently selected articles was carried out, where duplication was found in two articles; therefore, a total of 40 articles were finally left. In this phase, its scientific relevance and methodological relevance were critically assessed, also adding that the reading of the articles from which the set of studies carried out subsequently for qualitative research was ultimately elaborated, as well as in short, this procedure allowed to gradually reduce the number of studies initially selected and also to guarantee the selection of appropriate and updated research related to qualitative research line of the objectives of this study [27].

F. Analysis of Information

In this section, the research selection process that underpins the systematic review that was carried out according to the PRISMA diagram model is detailed, in which the phases of identification, filtering, screening, and inclusion of the studies formed in a logical sequence are organized. In the first stage of identification, a total of 745 of the records were obtained from the 4 selected databases and were collected: Scopus (41), IEE Xplore (178), PubMed (200), Web of Science (226). In this sense, this phase aimed to obtain a high number of publications that could be relevant in terms of microgravity and its effects on erythrocytes in order to configure a broad initial base for the analysis, Thus, in the second phase of filtering, the inclusion and exclusion criteria were established in order to purify the records obtained, Likewise, in this phase, criteria were established such as the type of document taken as a basis, with preferable those investigations that are aligned with the original article, as well as the direct relationship with the topic of study pointed out in terms of the conditions of microgravity or spaceflight, anemia, impact on erythrocytes and their implications.

However, specific variables such as hemolysis, anemia, osmotic fragility, membrane stability, and deformability were evaluated. It should be noted that only studies published in the period of 2021-2025 were included, corresponding to articles available in English and, likewise, with access to the full text. As a result of this process, around 75 articles were obtained in the eligibility phase: Scopus (28); IEEE Xplore (24); PubMed (4); Web of Science (19). In the screening phase, the titles and abstracts of the articles obtained were meticulously analyzed. In this phase, 42 investigations were obtained that were taken into consideration for subsequent analysis. In this phase, 33 studies were excluded since they did not meet the methodological or thematic criteria that we had established. Therefore, in the inclusion phase, only 2 duplicate articles were detected; therefore, they were eliminated to avoid content redundancies. Therefore, a set of 40 articles was obtained that make up the database of this systematic review, which were organized systematically in order to facilitate the analysis.

For each collection study, information was collected based on relevant bibliographic data, such as the year of publication, authors, source of origin, which allowed it to be structured in an orderly manner, facilitating the analysis of the different approaches used in research on erythrocyte alterations in conditions of microgravity, spatial anemia, as well as the possibility of contrasting the methods in the different articles. However, for the organization and management of the articles, specialized tools such as bibliographic managers were used, in which it was very useful, since they allowed storing the records, identifying duplicate articles and thus optimizing the review process, likewise, the VOSviewer software was used for the elaboration of bibliometric maps and collaboration networks between authors and countries, allowing a visual analysis of scientific production to be carried out.

Together, the selection method applied to the literature made it possible to reduce a large amount of scientific literature until a final set of relevant studies was obtained. It should be noted that the rigorous application of the inclusion and exclusion criteria in each phase made it possible to guarantee the coherence of the selected articles, building a solid database for the analysis of erythrocyte alterations under microgravity conditions and the analysis of spatial anemia. In this way, the included studies provide an up-to-date view of the state of research in this field, as well as a starting point for future scientific research (see Fig. 1).

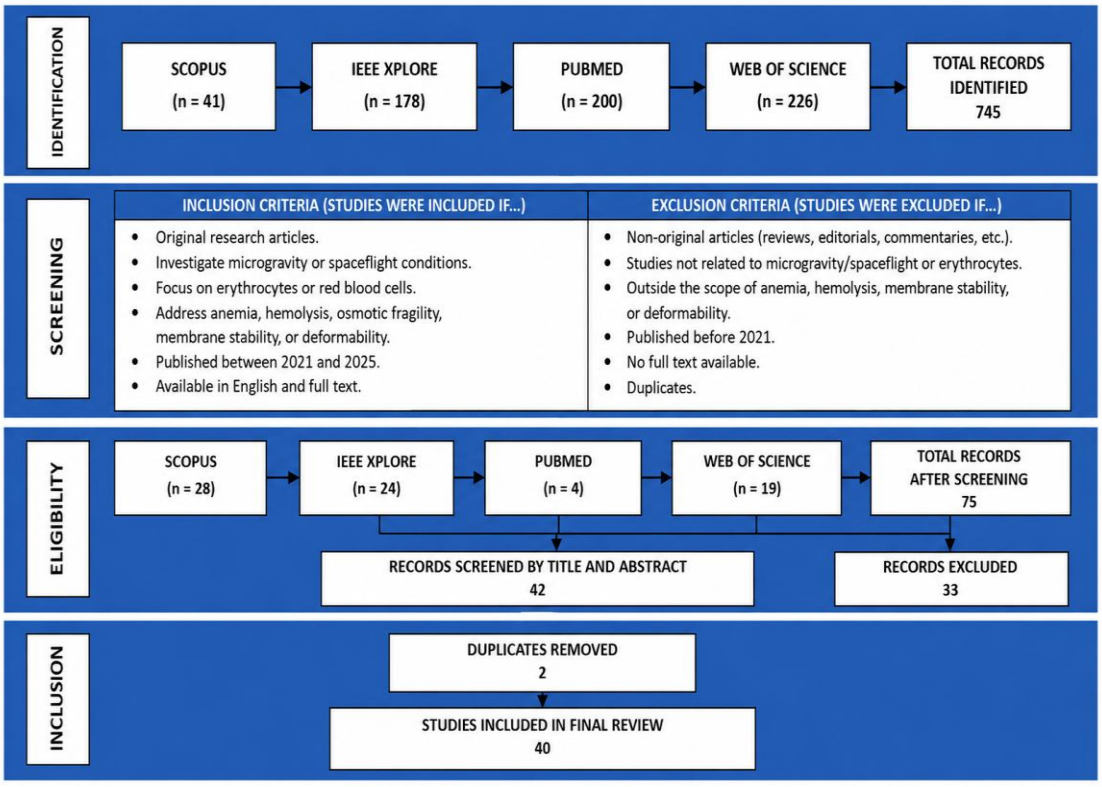

Fig. 1. PRISMA methodology

IV. Results

In this section are the results of the systematic review. There was an increase in scientific interest in researching the effects of microgravity on erythrocytes, with a particular focus on problems such as hemolysis, spatial anemia and alterations in the mechanical characteristics of red blood cells. In this sense, the information based on the analyzed literature shows how this field has been consolidating itself as a relevant area within aerospace biomedical research, due to its impact on the health of astronauts during their prolonged missions.

In general terms, the studies reviewed show an inclination towards the use of experimental models, both in real and simulated microgravity conditions, as well as including places such as the International Space Station and devices designed for simulation on Earth. These approaches allow the analysis of physiological changes in erythrocytes such as osmotic fragility, membrane stability, deformability and in general the fundamental aspects in order to understand the appearance of the so-called spatial anemia, in this way, the results allowed to identify variations in the methods used, as well as the type of samples analyzed and the level of evidence achieved by the studies. An unequal geographical distribution of scientific production is also observed, these findings offer a current view of the state of research and serve as the basis for the bibliometric analysis developed below.

A. Keyword Co-occurrence Map

In this section, an analysis of keyword co-occurrence was carried out with the 40 selected articles, using the VOSviewer tool, with the aim of determining the most important thematic lines in research on microgravity and erythrocytes. Therefore, in Fig. 2, you can see the map produced where he identified an extensive network of interrelated terms, organized in multiple clusters. In this sense, in this representation, the size of nodes indicates the frequency of occurrence of each keyword, however, the thickness of the links reflects the intensity of the relationship between the terms and the colors, since they facilitate the distinction of different thematic groups [28].

Likewise, several central nuclei were identified that are clearly delimited. Therefore, the concepts "spaceflight" "microgravity", "erythrocyte", and "hemolysis" are the ones that stand out the most, which constitute the main axis of the research, and demonstrate that most of the studies are carried out in space conditions or simulated microgravity. Likewise, terms such as "ISS" or "international space station" emphasize the importance of the experimental spaces used in this field. In addition, a group focused on "RBC", "erythrocyte", and "erythrocytes" is seen. Therefore, this confirms that erythrocytes are the most important biological center of the literature analyzed. This set is strongly linked to physiological variables such as hemolysis, which is presented as one of the most essential terms and thus shows interest in the process of damage or destruction of red blood cells in microgravity conditions.

In this sense, terms related to biochemical and cellular processes are identified, such as "function", "oxidative stress", "membrane", "lipidomic", which indicate that a significant part of the research is focused on understanding the underlying mechanisms that explain the functional and structural alterations of erythrocytes [29]. Therefore, the presence of terms related to

methodological and technological aspects was identified, such as "flow", "ultrasound", "impedance", "channel", which indicated the use of various experimental techniques for the analysis of erythrocyte properties [30].

Overall, the co-occurrence map shows a strong relationship between microgravity conditions and the changes they cause in erythrocytes, particularly hemolysis and oxidative stress, which are essential processes for understanding spatial anemia [31]. It also demonstrates the combination of experimental and technological methods in investigating this phenomenon, which highlights the multidimensionality and complexity of research in this area (see Fig. 2).

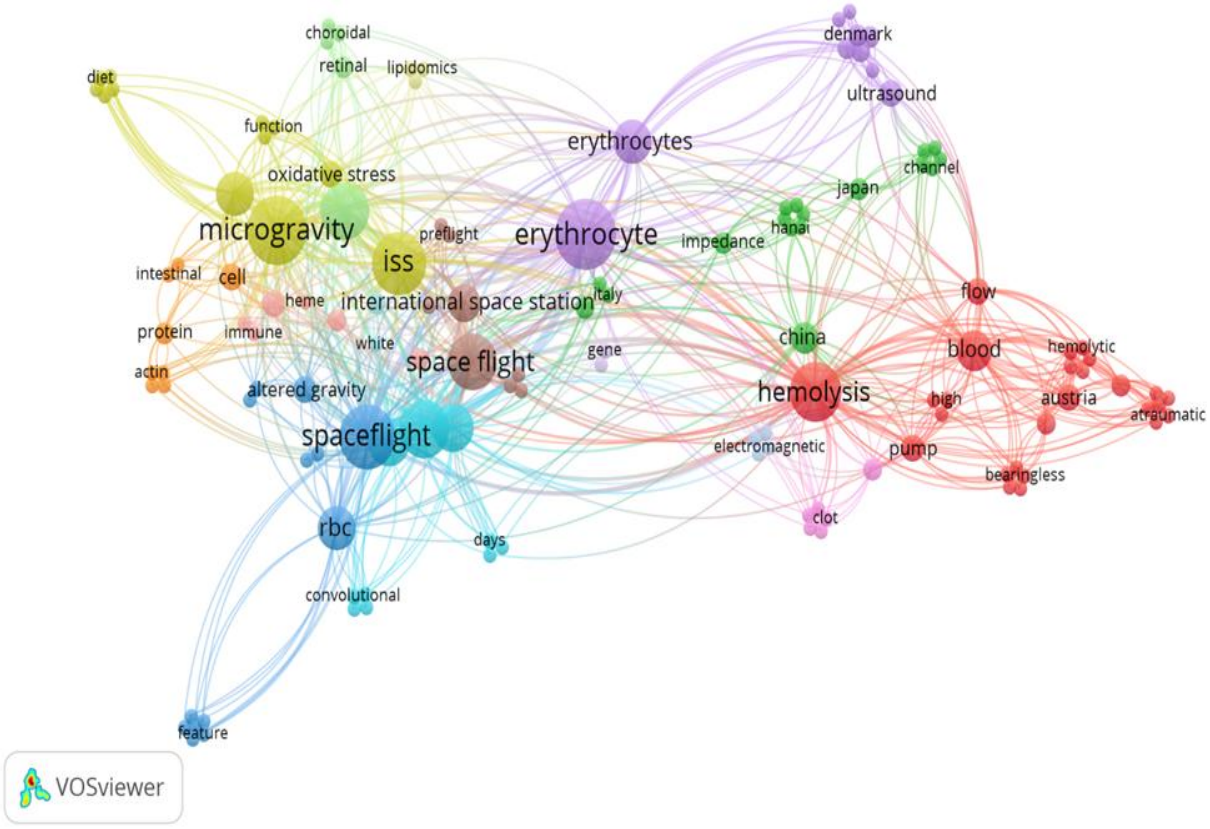

Fig. 2. Keyword co-occurrence map

B. Co-authorship Map

A co-authorship analysis was carried out with the aim of determining the cooperative links between scientists who have contributed to the study of microgravity and its repercussions on erythrocytes. In this way, the VOSviewer software was used, which made it possible to graphically represent the relationships between authors from the 40 articles chosen, as can be seen in Fig. 3; therefore, the map obtained reveals a network organized into two main groups of collaboration. The first largest cluster brings together authors such as Ryan, K. A., Houerbi, N., Kim, J., Mason, C. E., Mateus, J., Najjar, D., Afshin, E. E., and Damle, N., all of whom have numerous connections between them.

Therefore, the high concentration of links shows a close and recurrent collaboration within this group, which indicates the presence of a consolidated research team working in this thematic line [32]. On the other hand, a second cluster formed by Overbey, E. G., and Pecaut, M. J., characterized by a smaller structure and with fewer connections, is identified. However, the role of Overbey, E. G., as a link node between both groups stands out, since it maintains connections both with the main cluster and with other authors, thus facilitating interaction between different lines of research.

In this way, the presence of these two groups reflects a partially fragmented network of collaboration, in which highly interconnected research nuclei coexist with other, more independent ones. Likewise, the existence of authors who act as bridges between clusters highlights the importance of certain researchers in the articulation of knowledge within the field. Overall, the co-authorship analysis suggests that, although there are consolidated research groups in the study of microgravity and erythrocytes, global collaboration is still at a moderate level, which opens the possibility of strengthening broader scientific networks in future research (see Fig. 3).

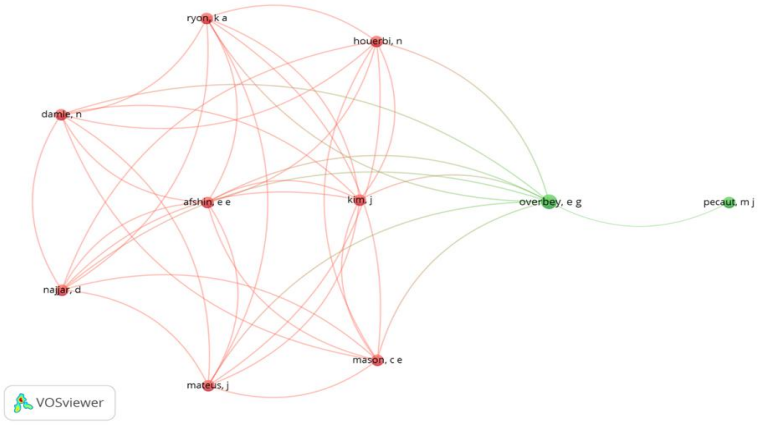

Fig. 3. Co-authorship map

C. Map of Co-authorship by Country

In this section, the graphical representation facilitates the analysis of international collaboration between countries within a set of selected studies, as can be seen in Fig. 4. Two main groups were identified that were distributed in five countries and are linked by several co-authorship links. Thus, in this type of map, each node represents a country in the same way the lines indicate the existence of publications made by a group of authors from different nations [33].

In this sense, the network shows that international collaboration is limited, due to the fact that there are few countries that have co-authorship links, which indicates that most of the research is carried out in small teams and is also developed in national contexts. However, Austria is a point of connection between the European group (Austria, Germany, Switzerland) and the Asian group (China and Japan), allowing for intercontinental interaction [34]. On the other hand, closer ties are observed in each of the groups, especially in the European bloc, indicating more consolidated regional cooperation. In Asia, cooperation and collaboration are mainly concentrated in Japan and China, the latter being an important node because it maintains relations not only within its geographical area but also with Europe; therefore, the analysis of co-authorship reveals a sparse network with concrete links, which evidences a specialized field of research. This indicates that, despite international cooperation efforts, there is still room to strengthen cooperation between countries and to promote joint research that broadens the scope and also the robustness of research in this area (see Fig. 4).

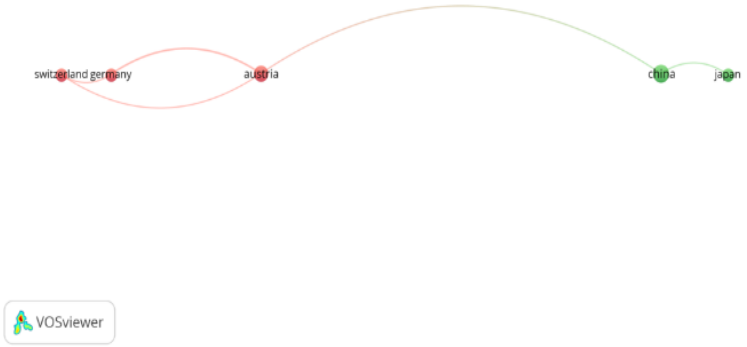

Fig. 4. Co-authorship map by country.

D. Annual Evaluation of Scientific Production

Fig. 5 shows how the annual scientific production linked to research into microgravity and its impacts on erythrocytes has changed. The review was carried out based on the 40 selected articles. Thus, the vertical axis of the graph shows how many articles were published in each period, while the horizontal axis shows the representation of the years of publication, in general terms, between 2021 and 2025. Scientific production represents a variable behavior. Consequently, 9 publications were registered in 2021, but the production dropped to 7 articles in 2022. Subsequently, in 2023, the lowest value of the entire period (3 publications) is appreciated. This indicates a temporary decrease in the number of studies reported on this topic.

Since 2024, a significant increase in scientific production has been observed, reaching its peak in the period with 12 investigations. This increase indicates a more recent interest in investigating alterations in erythrocytes that occur in microgravity, such as spatial anemia, hemolysis, and variations in red blood cell function and stability. In 2025, production remains at a high level with 9 articles, which supports the permanence of this line of research. In general, the trend observed despite the fact that production was not constant during all years, in the most recent periods there was a significant increase. This allows us to infer that research on microgravity and its impacts on erythrocytes has established itself as an emerging area of interest, with a projection to continue developing in future research [35].

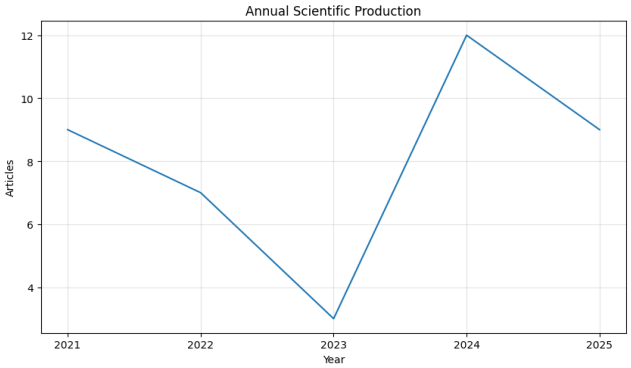

Fig. 5. Annual scientific production

E. Distribution of Publications by Journal

This section refers to the distribution of publications by scientific journals, as can be seen in Fig. 6. It allowed us to identify the most relevant sources within the field of study related to microgravity and erythrocytes. Therefore, with the results obtained from 40 articles, it was identified that the journal Studies in Health Technology and Informatics concentrates the largest number of publications, with a total of 5 articles, positioning itself as the main source of dissemination in this field. Therefore, this result indicates that it is of utmost importance in research that integrates technology and health, especially in innovative contexts such as microgravity.

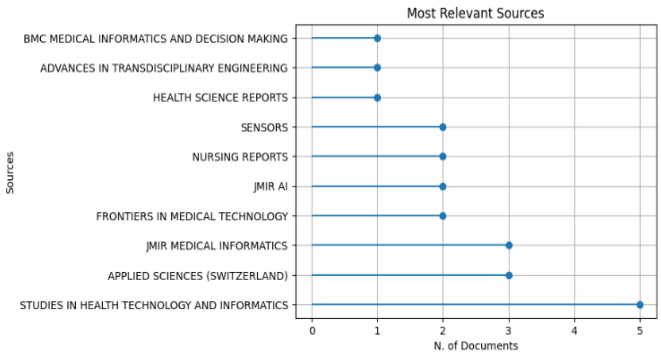

Fig. 6. Most relevant sources

Consequently, the journals Applied Sciences (Switzerland) and JMIR Medical Informatics stand out, with 3 publications each, which shows their significant contribution to the dissemination of studies related to computational and technological analysis applied to biological phenomena. Likewise, several journals with an intermediate production are identified, such as Frontiers in Medical Technology, JMIR AI, Nursing Reports and Sensors, each with 2 published articles. These sources reflect the thematic diversity of the field, spanning approaches from biomedical engineering to clinical applications.

On the other hand, journals such as Health Science Reports, Advances in Transdisciplinary Engineering and BMC Medical Informatics and Decision Making have a lower participation, with 1 article each, which indicates a more specific contribution within the analyzed set. Overall, the observed distribution shows that scientific production is not concentrated in a single journal, but is dispersed in various sources, which confirms the interdisciplinary nature of the research topic. In addition, this diversity favors the dissemination of knowledge and the development of new lines of study in the field of microgravity and its effects on erythrocytes [36].

F. Content Analysis

With respect to content analysis, the selected articles allowed the identification of the main methodological, thematic and conceptual approaches present in the literature in relation to microgravity and its effects on erythrocytes. Therefore, this analysis was carried out based on the review of the 40 studies, which made it possible to organize the information into important categories. It should be noted that a significant part of the research was identified focused on the study of the physiological alterations of erythrocytes under the conditions of both real and simulated microgravity. In this sense, the scientific articles analyzed highlight changes in the stability, structure and functionality of red blood cells, evidencing their impact on processes such as spatial anemia and hemolysis. Therefore, with respect to the analysis of the osmotic fragility of erythrocytes, it is considered as a key indicator of the integrity of the cell membrane. Therefore, several studies agree that exposure to microgravity can increase the susceptibility of erythrocytes to rupture, which causes an alteration in their mechanical and biochemical properties [37].

On the other hand, research aimed at the study of molecular and cellular mechanisms, including oxidative stress, is identified; therefore, the factors are frequently related to the decrease in erythrocyte stability and the increase in hemolytic processes. As for the methodological approaches, the use of experimental models of simulated microgravity, such as the clinostat, as well as studies carried out in real environments such as the International Space Station, is evidenced. Therefore, these methods make it possible to analyze the effects of the space environment on blood cells in a controlled manner. Likewise, the content analysis identified that the studies present a diversity of interdisciplinary approaches, thus integrating areas such as biomedicine, biochemistry, physiology, and engineering. In this way, this reflects the difficulty of the phenomenon studied and also the need to address it from different perspectives. Thus, the results regarding the content analysis showed that research in this field of development has made important advances in the understanding of the effects on microgravity on erythrocytes. However, gaps in the literature are also identified, especially in relation to long-term clinical studies and the standardization of methodologies, which suggests the need to continue deepening this line of research [38].

G. Distribution of Journals on Microgravity and Erythrocyte Studies

Fig. 7 shows the distribution of the scientific articles analyzed according to the journals in which they were published, which allows us to identify the main sources of dissemination when investigating microgravity and its impacts on erythrocytes. Therefore, from the 40 articles selected in this systematic review, it is observed that the journal Studies in health Technology and Technology and Informatics concentrates the largest number of publications with a total of 5 articles, positioning itself as the most relevant source in the field. Thus, this result shows the focus on research that integrates

health and technology, especially in innovative contexts such as microgravity. It should also be noted that the journals (Switzerland), JMIR Medical Informatics and Applied Sciences with 3 publications each, reflect their significant contribution to the dissemination of studies related to the analysis of biological phenomena through computational and technological approaches.

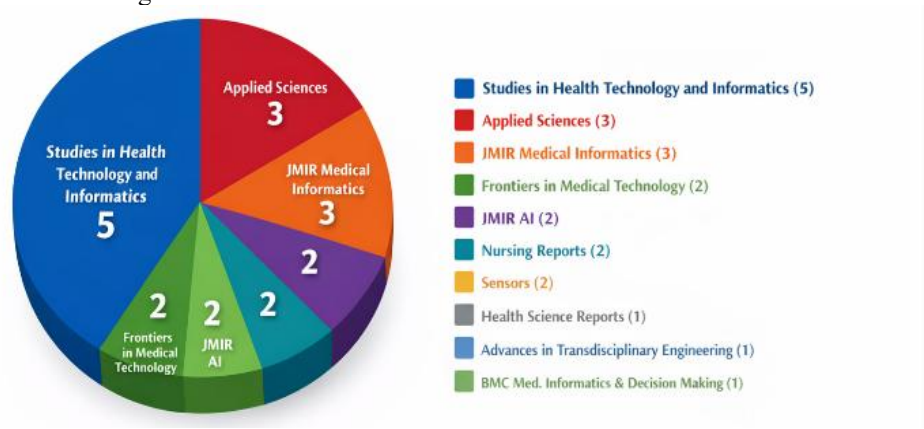

Fig. 7. Content analysis

Likewise, several journals with an intermediate production are identified, including Frontiers in Medical Technology, JMIR AI, Nursing Reports and Sensors, each with 2 published articles. These journals reflect the diversity of approaches present in the literature, ranging from biomedical engineering to clinical applications related to the analysis of erythrocytes in microgravity conditions. On the other hand, journals such as Health Science Reports, Advances in Transdisciplinary Engineering and BMC Medical Informatics and Decision Making have a lower participation, with 1 article each, which indicates a more specific contribution within the analyzed set.

Thus, the observed distribution shows that the scientific production is dispersed in various journals, which confirms the interdisciplinary nature of the study of erythrocytes and microgravity. Therefore, this diversity favors the dissemination of knowledge and also contributes to the development of new lines of research in the field of biochemistry and aerospace medicine [39].

H. Comparison of Studies on the Effects of Microgravity on Erythrocytes and Their Relationship with Osmotic Fragility

As can be seen in Table I, of the 40 articles that were selected, only 8 studies were taken into account for a comparative analysis, because only this small group of articles provided quantitative or qualitative information directly associated with erythrocyte osmotic fragility, hemolysis, membrane stability, or equivalent indicators associated with the adaptation of erythrocytes to microgravity conditions. Likewise, these studies had a more complete description of the experimental protocols used and reported results that facilitated comparisons between the different methodological approaches. It should be mentioned that the remaining studies were considered during the general synthesis of the systematic review evidence, but did not provide sufficient information about the specific variables analyzed in this table. To this end, they were distributed by authorship, year, title, experiment-protocol (brief), metrics (main findings) and limitations, likewise, it is evident that most of the studies analyzed coincide in microgravity conditions, both simulated and real, which can generate important alterations in erythrocytes. Therefore, these modifications are not always directly evaluated by classic tests such as the OFT (Osmotic Fragility Test) or MCF/H50 (Mean Corpuscular Fragility-H50) tests, but they do manifest themselves through functional, biochemical and structural changes that affect cell stability. Therefore, firstly, some studies, such as that of Agramont et al. (2023), directly report an increase in osmotic fragility and also in susceptibility to hemolysis, suggesting a lower resistance of erythrocytes to changes in the osmotic environment. This type of evidence is especially relevant, as it allows a more direct relationship to be established between erythrocyte damage and microgravity.

Therefore, a large part of the studies provides indirect evidence, since research such as that of Manis (2022, 2023) indicates an increase in oxidative stress, alterations in the composition of the membrane and metabolic changes, factors that are closely related to the loss of cell stability. Therefore, Murali and Sarkar (2025) analyze changes in the deformability and behavior of erythrocytes, which may affect their ability to resist adverse situations and increase their susceptibility to hemolysis. In studies carried out in real microgravity, such as Trudel et al. (2022), there are evidence of a sustained increase in hemolysis during prolonged space missions, which supports the notion that the destruction of red blood cells is an active process in this context, which favors the emergence of the so-called spatial anemia. In this sense, according to Hinge et al. (2024) they show morphological and functional alterations in erythrocytes both under simulated conditions and in reality, which indicates that experimental models on the ground can partially replicate the effects seen in space. Finally, certain studies considered as additional support according to Stuart et al. (2024) and Kashirina et al. (2022), offer evidence from a physiological and molecular perspective. These studies indicate that elements such as inflammation or molecular stress may increase the fragility of erythrocytes, thus contributing to a better understanding of the underlying mechanisms, even if they are not directly related to microgravity.

TABLE I. PROPOSED MODEL STUDIES

No.	Author	Year	Title	Experiment-Protocol (brief)	Metrics - Main findings	Limitations
[9]	Agramont N.; Carrasco M.; Flores B.; Quenta D.; Chávez G.	2023	Osmotic Fragility and its Relationship with Space Anemia	A study focusing on the osmotic fragility of erythrocytes and its relationship to space anemia under conditions associated with simulated microgravity	Osmotic fragility: increased. Hemolysis: increased susceptibility. MCF/H50: not reported. p-value: not reported	The abstract does not provide standardized quantitative values; there is limited numerical evidence in the available excerpt.
[10]	Manis C.; Manca A.; Murgia A.; Uras G.; Caboni P.; Congiu T.; Faa G.; Pantaleo A.; Cao G.	2022	Understanding the Behavior of Human Cell Types under Simulated Microgravity Conditions: The Case of Erythrocytes	Human red blood cells under simulated microgravity; analysis of structural and biochemical changes in the cell membrane	Oxidative stress: increased. Antioxidant capacity: decreased. Erythrocyte membrane: altered. Osmotic fragility: indirect evidence of an increase. MCF/H50: not reported. p-value: not reported	It does not directly assess OFT or MCF50 in the available content; the relationship to osmotic fragility is indirect
[12]	Manis C.	2023	Study of metabolic changes in human erythrocytes and plasma under simulated microgravity conditions	Metabolic study of erythrocytes and plasma under simulated microgravity	Erythrocyte metabolic changes: present. Cell stability: compromised. Osmotic fragility: indirect evidence of increased levels. MCF/H50: not reported. p-value: not reported.	The abstract does not include complete numerical results or a full description of the methodology; verification against the full text is required.
[11]	Murali A.; Sarkar R. R.	2025	Impact of gravitational forces on Red Blood Cell dynamics in biofluid suspension	Evaluation of erythrocytes under different gravitational conditions; analysis of shape, deformability, and cell dynamics	Erythrocyte deformability: altered. Cell dynamics: altered. Susceptibility to hemolysis: indirectly increased. Osmotic fragility: indirect evidence. MCF/H50: not reported. p-value: not reported	It does not report direct measurements of osmotic fragility in the study; the evidence is primarily mechanical and functional.
[13]	Trudel G.; Shahin N.; Ramsay T.; Laneuville O.; Louati H.	2022	Hemolysis contributes to anemia during long-duration space flight	Study of actual microgravity during long-duration spaceflight; analysis of hemolysis and space anemia.	Hemolysis: consistently elevated. Space-occupying anemia: associated with persistent red blood cell destruction. Osmotic fragility: not directly assessed. MCF/H50: not reported. p-value: not reported in the abstract.	The primary outcome is hemolysis, not direct OFT; in a real-world setting, there may be additional confounding factors related to spaceflight.
[5]	Hinge S.; Dixit J.; Vidyasagar P.; Kulkarni G.	2024	Comparative analysis of red blood cell under real and simulated microgravity conditions	Comparison of erythrocytes in real and simulated microgravity; structural and functional analysis	Red blood cell morphology: abnormal. Functional changes: present. Osmotic fragility: not directly reported in the abstract. MCF/H50: not reported. p-value: not reported	The exact quantitative results are not detailed in the abstract; a full review of the article is required for a detailed analysis.
[2]	Kashirina D. N. et al.	2022	Proteomic characterization of dry blood spots of healthy women during simulation the microgravity effects using dry immersion	Simulated microgravity model using dry immersion; proteomic characterization of blood samples	Hematological proteomic changes: present. Osmotic fragility: indirect evidence; not measured directly. Hemolysis: not reported directly. MCF/H50: not reported. p-value: not reported in the abstract.	It provides additional molecular evidence, but does not focus directly on OFT or quantified erythrocyte hemolysis.
[17]	Stuart C. M.; Jacob C.; Varatharaj A.; Howard S.; Chouhan J. K.; Teeling J. L.; Galea I.	2024	Mild Systemic Inflammation Increases Erythrocyte Fragility	Clinical study of erythrocyte fragility in the context of mild systemic inflammation; included as a complementary mechanistic basis	Erythrocyte fragility: increased. Microgravity: not directly assessed. MCF/H50: not reported in the abstract. p-value: not reported in the abstract	This does not correspond to direct microgravity; it should be interpreted as supplementary evidence rather than as a key spatial finding.

Thus, the findings suggest that although there is an evident tendency to increase the fragility and hemolysis of red blood cells in situations of microgravity, the information found is diverse and in many cases is indirect, likewise, there is a lack of standardization of the methodologies used, since few studies present specific quantitative parameters such as MCF/H50 (Mean Corpuscular Fragility-H50) or osmotic fragility curves, which complicates the direct comparison between the investigations [40].

V. DISCUSSION

The results of this systematic review show that there is a general consensus that microgravity affects erythrocyte stability, however, the mechanisms responsible for these alterations differ among the studies analyzed. While some studies attribute these changes mainly to membrane damage and oxidative stress, others suggest that metabolic alterations and reduced cell deformability play a relevant role. These differences may be related to the variability of the experimental models used and the duration of exposure to microgravity. It should be noted that, in

both simulated and real situations, they have a significant impact on the functional and structural stability of erythrocytes. Therefore, the research examined indicates that this environment favors alterations associated with hemolysis, membrane damage, metabolic variations and decreased cell deformability, thus all the processes related to the emergence of special anemia and a possible increase in the osmotic fragility of red blood cells. Although not all studies directly analyzed classical parameters such as OFT (Osmotic Fragility Test) curves or MCF/H50 (Mean Corpuscular Fragility-H50) values, the evidence collected suggests a clear trend towards deterioration of erythrocyte integrity when exposed to microgravity [41].

Overall, the results obtained support the notion that microgravity affects the red blood cell membrane and thus alters its ability to withstand variations in the osmotic medium. This is most clearly evidenced in the research of Agramont et al. [10], in which osmotic fragility is linked with spatial anemia and a greater predisposition to hemolysis. This discovery is particularly significant as it establishes a more direct relationship between microgravity conditions and reduced cell stability. Consequently, from a pathophysiological approach, this indicates that exposure to extreme situations can weaken the mechanical and osmotic resistance of the erythrocyte, in this sense, favoring its Destruction and altering the interpretation of hematological analyses in aerospace environments. However, this finding coincides with the results reported by Trudel et al., who also identified an increase in erythrocyte destruction during prolonged exposures to the space environment; however, Agramont et al. establish a more direct relationship related to osmotic fragility, while Trudel et al. highlight hemolysis as the main clinical manifestation. This difference reflects the diversity of approaches used to study spatial anemia.

However, several studies incorporated in this review presented indirect but consistent evidence of red blood cell deterioration. Therefore, studies by Manis et al. [13] showed that an increase in oxidative stress, modifications in the lipid composition of the membrane, reduction of antioxidant capacity, and alterations that directly impact the stability of red blood cells and homeostasis. Similarly, Murali and Sarkar [12] analyzed changes in the shape, deformability, and dynamics of erythrocytes under various gravitational conditions, emphasizing that gravitational field variation affects the physical properties crucial to erythrocyte survival. However, although these studies do not measure osmotic fragility uniformly through a standardized parameter, they reinforce the idea that microgravity causes changes that favor hemolysis and the loss of membrane integrity. Overall, these studies suggest that erythrocyte damage induced by microgravity is multifactorial. On the contrary, the absence of standardized methodologies makes it difficult to establish which mechanism has the greatest influence on osmotic fragility. In short, this limitation makes it impossible to determine whether oxidative stress is the primary cause of damage or a secondary consequence of other cellular alterations.

Therefore, research conducted in microgravity conditions provides an extra level of clinical significance. Trudel et al. [14] documented that hemolysis plays an ongoing role in anemia during prolonged spaceflight, indicating that erythrocyte destruction is not just a transient adaptive response, but a long-lasting active process. Next, the result challenges the traditional hypothesis that spatial anemia is only a transient adaptive response to the redistribution of body fluids. Meanwhile, the persistence of observed hemolysis suggests the existence of active biological mechanisms capable of compromising erythrocyte survival during prolonged missions. Therefore, this finding supports the hypothesis that the spatial environment influences erythrocyte longevity through various pathways, including oxidative stress, metabolic changes, and cellular membrane variations. In summary, spatial anemia should be considered a multi-factor phenomenon, in which the fragility of the erythrocyte plays a major role along with other system adaptation mechanisms.

It is worth highlighting that a crucial aspect that emerges from this review is the methodological variability of the studies analyzed, studies carried out in real microgravity, simulated models such as clinostat or dry immersion and molecular or biochemical approaches aimed at detailing alterations in membrane, proteomics in blood, or metabolism. This variety shows that the analysis of the erythrocyte in microgravity is a clearly interdisciplinary area, but at the same time highlights one of its main weaknesses: the lack of standardization, while certain studies examine the hemolysis, or others focus on deformability. Likewise, some prioritize molecular biomarkers and only a small fraction focus directly on osmotic fragility. This diversity complicates comparison between studies and thus restricts the ability to reach quantitative conclusions that are more important [42]. Importantly, not all studies reported the same magnitude of erythrocyte alteration. However, some studies documented significant changes in hemolysis, membrane stability, and deformability; others found more moderate effects. Consequently, these discrepancies can be attributed to differences in the experimental models used, as well as the exposure conditions, the assessment methods used and the exposure conditions, the duration. Therefore, direct comparison between studies should be made with caution.

From this perspective, one of the discoveries that is significant of this review is that most of the existing studies offer indirect evidence rather than direct measurements of osmotic fragility. This does not dismiss their contributions, but it does require interpreting the results with caution. By entering the modification of the erythrocyte membrane, the increase in oxidative stress, the existence of damaged lipids and also the alterations in energy metabolism are indications of greater cellular vulnerability, although it does not always correspond to an accurate diagnosis through standardized osmotic tests. Therefore, the findings of this review indicate that there is a strong biological basis linking microgravity to increased erythrocyte susceptibility, although research assessing this phenomenon in a direct and comparable way is still needed.

Similarly, the data analyzed indicate that microgravity influences not only the structure of the erythrocyte but also its physiological function. Therefore, decrease in the mass of red blood cells, biochemical alterations, and an increase in hemolysis. Findings in several studies support the notion that oxygen transport can be affected during prolonged exposures to the space environment. This has significant relevance for aerospace medicine, as it indicates that hematological

surveillance in astronauts must take into account not only the erythrocyte count, but also their functionality, stability, and vulnerability to destruction. That is, erythrocyte research in microgravity should not focus solely on quantitative analysis, but also include mechanical, biochemical and osmotic factors to understand more fully the phenomenon of anemia in space [43].

In addition, this review facilitates the identification of obvious gaps in the literature; there are few studies that present standardized quantitative values on osmotic fragility MCF-H50 (Mean Corpuscular Fragility-H50), OFT (Osmotic Fragility Test) curves, or percentages of hemolysis under similar protocols. Therefore, numerous studies show small samples, as well as varied experimental designs or methods focused on indirect variables. However, research remains fragmented among several disciplined models, which complicates the creation of a coherent framework of interpretation. These restrictions indicate that, although studies have increased considerably in recent years, still there is not enough methodological uniformity to make direct comparisons solid between investigations.

Thus, the trend presented in this review is Coherent: Microgravity promotes changes in erythrocytes that increase cellular susceptibility and contribute to hemolytic processes linked to spatial anemia. However, the evidence you have found is stronger. Still, in the case of structural, functional and metabolic markers rather than direct osmotic evidence, the key contribution of this analysis focuses on bridging the scattered evidence and demonstrating that osmotic fragility can be seen as an important explanatory axis in erythrocyte pathophysiology in microgravity, although it is important to understand the importance of the Osmotic Pathophysiology. They need studies to be more concrete to validate it more accurately.

In other words, these findings suggest that the hematological monitoring of astronauts should incorporate additional functional indicators beyond the conventional erythrocyte count. That is, the evaluation of biomarkers related to hemolysis, membrane stability, and oxidative stress could contribute to an earlier detection of hematological alterations during prolonged space missions. In addition to this, the findings of this review indicate that future research should focus on creating experimental studies with standardized protocols, samples more extensive and also evaluations simultaneous of hemolysis, deformability, biomarkers of membrane damage, and osmotic fragility. A strategy of this type would make it easier not only to compare between studies, but also to enhance the understanding of the mechanisms that cause spatial anemia. Therefore, the osmotic fragility of erythrocytes is presented as an area of attractive interest for biomedical research and aerospace medicine, as it can be a marker of functional adaptation and cell damage under microgravity conditions.

VI. Conclusion

It is concluded, according to the analysis carried out, that microgravity in both simulated and real environments causes significant alterations in erythrocytes that impact functional and structural stability. Therefore, these variations are mainly expressed by an increase in hemolysis, as well as alterations in the cell membrane and changes in oxidative and metabolic processes that together favor the emergence of the so-called spatial anemia. Thus, the evidence analyzed in detail indicates that there is a connection between these alterations and a possible increase in the osmotic fragility of red blood cells. However, this connection has not always been examined directly, since most of the research reviewed is based on indirect indicators such as cellular elasticity, oxidative stress, or the lipid composition of the membrane.

In this sense, despite the constant phenomenon, there is still not enough research that applies standardized methods to evaluate osmotic fragility in a specific way. On the other hand, considerable variability was detected in the methods used, covering research in true microgravity, molecular analysis, and simulated models, which manifests the interdisciplinary nature of the field. However, this variety also implies a restriction, because it complicates the direct comparison of the results and the elaboration of the most accurate quantitative conclusions.

Taken together, the findings suggest that microgravity has a significant influence on the physiology of red blood cells, impacting not only their quantity but also their capacity and functional quality. Thus, osmotic fragility appears as a useful indicator to analyze the integrity of erythrocytes, although its investigation still needs further investigation.

Finally, this research helps to unite the existing evidence and also to point out the gaps present in the literature, underlining the urgency of further investigating this phenomenon through more consistent studies and with comparable methodologies, as they facilitate a better understanding of the mechanisms involved and their effect on human health in microgravity situations.

VII. Recommendations for Future Studies

Based on the results in the literature, the following recommendations are proposed to guide future research on the impacts of microgravity on red blood cells. For example, create and use standardized techniques to assess osmotic fragility, incorporating the use of OFT curves and parameters such as MCF/H50 (Mean Corpuscular Fragility-H50), which will allow an objective comparison between the multiple investigations. Evaluate research that includes various variables, such as erythrocyte deformability, hemolysis, oxidative stress, and membrane changes, in order to understand the most comprehensive form of the mechanisms involved. Promote the standardization of experimental protocols and reporting criteria, as well as the use of larger and more varied samples, to support the validity and replicability of the results. To carry out experimental and longitudinal research that facilitates the evaluation of variations in erythrocytes over time in order to deepen the evolution of hemolysis and cellular vulnerability in microgravity environments. Finally, increase the number of studies in conditions of true microgravity, as well as carry out direct comparisons with simulated models, in this sense to be able to corroborate the validity of the results obtained in the laboratory.

WESCOP, Wesleyan University-Philippines, Cabanatuan City, Philippines[1, 8, 9]

***Abstract*—This study conducted an Artificial Intelligence-assisted community needs assessment of partner-community respondents of Wesleyan University-Philippines, with emphasis on the Tricycle Operators and Drivers Association. Using a descriptive-quantitative design, five objectives were addressed: to describe the socioeconomic profile of the respondents; to determine livelihood and income conditions; to identify health, educational, and public-service needs; to rank priority community needs; and to develop a transparent, data-driven Artificial Intelligence-assisted framework. A cleaned dataset of 151 respondents was analyzed, of whom 46 were formally affiliated with tricycle operator and driver associations. Frequency, percentage, mean, and a proportion-based priority score summarized the data, while an Artificial Intelligence-assisted workflow supported response coding, respondent clustering, pattern detection, and need-to-intervention matching. Results showed that the transport subgroup consisted entirely of male drivers with lower average income, stronger income-expenditure pressure, greater reliance on borrowing and relatives, and recurring health concerns, including respiratory illness, hypertension, dental problems, and diabetes. Educational needs centered on books and learning materials. Ranked priorities were transport-oriented support, public-service linkage, health and wellness, educational assistance, livelihood and financial stability, skills training, and environmental support. The study concludes that pairing descriptive statistics with a reproducible Artificial Intelligence-assisted procedure produces more targeted, equitable, and responsive extension planning, and offers a practical template for other higher-education institutions.**

***Keywords*—Artificial Intelligence; Community Needs Assessment; data-driven extension program; tricycle drivers; needs prioritization; decision support**

I. Introduction

Community needs assessment is a critical process for identifying the social, economic, health, livelihood, and service-related concerns of a target population. In university extension work, it provides an empirical basis for designing programs that respond to the actual conditions of partner communities rather than to assumptions or generalized interventions. Prior studies have shown the value of structured surveys for determining industry and community priorities, building extension programs, and identifying future research and service needs [1]–[6]. These studies indicate that systematic data collection can help institutions align their programs with the needs of specific beneficiary groups.

At Wesleyan University-Philippines, the Tricycle Operators and Drivers Association represents an important community sector. Tricycle drivers contribute directly to local mobility, campus access, and everyday transportation. Like other transport-dependent and underserved groups, they may face income instability, high household expenses, limited access to public services, unmet health needs, and gaps in skills development. Transportation research has emphasized that mobility systems are closely connected to social equity, public participation, and access to opportunities [7]–[11]. Assessing the needs of these members is therefore not only a question of livelihood analysis but also one of inclusive community planning and equitable service delivery.

Public participation is also essential to identifying community priorities. Arnstein's framework on citizen participation stresses the importance of moving beyond token consultation toward meaningful involvement in decision-making [12]. Later work similarly argues that effective planning requires participatory approaches that let affected groups express their needs and lived experiences [13]–[17]. For transport workers, participatory needs assessment can help ensure that university extension initiatives address genuine concerns such as livelihood support, financial literacy, health services, skills training, and access to institutional assistance.

Traditional needs assessment, however, often produces large amounts of survey data that require careful interpretation. Artificial Intelligence offers a way to improve this analysis by assisting in pattern detection, classification, prioritization, and decision support. Applied responsibly, it can help identify which needs are most urgent, which respondent groups are most vulnerable, and which interventions are most appropriate for a given community profile. This direction is consistent with survey-based studies that used structured instruments and quantitative analysis to evaluate community or industry needs [5], [18], [19], and with a growing body of work that applies machine learning to community and poverty data [26]–[31].

*Corresponding author

Equity-oriented planning literature further supports examining communities that may be disadvantaged, underrepresented, or underserved in formal decision-making [20]–[23], [9], [11]. Studies on transportation equity and public engagement show that vulnerable communities are often affected by planning decisions yet have limited influence over the programs intended to serve them [24], [9]–[11], [25]. An Artificial Intelligence-assisted needs assessment can provide a more systematic way to prioritize interventions and ground extension programs in evidence, equity, and participation.

This study analyzed all 151 respondents in the dataset, while giving particular emphasis to the 46 respondents who were formally affiliated with tricycle operator and driver associations. The emphasis is justified because these members form a coherent transport-sector subgroup that shares an occupation, an income structure, and a set of road-related exposures; retaining the full sample allows their conditions to be benchmarked against the broader partner community. Accordingly, the study addressed five objectives: 1) to describe the socioeconomic profile of the respondents; 2) to determine their livelihood and income conditions; 3) to identify their health, educational, and public-service needs; 4) to rank their priority community needs; and 5) to develop a data-driven, Artificial Intelligence-assisted community extension framework.

The contribution of the study is threefold. First, it documents a transparent and reproducible Artificial Intelligence-assisted workflow—covering response coding, clustering, pattern detection, proportion-based prioritization, and need-to-intervention matching—rather than treating Artificial Intelligence as a black box. Second, it shows how this workflow adds value beyond conventional frequency-and-percentage reporting by isolating a vulnerable subgroup and linking each surfaced need to a concrete extension response. Third, it provides a deployable framework that a university can reuse for planning, implementation, monitoring, and evaluation of extension programs for transport and other partner communities.

II. Related Work

A. Community Needs Assessment and University Extension

Structured surveys have long been used to characterize the needs of specific industries and communities and to translate those needs into extension programs [1]–[6]. This literature established that descriptive instruments, careful coding, and ranking can yield actionable priorities, and that ongoing evaluation is needed to keep programs aligned with beneficiaries [3]. Community-engaged health-needs assessments similarly combine closed and open-ended items with descriptive and thematic analysis to direct concrete public-health initiatives [28]. The present study builds on this tradition but extends it to a transport-sector partner community of a university.

B. Transportation Communities, Equity, and Informal Transport Workers

Transportation scholarship frames mobility as a matter of social equity and meaningful participation, noting that underserved communities are frequently shaped by decisions they have little power to influence [7]–[11], [24], [25]. Within this literature, informal transport workers are a distinctly vulnerable group. Drivers of tricycles, pedicabs, and similar vehicles face poverty risks linked to low educational attainment, prolonged participation in the informal economy, and limited social protection, as recent machine-learning and econometric analyses of informal transportation in the Philippines demonstrate [26], [27]. These conditions motivate a needs assessment that treats tricycle operators and drivers as a priority sector rather than as an undifferentiated part of the population.

C. Artificial Intelligence Needs Assessment and Decision Support

A rapidly expanding body of work applies machine learning to survey and administrative data for social purposes. Studies have used supervised and tree-based models to predict healthcare needs and access barriers from community surveys [28], and to predict and target poverty across localities, often finding ensemble methods such as random forests effective [27], [29], [30]. For unstructured responses, topic modeling, embedding-based clustering, and few-shot classification with language models now support faster and more consistent coding of open-ended items, while still requiring human interpretation of the resulting clusters [31]. Collectively, this literature positions Artificial Intelligence as a decision-support layer that augments, rather than replaces, descriptive analysis and expert judgment.

D. Research Gap and Positioning of the Study

Two gaps remain. First, machine-learning poverty and needs studies typically operate at a regional or national scale and rarely target a single university partner community, such as a campus-serving tricycle association. Second, many "Artificial Intelligence-assisted" community studies describe the technology only in general terms, without specifying the workflow, inputs, and outputs. This study addresses both gaps by focusing on a defined transport-sector partner community and by documenting an explicit, reproducible Artificial Intelligence-assisted procedure that maps surfaced needs to specific extension responses. In doing so, it differs from conventional survey-based assessment, which usually stops at frequency, percentage, mean, and ranking, by adding respondent grouping, pattern detection, and need-to-intervention matching that can be carried into program monitoring.

III. Methodology

A. Research Design

This study employed a descriptive-quantitative research design integrated with Artificial Intelligence-assisted data analysis to assess and prioritize the needs of members of the Tricycle Operators and Drivers Association of Wesleyan University-Philippines and of the broader partner community. The descriptive component determined the demographic, socioeconomic, livelihood, health, educational, skills-development, and public-service profile of the respondents. The Artificial Intelligence-assisted component supported response coding, clustering, pattern recognition, and prioritization of needs.

The design is appropriate because community needs assessment studies commonly use structured survey data to identify priority concerns and guide extension programs [1]–[6]. Here, Artificial Intelligence served as a decision-support tool

that helped organize and interpret patterns in the dataset. The overall methodological flow is shown in Table I.

TABLE I. RESEARCH DESIGN MATRIX

Component	Description	Purpose	Expected Output
Research Design	Descriptive-quantitative with Artificial Intelligence-assisted analysis	To describe and analyze the needs of the respondents.	Community needs profile
Data Source	Community Needs Assessment Survey	To gather demographic, socioeconomic, health, livelihood, and service-related data.	Encoded dataset
Statistical Analysis	Frequency, percentage, mean, and proportion-based priority score	To identify dominant respondent characteristics and priority needs.	Summary tables and ranked needs
Artificial Intelligence-Assisted Analysis	Coding, clustering, pattern recognition, and prioritization	To group respondents and determine high-priority intervention areas.	Needs-priority model
Final Output	Data-driven extension program framework	To guide university extension planning.	Proposed extension program

The overall methodological flow of the study is presented in Fig. 1.

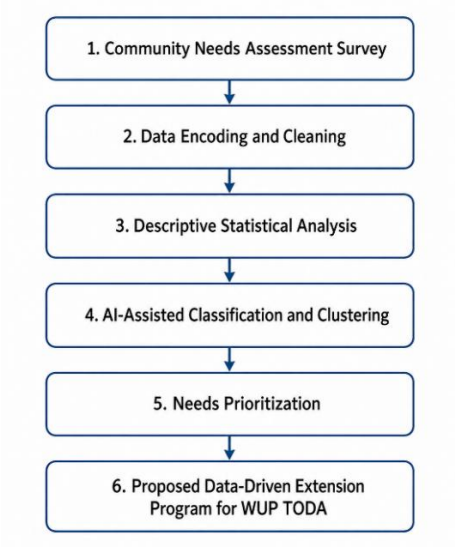

Fig. 1. Methodological flow of the AI-assisted community needs assessment.

B. Research Locale

The study was conducted at Wesleyan University-Philippines, with emphasis on tricycle operators and drivers working within and around the university premises. The dataset included respondents associated with WUP TODA, WUP Main Gate TODA, TODA WUP, and other tricycle associations near the university. The locale was selected because these members provide daily transportation to students, employees, and nearby residents, which makes them a relevant partner community for university-based extension services.

C. Respondents of the Study

The study used secondary data from an existing Community Needs Assessment, so no new sampling was performed by the researchers during analysis. The dataset was treated as a complete enumeration of the available respondents: all 151 records that passed data screening were analyzed rather than a probability sample drawn from them. Within this total enumeration, a purposive emphasis was placed on the 46 respondents who were formally affiliated with tricycle operator and driver associations, because they constitute the priority transport sector for the university's extension work. The combined approach is therefore a complete enumeration of an available, non-probability dataset with a purposively defined subgroup. This choice is consistent with the descriptive aim of the study, but it limits statistical generalization beyond the participating community, a point revisited in the limitations.

The respondents were members of the partner community of Wesleyan University-Philippines, including tricycle drivers, operators, and household representatives recorded in the Community Needs Assessment dataset. They were described according to demographic and socioeconomic variables such as age, sex, civil status, educational attainment, occupation, household size, monthly income, expenses, skills, health condition, access to services, and identified priority needs (Table II).

TABLE II. PROFILE VARIABLES OF THE RESPONDENTS

Variable Category	Specific Variables	Purpose of Analysis
Demographic Profile	Age, sex, civil status, household size	Described the general characteristics of partner community respondents.
Educational Profile	Highest educational attainment and school-age dependents	Identified education-related needs and possible learning support programs.
Economic Profile	Occupation, monthly income, and household expenses	Assessed income stability and financial vulnerability.
Livelihood Profile	Main source of income, additional livelihood, and skills	Determined livelihood and skills-training needs.
Health Profile	Health concerns and access to health services	Identified possible medical, wellness, or health-extension needs.
Public Service Access	Access to government or community services	Determined gaps in service delivery.
Priority Needs	Stated household and community needs	Ranked intervention areas for extension planning.

D. Research Instrument

The primary instrument was the Community Needs Assessment Survey Form. It contained items on respondent profile, socioeconomic condition, livelihood status, educational background, health concerns, available skills, access to services, environmental concerns, and priority community needs. Scaled or selection-type responses were interpreted using proportion-based scoring and ranking, consistent with structured measurement in survey research [18]. The survey results also

served as the input dataset for the Artificial Intelligence-assisted analysis.

E. Data Gathering Procedure

The study used the existing Community Needs Assessment data collected from respondents of Wesleyan University-Philippines. The data were reviewed, encoded, cleaned, and organized prior to statistical and Artificial Intelligence-assisted analysis. The procedure followed seven steps: responses were collected and organized; reviewed for completeness, consistency, and relevance; checked and corrected for duplicate, unclear, or inconsistent entries; coded into analyzable categories for categorical and text-based items; prepared for descriptive and Artificial Intelligence-assisted processing; summarized into tables, patterns, clusters, and rankings; and finally translated into a proposed data-driven extension program.

F. Data Preparation, Coding, and Reliability

Before analysis, the dataset was preprocessed to improve accuracy and consistency. Missing values, inconsistent entries, duplicate responses, and unclear categories were checked. Categorical responses were standardized, and open-ended responses were grouped into common themes (Table III). For the Artificial Intelligence-assisted analysis, categorical variables were converted into coded values, and multiple-response items such as skills, services needed, and priority concerns were transformed into binary indicators.

To strengthen the thematic grouping of open-ended responses, a documented coding protocol was applied. A draft codebook of recurring themes was first prepared from an initial read of the responses. A language-model assistant proposed candidate theme labels for each response, and two researchers independently reviewed and assigned the final codes against the codebook. Disagreements were resolved by discussion and consensus, and a sample of coded responses was re-checked for consistency. In this way, the Artificial Intelligence output was used as a suggestion that researchers verified, not as a final categorization, which preserves human control over interpretation.

TABLE III. DATA PREPROCESSING AND CODING PLAN

Data Type	*Example Variables*	*Preprocessing Procedure*	*Output*
Numeric Data	Age, income, expenses, household size	Missing values and outliers were checked.	Clean numeric dataset
Categorical Data	Sex, civil status, occupation, educational attainment	Responses were standardized and coded.	Coded variables
Text-Based Data	Skills, stated needs, livelihood concerns	Similar responses were grouped into themes.	Thematic categories
Multiple-Response Data	Priority needs, services needed, training interests	Responses were converted into binary or frequency indicators.	Needs matrix
Incomplete Entries	Blank or inconsistent responses	Entries were validated, corrected, or excluded when necessary.	Final cleaned dataset

G. Statistical Treatment of Data

Descriptive statistics summarized the profile and needs of the respondents. Frequencies and percentages were used for categorical variables, and the mean was used for continuous variables such as age, income, and expenditure. The percentage for category i was computed as $\%_i = (f_i / n) \times 100$, where f_i is the frequency of category i and n is the number of valid responses. The arithmetic mean was computed as $\bar{x} = (\Sigma x_i) / n$.

For multiple-response and binary-coded needs, a proportion-based priority score (endorsement rate) was used. For need j, the score was $ER_j = (\Sigma_i b_{ij}) / n$, where $b_{ij} = 1$ if respondent i endorsed need j and 0 otherwise, and n is the relevant denominator (151 for all respondents and 46 for the transport subgroup). The score ranges from 0 to 1 and equals the proportion of respondents who indicated the need; needs were then ranked in descending order of ER_j. This formulation is reported transparently because the values in Table IV are endorsement rates, and the column is labeled accordingly. Computational tools were used to organize and process the dataset, consistent with survey-based studies that applied statistical software [19].

TABLE IV. STATISTICAL TREATMENT OF DATA

Research Objective	*Data Required*	*Statistical Tool*	*Interpretation*
Describe the profile of respondents	Demographic and socioeconomic variables	Frequency and percentage	Identified dominant respondent characteristics.
Determine livelihood and income conditions	Income, occupation, expenses, livelihood source	Frequency, percentage, and mean	Showed economic status and livelihood vulnerability.
Identify health, education, and service needs	Health concerns, educational needs, public-service access	Frequency and ranking	Determined common social-service needs.
Rank priority community needs	Stated needs and intervention preferences	Endorsement rate (proportion) and rank	Identified the most urgent areas for extension.
Develop an Artificial Intelligence-assisted framework	Ranked needs, cleaned and coded dataset, profile and livelihood indicators	Coding, normalization, pattern identification, proportion-based prioritization, framework mapping	Produced a framework identifying priority intervention areas.

H. Artificial Intelligence-Assisted Data Analysis

Artificial Intelligence was integrated to support deeper interpretation of the dataset, focusing on coding, clustering, pattern recognition, and needs prioritization. To make the procedure transparent and reproducible, the specific tools and workflow are described here. A general-purpose large language model assistant was used for assisted thematic coding of open-ended responses, and a Python environment with the pandas and scikit-learn libraries was used for the quantitative steps.

The workflow proceeded in seven steps: 1) The cleaned and coded dataset was ingested. 2) Open-ended responses were thematically coded with language-model assistance and researcher review, as described in Section III G. 3) Categorical

and multiple-response items were converted into numeric and binary features. 4) Respondents were grouped using k-means clustering on standardized socioeconomic features, while text needs were grouped using term-frequency representations and similarity-based clustering. 5) Patterns were detected through cross-tabulation and association checks, for example, between income level and livelihood needs, household size and financial difficulty, or occupational exposure and health concerns. 6) Needs were prioritized using the endorsement-rate score defined above. 7) Each high-priority need was matched to a candidate extension response through a rule-based mapping that researchers reviewed. The input variables and expected outputs of each procedure are summarized in Table V, and the prioritization logic is illustrated in Fig. 2.

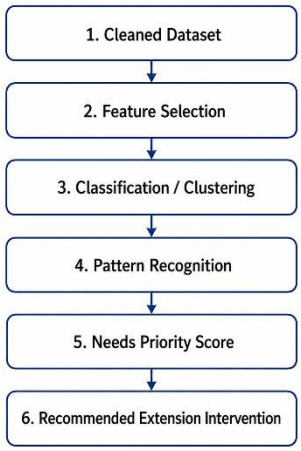

Fig. 2. AI-assisted needs prioritization framework.

TABLE V. AI-ASSISTED ANALYSIS PLAN

AI Procedure	*Purpose*	*Possible Input Variables*	*Expected Output*
Classification / Coding	Categorized respondents and responses by dominant need	Income, occupation, skills, health and education needs	Respondent and response need categories
Clustering	Grouped respondents with similar conditions	Socioeconomic and household variables	Clusters of similar respondents
Pattern Recognition	Detected relationships among variables	Income, expenses, household size, livelihood, needs	Identified trends and associations
Priority Modeling	Determined urgent intervention areas	Endorsement rate of needs, respondent profile	Ranked community priorities
Decision Support	Guided extension program design	Artificial Intelligence and statistical results	Proposed intervention framework

The Artificial Intelligence-assisted analysis was not a replacement for the researcher's interpretation. It functioned as a decision-support mechanism that revealed patterns and priority areas. Its value beyond conventional descriptive statistics is summarized as follows: whereas frequency, percentage, mean, and ranking describe the dataset one variable at a time, the assisted workflow additionally grouped respondents into comparable clusters, detected co-occurring needs across variables, isolated the more vulnerable transport subgroup, and linked each surfaced need to a specific intervention. These capabilities turn a set of summary tables into a reusable decision-support layer for planning, implementation, and monitoring.

I. Needs Prioritization Procedure

Priority needs were determined using both the endorsement-rate ranking and the Artificial Intelligence-assisted analysis. Needs that appeared frequently across respondents were identified and ranked, then examined in relation to profile variables such as income, household expenses, occupation, health status, household size, and available skills. A prioritization matrix connected each identified need with a possible university extension response (Table VI).

TABLE VI. NEEDS PRIORITIZATION MATRIX

Priority Area	*Basis for Ranking*	*Possible Extension Response*
Livelihood and Income Support	Low income, high expenses, and unstable livelihood	Livelihood training and income-generating projects
Skills Development	Existing skills and training interests	Technical, vocational, or entrepreneurial training
Health and Wellness	Reported health concerns or limited access to health services	Medical mission, health education, and wellness programs
Financial Literacy	Income-expense gap and household financial difficulty	Budgeting seminar, savings orientation, and microenterprise training
Educational Support	Education-related household needs	Scholarship orientation, tutorial support, and learning assistance
Public Service Access	Limited access to government or community services	Linkage with local government units and social-service agencies

J. Validation of Results

The statistical and Artificial Intelligence-assisted results were reviewed to ensure that the generated priorities were reasonable, interpretable, and aligned with the actual responses. Validation compared the assisted outputs with the descriptive statistical results and the stated needs of the respondents. The interpretation also considered the importance of meaningful community participation in planning, because participatory approaches strengthen the relevance of community-based programs by allowing affected groups to express their actual needs and priorities [13]–[17], [24], [25].

K. Ethical Considerations

The study observed ethical standards in handling community data. Respondent information was treated confidentially, and personal identifiers were removed before analysis. The dataset was used only for academic and extension-planning purposes. Because the study involved Artificial Intelligence-assisted analysis, the generated outputs were reviewed carefully before interpretation. The researchers ensured that findings were presented in a respectful, community-centered, and equity-oriented manner, and that results were used to identify appropriate support programs rather than to stigmatize respondents.

IV. Results and Discussions

A. Data Screening and Scope of Analysis

The Community Needs Assessment dataset contained 151 respondents, and the analysis covered all of them. Because the study prioritized tricycle operators and drivers of Wesleyan University-Philippines, a transport-focused comparison was also made. Of the 151 respondents, 46 (30.5%) were formally affiliated with tricycle associations, including WUP TODA, WUP Main Gate TODA, TODA WUP, Mabini Ext TODA, and a senior-citizen WUP TODA entry; among them, 36 (23.8%) were directly linked to WUP-related groups. Multiple-response items were treated as selected when the corresponding cell contained an entry, so percentages in some tables may exceed 100%.

This emphasis on the transport subgroup is methodologically defensible: the 46 members share an occupation, an income structure, and a set of road-related exposures, which makes them a coherent unit for targeted planning, while the full sample provides a comparison baseline. The framing as a transport-focused study therefore reflects the analytical priority rather than an overstatement of the subgroup's share, and the title has been revised to make the broader respondent base explicit.

B. Profile of the Respondents

Frequency and percentage were used to identify dominant respondent characteristics (Table VII). The general respondent group was predominantly male, with 110 male respondents (72.8%). This pattern was stronger in the transport subgroup, where all 46 members (100.0%) were male, indicating that transport-related livelihood in the dataset was male-dominated.

By age, the largest group among all respondents was 40–49 years (63; 41.7%), and the same pattern held for the transport subgroup (14; 30.4%). The mean age was 45.78 years overall and 46.91 years for the transport subgroup, indicating a middle-adult population for whom household, livelihood, health, and educational responsibilities are typically high. For occupation, 80 respondents (53.0%) were in transport or driver-related work; among the transport subgroup, 45 of 46 (97.8%) were transport workers, confirming a clearly defined transport-sector community within the larger dataset.

TABLE VII. Profile of all Respondents with TODA Emphasis

Profile Variable	Category	All f	All %	TODA f	TODA %
Sex	Male	110	72.8	46	100.0
	Female	41	27.2	0	0.0
Age Group	Below 30	5	3.3	2	4.3
	30–39	37	24.5	13	28.3
	40–49	63	41.7	14	30.4
	50–59	31	20.5	7	15.2
	60 and above	14	9.3	9	19.6
	Not reported	1	0.7	1	2.2
Occupation	Transport/driver-related	80	53.0	45	97.8
	Other / not reported	71	47.0	1	2.2

C. Livelihood and Income Conditions

Frequency, percentage, and mean were used to show economic status and livelihood vulnerability (Table VIII). Valid monthly income data were available for 100 respondents. The mean monthly income of all respondents was ₱8,945.20 and the median was ₱9,250.00. For the transport subgroup, valid income data were available for 41 respondents, with a lower mean of ₱7,682.93 and a median of ₱9,000.00.

Income was concentrated at the lower ranges. In the full sample, 52 respondents (34.4%) earned below ₱10,000 per month; among the transport subgroup, the share rose to 26 of 46 (56.5%). This greater concentration of low income is consistent with machine-learning and econometric findings that informal transport workers in the Philippines face elevated poverty risk tied to low educational attainment and prolonged informal-sector participation [26], [27].

TABLE VIII. Monthly Income Distribution

Monthly Income Range	All f	All %	TODA f	TODA %
Below ₱5,000	24	15.9	14	30.4
₱5,000–₱9,999	28	18.5	12	26.1
₱10,000–₱14,999	31	20.5	12	26.1
₱15,000–₱19,999	16	10.6	3	6.5
₱20,000 and above	1	0.7	0	0.0
Not reported / non-numeric	51	33.8	5	10.9

Household expenditure patterns reinforced this picture (Table IX). Food was the most frequently reported expense overall, followed by electricity or gas, education, water, and cooking fuel. Among the transport subgroup, food, electricity or gas, and water were equally common, each reported by 18 respondents (39.1%). Valid total monthly expenditure was available for 48 respondents, with a mean of ₱11,044.17 and a median of ₱9,275.00; for the transport subgroup (12 respondents), the mean was ₱8,438.33 and the median ₱8,300.00.

TABLE IX. Common Household Expenditure Categories

Expenditure Category	All f	All %	TODA f	TODA %
Food	63	41.7	18	39.1
Electricity / Gas	57	37.7	18	39.1
Education	51	33.8	12	26.1
Water	46	30.5	18	39.1
Cooking Fuel	40	26.5	13	28.3
Soap	27	17.9	13	28.3
Clothing	26	17.2	14	30.4

Among respondents with both valid income and expenditure data, 20 of 39 (51.3%) had expenses exceeding income; among the transport subgroup, 8 of 12 (66.7%) did. This stronger income-expenditure pressure helps explain the coping strategies reported (Table X). The most common strategy overall was

borrowing money (73; 48.3%), whereas in the transport subgroup the most common was asking relatives for help (25; 54.3%).

These findings indicate heavy dependence on informal support networks. While family assistance can cushion financial difficulty, reliance on borrowing and on relatives also signals economic instability, echoing accounts of the financial precarity of Filipino tricycle drivers in the informal economy [26]. They support the need for financial literacy, savings orientation, debt management, and livelihood support programs.

TABLE X. COPING STRATEGIES

Coping Strategy	All f	All %	TODA f	TODA %
Borrow money	73	48.3	20	43.5
Ask relatives for help	46	30.5	25	54.3
Endure without resources	11	7.3	6	13.0
Keep children from school	4	2.6	0	0.0
Others	11	7.3	1	2.2

D. Health, Education, and Service Needs

The third objective was to identify health, education, and service needs. Frequency and ranking were used to determine the common social service needs of respondents.

1) Health needs: Frequency and ranking were used to determine common social-service needs (Table XI). The leading health concern in both groups was cough, colds, or fever (106; 70.2% overall and 30; 65.2% in the transport subgroup). High blood pressure was more pronounced among transport members (12; 26.1%) than in the full sample (21.2%). This is notable because tricycle drivers are routinely exposed to heat, road dust, pollution, fatigue, and long hours, conditions that plausibly elevate cardiovascular and respiratory risk. The results support preventive services such as blood-pressure monitoring, respiratory-health education, dental check-ups, diabetes screening, and wellness activities.

TABLE XI. REPORTED HEALTH CONCERNS

Rank	Health Concern	All f	All %	TODA f	TODA %
1	Cough, colds, or fever	106	70.2	30	65.2
2	Toothache	34	22.5	9	19.6
3	High blood pressure	32	21.2	12	26.1
4	Diabetes	13	8.6	5	10.9
5	Others	7	4.6	3	6.5
6	Skin disease	5	3.3	1	2.2
7	Lung disease	3	2.0	1	2.2

2) Educational needs: Books were the most common educational need in both groups (84; 55.6% overall and 27; 58.7% in the transport subgroup), as shown in Table XII. Educational support thus remained a relevant household concern, and especially so for transport households whose income was generally low and unstable. Assistance may include book donation, school supplies, tutorial assistance, digital-literacy orientation, and scholarship information drives.

TABLE XII. EDUCATIONAL SUPPORT NEEDS

Rank	Educational Need	All f	All %	TODA f	TODA %
1	Books	84	55.6	27	58.7
2	Others	26	17.2	9	19.6
3	Radio	18	11.9	4	8.7
4	Reading materials	5	3.3	0	0.0
4	Educational toys	5	3.3	2	4.3
6	Computer	4	2.6	4	8.7
6	Video camera	4	2.6	1	2.2

3) Public service access: The most frequently identified services overall were elementary education, day-care center, tanod patrol, health center, and cemented road (Table XIII). For the transport subgroup, day-care center, tanod patrol, elementary education, police monitoring, cemented road, and curfew were highly reported. Awareness of existing services did not eliminate household-level needs in health, education, livelihood, and income. The university can therefore act as a linkage institution, connecting members to barangay services, health centers, road-safety programs, livelihood agencies, and social-welfare offices, an approach aligned with calls for meaningful public involvement of underserved transport communities [9], [24], [25].

TABLE XIII. COMMON PUBLIC SERVICES AND FACILITIES IDENTIFIED

Rank	Public Service / Facility	All f	All %	TODA f	TODA %
1	Elementary education	120	79.5	39	84.8
2	Day-care center	115	76.2	44	95.7
3	Tanod patrol	93	61.6	40	87.0
4	Health center	87	57.6	24	52.2
5	Cemented road	77	51.0	38	82.6
6	Basketball court	73	48.3	13	28.3
7	Supplemental feeding	67	44.4	24	52.2
8	Trained community health workers	64	42.4	22	47.8
9	Curfew	63	41.7	38	82.6
10	Police monitoring	61	40.4	39	84.8

E. Ranked Priority Community Needs

Because the dataset used multiple-response and binary-coded items, the priority of each need was measured by the endorsement rate (the proportion of respondents who indicated it), with denominators of 151 for all respondents and 46 for the

transport subgroup (Table XIV). The highest-ranked area for the full sample was transport-oriented support (0.894), driven by the many respondents linked to transport work, tricycle use, road-related indicators, or formal membership; among the transport subgroup this reached 1.000.

TABLE XIV. RANKED PRIORITY COMMUNITY NEEDS

Rank (All)	Priority Area	All f	Endorsement Rate (All)	Rank (TODA)	TODA f	Endorsement Rate (TODA)
1	Transport-oriented support	135	0.894	1	46	1.000
2	Public-service linkage / access	133	0.881	1	46	1.000
3	Health and wellness support	126	0.834	4	39	0.848
4	Educational support	121	0.801	3	40	0.870
5	Livelihood and financial stability	120	0.795	4	39	0.848
6	Skills training and diversification	108	0.715	7	30	0.652
7	Environmental and climate-related support	94	0.623	6	36	0.783

Public-service linkage also ranked highly (0.881 overall; 1.000 for the transport subgroup). Because these items reflected services and facilities identified by respondents, the result should be read as an opportunity for stronger linkage rather than as evidence that all services were absent. Health and wellness ranked third overall and remained important for the transport subgroup, consistent with the high frequency of respiratory illness, hypertension, dental problems, and diabetes.

Educational support ranked fourth overall but higher within the transport subgroup, indicating strong education-related needs—especially for books and learning materials—among lower-income transport households; this mirrors community-survey evidence that educational access is a recurrent social-determinant need [28]. Livelihood and financial stability also emerged as a major priority, supported by low income, borrowing, reliance on relatives, lack of capital, and negative income-expenditure gaps, with the transport subgroup showing stronger vulnerability than the full sample. Skills training and environmental support ranked lower but remained relevant; environmental and climate-related support was especially salient for the transport subgroup, whose members work outdoors and are directly exposed to extreme heat and changing weather.

F. Artificial Intelligence-Assisted Framework and Decision Support

The fifth objective was to translate the cleaned and coded dataset into an Artificial Intelligence-assisted framework. The resulting framework (Fig. 3) shows how technology can support a more responsive extension program. Instead of using survey results only for manual reporting, the workflow transforms the dataset into a decision-support layer that can identify which respondents need livelihood assistance, which households require educational support, which health concerns to prioritize, and which transport-related issues require targeted intervention.

For the transport subgroup, the assisted analysis is especially useful because members share common conditions as transport workers. It distinguishes their needs from the general population by detecting patterns in income, occupation, coping strategies, health risks, road-related concerns, and environmental exposure, allowing the university to design interventions specifically for them. The framework also extends into implementation: it can support a beneficiary database, recommend training modules, identify priority households, monitor participation, and evaluate whether the program improved income, health awareness, skills, or access to services. In this sense, Artificial Intelligence becomes a continuing tool for planning, implementation, monitoring, and evaluation.

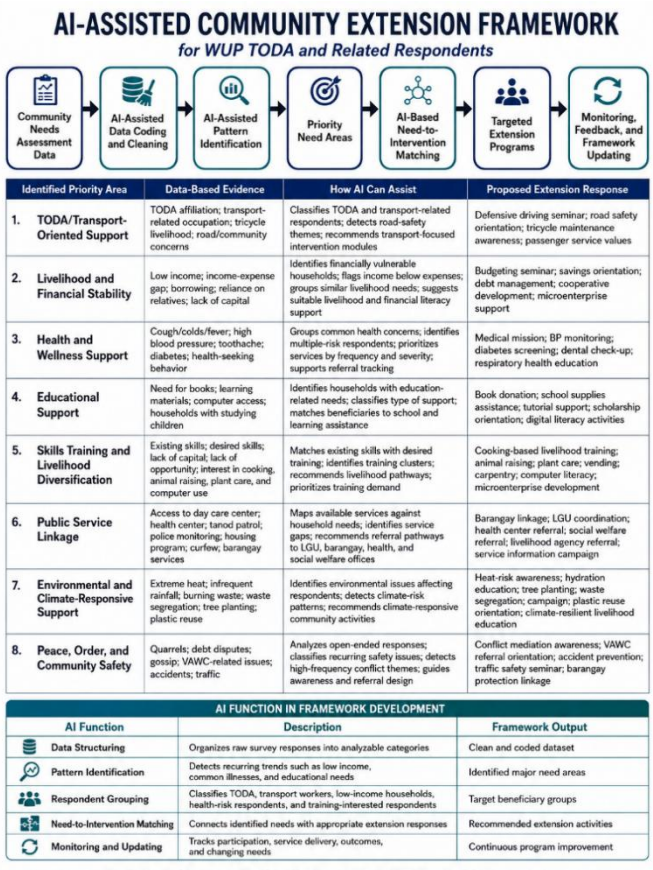

Fig. 3. Artificial Intelligence-assisted community extension framework for the partner community and transport subgroup.

V. CONCLUSION

The Community Needs Assessment dataset of 151 respondents revealed substantial needs in livelihood, health, education, public-service access, transportation support, skills development, and environmental awareness. While all respondents were analyzed, the results emphasized the transport subgroup, which formed a distinct priority sector composed entirely of male tricycle drivers with lower average income and higher livelihood vulnerability.

Profile results showed a largely middle-aged population with household and income responsibilities, and tricycle driving as the dominant livelihood within the transport subgroup. Income and expenditure results indicated financial pressure, particularly for transport members, whose average income was lower than the overall sample. Borrowing and reliance on relatives were common coping strategies, pointing to the need for financial literacy, savings orientation, cooperative development, and livelihood assistance. Health and education were also major concerns, supporting regular medical missions, blood-pressure monitoring, diabetes screening, dental check-ups, respiratory-health education, wellness programs, and educational assistance such as book donations, school supplies, tutorial support, scholarship orientation, and digital-literacy activities.

The ranked priorities indicated that the most important extension areas were transport-oriented support, public-service linkage, health and wellness, educational support, livelihood and financial stability, skills training, and environmental support. Wesleyan University-Philippines should therefore develop an integrated, data-driven extension program for its transport and related partner communities, potentially including defensive-driving seminars, road-safety orientation, tricycle-maintenance awareness, livelihood training, financial literacy, health services, educational assistance, skills development, and barangay or local-government referral support.

Several limitations should be acknowledged. First, the study was confined to a single university partner community, so the findings describe that community and are not statistically generalizable to other settings. Second, the sample was modest (151 respondents, of whom 46 belonged to the transport subgroup), which limits subgroup-level statistical power and the stability of some estimates. Third, the analysis relied on self-reported survey data, which are subject to recall and social-desirability biases, and several income and expenditure fields were incomplete, reducing the number of valid cases for those computations. Fourth, the design was descriptive and cross-sectional; it characterizes needs at one point in time and does not establish causal relationships or change over time. Finally, the Artificial Intelligence component was assistive rather than fully automated, and its clustering and coding outputs depended on researcher review and on the chosen features and parameters.

These limitations point to several directions for future research. Larger and, where feasible, probability-based or multi-community samples would improve representativeness and allow stronger subgroup comparisons. Longitudinal designs could track whether interventions improve income, health awareness, skills, or service access over time. Mixed methods—interviews and focus group discussions—could validate and enrich the quantitative findings. Methodologically, supervised predictive models and more advanced text-embedding or language-model pipelines could be benchmarked against the present descriptive approach, and a full Artificial Intelligence-based decision-support system could be developed and validated for community needs assessment and extension planning.

Finally, the study concludes that Artificial Intelligence can strengthen community extension planning by organizing raw survey data, identifying patterns, grouping respondent populations, ranking priority needs, matching needs with suitable interventions, and supporting monitoring and evaluation. The originality of the work lies in documenting this assistive workflow transparently and showing how it adds value beyond conventional descriptive reporting. It is recommended that the university adopt the proposed framework to make extension programs more targeted, evidence-based, and responsive, and that future researchers validate the findings through interviews, focus group discussions, and the development of an Artificial Intelligence-based decision-support system.

A Comparative Analysis of Decision Tree, Random Forest, and Logistic Regression Models in Predicting Business Readiness for Digital Technology Integration

Gloria M. Ducut
College of Technology and Business, Pangasinan State University, Asingan Campus, Pangasinan, Philippines

***Abstract*—This study compared the performance of Decision Tree, Random Forest, and Logistic Regression models in predicting business readiness for digital technology integration using survey data from 400 business respondents in Pangasinan, Philippines. The analysis utilized variables related to technology utilization, perceived helpfulness, willingness to integrate technology, and challenges encountered in adopting digital marketing, e-commerce, and digital payment technologies. Business readiness was operationalized from respondents' willingness scores and classified into Ready and Less Ready categories. Descriptive results revealed very low technology utilization despite high perceived helpfulness, indicating a gap between awareness of digital technologies and their actual adoption. Lack of awareness emerged as the most frequently reported barrier, followed by data security concerns. Using an 80:20 train test split, the machine learning models achieved moderate predictive performance, with Decision Tree and Random Forest attaining the highest accuracy of 63.75%. Random Forest produced the best overall performance, achieving the highest weighted F1 score and demonstrating a more balanced classification capability than the other models. The findings highlight the potential of machine learning as a decision support tool for assessing business readiness and generating evidence-based insights that can support digital transformation planning, technology adoption strategies, and capacity building initiatives among businesses.**

Keywords*—Business readiness; digital technology integration; machine learning

I. Introduction

The rapid advancement of digital technologies has significantly transformed the business landscape, compelling organizations to adopt innovative tools and strategies to remain competitive. Digital transformation has become a critical driver of organizational growth, enabling businesses to improve operational efficiency, strengthen customer engagement, expand market reach, and enhance overall performance [1], [2]. As organizations increasingly integrate digital technologies such as social media platforms, e-commerce systems, and digital payment solutions into their operations, the concept of business readiness has gained considerable attention. Business readiness reflects an organization's preparedness to adopt, utilize, and sustain digital technologies through the availability of technological resources, organizational capabilities, employee competencies, and leadership support [3], [4].

Despite the recognized benefits of digital transformation, many organizations continue to face challenges in technology adoption. Small and medium-sized enterprises (SMEs), in particular, often encounter barriers related to limited awareness, inadequate digital skills, financial constraints, resistance to change, and insufficient organizational support [3],[5]. Consequently, understanding the factors that influence business readiness has become increasingly important for supporting successful digital transformation initiatives. Previous studies have emphasized that organizations with higher levels of digital readiness are better positioned to exploit digital opportunities, improve business processes, and achieve sustainable growth in dynamic business environments [1], [2], [4].

Theoretical perspectives on technology adoption provide valuable insights into the determinants of business readiness. The Technology Acceptance Model (TAM) suggests that perceived usefulness and perceived ease of use influence an individual's intention to adopt technology [6]. Similarly, the Unified Theory of Acceptance and Use of Technology (UTAUT) highlights the importance of performance expectancy, facilitating conditions, and organizational support in shaping technology adoption behavior [7]. Guided by these theoretical perspectives, technology utilization, perceived helpfulness, willingness to integrate technology, and challenges encountered are considered key determinants of organizational readiness for digital technology integration.

Recent developments in machine learning have created new opportunities for analyzing complex datasets and generating predictive insights for decision-making. Machine learning classification techniques have been widely applied in text classification, pattern recognition, predictive analytics, and decision-support systems because of their ability to identify hidden relationships and classify observations based on multiple predictor variables [8]-[11]. Various machine learning approaches, including neural networks, support vector machines, deep learning models, and ensemble learning methods, have demonstrated strong performance in classification tasks across diverse application domains [12]-[15],[18]-[21]. Furthermore, machine learning has been successfully applied to organizational and operational problems such as human resource management, production optimization, and decision-support systems, highlighting its potential for business analytics and strategic planning [16], [17], [22].

Among the commonly used classification algorithms, Decision Tree, Random Forest, and Logistic Regression have attracted considerable attention because they provide a balance between predictive performance and interpretability [23], [24], [25]. Decision Tree models generate transparent decision rules that facilitate understanding of classification outcomes, while Random Forest improves predictive accuracy through ensemble learning and reduced overfitting [25]. Logistic Regression remains a widely used statistical classification method capable of estimating the probability of categorical outcomes and explaining relationships between predictor variables and target classes [23]. These characteristics make the three algorithms suitable for analyzing survey-based datasets involving organizational and behavioral variables.

Although digital readiness and digital transformation have been extensively investigated in information systems and organizational research, the application of machine learning classification techniques for predicting business readiness remains limited. Furthermore, comparative evaluations of Decision Tree, Random Forest, and Logistic Regression models using survey-based organizational data are scarce. This limitation restricts the availability of data-driven tools that can support digital transformation planning and readiness assessment.

Addressing this gap, the present study compares the predictive performance of Decision Tree, Random Forest, and Logistic Regression models in classifying business readiness for digital technology integration. Using indicators related to technology utilization, perceived helpfulness, willingness to integrate technology, and challenges encountered, the study aims to identify the most suitable classification model and generate evidence-based insights that may support digital transformation planning and technology adoption strategies among businesses.

II. Methodology

A. Research Design

This study employed a quantitative predictive research design to evaluate business readiness for digital technology integration using machine learning techniques. Specifically, the predictive performance of Decision Tree, Random Forest, and Logistic Regression models was compared using survey-based data to determine the most accurate and reliable classification algorithm. The study focused on technology adoption in three key areas: digital marketing and social media technologies, e-commerce and online sales platforms, and digital payment solutions. Data were collected through a structured questionnaire that measured respondents' technology utilization, perceived helpfulness of digital tools, willingness to integrate technology into business operations, and challenges encountered during adoption. These variables served as predictors of business readiness and formed the basis for developing and evaluating the machine learning models, thereby providing a data-driven approach to assessing organizational preparedness for digital transformation.

B. Data Source

The dataset used in this study was derived from survey responses collected from business owners and operators in Pangasinan, Philippines. The structured questionnaire gathered information on the adoption and utilization of digital technologies, challenges encountered during technology use, willingness to integrate digital tools into business operations, and perceptions regarding the usefulness of technology in enhancing business performance. Specifically, the survey covered digital marketing technologies, including social media platforms (Facebook, Instagram, TikTok, and YouTube), blogs, Mailchimp, Search Engine Optimization (SEO), Pay-Per-Click (PPC) advertising, Content Management Systems (CMS), marketing analytics tools, and influencer marketing platforms. The dataset also included the use of e-commerce platforms such as Lazada, Shopee, Zalora, and Shein, as well as digital payment solutions including GCash, PayMaya, DragonPay, online banking transfers, and Coins.ph. These responses served as the primary data source for developing and evaluating the machine learning models used to predict business readiness for digital technology integration.

C. Respondents of the Study

The respondents of the study consisted of business owners, managers, and authorized business representatives from various enterprises in Pangasinan, Philippines. These individuals were selected because they possessed sufficient knowledge of their organizations' digital technology practices, including the adoption and utilization of digital marketing tools, e-commerce platforms, and digital payment systems. As key decision-makers or individuals directly involved in business operations, they were considered reliable sources of information regarding technology usage, challenges encountered during digital adoption, and the willingness of their businesses to integrate additional digital technologies. Only complete and valid responses were included in the analysis. Prior to model development, the dataset underwent a data cleaning process to identify and address incomplete, inconsistent, or erroneous entries, ensuring the quality and reliability of the data used for machine learning classification.

D. Variables of the Study

The dependent variable in this study was business readiness for digital technology integration. Since the survey instrument did not directly measure readiness, a readiness index was operationalized using respondents' willingness to integrate technology. This approach is grounded in the Technology Acceptance Model (TAM), which identifies behavioral intention as a key determinant of technology adoption, and the Unified Theory of Acceptance and Use of Technology (UTAUT), which emphasizes the influence of performance expectancy and facilitating conditions on technology acceptance and use [6], [7]. Accordingly, willingness to integrate technology was used as a proxy indicator of readiness because it reflects an organization's intention and preparedness to adopt digital technologies when enabling conditions are present. Guided by these theoretical frameworks, technology utilization, perceived helpfulness, and challenges encountered were selected as predictor variables because they represent important dimensions of technology acceptance, perceived value, and adoption barriers that may influence readiness for digital technology integration [6], [7]. These variables served as the primary inputs for the machine learning models used to classify

business readiness and examine the factors associated with digital technology adoption.

TABLE I. VARIABLES USED IN THE MACHINE LEARNING MODELS

Variable	Description	Type	Coding
Technology Utilization	Level of use of digital technologies in business operations	Ordinal	1 = Not Utilized, 2 = Low Utilization, 3=Moderate Utilization, 4 = High Utilization, 5 = Heavily Utilized
Perceived Helpfulness	Perceived usefulness of digital technologies for business operations	Ordinal	1 = Not Helpful, 2 = Slightly Helpful, 3=Moderately Helpful, 4 = Helpful, 5 = Extremely Helpful
Willingness to Integrate Technology	Intention to adopt and integrate digital technologies	Ordinal	1 = Not Willing, 2 = Slightly Willing, 3=Moderately Willing, 4 = Very Willing, 5 = Extremely Willing
Challenges Encountered	Presence of barriers to technology adoption	Binary	0 = No, 1 = Yes
Business Readiness	Target variable derived from willingness scores	Categorical	Less Ready (< 3.00), Ready (≥ 3.00)

Table I outlines the variables used in the machine learning models for predicting business readiness for digital technology integration. Technology utilization, perceived helpfulness, and challenges encountered served as the predictor variables, while business readiness was used as the target variable. Since the survey instrument did not contain a direct measure of readiness, business readiness was derived from respondents' willingness to integrate technology and classified into two categories: Less Ready and Ready. The selection of these variables was guided by the Technology Acceptance Model (TAM) and the Unified Theory of Acceptance and Use of Technology (UTAUT), which emphasize the roles of perceived usefulness, behavioral intention, and facilitating conditions in influencing technology adoption.

E. Data Preparation

Prior to model development, the survey dataset underwent data preparation and preprocessing to ensure its quality, consistency, and suitability for machine learning analysis. The dataset was examined for missing values, duplicate records, inconsistent responses, and invalid entries, with incomplete responses excluded and minor missing values addressed through appropriate imputation techniques. Because the survey data primarily consisted of categorical and ordinal responses, these variables were transformed into numerical values to facilitate model training. Ordinal responses related to technology utilization, willingness to integrate technology, and perceived helpfulness were encoded using a five-point scale, while challenge-related variables were converted into binary values, with 1 indicating the presence of a challenge and 0 indicating its absence. Following data transformation, the dataset was reviewed to remove variables with excessive missing values, limited variability, or minimal analytical relevance. Business readiness was subsequently derived from respondents' willingness to integrate technology and classified into Ready and Less Ready categories based on the established readiness threshold. To avoid target leakage, willingness variables were used solely for the construction of the target variable and were not included as predictors during model training. Consequently, technology utilization, perceived helpfulness, and challenges encountered were retained as the final predictor variables used in the machine learning models.

F. Data Splitting

Following data preprocessing, the dataset was partitioned into training and testing sets to support model development and evaluation. The training dataset was used to train the Decision Tree, Random Forest, and Logistic Regression models, while the testing dataset was reserved for assessing their predictive performance using previously unseen observations. An 80:20 train test split was employed, with 80% of the data allocated for model training and 20% reserved for testing. This proportion is widely used in supervised machine learning studies because it provides sufficient data for model learning while maintaining an independent dataset for performance evaluation. Prior to model training, the distribution of the target variable was examined to identify potential class imbalance issues. Where necessary, appropriate measures were considered to ensure that the classification models were not overly influenced by the majority class, thereby improving the reliability and robustness of the prediction results.

G. Machine Learning Models

This study employed three supervised machine learning classification algorithms, namely Decision Tree, Random Forest, and Logistic Regression, to predict business readiness for digital technology integration. The Decision Tree model was selected because of its ability to generate clear and interpretable decision rules, making it useful for understanding how different predictor variables contribute to readiness classification. Random Forest was included as an ensemble learning technique that combines multiple decision trees to improve predictive performance and reduce the risk of overfitting. Logistic Regression was utilized as a statistical classification approach that estimates the probability of membership in a particular readiness category and provides interpretable relationships between predictor variables and classification outcomes. The inclusion of these three models allowed for a comprehensive comparison of classification performance, enabling the identification of the most suitable algorithm for predicting business readiness using survey-based data.

H. Model Training and Testing

Each classification model was trained using the training dataset, with technology utilization, perceived helpfulness, and challenges encountered serving as the predictor variables. The target variable was the business readiness classification derived from respondents' willingness to integrate technology. Following model training, the Decision Tree, Random Forest, and Logistic Regression models were evaluated using the testing dataset, which contained observations not included during the training process. This approach enabled the assessment of each model's predictive performance on previously unseen data and provided an indication of its ability to generalize beyond the

training dataset. By separating model training from model evaluation, the study minimized the risk of overestimating model performance and ensured a more objective comparison of the classification algorithms.

I. Evaluation Metrics

The predictive performance of the Decision Tree, Random Forest, and Logistic Regression models was evaluated using standard classification metrics, including accuracy, precision, recall, F1 score, and the confusion matrix. Accuracy measured the overall proportion of correctly classified observations, while precision assessed the proportion of correct predictions within a given readiness category. Recall measured the ability of the model to correctly identify actual readiness classifications, and the F1 score provided a balanced assessment of precision and recall. The confusion matrix offered a detailed summary of correct and incorrect classifications across the readiness categories, enabling a more comprehensive evaluation of model behavior. Collectively, these metrics were used to compare the performance of the three machine learning algorithms and identify the most effective model for predicting business readiness for digital technology integration.

J. Comparative Analysis

Following model evaluation, a comparative analysis was conducted to assess the performance of the Decision Tree, Random Forest, and Logistic Regression models using accuracy, precision, recall, F1 score, and confusion matrix results. The model demonstrating the strongest overall performance across these metrics was identified as the most suitable approach for predicting business readiness for digital technology integration. In addition to predictive performance, model interpretability was also considered to support practical decision making. Accordingly, the models were compared not only in terms of classification accuracy but also in their ability to provide insights into how technology utilization, perceived helpfulness, and challenges encountered influence business readiness. This approach enabled the evaluation of both the predictive effectiveness and practical applicability of the machine learning models.

K. Ethical Statement

Participation was voluntary, and informed consent was obtained from all respondents prior to data collection. Respondents were assured that their responses would remain confidential and would be used solely for academic and research purposes. No personally identifiable information was collected or reported. All data were analyzed and presented in aggregated form to protect respondent privacy and comply with applicable ethical and data protection guidelines.

III. Results and Discussion

A. Descriptive Analysis of Business Readiness and Technology Adoption

The analysis was based on the raw survey dataset consisting of 400 valid respondent records collected from businesses in Pangasinan, Philippines. The survey measured key dimensions of digital technology adoption, including technology utilization, challenges encountered, willingness to integrate technology, and perceived helpfulness of digital marketing, e-commerce, and digital payment tools. These variables were aligned with the study's conceptual framework and served as the primary inputs for the machine learning models. Since the dataset did not contain a direct measure of business readiness, a readiness index was operationalized using respondents' willingness to integrate digital technologies. Consistent with technology adoption theories that identify behavioral intention as a strong predictor of actual technology use [6], [7], readiness was derived from the average willingness scores across the technology categories included in the survey. Respondents with an average willingness score of 3.00 or higher were classified as Ready, while those with scores below 3.00 were classified as Less Ready. This classification approach provided a practical and theoretically grounded method for generating the target variable used in the machine learning analysis.

TABLE II. Technology Utilization, Willingness to Integrate, and Perceived Helpfulness by Technology Category.

Technology Category	Mean Utilization	Mean Willingness	Mean Helpfulness
Digital Marketing and Social Media	1.12	2.79	4.38
E-commerce and Online Sales	1	3.03	4.56
Digital Payment Solutions	1.56	3.25	4.31

Table II presents the technology utilization, willingness to integrate, and perceived helpfulness of digital technologies across three major categories: digital marketing and social media, e-commerce and online sales, and digital payment solutions. The results revealed that digital payment solutions recorded the highest mean utilization score (1.56), indicating that these technologies were more widely adopted than the other categories. This finding suggests that businesses tend to prioritize digital technologies that provide immediate operational benefits, such as faster transactions, improved payment convenience, and enhanced customer service. The relatively high utilization of GCash and other digital payment platforms reflects the growing acceptance of cashless transactions and the practical value of digital payment systems in supporting day-to-day business activities.

In contrast, e-commerce and online sales technologies exhibited the lowest mean utilization score (1.00), indicating limited adoption among the surveyed businesses. Despite this low level of utilization, e-commerce received the highest perceived helpfulness score (4.56), demonstrating that respondents recognized its potential to expand market reach, improve customer access, and increase business opportunities. This disparity between perceived helpfulness and actual utilization suggests that businesses may be aware of the benefits of e-commerce but face barriers that prevent its full adoption. Similar observations have been reported in digital transformation studies, which emphasize that awareness of technology benefits does not automatically translate into implementation due to constraints related to resources, digital competencies, organizational readiness, and facilitating conditions [1]-[5].

Digital payment solutions also achieved the highest willingness to integrate score (3.25), followed by e-commerce

technologies (3.03). These findings indicate that businesses are more prepared to adopt technologies that offer visible and immediate advantages. According to the Technology Acceptance Model, perceived usefulness significantly influences behavioral intention toward technology adoption [6]. Likewise, the Unified Theory of Acceptance and Use of Technology highlights the role of performance expectancy and facilitating conditions in shaping adoption behavior [7]. The relatively higher willingness scores observed for digital payment and e-commerce technologies suggest that businesses perceive these tools as beneficial and potentially valuable for improving operational efficiency and competitiveness.

The findings further reveal a notable gap between technology utilization and perceived helpfulness across all categories. Although respondents generally viewed digital technologies as useful, actual adoption remained limited. This pattern suggests that readiness for digital transformation is influenced by factors beyond perceived usefulness alone. Previous studies have identified organizational capabilities, digital literacy, leadership support, technological infrastructure, and strategic readiness as important determinants of successful digital transformation [1]–[5]. Consequently, initiatives aimed at improving awareness, digital skills, and access to technology resources may help bridge the gap between positive perceptions and actual technology adoption. Overall, the results indicate that while businesses recognize the value of digital technologies, further support and capacity-building efforts are needed to enhance readiness and promote broader digital technology integration.

TABLE III. MOST UTILIZED TECHNOLOGIES

Rank	Technology	Mean Utilization
1	GCash	3.71
2	Facebook	2.44
3	Reels	1.14
4	Online Banking Transfer	1.07
5	TikTok	1.04

Table III shows the most utilized technologies. The most utilized tool was GCash, with a mean utilization score of 3.71, followed by Facebook with 2.44. This suggests that respondents were most familiar with technologies that directly support payment transactions and customer communication. Most other tools had very low utilization, with several platforms recording a mean score of 1.00, including Lazada, Shopee, Zalora, Shein, PayMaya, DragonPay, and Coins.ph.

TABLE IV. HIGHEST WILLINGNESS TO INTEGRATE TECHNOLOGIES

Rank	Technology	Mean Willingness
1	GCash	4.64
2	Facebook	4.15
3	Online Banking Transfer	3.8
4	YouTube	3.73
5	Shopee / Lazada	3.5

Table IV presents the technologies with the highest willingness to integrate among the respondents. The respondents showed the highest willingness to integrate GCash, with a mean willingness score of 4.64, followed by Facebook with 4.15. This means that digital payment and social media tools were the most acceptable technologies among the respondents. On the other hand, lower willingness scores were observed for Coins.ph, Content Management Systems, Marketing Analytics, and Pay-Per-Click Advertising, suggesting that these tools may require more awareness, training, or support before businesses become ready to adopt them.

TABLE V. CHALLENGES ENCOUNTERED

Challenge	Frequency	Percentage
Lack of awareness	6,040	65.65%
Data security concerns	1,514	16.46%
Inadequate skills, training, and support	446	4.85%
Resistance to change among employees	443	4.82%
Lack of financial resources	439	4.77%
Connectivity or infrastructure issues	293	3.18%
Complexity of the technology/system	25	0.27%

[a] **Note:** Frequencies and percentages were calculated from the total number of coded challenge responses because respondents were allowed to select multiple challenges.

Table V illustrates the challenges encountered by businesses in adopting digital technologies. Lack of awareness emerged as the most frequently reported barrier, accounting for 65.65% of all coded responses, indicating that many businesses may have limited knowledge of available digital tools and their potential benefits for business operations. Data security concerns ranked second at 16.46%, suggesting that issues related to privacy, trust, and the protection of digital transactions also influence technology adoption decisions. In contrast, the low frequency of responses related to technology complexity indicates that businesses do not necessarily perceive digital tools as difficult to use. Rather, the findings suggest that limited awareness and concerns regarding security represent the primary obstacles to digital technology integration. These results highlight the importance of digital literacy initiatives, awareness campaigns, and cybersecurity education programs to improve business readiness and encourage wider adoption of digital technologies.

TABLE VI. BUSINESS READINESS CLASSIFICATION

Readiness Classification	Frequency	Percentage
Less Ready	240	60.00%
Ready	160	40.00%
Total	400	100.00%

Table VI presents the business readiness classification of the respondents. Based on the established readiness threshold, 240 respondents (60.00%) were classified as Less Ready, while 160 respondents (40.00%) were classified as Ready for digital technology integration. These findings indicate that although respondents generally recognized the benefits and usefulness of digital technologies, the majority had readiness scores below the threshold required for classification as Ready. The results suggest that positive perceptions of digital technologies do not necessarily translate into readiness for adoption, highlighting the need for greater awareness, capacity building, and support

mechanisms to facilitate digital technology integration among businesses.

TABLE VII. MACHINE LEARNING MODEL RESULTS

Model	Accuracy	Weighted Precision	Weighted Recall	Weighted F1-Score
Decision Tree	0.6375	0.625	0.6375	0.6129
Random Forest	0.6375	0.6325	0.6375	0.6341
Logistic Regression	0.6125	0.6356	0.6125	0.6163

Table VII provides the performance of the machine learning models using an 80:20 train-test split. Decision Tree and Random Forest achieved the highest accuracy of 63.75%, while Random Forest obtained the highest weighted F1 score (0.6341), indicating the best overall classification performance. Logistic Regression achieved a slightly lower accuracy of 61.25% but recorded the highest weighted precision (0.6356). The moderate predictive performance of the models reflects the complexity of business readiness, which is influenced by multiple organizational and contextual factors beyond those captured in the survey. Despite relying on perception-based variables, the results demonstrate that machine learning, particularly Random Forest, can effectively identify readiness patterns and support data-driven decision-making for digital technology integration. Future studies may improve predictive performance by incorporating additional variables related to organizational capabilities, digital literacy, internet accessibility, and prior technology experience [1]-[5], [25].

TABLE VIII. CONFUSION MATRIX RESULTS

Model	Actual Less Ready Correctly Predicted	Actual Less Ready Predicted Ready	Actual Ready Predicted Less Ready	Actual Ready Correctly Predicted
Decision Tree	40	8	21	11
Random Forest	35	13	16	16
Logistic Regression	28	20	11	21

Table VIII summarizes the confusion matrix results of the three machine learning models. The Decision Tree model correctly classified most Less Ready businesses but showed limited effectiveness in identifying Ready businesses, indicating a tendency toward the majority class. Logistic Regression demonstrated better performance in identifying Ready businesses; however, it produced a higher number of false positive classifications, which reduced its overall accuracy. In contrast, the Random Forest model achieved a more balanced classification performance by accurately identifying both Less Ready and Ready businesses. Although its accuracy was comparable to that of the Decision Tree model, its higher weighted F1 score reflected a better balance between precision and recall across the two readiness categories. These findings suggest that Random Forest provided the most reliable and practical predictive performance for assessing business readiness for digital technology integration, making it the most suitable model for supporting data driven decision making and digital transformation planning.

B. Discussion

The findings revealed a notable gap between the perceived usefulness of digital technologies and their actual utilization among businesses in Pangasinan. Although respondents generally recognized the value of digital technologies in improving business operations, customer engagement, and market reach, actual technology utilization remained relatively low. This disparity suggests that positive perceptions alone do not guarantee technology adoption. According to the Technology Acceptance Model (TAM), perceived usefulness influences behavioral intention, which subsequently affects technology use [6]. Similarly, the Unified Theory of Acceptance and Use of Technology (UTAUT) highlights the importance of facilitating conditions and organizational support in translating intention into actual adoption behavior [7]. Thus, while businesses may acknowledge the benefits of digital technologies, existing barriers may prevent them from fully integrating these tools into their operations.

Among the technology categories examined, digital payment solutions demonstrated the highest level of adoption and readiness, largely driven by the widespread use of GCash and other mobile payment platforms. This finding suggests that businesses are more inclined to adopt technologies that offer immediate operational benefits, including transaction convenience, improved efficiency, and reduced cash handling risks. Previous studies have shown that organizations prioritize digital technologies that provide clear business value and contribute directly to operational performance and competitiveness [1],[2]. In contrast, the relatively low utilization of e-commerce platforms indicates that many businesses have not fully embraced online selling despite recognizing its usefulness. This finding may reflect gaps in digital competencies, awareness, organizational capabilities, and readiness, which have been identified as important determinants of successful digital transformation [3]-[5].

The challenge analysis further supports this interpretation. The predominance of lack of awareness as a reported barrier suggests that informational and knowledge-related constraints may be more significant than purely financial or technical limitations. This finding underscores the importance of digital literacy programs, technology demonstrations, business mentoring, and capacity building initiatives to enhance readiness for digital technology integration. Previous research has emphasized that digital readiness extends beyond technological infrastructure and includes leadership support, organizational capabilities, employee competencies, and the ability to adapt to changing business environments [3]-[5]. Consequently, efforts aimed at improving awareness and digital skills may substantially increase the likelihood of successful technology adoption among businesses.

With respect to predictive modeling, Random Forest emerged as the best-performing classification algorithm, achieving the highest overall accuracy and weighted F1 score among the evaluated models. The superior performance of Random Forest may be attributed to its ensemble learning mechanism, which combines multiple decision trees to improve predictive accuracy and reduce overfitting [25]. Although Decision Tree and Logistic Regression provided greater interpretability and clearer explanations of classification

outcomes, Random Forest demonstrated a stronger ability to accurately classify both Ready and Less Ready businesses. These findings suggest that machine learning techniques can effectively predict business readiness using variables related to technology utilization, perceived helpfulness, and challenges encountered. The ability of the models to identify readiness patterns demonstrates the usefulness of machine learning as a decision support tool for assessing digital transformation readiness and technology adoption behavior. Consistent with previous studies, machine learning algorithms have proven effective in classification, prediction, and decision support applications across various organizational and operational contexts [16], [17], [22]. Although the predictive performance observed in this study was moderate, the results indicate that technology adoption characteristics can provide meaningful insights into business readiness and may support evidence-based planning, capacity building, and digital transformation initiatives among businesses.

The results further indicate that business readiness is influenced by factors beyond those captured in the present dataset. Although willingness to integrate technology served as a practical proxy for readiness, digital transformation literature recognizes readiness as a multidimensional construct that includes organizational resources, technological infrastructure, leadership commitment, digital competencies, and strategic orientation [1]-[5]. While TAM and UTAUT support the use of behavioral intention as a predictor of technology adoption [6], [7], future research should develop and validate more comprehensive readiness frameworks that incorporate technological, organizational, financial, and human resource dimensions. Such an approach would strengthen the conceptual measurement of readiness while improving the predictive capability of machine learning models.

Several limitations should be considered when interpreting the findings. First, the study employed a single 80:20 train-test split for model evaluation, which may influence performance estimates because classification results can vary depending on how the data are partitioned. Future studies should employ more robust validation approaches, such as k-fold cross-validation, stratified k-fold validation, or repeated random subsampling, to generate more stable and reliable performance estimates. Second, although the dataset consisted of 400 valid responses, only a subset was used for testing, which may affect the generalizability of the reported performance metrics. Third, the study focused on businesses within a specific geographical context, potentially limiting the applicability of the findings to other regions or business sectors. Future studies should therefore utilize larger and more diverse datasets to improve model robustness and external validity.

Another limitation is that feature importance analysis was not performed for the Random Forest model. Although Random Forest achieved the highest predictive performance, the relative contribution of individual predictor variables was not quantified. Consequently, the study focused primarily on model comparison and predictive accuracy rather than model explainability. Future research should incorporate feature importance analysis and model interpretation techniques such as permutation importance and SHAP (Shapley Additive Explanations) to identify the variables that most strongly influence business readiness. Such analyses would provide deeper insights into technology adoption behavior and support the development of more targeted and evidence based digital transformation strategies.

Guo (2025) [26] compared Decision Tree, Logistic Regression, AdaBoost, and Random Forest models in predicting corporate credit default and reported that the improved Random Forest model achieved superior predictive performance, with an accuracy of 94.2%, recall of 93.5%, and F1-score of 92.8%. The study attributed the strong performance of Random Forest to its ensemble structure, which enhances classification accuracy while reducing the risk of overfitting commonly associated with single-tree models. Although the predictive performance observed in the present study was more moderate due to the complexity and perception-based nature of business readiness data, the superior performance of Random Forest similarly demonstrates its capability to capture complex relationships among predictor variables and generate more balanced classifications than Decision Tree and Logistic Regression models. These findings further support the suitability of Random Forest as a practical decision-support tool for organizational assessment, technology adoption studies, and business analytics applications.

The findings of the present study are consistent with recent machine learning research that highlights the effectiveness of ensemble learning methods for classification tasks. Guo (2025) compared Decision Tree, Logistic Regression, AdaBoost, and Random Forest models in predicting corporate credit default and reported that the improved Random Forest model achieved superior predictive performance, with an accuracy of 94.2%, recall of 93.5%, and F1-score of 92.8%. The study attributed the strong performance of Random Forest to its ensemble structure, which enhances classification accuracy while reducing the risk of overfitting commonly associated with single-tree models. Although the predictive performance observed in the present study was more moderate due to the complexity and perception-based nature of business readiness data, the superior performance of Random Forest similarly demonstrates its capability to capture complex relationships among predictor variables and generate more balanced classifications than Decision Tree and Logistic Regression models. These findings further support the suitability of Random Forest as a practical decision-support tool for organizational assessment, technology adoption studies, and business analytics applications.

IV. Conclusion and Recommendations

A. Conclusion

The study concluded that business readiness for digital technology integration among businesses in Pangasinan remains in the developmental stage. Although respondents generally perceived digital technologies as highly beneficial for improving business operations, customer engagement, and market expansion, actual utilization levels remained relatively low, indicating a gap between awareness of benefits and practical adoption. Digital payment solutions, particularly GCash, exhibited the highest levels of utilization and willingness to integrate, suggesting that businesses are more likely to adopt technologies that provide immediate and tangible operational advantages. In contrast, e-commerce platforms and several digital marketing technologies remained underutilized despite

their perceived usefulness. Lack of awareness emerged as the primary barrier to adoption, followed by concerns regarding data security, highlighting the need for digital literacy initiatives, technology training, and business support programs. Among the machine learning models evaluated, Random Forest demonstrated the strongest predictive performance and was identified as the most suitable model for classifying business readiness, while Decision Tree and Logistic Regression provided valuable interpretability and baseline comparisons. Further, the findings demonstrate that machine learning can serve as an effective tool for predicting business readiness and generating evidence-based insights that support digital transformation planning and technology adoption strategies among businesses.

B. Recommendations

Businesses should strengthen digital awareness and skills through training and digital literacy programs, particularly in digital marketing, e-commerce, and digital payment systems. Given that lack of awareness was the primary barrier to adoption, local government units, business support organizations, and technology providers should collaborate in providing technical assistance and capacity-building initiatives. Future studies should utilize larger datasets, incorporate additional organizational and contextual variables, and explore advanced machine learning algorithms to improve the prediction of business readiness for digital technology integration. Future studies should also employ k-fold cross-validation and feature importance analysis to improve model robustness and enhance the interpretability of machine learning predictions.

ACKNOWLEDGMENT

The author gratefully acknowledges the Pangasinan State University for its support in the conduct and completion of this study. The author also utilized artificial intelligence-assisted tools to improve language clarity, readability, and editorial quality during manuscript preparation. These tools were not used to generate research data, perform data analysis, interpret results, or draw conclusions. All analysis, interpretations, and final manuscript content were reviewed, verified, and approved by the author, who assumes full responsibility for the accuracy and integrity of the work.

Abstract*—Pupillary distance (PD) is an important ocular measurement for optical dispensing and vision-related applications, but standard MediaPipe FaceMesh outputs do not provide true pupil-centre or iris-boundary landmarks when only the 468-landmark representation is available. This study proposes a canthus-scaled 468-landmark framework for estimating PD using facial landmarks and Malay young-adult normative palpebral fissure width. A dataset of 44 subjects was used, where each record contained ground-truth PD and 1,404 coordinate values representing 468 FaceMesh landmarks in three dimensions. Since true pupil centres were unavailable, medial and lateral canthus landmarks were used to construct eye-centre proxies and to compute a subject-specific millimetre scale. A direct canthus-scaled proxy was first evaluated as a deterministic baseline, after which canthus-scaled geometric features were used in a nested AutoML calibration framework. Model development used repeated nested cross-validation, with an outer repeated 5-fold design and an inner 4-fold model-selection loop. The direct proxy achieved a mean absolute error (MAE) of 4.26 mm and showed systematic overestimation. The calibrated nested AutoML model improved performance, achieving a subject-level MAE of 3.510 mm, root mean squared error of 4.22 mm, a bias of −0.08 mm, and 75.0% of predictions within ±5 mm. The calibrated nested AutoML model improved overall error and reduced systematic bias compared with the direct canthus-scaled proxy. However, the Bland–Altman limits of agreement remained wide, indicating that the proposed method should be interpreted as an approximate proxy-based estimation approach rather than a substitute for clinical pupillometer- or ruler-based PD measurement. The framework is most relevant for research settings or datasets where only standard 468-landmark FaceMesh data are available, and iris-refined landmarks are absent.

Keywords*—Pupillary distance; MediaPipe FaceMesh; facial landmarks; canthus scaling; palpebral fissure width; AutoML; nested cross-validation; computer vision

I. Introduction

Pupillary distance (PD), commonly discussed as interpupillary distance (IPD), is the horizontal distance between the centres of the two pupils and is an important measurement in optometry, ophthalmic dispensing, binocular vision assessment, and the fitting of ophthalmic lenses. Inaccurate PD measurement may affect optical centration and can contribute to visual discomfort, especially when lenses are prescribed or manufactured using incorrect centration parameters. Conventional PD measurement is commonly performed using clinical instruments such as pupillometers, autorefractors, or manual PD rulers. However, these approaches may require trained personnel, dedicated equipment, or direct clinical access, which motivates the development of low-cost and automated alternatives [1], [2].

Recent studies have investigated smartphone- and computer-vision-based methods for estimating PD or related ocular measurements. Jung and Chu compared modern IPD measurement methods, including clinical and mobile application approaches, showing the growing interest in non-contact digital PD estimation [1]. Han et al. evaluated smartphone applications for IPD measurement, further supporting the feasibility of mobile-based measurement but also highlighting the need for accuracy validation [2]. Zhang et al. proposed a computer-vision method for IPD and pupil-height measurement using ensemble regression trees and segmentation-based techniques, demonstrating that automated ocular measurement remains an active area of applied vision research [3]. Similarly, pupil-centre detection has been investigated using convolutional neural networks and webcam-based systems, indicating that accurate pupil localization is technically challenging but central to reliable ocular measurement [4].

MediaPipe FaceMesh has become a widely used framework for real-time facial landmark extraction because it can estimate dense three-dimensional facial landmarks from ordinary RGB images. The standard FaceMesh model estimates 468 facial landmarks, making it attractive for lightweight and non-invasive facial analysis applications [5]. However, the standard 468-landmark representation does not include true iris-boundary or pupil-centre landmarks. MediaPipe Iris extends the FaceMesh framework by estimating additional iris and eye-contour landmarks, enabling more direct iris- and pupil-related measurements from a single RGB camera [6], [7]. In datasets where only the 468 FaceMesh

*Corresponding author.

landmarks are available, PD cannot be measured directly from true pupil centres; instead, proxy-based estimation using periocular landmarks is required.

Population-specific anthropometric information is important when facial or ocular landmarks are converted from image-space distances into metric units. Ngeow and Aljunid established craniofacial anthropometric norms for young adult Malaysian Malays aged 18–25 years, providing population-relevant reference measurements for craniofacial and orbital regions [8]. Othman et al. further established three-dimensional facial soft-tissue morphology for adult Malay subjects using stereophotogrammetry, reinforcing the importance of population-specific facial measurements in Malaysian samples [9]. Additional Malaysian and regional studies on palpebral fissure and canthal measurements show that periocular dimensions vary across sex and ethnic groups, supporting the use of appropriate normative references when converting facial landmark distances into estimated millimetres [10]–[13].

Although iris-based scaling is preferable when iris landmarks are available, many existing landmark datasets contain only 468 FaceMesh landmarks. In such cases, canthus-based scaling provides a practical alternative. The medial and lateral canthus landmarks can be used to estimate palpebral fissure width, and a normative palpebral fissure width value can then be used as a scale reference. This allows the distance between canthus-derived eye-centre proxies to be converted into an estimated PD value. However, because the eye-centre proxies are not anatomical pupil centres, a direct normative conversion may introduce systematic bias. Machine-learning calibration can therefore be used to learn the relationship between canthus-scaled facial landmark features and ground-truth PD.

The key limitation addressed in this study is that many existing facial-landmark datasets contain only the standard 468 MediaPipe FaceMesh landmarks and do not include iris-boundary or anatomical pupil-centre landmarks. Under this constraint, PD cannot be measured directly from the true pupil centres. This study, therefore, investigates a two-stage framework: first, a geometric canthus-scaled proxy is constructed using medial and lateral canthus landmarks and Malay young-adult normative palpebral fissure width; second, a predictive calibration model is trained to reduce systematic proxy error using nested cross-validation. The contributions of this study are: 1) a 468-landmark canthus-scaled proxy method for approximate PD estimation, 2) an evaluation of direct geometric estimation versus calibrated prediction, 3) a nested AutoML validation strategy for a small biomedical dataset, and 4) an explicit discussion of the clinical and deployment limitations of the proxy-based approach.

II. Related Work

Previous work on pupillary distance estimation can be grouped into four main areas: conventional clinical measurement, smartphone- and computer-vision-based ocular measurement, facial landmark and iris-based estimation, and validation methods for small-sample prediction models. Conventional PD measurement is commonly performed using pupillometers, autorefractors, or manual rulers, which remain more appropriate for clinical dispensing because they are designed to measure ocular centration directly. However, these approaches require equipment, trained personnel, or clinical access, motivating low-cost computer-vision alternatives.

Smartphone and computer-vision methods have shown promise for non-contact PD and related ocular measurements, but their accuracy depends strongly on pupil or iris localization, camera geometry, subject pose, and calibration strategy. Methods that use direct pupil or iris detection are conceptually closer to anatomical PD measurement, whereas approaches based only on facial landmarks must rely on surrogate geometric features. MediaPipe FaceMesh provides dense facial landmarks and is attractive for lightweight facial analysis, but the standard 468-landmark model does not include true pupil-centre or iris-boundary landmarks. MediaPipe Iris extends this representation with additional iris-related landmarks and is therefore preferable when iris landmarks are available.

In contrast, the present study focuses on the more restricted setting where only 468 FaceMesh landmarks are available. Under this condition, canthus landmarks provide a practical periocular reference because they are visible in the standard model and can be linked to palpebral fissure width. Anthropometric scaling is also important because image-space distances must be converted into millimetres. Population-specific normative values may reduce scaling error compared with arbitrary scaling, but they cannot account fully for inter-subject periocular variation. Therefore, this study treats canthus scaling as an approximate population-level calibration rather than a subject-specific physical calibration.

Finally, because the dataset is small and model selection is part of the modelling process, nested cross-validation is used to reduce optimistic performance estimation. This is important because using cross-validation both for model selection and final error estimation can introduce biased performance estimates [14]. In addition, the reporting of the proposed prediction framework was informed by TRIPOD+AI guidance for regression and machine learning-based prediction models, particularly in relation to transparent description of the data, predictors, validation procedure, performance metrics, and limitations [15].

III. Methodology

The proposed framework consists of two conceptually distinct stages. Stage 1 is geometric proxy estimation, in which canthus landmarks are used to estimate palpebral fissure width, construct eye-centre proxies, and convert landmark distances into estimated millimetres. Stage 2 is predictive calibration, in which canthus-scaled geometric features are used to learn the relationship between proxy geometry and reference PD. The first stage is deterministic and interpretable, whereas the second stage is a data-driven correction layer. The calibrated model should therefore be interpreted as a correction of a canthus-derived proxy, not as a direct measurement of anatomical pupil-centre distance.

A. Dataset and Landmark Representation

This study used a subject-level facial landmark dataset for pupillary distance (PD) estimation. Each record contained a subject identifier, a ground-truth PD value in millimetres, and

1,404 coordinate values representing 468 MediaPipe FaceMesh landmarks in three-dimensional form. The landmark values were arranged as 468 x-coordinates, 468 y-coordinates, and 468 z-coordinates. The dataset contained 44 usable subjects after retaining records with valid subject identifiers, ground-truth PD values, and complete landmark coordinates.

The standard 468-landmark FaceMesh representation does not include anatomical pupil centres or iris-boundary landmarks. Therefore, this study estimated PD using canthus-derived eye-centre proxies and a canthus-based normative scaling procedure. The complete methodological workflow is illustrated in Fig. 1.

B. Landmark Pre-processing

The uploaded landmark matrix was first parsed into a structured coordinate tensor. For each subject, the 1,404 landmark values were reshaped into a 468×3 matrix, where each landmark was represented by x, y, and z coordinates. Records of missing or non-numeric landmark values were excluded to ensure complete geometric calculations.

The following FaceMesh landmarks were used as the primary ocular reference points:

L_33and L_133: right-eye lateral and medial canthus region landmarks.

L_263and L_362: left-eye lateral and medial canthus region landmarks.

These landmarks were selected because they are available in the 468-landmark FaceMesh model and correspond to the canthal region required for palpebral fissure width estimation.

C. Canthus-Based Normative Scaling

Since no physical calibration object or iris landmarks were available, image-space landmark distances were converted into millimetres using a population-level canthus-based normative scale. A normative palpebral fissure width (PFW) of 29.100 mm was used as the scaling constant for the Malay young-adult population.

For each subject, the right and left image-space palpebral fissure widths were calculated as:

$$PFW_R = d(L_{33}, L_{133}) \quad (1)$$

$$PFW_L = d(L_{263}, L_{362}) \quad (2)$$

The subject-specific image-space palpebral fissure width was then computed as:

$$PFW_{image} = \frac{PFW_R + PFW_L}{2} \quad (3)$$

The millimetre-per-landmark-unit scale factor was calculated as:

$$S = \frac{PFW_{normative}}{PFW_{image}} \quad (4)$$

where, PFW_normative=29.100mm.

This scale factor was applied to convert selected landmark distances from landmark units into estimated millimetres. This scaling approach assumes that the selected normative palpebral fissure width is representative of the target population. However, it does not account for subject-specific anatomical variation in eyelid aperture, canthal position, sex-related differences, or facial pose. To make this limitation explicit, the subject-specific scale factor and right-left palpebral fissure asymmetry were retained as scale quality-control variables.

D. Eye-Centre Proxy Estimation

Because true pupil centres were not available in the 468-landmark representation, this study did not attempt to measure anatomical PD directly. Instead, each eye was represented by a canthus-derived geometric proxy defined as the midpoint between the medial and lateral canthus landmarks. The right and left eye-centre proxies were calculated as:

$$E_R = \frac{L_{33} + L_{133}}{2} \quad (5)$$

$$E_L = \frac{L_{263} + L_{362}}{2} \quad (6)$$

The direct canthus-scaled proxy PD was then calculated as:

$$PD_{proxy} = d(E_R, E_L) \times S \quad (7)$$

This direct proxy was used as a deterministic baseline for comparison with the machine-learning-based prediction model. This midpoint is expected to differ from the true anatomical pupil centre because the pupil position depends on gaze, eyelid aperture, ocular anatomy, and camera perspective. Therefore, the direct canthus-scaled estimate was treated only as a deterministic baseline and not as a clinical PD measurement.

E. Feature Engineering

Canthus-scaled geometric features were constructed from the 468-landmark coordinate representation. The engineered feature groups included:

- Eye-corner midpoint distance, computed from the distance between the right and left canthus-derived eye-centre proxies.
- Eye-contour centroid distance, computed from the centroid of available eye-contour landmarks.
- Anatomical pairwise landmark distances, including ocular, facial-width, mouth-width, and vertical face-distance proxies.
- Scale quality-control features, including the subject-specific scale factor and the percentage asymmetry between right and left palpebral fissure widths.
- Full landmark representations, including all 468 landmarks and subject-level normalized landmark features.

All distance-based geometric features were converted into estimated millimetres using the subject-specific canthus scale factor. Because the number of subjects was limited, the high-dimensional all-landmark representation was treated cautiously. The candidate model set, therefore, included low-dimensional eye-region and anatomical-distance feature sets, scale quality-control variables, and regularized models. The all-landmark feature set was included only as one candidate representation within the nested selection procedure, not as the default model.

F. Direct Proxy Baseline

A direct canthus-scaled PD proxy was calculated for each subject using only the eye-centre proxy distance and the normative canthus scale factor. This method did not require model training and served as an interpretable baseline for evaluating whether a simple normative conversion was sufficient for PD estimation.

To evaluate whether the added complexity of AutoML calibration was justified, simple statistical calibration baselines were added. These included a linear correction model using the direct canthus-scaled proxy as the predictor and a polynomial correction model using first- and second-order terms of the direct proxy. These models were evaluated using the same outer cross-validation structure as the AutoML framework, so that calibration performance could be compared under the same validation conditions.

G. Nested AutoML Prediction Model

A nested cross-validation framework was used to train and evaluate machine-learning models while avoiding data leakage. The outer loop used repeated 5-fold cross-validation with 10 repeats. In each outer fold, subjects in the test split were held out and were not used during model selection or hyperparameter tuning. The inner loop used 4-fold cross-validation on the training split to select the optimal feature set, estimator, and hyperparameters.

The AutoML candidate set included baseline and regression-based models using canthus-scaled feature sets. Candidate models included dummy regression, linear eye-region estimators, Ridge regression, ElasticNet regression, support vector regression, and partial least squares regression. Model selection was based on minimizing mean absolute error in millimetres within the inner cross-validation loop.

For each outer fold, the best-performing model from the inner loop was refitted on the corresponding outer training set and used to predict PD for the held-out subjects. Repeated outer-fold predictions were averaged to obtain one subject-level prediction per participant.

A landmark perturbation analysis was conducted to evaluate sensitivity to plausible localization error. Key canthus landmarks and eye-contour landmarks were perturbed with zero-mean random noise at predefined magnitudes, and the direct proxy and calibrated predictions were recomputed. Performance was summarized using MAE, RMSE, bias, and Bland–Altman limits of agreement. Because the available dataset contained landmark coordinates rather than raw images, image-level effects such as illumination variation, motion blur, occlusion, and head-pose changes could not be fully evaluated. These image-level robustness factors are therefore identified as priorities for future validation.

H. Evaluation Protocol

The direct proxy baseline and nested AutoML predictions were evaluated against ground-truth PD values. The evaluation metrics included mean absolute error, root mean squared error, bias, standard deviation of error, median absolute error, coefficient of determination, Bland–Altman limits of agreement, and the percentage of predictions within ±2 mm and ±5 mm.

Bootstrap resampling was used to estimate confidence intervals for subject-level performance metrics. The final analysis compared the deterministic canthus-scaled proxy with the calibrated nested AutoML model to assess whether learned calibration improved PD estimation from 468-landmark canthus-scaled features.

I. Workflow Summary

The proposed methodology consists of landmark parsing, canthus-based scale estimation, eye-centre proxy calculation, direct proxy PD estimation, canthus-scaled feature construction, nested AutoML calibration, and final evaluation. This process is summarized in Fig. 1.

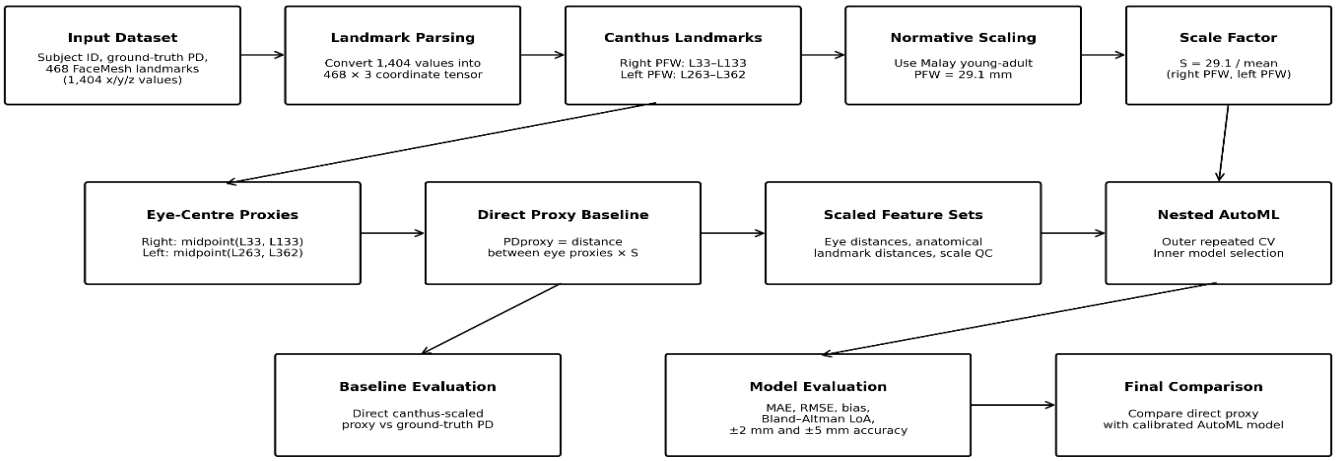

Fig. 1. Overall methodology of the 468-landmark canthus-scaled PD estimation framework.

IV. Results and Discussion

A. Dataset and Experimental Configuration and Acronyms

The final analysis included 44 subjects with complete 468-landmark FaceMesh data and corresponding ground-truth pupillary distance (PD) values. Each subject contributed 1,404 landmark coordinate values, representing 468 landmarks in x, y, and z dimensions. The proposed workflow used a canthus-based normative scaling procedure, where landmarks 33–133 and 263–362 were used to estimate right and left palpebral fissure widths, respectively. The overall experimental configuration is summarized in Table I.

The use of nested cross-validation was appropriate because the dataset was small and model selection was performed during training. In small-sample prediction modelling, non-nested validation may produce unstable or optimistic estimates, whereas nested validation separates model selection from performance estimation [16], [17].

The canthus-based scale factor showed measurable inter-subject variability. The mean scale factor was 1109.74 mm per landmark unit with a standard deviation of 141.41 mm per landmark unit. The mean right-left palpebral fissure width asymmetry was 4.95%, while the maximum asymmetry reached 44.09%. These values indicate that although normative scaling provides a practical conversion from landmark units to millimetres, individual periocular morphology and landmark asymmetry may introduce scaling error.

B. Direct Canthus-Scaled Proxy Baseline

The direct canthus-scaled proxy served as a deterministic baseline. This method estimated PD by calculating the distance between the right and left canthus-derived eye-centre proxies and multiplying it by the subject-specific canthus scale factor. As shown in Table II, the direct proxy achieved an MAE of 4.26 mm and RMSE of 4.91 mm. The bias was +2.83 mm, indicating that the direct proxy generally overestimated the ground-truth PD.

This finding suggests that canthus-based scaling alone is insufficient for accurate PD estimation when true pupil centres are unavailable. The direct proxy is interpretable and simple, but it depends on the assumption that the midpoint between the medial and lateral canthus approximates the pupil centre. Since the 468-landmark representation does not include actual pupil-centre landmarks, systematic geometric bias is expected.

TABLE I. Dataset and Experimental Configuration

Item	Value
N usable subjects	44
Target PD mean (mm)	63.59
Target PD SD (mm)	4.26
Target PD median (mm)	62.50
Target PD min (mm)	55.00
Target PD max (mm)	72.00
Landmark values per subject	1404.00
Interpreted landmarks	468.00
Metric scaling approach	468-landmark canthus-based normative scaling
Normative palpebral fissure width (mm)	29.10
Scale landmarks	Right 33-133 and left 263-362; scale = normative PFW / mean observed PFW
Direct proxy formula	distance(midpoint(33,133), midpoint(263,362)) x canthus scale
Outer CV	Repeated 5-fold CV x 10 repeats
Inner CV	4-fold CV
Primary model selection metric	Mean absolute error (MAE), mm

TABLE II. Performance Comparison Between Direct Proxy and Nested AutoML

Analysis level	MAE (mm)	RMSE (mm)	Bias (mm)	Median AE (mm)	Within +/-2 mm (%)	Within +/-5 mm (%)	LoA lower (mm)	LoA upper (mm)	95% CI
Direct canthus-scaled proxy	4.26	4.91	2.83	4.31	20.45	59.09	-5.12	10.80	
Nested AutoML subject-level	3.51	4.23	-0.08	3.57	31.82	75.00	-8.45	8.30	MAE 2.82-4.21; RMSE 3.47-4.91; Bias -1.34-1.12
Nested AutoML outer-fold	3.61	4.35	-0.08	3.46	32.27	72.05	-8.61	8.46	

TABLE III. AutoML-Selected Candidate Frequency Across Outer Folds

Selected candidate	Selected feature set	Outer folds	Mean inner MAE (mm)	SD inner MAE (mm)	Selection (%)
Eye-centroid estimator	eye_centroid_scaled_mm	23	3.45	0.21	46.00
Eye-corner estimator	eye_corner_scaled_mm	6	3.21	0.35	12.00
Geometry SVR-RBF	geometry_26_scaled_mm	6	3.28	0.17	12.00
Geometry Ridge	geometry_26_scaled_mm	6	3.47	0.22	12.00
Geometry ElasticNet	geometry_26_scaled_mm	5	3.22	0.13	10.00
All-landmarks PLS	all_landmarks_scaled_mm	3	3.39	0.14	6.00
Dummy median baseline	geometry_26_scaled_mm	1	3.396		2.00

C. Nested AutoML Prediction Performance

The nested AutoML model improved the overall prediction accuracy compared with the direct proxy baseline. As reported in Table II, the subject-level nested AutoML prediction achieved an MAE of 3.51 mm, RMSE of 4.22 mm, and bias of −0.08 mm. The proportion of predictions within ±5 mm increased to 75.00%, compared with 59.09% for the direct proxy baseline. The bootstrap 95% confidence interval for subject-level MAE was 2.82–4.21 mm, indicating the expected uncertainty range of the model's average absolute error.

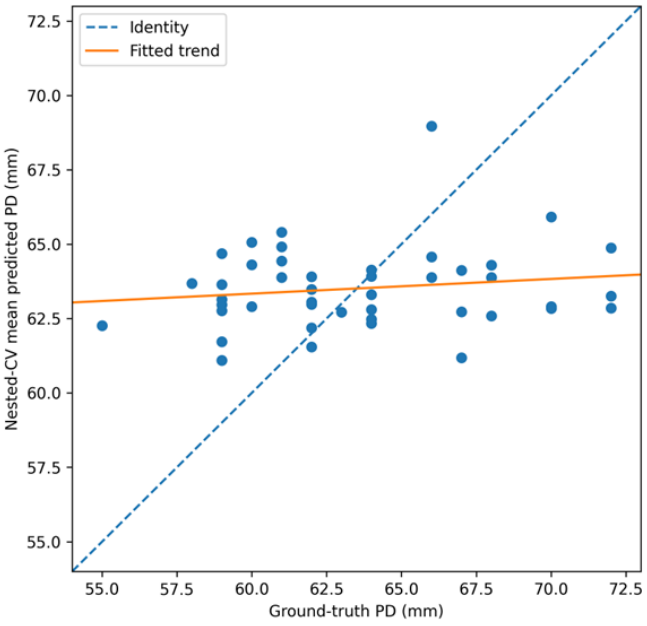

Fig. 2. Predicted versus ground-truth PD using nested AutoML.

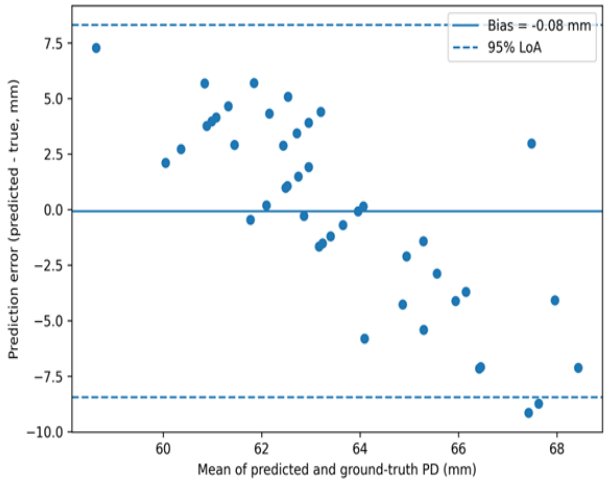

Fig. 3. Bland-Altman analysis of nested AutoML PD estimation.

The predicted-versus-ground-truth plot in Fig. 2 shows that the AutoML predictions were concentrated within a narrower prediction range than the ground-truth PD values. This indicates that the model learned a calibrated central tendency but had limited ability to fully represent the extremes of the PD distribution. This behaviour is common in small-sample regression models, where predictions may shrink toward the mean when the training set contains limited variation [18].

D. Agreement Analysis

The Bland–Altman plot in Fig. 3 provides a clinically interpretable view of agreement between the nested AutoML predictions and the ground-truth PD values. The average bias was close to zero, which indicates that the learned calibration model corrected the systematic overestimation observed in the direct proxy baseline. However, the limits of agreement remained relatively wide, showing that individual-level prediction error may still be meaningful.

Bland–Altman analysis is useful in this context because correlation or fitted trend alone does not fully describe agreement between a new measurement method and a reference method [19]. Therefore, Fig. 3 is more informative than relying only on the scatter plot in Fig. 2, especially for evaluating whether the method is suitable for measurement-related applications.

E. AutoML Model-Selection Behaviour

The AutoML selection results are summarized in Table III. The selection frequencies indicate that simpler eye-region and geometry-based models were selected more often than the full all-landmark model. The eye-centroid estimator was selected in 46.0% of outer folds, whereas the all-landmarks PLS model was selected in only 6.0% of outer folds. This suggests that the nested selection procedure did not consistently favor the highest-dimensional representation. Nevertheless, the small sample size means that feature selection may still be unstable, and the selected model frequencies should be interpreted as exploratory rather than definitive evidence of feature importance.

This selection pattern suggests that interpretable eye-region features were more stable than the full high-dimensional landmark representation. The relatively low selection frequency of the all-landmark PLS model indicates that using all 468 landmarks did not consistently improve model selection. This is methodologically important because the sample size was small relative to the number of potential landmark predictors. Prediction modelling literature recommends caution when the number of predictors is large compared with the number of observations, since overfitting and unstable selection may occur [17], [18].

F. Comparison Between Direct Proxy and Learned Calibration

The comparison between the direct proxy and nested AutoML model shows that the main benefit of AutoML was not simply reducing error magnitude but reducing systematic bias. The direct canthus-scaled proxy was easy to compute but overestimated PD. In contrast, the nested AutoML model used the same canthus-scaled landmark information while learning a calibration relationship between proxy geometry and reference PD. This explains why the AutoML model achieved a much smaller bias while also improving MAE and RMSE.

For the manuscript, the direct proxy should therefore be presented as a baseline rather than the final proposed estimator. The final model should be described as a calibrated 468-

landmark canthus-scaled PD estimation framework. This framing is important because the 468-landmark FaceMesh model does not provide anatomical pupil centres; consequently, the model estimates PD from canthus-derived ocular proxies rather than measuring pupil-centre distance directly.

G. Practical Implications and Limitations

The proposed approach is useful when only standard 468 FaceMesh landmarks are available, and iris landmarks cannot be extracted. It provides a practical method for converting landmark geometry into estimated millimetres using Malay young-adult normative palpebral fissure width and then calibrating the estimate using nested AutoML.

However, several limitations should be considered. First, the method relies on normative palpebral fissure width rather than subject-specific physical calibration. Second, the eye-centre proxy is derived from canthus landmarks and is not equivalent to a true pupil centre. Third, the dataset contained only 44 subjects, so the reported performance should be interpreted as preliminary. Finally, the model should be externally validated on a larger independent Malay undergraduate cohort before being used as a general-purpose PD estimation method.

Overall, the results support the feasibility of canthus-scaled 468-landmark PD estimation, but they also show that direct geometric conversion is not sufficient on its own. Learned calibration through nested AutoML improved bias and overall error while preserving an interpretable landmark-based measurement framework.

H. Clinical Suitability and Agreement Limits

Although the nested AutoML model reduced the average bias to −0.08 mm, the Bland–Altman limits of agreement remained wide, ranging from −8.45 to +8.30 mm. The total agreement width was therefore approximately 16.75 mm. This level of variability is not acceptable for clinical spectacle dispensing, where centration errors of only a few millimetres can be practically important, particularly for progressive or high-powered lenses. Therefore, the proposed framework should not be interpreted as a replacement for clinical PD measurement using a pupillometer, autorefractor, or trained manual measurement. Its current value is as an approximate proxy-estimation method for research use, preliminary screening, or retrospective datasets where only 468 FaceMesh landmarks are available.

I. Interpretation of the Canthus-Derived Eye-Centre Proxy

The central assumption of the geometric stage is that the midpoint between the medial and lateral canthus provides a stable periocular reference. This assumption is useful computationally because the landmarks are available in the standard 468-landmark FaceMesh representation. However, the canthus midpoint is not equivalent to the anatomical pupil centre. Differences between the proxy and the true pupil centre may arise from gaze direction, eyelid shape, palpebral fissure morphology, subject pose, and landmark localization error. The systematic overestimation observed in the direct proxy baseline is consistent with this limitation. The calibrated AutoML model partially reduced this bias, but it cannot fully recover true pupil-centre geometry when the relevant anatomical landmarks are absent.

J. Effect of Periocular Anatomical Variability

The use of Malay young-adult normative palpebral fissure width provides a population-relevant scale reference, but it does not eliminate inter-subject anatomical variability. Subjects with wider or narrower palpebral fissures than the normative value, asymmetric canthal landmarks, or atypical eyelid morphology may receive inaccurate scale factors. The observed scale-factor variability and palpebral fissure asymmetry support this concern. Future work should investigate sex-specific scaling, subject-specific calibration objects, iris-based scaling when available, and exclusion or quality-control criteria for cases with high canthal asymmetry.

K. Small Sample Size and Model Generalizability

The dataset contained 44 subjects, which is small relative to the number of possible landmark-derived predictors. Although repeated nested cross-validation was used to reduce optimism from model selection, it cannot fully remove the risk of unstable feature selection or limited external generalizability. The results should therefore be interpreted as preliminary internal-validation findings. External validation on a larger independent cohort is required before the method can be recommended for broader deployment.

L. Robustness to Real-World Image Variation

The present dataset contained processed landmark coordinates rather than raw images. Therefore, the study could not directly evaluate the effect of illumination, image blur, camera resolution, head pose, gaze direction, eyelid occlusion, or partial landmark failure. These factors may substantially affect practical performance because the proposed framework depends on accurate detection of canthus and eye-contour landmarks. The perturbation analysis provides an initial landmark-level sensitivity assessment, but image-level robustness must be evaluated in future studies using controlled acquisition protocols and raw image data.

V. Conclusion

This study developed and evaluated a canthus-scaled 468-landmark framework for estimating pupillary distance from MediaPipe FaceMesh landmarks. Since the standard 468-landmark representation does not provide true pupil centres or iris-boundary landmarks, the proposed approach used medial and lateral canthus landmarks to construct eye-centre proxies and to derive a subject-specific metric scale based on normative Malay young-adult palpebral fissure width. This enabled pupillary distance estimation from landmark geometry without requiring iris-refined landmarks or a physical calibration object.

The direct canthus-scaled proxy provided a simple and interpretable baseline; however, it was limited by systematic overestimation because canthus-derived midpoints are not equivalent to anatomical pupil centres. The nested AutoML calibration model improved the estimation by learning the relationship between canthus-scaled landmark features and ground-truth pupillary distance. The use of repeated nested cross-validation reduced optimism from model selection and

provided a more reliable estimate of predictive performance for the small dataset.

Overall, the findings indicate that standard 468 FaceMesh landmarks can support approximate proxy-based PD estimation when combined with population-specific canthus scaling and calibration. However, the approach should not be regarded as a direct clinical measurement of pupil-centre distance. The wide limits of agreement, small sample size, reliance on normative scaling, and absence of true iris or pupil landmarks limit immediate clinical applicability. Future work should validate the framework on a larger independent cohort, compare simple calibration models with AutoML models, evaluate robustness to landmark and image-level errors, incorporate sex-specific or subject-specific scaling, and benchmark the 468-landmark approach against iris-refined landmark models and standard clinical PD measurement instruments.

A Hybrid CNN-Ensemble Framework for Robust DeepFake Image Detection

Mohammad Alsulami
College of Computer Science and Information Systems, Najran University, Najran, Saudi Arabia

***Abstract*—The fast development of deepfake technologies has caused growing concerns related to the authentication of digital media, the integrity of personal identification, and the spreading of disinformation. Therefore, there is a growing need for effective automatic detectors of deepfakes. Meanwhile, existing techniques of deepfake detection encounter a large number of difficulties. First, it is difficult to distinguish the subtle manipulation details of faces. Another problem is poor generalization when applying models to novel datasets or highly realistic, generated synthetic faces. Another issue is low accuracy in the case of imbalanced data, where samples of one class dominate others. Thus, to address those problems, this study proposes a novel hybrid approach based on a combination of deep learning (DL) and conventional machine learning (ML) for detecting deepfake images. More precisely, two pre-trained CNNs (MobileNetV2 and ResNet50) were applied to generate features and classify them via the Random Forest (RF) algorithm. The experiments have been conducted on a benchmark of 6,557 facial images marked as either real or fake. The findings reveal that the MobileNetV2+RF achieved the highest accuracy 99%, followed by MobileNetV2 with 98% and ResNet50 with 97% accuracy. This suggests that the hybrid architecture helps to increase the effectiveness of the solution. A statistical significance test reveals that none of the models' performances differ significantly from each other ($p > 0.05$). Overall, the proposed system demonstrates excellent metrics concerning accuracy and precision.**

I. Introduction

The rapid evolution in the fields of artificial intelligence (AI), deep learning, and multimedia technologies has transformed the way people interact and engage in creating digital information [1]. Currently, smartphones, laptop computers, and sophisticated computer systems provide individuals with the capacity to develop, disseminate, and access digital multimedia in a faster way by using online platforms. This technological development has enabled many benefits in fields such as entertainment, the educational sector, health care services, and even social media communications. However, they have posed many problems associated with digital security and integrity [2]. Deepfake technology is one of those serious problems.

Deepfakes refer to media that have been modified using digitally manipulated images, videos, or audio that were produced through artificial intelligence techniques [3]. The artificial intelligence used includes generative adversarial networks and autoencoders. Through this technology, highly accurate fake faces and voices have been produced since the technology is capable of mimicking human facial expressions and their voices. Deepfake technology has experienced great progress ever since its invention in 2017 due to the emergence of free and available artificial intelligence technology, the availability of big data online, and the availability of computational power [4].

Misuse of deepfake technology has caused several significant threats to individuals, organizations, and even society as a whole. The uses of deepfakes have been identified to mislead people, shape their opinions politically, engage in identity fraud, conduct financial crimes, and create inappropriate content. Social media platforms like Facebook, Instagram, Youtube have made deepfake videos and other forms of content go viral on the internet in an instant due to the speed at which information can travel over them. On the other hand, deepfake technology is a concern in many fields, including forensics, surveillance, and biometrics [5], [6], [7].

Facial recognition and identification systems based on conventional methods depend heavily on using biometric data associated with the face. In most cases, such algorithms do not cope with the identification of manipulated images of people's faces. They are less efficient with images that have undergone various types of manipulations, such as blur processing, compression, sizing, filtering, and enhancement. Meanwhile, development in the field of image manipulation and AI-based face generation has increased the realism of synthetic faces [8], [9].

To address these issues, recent works in this field have been concentrating on designing techniques for automatically detecting deepfakes through deep learning methods. Convolutional Neural Networks (CNNs) have been mostly applied since they are able to efficiently extract visual features from these manipulated images. Models like MobileNetV2 and ResNet50 are usually used because of their excellent ability to do so, along with being computationally efficient. Nevertheless, it might not be effective to solely rely on deep learning-based techniques for obtaining the optimal results [10] [11].

Recent studies reveal that a combination of deep learning methods with classifiers of machine learning is useful for enhancing detection precision and reliability of the overall framework. Methods of machine learning, such as Random Forest (RF), Support Vector Machine (SVM), and Logistic Regression (LR), can be used to make decisions using features obtained from CNN algorithms. Hybrid models tend to increase efficiency, feature exploitation, and generalization power over pure deep learning-based frameworks [12].

Even though advancements have been made to improve deepfake generation and detection systems recently, current facial forgery detectors still experience certain limitations while working with sophisticated manipulations within realistic images. In particular, traditional approaches demonstrate decreased effectiveness in the presence of manipulations performed by means of compression, resizing, filtration, and blurring. Moreover, several current approaches require the use of a deep learning classifier only, meaning the high level of computation costs and inability to work efficiently with diverse manipulated images. Conversely, the fast development of AI-based facial image manipulation has led to the necessity of creating new detection systems, allowing for achieving both effective feature extraction and efficient classification in order to ensure higher levels of performance and detection effectiveness. Thus, there is a significant need for developing an approach for deepfake detection that would involve both deep learning and machine learning algorithms [13], [14].

The reason behind developing a dependable, effective, and generalized model for detecting deepfakes became one of the key areas of study in digital security and forensics. Reliable frameworks are needed to maintain confidence in digital media, develop biometric recognition systems, decrease the dissemination of misinformation, and verify the authenticity of digital data.

The primary goal of this research work is to design a detection model utilizing deep learning and machine learning techniques. In the proposed approach, pre-trained CNNs would be used to extract the features from the images. Machine learning classifiers would be utilized to increase the reliability and performance of the detection algorithm. To achieve our objective, the proposed study was designed following the research questions (RQ):

RQ1: How effectively do transfer learning-based CNN models like MobileNetV2 and ResNet50 help in detecting important facial characteristics to detect deepfake images?

RQ2: Is there any improvement in the detection of deepfake images if we combine ML classifiers such as Random Forest (RF) with deep learning-based facial feature extraction methods?

RQ3: Which is the most suitable and accurate combination of deep learning models and ML classifiers for detecting deepfake facial images?

Some of the key contributions of this research work are as follows:

- A novel framework for detecting deepfakes by implementing machine learning and deep learning approaches has been introduced.
- Deepfakes have been detected by using transfer learning-based CNN architectures such as MobileNetV2 and ResNet50.
- Different machine learning classifiers like RF, SVM, and logistic regression have been utilized to increase classification performance.
- Data augmentation, class imbalance problem, early stopping, and learning rate scheduling have been utilized to enhance generalization performance.
- Experiments were performed based on the ROC curve, confusion matrix, and comparative analysis of accuracy.

This study is significant since it helps in solving one of the biggest issues currently facing digital security: identifying manipulated facial content using Artificial Intelligence. This study presents some contributions to cybersecurity, biometrics, digital forensics, and media validation through the improvement of AI deepfake detection technology. This study is practically applicable to social media monitoring, online identity verification systems, surveillance systems, and misinformation detection, among others. Additionally, the use of deep learning and machine learning in this process gives a precise and effective computational method to help design intelligent security systems in the future.

The rest of the study is structured as follows: Section II identifies the key research gap. In Section III, detailed steps for conducting the proposed study are discussed. Key findings, interpretation, and discussion are explained in Section IV. Section V outcome / future directions are presented.

II. Literature Review

Deepfakes are facial images that are generated using AI. It is a major problem for the security of the web, privacy online, and the authenticity of data present online. Several deep learning architectures can be used to detect DeepFakes. There are several pretrained CNN architectures, such as Inception netv3, Resnet 50, Resnet 101, and DenseNet121, trained using available benchmark datasets such as real and fake face detection using 2k samples, real versus fake face detection using 140k samples, and deepfake and real images using 190k samples. The efficiency of these pretrained CNN models depends on the availability of the number of samples and their resolution. The current pretrained models do not perform well in terms of efficiency; for example, a pretrained model performs with an accuracy of 55% in an imbalanced and limited data set, such as the one with a real and fake data set of 2k samples. In this study, a hybrid DL model combining both the capability of a pretrained model and a GAN with an SE attention mechanism achieves an accuracy of 89% [15]. With the rising cases of counterfeit digital images and increasing adoption of the deep fake technology, there is a need for developing efficient algorithms that can be able to detect counterfeit pictures. This study [16] provides a deep neural network algorithm known as DeepFaceGuard with an objective of detecting counterfeit pictures using a multi-layer architecture in order to ensure low detection time without compromising on accuracy. A pre-trained model of VGG-16 was used to increase visualization, while the principal component analysis technique was used to reduce dimensions. Accuracy and F1-score of 0.83 were some of the measures used to evaluate the proposed model by use of 140,000 image dataset. It was found that DeepFaceGuard had an accuracy of more than 83%. This shows its efficiency in detecting counterfeit images. DeepFaceGuard attained a verification accuracy of 84% in only 184 seconds (8 seconds × 23 epochs). Prior studies involved residual convolutional blocks or the use of an attention mechanism for DF detection; unfortunately, most researchers

consider each of these separately without any emphasis on fairness, out-of-distribution generalization, statistical tests, or artifact-based detection. This study [17] proposes a method named ARC-Net that employs both attention and residual convolutional blocks, along with a popular base, EfficientNet B0, and an attention mechanism. For testing ARC-Net alongside the rest of the four pre-trained DL models, a real image dataset of 500 images from Bangladesh, in addition to a 140k mixed real and fake faces data set, was used. ARC-Net outperformed the traditional and state-of-the-art methods significantly with an accuracy of 99%, a precision of 1.0, a recall of 0.97, and an F1 score of 0.98, obtaining the best possible reliability for DF detection. For evaluating the external validity and generalizability of ARC-Net, two new data sets, the Deepfake dataset and the Deepfake database, have been tested for the model, and it showed consistent and highly reliable results in all experiments conducted, which also include varying scales. Three OOD tests were performed; the first test examined the South Asian dataset, and we observed that including less than one percent of the actual Bangladeshi image data lowered the FPR and enhanced the probability calibration significantly, whereas the other two cross-dataset tests exhibited high transferability. We have also done an ablation test to observe the effect of various components in a model by deleting and changing them, and we have used McNemar's Statistical Test to determine statistical significance between rival classifiers. Furthermore, we have utilized Explainable AI (XAI) approaches such as Grad-CAM and LIME to provide transparency regarding the outcomes, considering that the facial region needs to be prioritized for detection. The fast-paced development of Deep Learning (DL) algorithms has caused the extensive emergence of DeepFake (DF) images in real life, which raises real-life challenges. In the present work, DeepDect is proposed and evaluated within a real-life context. The platform has been developed through a human-centered approach, considering insights (requirements) from both regular users and DF experts. The most effective DL models (ResNet-50 and Random Forest for face-swapping detection, Capsule Forensics v2, and CNN for AI-generated images) have been incorporated into the platform as a detection engine. An Explainable AI (XAI) module has been designed and incorporated into DeepDect for visual (Grad-CAM heatmaps) and textual explanations. Real-life evaluation has been conducted with the participation of 108 users to measure the performance of DeepDect against humans. DeepDect has obtained 81% detection accuracy and outperformed human users in terms of DF detection rate, emphasizing the necessity for such a solution in real-life contexts [18]. With the fast development of face manipulation techniques through Generative Adversarial Networks (GANs) and Stable Diffusion-based approaches, this study [19] presents an investigation into the topic of deepfake content generation. This study examines the possibility of utilizing Vision Transformers (ViTs) for deepfake image detection based on the ability of such networks to extract global features. To determine the efficiency of ViTs for multiclass deepfake image detection was used. The proposed model shows high levels of accuracy, precision, and recall, and the F1 score of 99.90% on a multiclass-prepared dataset. The presented findings show that there is a great potential in ViTs to help make the internet safer from deepfake threats, especially caused by Stable Diffusion and StyleGAN2. The developed model demonstrated better performance than state-of-the-art CNN-based models, i.e., ResNet-50 and VGG-16. Currently, deepfakes have been considered a popular research area because of the considerable improvements made in the field of artificial intelligence (AI). Images produced by the generative AI system are realistic and entirely new. Hence, detecting the fake material using AI is very important. In this study[20], transfer learning was implemented on four models, including VGG16, VGG19, MobileNetV2, and ResNet50V2. The proposed model in this study is the one that is developed based on the pre-trained VGG16 model. In this method, we used the input of the VGG16 model along with the output of two more convolutional and MaxPooling layers for further feature extraction after concatenation, followed by three dense layers. According to the experimental values provided in this study, the proposed model achieves better performance compared to other approaches with 98.4% accuracy rate. It can be concluded that the detection of deepfakes will be feasible in the future through machine learning techniques. Deepfake technology development has outpaced that of video manipulation detection methods, posing some issues in terms of media security and forensic digital analysis. In this case study [21], we implemented a multimodel machine learning approach by implementing traditional as well as modern deep learning classifier models for deepfake video detection. For our case, the experiment made use of a subset of the dataset, which included 401 samples of training and 400 samples of testing data, but with an imbalance in classes in favor of FAKE videos. Our methods involved data preprocessing, EDA, face detection using Haar Cascade Classifiers in OpenCV, and data feature extraction. Models, including Random Forest, Support Vector Machines, and Convolutional Neural Network (CNN), among other models, were trained and tested using the model accuracy, precision, recall, and F1 score as metrics. Our deep learning model performed better than any other model in all metrics, indicating its capability in deepfake video detection. The study above shows how deepfake video detection requires a combination of classical and modern machine learning techniques. With the rise of hyper-realistic fake media generation techniques through deep learning applications, there is a need for detecting the authenticity of images online. In this study [22], an ensemble learning-based technique integrating InceptionV3, VGG16, and Xception architectures was applied to develop a deepfake detection system. The method yields an accuracy of 97.40% with 97.00% sensitivity and 98.00% specificity on a balanced dataset containing 70,000 real and 70,000 fake images. A comparison with ResNet50 and EfficientNet baseline models shows that our model is 5.6% more accurate than ResNet50 and 3.0% more accurate than EfficientNet in terms of AUC. Our findings indicate that the proposed method is promising in addressing the problem of detecting deepfake images. To assess the reliability of the developed model, extensive experiments were performed using a large number of real and synthetic images. In addition, Grad-CAM (Gradient-weighted Class Activation Mapping) was used to interpret the decision of the model. The deepfake videos have been distributed in recent years using several deepfake techniques (i.e., faceswap, face2face, etc.). The aim of this study [23] was to design a model that helps detect deepfake videos. Two hybrid models, consisting of a combination of machine learning and deep learning, were proposed. The first hybrid

model used CNN (convolutional neural network) for feature extraction along with different classifiers in machine learning, namely, SVM (Support Vector Machine), KNN (K-nearest Neighbor), DT (Decision Tree), RF (Random Forest), Logistic Regression, and Naive Bayes. In comparison, the second hybrid model utilized the concept of transfer learning using the VGG16 (Visual Geometry Group) pre-trained model and the same classifiers as the first model. Evaluation of both the hybrid models was done using the video dataset, FaceForensics++, containing four types of deepfake techniques: Deepfake, Faceswap, Face2Face, and Neural texture. Results obtained for both models were found to be promising due to high accuracy scores, proving the effectiveness of the proposed models that can be employed in the construction of a deepfake detector application. The first hybrid model gave maximum accuracy with the SVM classifier for the four deepfake techniques: 0.96, 0.87, 0.90, and 0.64, respectively. The impact of deepfake videos is immense and can range from identity theft to spreading misinformation to national security threats. Hence, there is a dire need to improve the performance of the algorithm used in deepfake detection. In this research [24], various feature extraction methods have been used to leverage the use of deep learning algorithms like Xception and ResNet50 in detecting deepfakes in a video using the DFDC data set. Further, several hybrid models comprising eight were created through the use of classification algorithms like SVM, KNN, MLP, and RF. ResNet50 and RF hybrid model showed the most promising results in terms of the accuracy rate, which stood at 98% and an area under the curve (AUC) of 99.65%. The emergence of manipulation on digital media poses a serious threat in today's society, hence the need to have accurate and reliable means of detection of these fakes. To provide an appropriate response to the problem, the study [25] proposes a novel hybrid structure known as CMNV2, which incorporates MobileNetV2 along with an invented CAFFE block. By simply introducing five extra layers in a pre-trained structure, this architecture is able to withstand even the most complicated situations in the real world to score 99.10% accuracy against 13 other CNN structures. The present study trained and tested the proposed CMNV2 architecture through DNNs, TL, and DL on 5,000 images that were divided into real faces and deepfake faces. When compared to the 13 CNN architectures in terms of some important parameters, the proposed model was superior in terms of accuracy, precision, recall, F1-score, error rate, and efficiency.

III. Methodology

This study presents an integrated method to detect deepfake images based on deep learning and machine learning techniques. The technique relies on the use of pre-trained CNN models to identify key features of the image, which are further used to classify them using conventional machine learning algorithms. The proposed methodology is based on a whole workflow, involving image preparation, dataset splitting, data augmentation, extraction of deep features, classification, and evaluation stages as illustrated in Fig. 1.

1) Data set collection and preprocessing: All the experiments in this study were conducted on the Deepfake Detection Dataset 2026, which was retrieved from the Kaggle portal [26] some samples images are shown in Fig. 2. It is a large dataset for detecting deepfakes, which includes facial images that are specially designed to help analyze deepfakes using machine learning methods. In the given facial image dataset, there are 6,557 images, which can be classified into two categories (2,790 real images and 3,767 fake images). The real images were obtained from Unsplash and include portraits of people of all age groups and genders. The artificial face images were generated by implementing highly sophisticated AI-based image generation algorithms, such as StyleGAN3 another. One of the key aspects that distinguishes this dataset from other commonly used deepfake image datasets is that it comes with comprehensive metadata information, which can be useful for conducting advanced analysis experiments using machine learning. The given dataset includes 17 different attributes that fall into the following categories, represented in Table I.

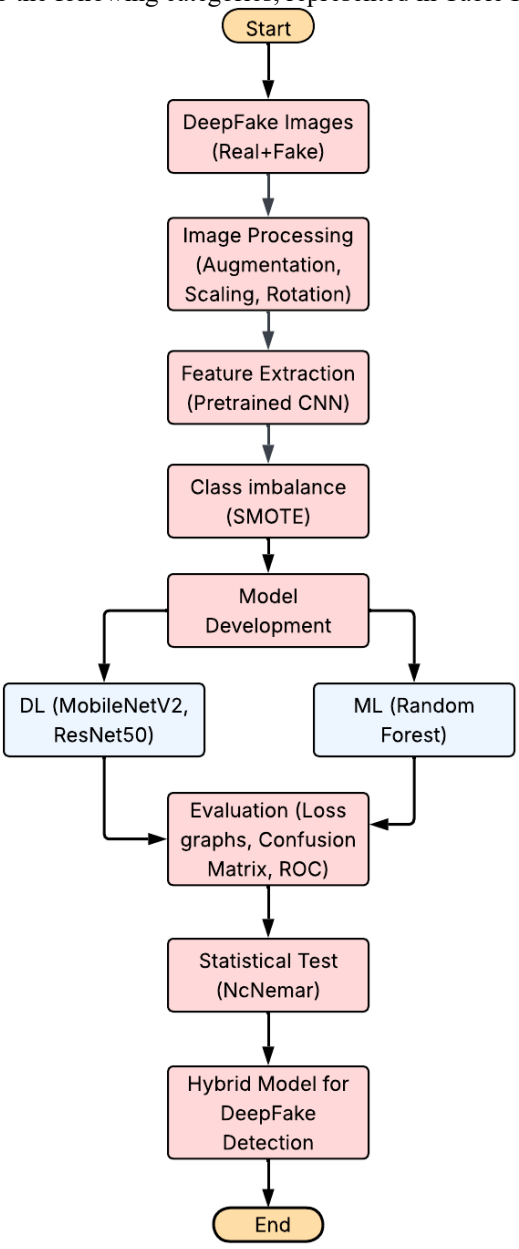

Fig. 1. Overall methodological flow chart of the proposed model.

TABLE I. DATASET CHARACTERISTICS

Dataset Characteristics	Values
Text Attributes	11
Numerical attributes	2
Unique	1
Others meta data	3
Class labels	Real or Fake
Difficulty level	Easy, Medium, Hard
Confidence score	Numeric
Source information	Text
Generation method information	

Only the high-quality faces were used in this dataset.

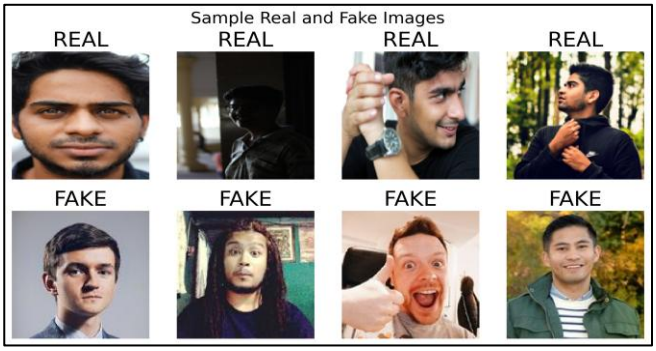

Fig. 2. Some sample images.

2) Image acquisition and preprocessing: All images are downloaded dynamically from URLs using HTTP requests. The preprocessing pipeline is shown in Fig. 3.

Fig. 3. Steps of preprocessing.

This preprocessing standardizes input dimensions and improves neural network convergence stability.

3) Data augmentation: Real-time augmentation of the dataset was done to increase the generalization capabilities of the model and minimize the risk of overfitting by applying augmentation only on the training set via the use of TensorFlow's ImageDataGenerator. Several types of augmentation were done to generate different variations of the face [27]. Fig. 4 shows the data augmentation parameters.

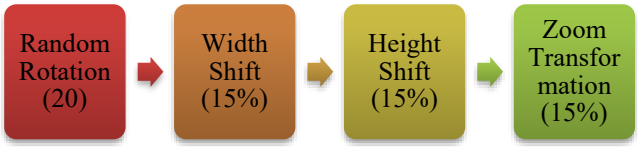

Fig. 4. Data augmentation parameters.

Fig. 4 shows the data augmentation parameters applied to images. This is to ensure that the model performs well and detects deepfake photos regardless of how the person looks in the real world.

4) Feature extraction: Feature extraction is one of the most crucial stages in the proposed system. This research utilizes pretrained convolutional neural networks (CNN) architectures as automatic feature extractors. Unlike handcrafted feature engineering, CNNs learn hierarchical spatial representations directly from facial images [28]. Given an input image be denoted as:

$$X \in \mathbb{R}^{H \times W \times C} \quad (1)$$

The conventional operation with K learnable convolution kernel and the extracted local feature map are represented as $(X * K)$, mathematically defined as:

$$(X * K)(i,j) = \sum_m \sum_n X(i-m, j-n)K(m,n) \quad (2)$$

These layers detect facial textures, blinding artifacts, compression traces, and illumination inconsistencies. The CNN extracts multilevel semantic representation using 3 layers: an early layer that learns low-level patterns using Eq. (3)-(5).

Eq. (3)-(5) represents the hierarchical feature learning conventional neural network, where each layer extracts progressively more abstract representations from the input image. The first layer captures low-level visual patterns learn more complex and discriminative features. The parameters W *and* b denote learnable weights and bias, $\sigma(.)$ denotes the nonlinear activation function.

$$\boldsymbol{F^{(1)} = \sigma\left(W^{(1)} * X + b^{(1)}\right)} \quad (3)$$

$$\boldsymbol{F^{(2)} = \sigma\left(W^{(2)} * F^{(1)} + b^{(2)}\right)} \quad (4)$$

$$\boldsymbol{F^{(3)} = \sigma\left(W^{(3)} * F^{(2)} + b^{(3)}\right)} \quad (5)$$

Furthermore, each convolution layer produces an activation map:

$$F_K = \sigma(W_K * K + b_K) \quad (6)$$

where,

- W_K: convention filters
- b_K: bias term
- σ: activation function

These feature maps are then compressed using global average pooling (GAP). For the feature map F_K :

$$g_K = \frac{1}{HW} \sum_{i=1}^{H} \sum_{j=1}^{W} F_K(i,j) \quad (7)$$

Thereby preserving dominant semantic activation.

The final feature representation can be mathematically expressed as:

$$f = [g_1, g_2, \ldots \ldots g_d] \; where \; f \in \mathbb{R}^d \quad (8)$$

This feature representation includes spatial inconsistencies, blind spots, and illumination.

The final feature vector generated through the (GAP) layer was provided as an input to the Random Forest classifier for the classification stage. The final feature vector included high-level features extracted by the network and characterized various aspects related to facial texture changes, lighting changes, compression distortions, and manipulation-related features. In order to make sure that all the features have equal weight in terms of classification, the z-score normalization was performed on the extracted features.

Dimensionality reduction techniques were not used since the GAP layer provided the compact representation of the input features. Thus, the normalized feature vectors were supplied directly into the Random Forest classifier. The classifier was designed using 100 decision trees and the Gini impurity criteria for splitting nodes. The bootstrap method was used to improve the generalization ability of the model. Moreover, the number of features for splitting was selected based on the square root rule. These configurations were chosen since they are commonly used for deep feature classification and have proved their effectiveness in the experimental analysis.

5) Handling class imbalance: There is a minor imbalance of classes, where the number of images that are not real is higher than that of the images that are real. To avoid bias towards the majority class when predicting, the class weights are assigned inversely to their frequencies, as demonstrated in Fig. 5. This was done during the training process, whereby the neural network could be trained to perform well for both classes of images. To solve the problem of unbalanced classes in the training dataset, SMOTE is employed. This approach helps synthesize more artificial samples for the class that is poorly represented by creating new samples based on existing features. Consequently, this improves the ability of the model to generalize from minority examples and eliminates any biases. To preserve the integrity of the evaluation process, SMOTE is not used for the test dataset but only for the training set to achieve the objectives [29].

6) Model development: In this study, 2 pre-trained DL models, such as MobileNetV2 and ResNet50, and 1 ML classifier, such as RF, are used.

a) MobileNetV2: MobileNetV2 was selected for this research due to its compact and efficient architecture that allows for less computational complexity. Depth-wise separable convolutions make it possible for the network to use a minimal amount of parameters and still perform efficient feature extraction.

b) ResNet50: ResNet50 was selected based on its ability to learn features in a deep network thanks to residual connections. Such an approach allows overcoming the problems associated with vanishing gradients and facilitates the process of training deep networks [30]. Models used in this research were pretrained with the ImageNet dataset with the following parameters:

- Include_top=False
- The convolutional part was not trainable during the initial training phase.

c) Random Forest Classifier (RF): RF is an ML classifier used to generate multiple decision trees. Predictions are made through a consensus of those trees, which enhances the accuracy and robustness of predictions. It is efficient in dealing with serious dimensional problems as well as in the identification of nonlinear associations between the behavioral (Fig. 6) [31].

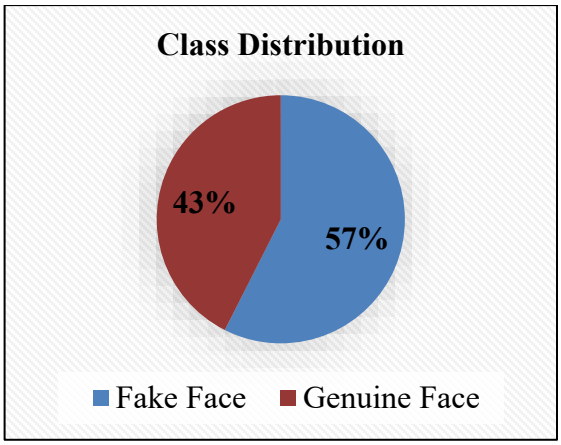

Fig. 5. Class distribution.

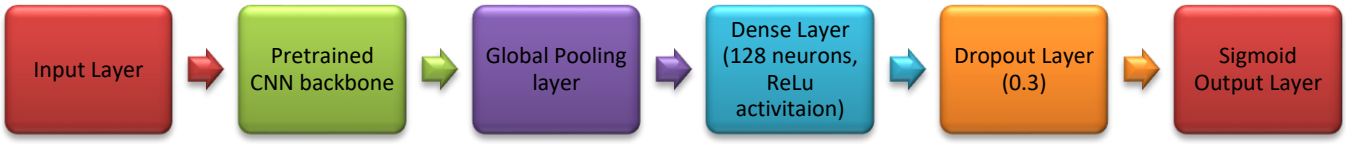

Fig. 6. Deep learning architecture parameters.

7) McNemar test: McNemar's test is a statistical procedure that can be used to make a comparison between two classifiers based on the same set of data. As opposed to testing overall accuracy, it tests the points where the two classifiers disagree. It is thus more appropriate for determining the differences between two classifiers [32].

8) Experimental setup: This experimental setup was designed to evaluate the efficacy of various ML and DL approaches that were utilized to detect real and fake faces. All experiments were conducted within the Python programming framework, utilizing typical libraries for analyzing and modeling data through machine learning techniques. Training was performed for up to 40 epochs with a batch size of 8. In order to make the training more efficient and improve the performance of the model, two callbacks were introduced.

a) Early stopping: The training was terminated automatically if no improvements in the validation loss

occurred within five epochs. This ensured that training stopped at the appropriate point, avoiding any overtraining.

b) Reducing learning rate on plateau: Another callback introduced was related to the adjustment of the learning rate. If the validation loss does not change over three epochs, then the learning rate is adjusted by multiplying with 0.5 [33].

The sigmoid activation function computes the probability of fake classes by:

$$\sigma(x) = \frac{1}{1+e^{-x}} \quad (9)$$

Moreover, binary cross-entropy was employed as a loss function, which can be mathematically calculated as:

$$l = -\frac{1}{N}\sum_{i=1}^{N}[y_i \ log(\hat{y}_i) + (1-y_i)\, log(1-\hat{y}_i)] \quad (10)$$

The Adam optimizer was used as a gradient optimization because of its adaptive learning-rate capability [34].

To prevent data leakage between subsets, the division of the dataset was made before the beginning of training. All the preprocessing techniques, including SMOTE oversampling and data augmentation, were applied only to the training subset. The validation and test subsets were untouched during the experiments to preserve their properties as representative data. Moreover, the feature extraction process based on the use of pretrained CNN models was performed separately on each subset. Despite the absence of identity, generation source, and near-duplicate relations labeling in the dataset, sample isolation was made during all stages of the experiment. In general, the described experimental configuration allowed obtaining unbiased results regarding the performance of the model on unseen data.

TABLE II. DISTRIBUTION OF SAMPLES

Training Samples	Validation	Testing Samples
2100	297	603

Table II depicts the distribution of samples into training and testing. To ensure consistency and reproducibility, the dataset was organized into a total samples (3000), consisting of both real and manipulated facial images. The dataset was divided into 70% (2100) samples, which were used for training, 297samples (approximately 10%) were used for validation, and 603 samples (approximately 20%) were used for testing. As for ML models, 70% used for training and 30% were used for testing, thereby maintaining consistency and enabling a comparison between the two methodologies. As far as DL methods are concerned, part of the training data set was kept for a validation data set, which helps in monitoring the progress of learning by the model, tuning the hyperparameters of the model, and minimizing the problem of overfitting. Whereas in the case of ML methodology, no separate validation data set was used because the training process involved in ML is much less complex as compared to DL methods.

IV. RESULTS AND DISCUSSION

The objective of this study is to evaluate the performance of various ML and DL classifiers for deepfake detection across multiple measuring standard metrics such as confusion matrix, loss graphs, ROC curve, etc.

TABLE III. PERFORMANCE EVALUATION OF ML MODELS

ML models	Accuracy	Precision	Recall	F1 score
MobileNetV2	98%	90%	91%	90%
MobileNetV2+RF	99%	98%	97%	97%
ResNet50	97%	93%	94%	93%
ResNet+RF	98%	94%	92%	92%

Table III presents the performance of various ML and DL models across all four measuring metrics. The obtained experimental results clearly indicated that hybrid CNNs combined with ML classifiers outperformed CNN models. The best performance was achieved by (MobileNetV2+RF) accuracy (99%), precision (98%), recall (97%), and F1score (97%). RF helps increase the performance of DL and decrease erroneous classifications by integrating feature extraction with accurate classification. Moreover, the ResNet+RF model also showed higher performance rates compared to ResNet50 alone, where accuracy was increased from 97% to 98%. This indicates that hybridization leads to improved feature extraction and discrimination. High performance of MobileNetV2+RF can be attributed to efficient feature extraction of MobileNetV2 through depthwise separable convolutions, which were followed by feature classification via RF. The results have once again proved that hybridizing CNN models with machine learning classifiers yields higher levels of stability and accurate classification compared to deep CNN-based classifiers.

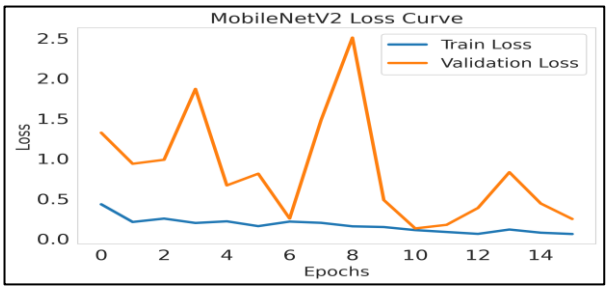

Fig. 7. Loss curves for the MobileNetV model.

Fig. 7 represents the training and validation loss of the MobileNetV2 model over 40 epochs. The decrease of MobileNetV2 training loss appears to be stable, meaning that the network successfully learns from training data and reaches good convergence during optimization. As the training loss consistently decreases, it is reasonable to believe that the network successfully extracts information from the provided training samples. The validation loss demonstrates inconsistent results and experiences sharp increases from time to time. This indicates the problem of overfitting when the neural network performs well on training data but has poor generalization capabilities when processing unknown samples. Altogether, even though the network successfully learns from training data, it requires further refinement to improve its generalization capabilities.

MobileNetV2 Validation Loss Plot demonstrates some fluctuations throughout the training process and even some

spikes. Such behavior might be a hint at a minor case of overfitting, but despite that, the overall plot tends to converge, which implies that learning is taking place. Fluctuations may be associated with the dataset variation and a relatively small number of records in the validation dataset. To improve the training stability, future improvements might include more aggressive regularization, changing the dropout probability, or using data augmentation.

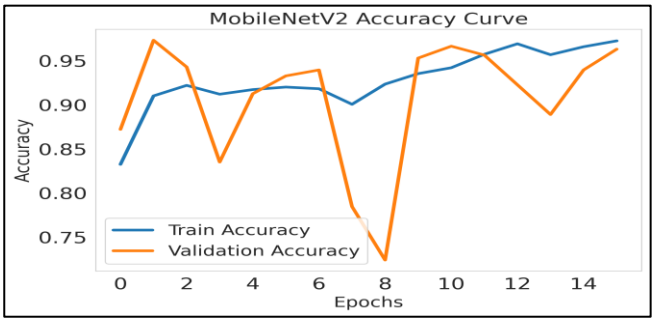

Fig. 8. Model accuracy curve.

Fig. 8 depicts the accuracy graph of the MobileNetV2 algorithm; the accuracy of the learning process by the network is good. With an increase in the epoch numbers, the training accuracy of the algorithm has been seen to increase. The validation accuracy increased along with the training accuracy; however, there have been slight differences in certain epochs due to differences in the validation data. By the last epochs of training, the validation accuracy and training accuracy are both seen to be around 96–97%. This suggests that the algorithm performed well and that there was no overfitting.

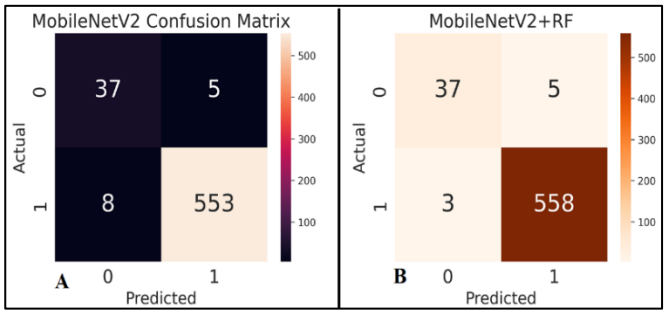

Fig. 9. Confusion matrix for MobileNetV2.

Fig. 9 shows the confusion matrix of MobileNetV2 (A) and MobileNetV2+RF Classifier (B). In Fig. 9(A), the total number of samples accurately classified as negative is 37, and the positive samples are 553. Also, 5 positive samples were wrongly classified as negative, and 8 positive samples were wrongly classified as negative. After using the RF Classifier with MobileNetV2, the correct positive samples classified were 558, and there were only 3 samples classified as negative from the positive class. There was no difference in correctly classified negative and false positive samples, which are 37 and 5, respectively. This implies that the combined model had high accuracy in terms of recall value for positive samples. The high effectiveness is due to the efficient use of the deep learning model by the RF Classifier. The hybrid model used ensemble learning to improve class separability and decrease the false positives in the positive class.

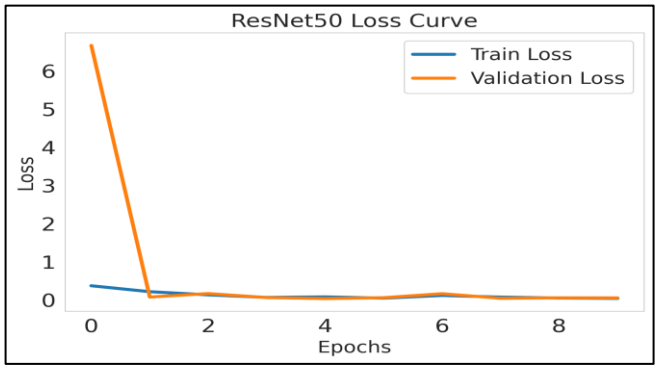

Fig. 10. Train and validation loss curves.

ResNet50 exhibits a smooth and constant learning curve throughout the entire training process, as shown in Fig. 10. Initially, the validation loss is high due to the fact that the model is trained with random weights in the early stages of training. However, following the first epoch, there is a sharp decline in the validation loss such that it is close to the training loss. The two lines are low for the rest of the training period and move almost in parallel without significant differences. Thus, the model successfully learns the critical elements of the data without overfitting. Moreover, the small gap between training and validation losses implies good generalization.

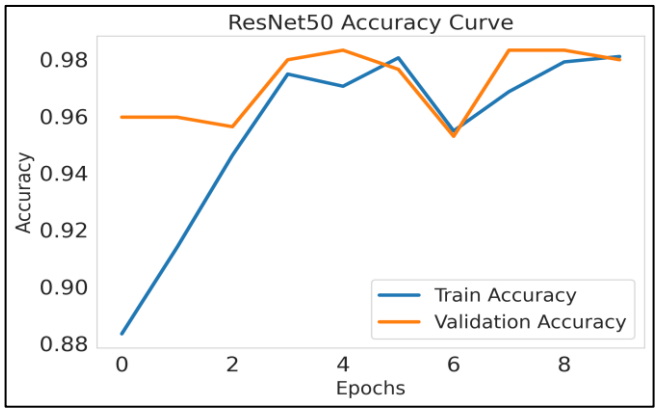

Fig. 11. Accuracy curves for ResNet50.

From Fig. 11, it can be concluded that the performance accuracy of the ResNet50 model is both consistent and accurate over 10 training epochs. The training and validation accuracy of the model increases gradually, and it eventually becomes almost 98%. Initially, the training accuracy starts at a point of 88%, and this implies that the model is learning important characteristics. The validation accuracy is fairly high and has small variations, meaning that the model does not suffer from much overfitting, and it has excellent generalization capabilities. This is evident since the training and validation graphs remain close for all epochs, meaning that the model does not experience problems related to overfitting and underfitting. There is no wide gap between the two lines, which implies that the ResNet50 model works well since it allows easy learning of deep networks. The residual learning technique makes gradient flow easy, and consequently, efficient learning becomes possible.

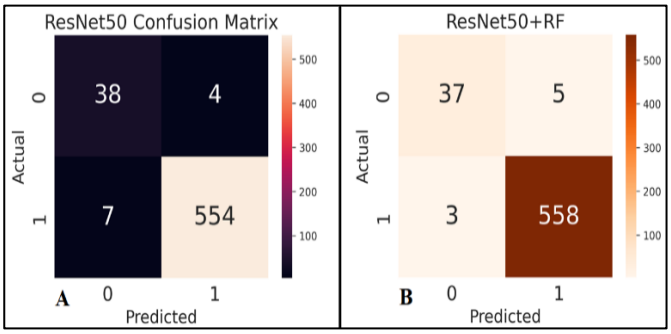

Fig. 12. Confusion matrices for ResNet50.

Fig. 12 shows the confusion matrices for standalone ResNet50 and ResNet50+RF models. Both the ResNet50 and ResNet50+RF models have an extremely high efficiency level since the majority of samples were predicted accurately. Specifically, the model of ResNet50 managed to correctly predict 38 samples of class 0 and 554 samples of class 1, misclassifying only several other samples. However, the combination of ResNet50 and RF increases the accuracy of prediction, lowering the false negatives to 3 (previously 7) and raising the number of correct predictions for class 1 from 554 to 558. It means that adding the Random Forest model to the ResNet50 algorithm significantly contributes to separating the classes correctly. Thus, the hybrid approach ensures more accurate and stable predictions than ResNet50 alone.

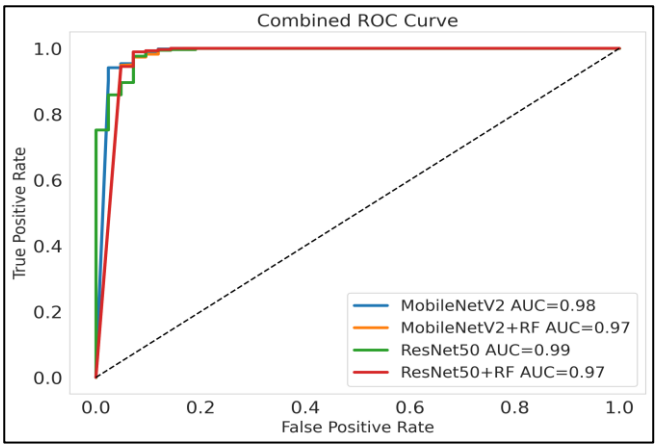

Fig. 13. ROC analysis of models.

Fig. 13 presents the ROC curve analysis results of all models analyzed. From these, the ResNet50 model managed to obtain the highest AUC value of 0.99, reflecting its superior performance in distinguishing classes. The MobileNetV2, with an AUC value of 0.98, while the RF with MobileNetV2(MobileNetV2+RF) model and the RF with ResNet50 (ResNet5+RF) model achieved an AUC value of 0.97. The findings show that the accuracy obtained by these models is quite high, and almost negligible errors were made. From these good AUC values, we can infer that our proposed deep learning models have worked well in differentiating between positive and negative classes. The ResNet50 model has performed better mainly due to its architecture, which enables efficient learning of deeper features in its structure.

TABLE IV. STATISTICAL TEST

Models	Statistic	P-Value
MobileNetV2 vs MobileNetV2+RF	3.2	0.073
MobileNetV2 vs ResNet50	0.05	0.823
MobileNetV2 vs ResNet50+RF	1.067	0.301

Table IV shows the statistical significance results of the comparative analysis among the evaluated models. The findings revealed that there is no statistically significant difference between, as all p-values are greater than the significance threshold of 0.05. Specifically, the comparison between MobileNetV2 and MobileNetV2+RF yields a test statistic of 3.2 with a p-value of 0.073, suggesting marginal improvement, this improvement is not significant. Moreover, it is possible to note that for MobileNetV2 and ResNet50, the p-value equals 0.823, while for MobileNetV2 and ResNet50+RF, it equals 0.301. In both cases, these models have almost similar classification performance levels. Thus, the analysis shows that all the methods provide rather good and quite stable results.

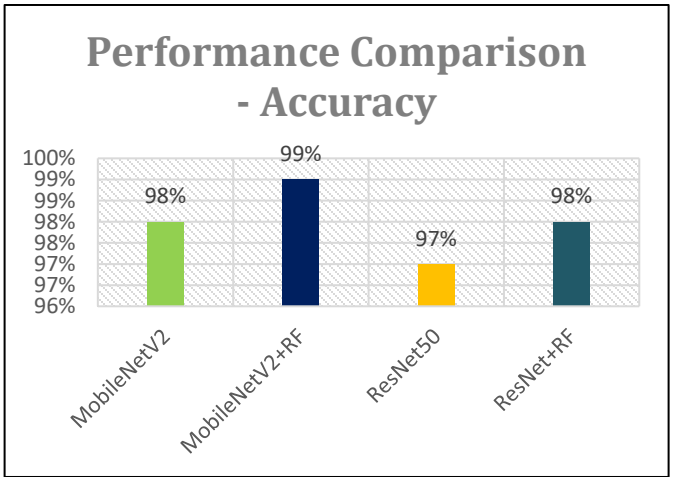

Fig. 14. Comparison of performance of ML/DL models.

In Fig. 14, the comparison of performance in terms of the accuracy metric is shown. The (MobileNetV2 + RF) achieved the highest accuracy rate (99%), attributed to its ability to classify well compared to other models. The model accuracy of MobileNetV2 and (ResNet50 + RF) was same (98%). The difference between their model accuracies is insignificant since they both differ by only 1%. Therefore, the inclusion of the RF algorithm in the deep features helps increase performance stability in classification. The accuracy of ResNet50 on its own was 97% as opposed to other models analyzed in this project. This indicates that the combination of hybrid and deep learning models provides excellent results in classification due to the high accuracy achieved.

V. DISCUSSION

The results of the experiment prove the statement that hybrid models of DL and ML provide better outcomes in terms of deepfake detection accuracy than single-layered CNN architectures, as illustrated in Table II and Fig 14. In particular, MobileNetV2 + RF appears to be the best-performing model that provides the highest accuracy rates among all other models

due to the positive influence of Random Forest on CNN-based image processing. Both MobileNetV2 and ResNet50 models perform effectively without any additional machine-learning model being applied, as illustrated in Table II. The accuracy of both models equals 98% and 97%, respectively. With the help of random forest, the performance of ResNet50 increases by one percent, reaching 98%. All these data suggest the effectiveness of hybrid models, as it was mentioned above. Fig. 14 proves the effectiveness of mobileNetV2 + RF once again.

Though MobileNetV2+RF had the best numerical results compared to other models concerning most metrics, according to McNemar's paired statistical test, there is no significant difference between the performance of the models ($p > 0.05$). It simply means that the performance difference is not statistically significant. Despite the slightly higher accuracy and better stability in the results of the hybrid model, we still cannot prove that there is any practical benefit of such a network over independent convolutional neural networks statistically. Consequently, it should be understood that MobileNetV2+RF only demonstrates better trends in performance. However, considering the improvement in different evaluation criteria, we can state that hybrid CNN architectures can be used in practice to detect deepfakes.

Furthermore, ROC results illustrated in Fig. 13 confirm these findings. ResNet50 has achieved the best AUC score, equal to 0.99, whereas MobileNetV2 is a close second, having an AUC score of 0.98. Hybrid models have obtained an AUC score of 0.97. These findings suggest that all three models are good classifiers with slight differences in their ability to separate classes. Additional confusion matrix results from Fig. 9 and 12 clearly demonstrate that hybrid models effectively decrease the number of false negatives and classify images correctly even in challenging conditions, especially when the Random Forest model is applied to CNN-based feature descriptors. Stable training behavior depicted in Fig. 7, 8, 10, and 11, as well as the absence of any overfitting problems observed with ResNet50, proves that hybrid models can be considered good general classifiers.

In conclusion, it can be stated that Tables II and III, as well as Fig. 7-14 illustrate the superior performance, reliability, and robustness of hybrid models when compared to standalone CNN-based classification methods.

RQ1: How effectively do transfer learning-based CNN models like MobileNetV2 and ResNet50 help in detecting important facial characteristics to detect deepfake images?

According to the results depicted in Table II and Fig.10 and 11, both architectures, namely, MobileNetV2 and ResNet50, demonstrate excellent ability to detect discriminative facial features that could help distinguish deepfakes. The accuracy rate is high for both cases, with MobileNetV2 achieving 98% and ResNet50 reaching 97%. The learning process can be clearly traced with the help of the training and validation curves depicted in Fig. 11 (ResNet50) and Fig. 8 (MobileNetV2), where one can notice the stable and consistent behavior of the curves with a slight gap between the performance of the models during training and validation procedures. Moreover, the ROC curves plotted in Fig. 13 prove the results obtained earlier because both models show high AUC values of 0.98 and 0.99. In other words, they demonstrate their ability to differentiate real images and images that have undergone manipulations.

RQ2: Is there any improvement in the detection of deepfake images if we combine ML classifiers, such as RF, with deep learning-based facial feature extraction methods?

Indeed, the fusion of the RF classifier with feature extractors based on CNNs provides a remarkable enhancement in classification performance according to Table II and Fig. 14. The hybrid architectures, namely MobileNetV2+RF and ResNet50+RF, always surpass the performance metrics provided by the plain CNN classifiers. Specifically, MobileNetV2+RF achieves the highest value of accuracy (99%), while ResNet50+RF improves the accuracy score from 97% to 98%. One can assume that RF assists in improving the decision-making process based on the deeper feature representation obtained via the CNN architecture. Furthermore, Fig. 9 and 12 illustrate that there are fewer cases of false negatives once the Random Forest technique is applied to classification, particularly when considering the performance metrics of MobileNetV2+RF. Thus, it becomes easier to distinguish between the real and manipulated images. As a result, the proposed hybrid approach demonstrates its effectiveness since a fusion of classical machine learning and CNNs helps improve the classification process significantly.

RQ3: Which is the most suitable and accurate combination of deep learning models and ML classifiers for detecting deepfake facial images?

Based on the results obtained from the comparative analysis shown in Table II, as well as the results shown in Fig. 14 and the ROC curves in Fig. 13, it can be seen that the combination of the MobileNetV2+RF model produces the best results for deepfake video identification. This model achieves 99% accuracy, 98% precision, 97% recall, and an impressive 97% F1-score. ResNet50, on the other hand, achieves a higher area under the curve of 0.99 in Fig. 13; however, it falls short of MobileNetV2+RF in terms of performance in other evaluation parameters. The statistics provided in Table III indicate no statistically significant differences among all the models used for testing ($p > 0.05$). This means that despite some deviations, there is no strong statistical evidence regarding the differences between them. Nevertheless, MobileNetV2+RF remains the best option in terms of reliability.

Across all comparisons in this study, the p-values were consistently above 0.05. This implies that despite the small improvements observed in the hybrid models' accuracy, there is no statistical significance in the differences. Generally, the models exhibit relatively even behavior in terms of classification ability.

The proposed framework shows better results for all used metrics, but the experiments were carried out over a single dataset, which makes it difficult to be sure about how the results are generalizable to any other conditions. The absence of cross-dataset experiments and k-fold validation on various deepfake benchmarks makes it difficult to evaluate the robustness of the model to manipulation types that could be applied to deepfakes in practice. Although the presented results indicate good

classification accuracy, more experiments need to be done to confirm the robustness of the model to various datasets.

1) Practical implications: The proposed approach holds practical relevance when applied to detect deepfakes. It can be applied in social networks to automatically detect manipulated images that contain fake information. The efficiency and reliability of the solution mean it could be used in cybersecurity to prevent identity theft and detect fraud. In particular, since the MobileNetV2 is rather lightweight, the solution can be applied even on devices with low computational power, like mobile phones or edge devices. Utilizing the MobileNetV2 as a feature extractor allows making the architecture of the neural network more compact and lowering the computational cost associated with running it. Additionally, the decision not to employ the full-fledged deep learning system in favor of using a Random Forest classifier significantly decreases the complexity of training the model. Additionally, due to the combination of deep learning algorithms with traditional machine learning, the approach can be scaled and used not only for images but also for other data types. The aspects like training time, inference speed, the size of the trained model, FLOPS, and memory requirements have not been evaluated. While these aspects have been considered during design, there was no formal evaluation done. Computational cost is a question that needs to be investigated in the future.

2) Limitations: Although the findings have shown high effectiveness, some limitations still exist in the experiment. First, the dataset, although diverse, is still limited in size when compared to the vast array of deepfake samples in practical situations, thus affecting the model's ability to accurately classify unknown samples that involve more complicated manipulation. Secondly, the proposed method utilizes CNN models trained by other researchers, and therefore, might not necessarily be adaptable enough for new types of deep fakes.

Although the proposed framework was successful in deepfake image recognition, the current study does not include any ablation analysis, through which the specific impact of each component would be examined. Therefore, it is difficult to understand how much the data augmentation, class balancing through the SMOTE technique, CNN-based feature extraction, and Random Forest classification have affected the outcome of the research.

Further study of these components is very important for the future. Through the process of excluding, replacing, and changing one element after another, it will be easier to see how each of the components affects the performance of the proposed framework.

Recent studies suggest that Vision Transformers (ViTs) achieve impressive results in detecting deepfakes, mainly due to the ability to encode long-range dependencies between different parts of an image. The ViT-based approaches have been mentioned in the literature review in order to represent recent advances in the field, but no comparisons with these approaches have been included in this experiment.

Conversely, the proposed study chosen to tackle the problem of detecting deepfakes is a pipeline, consisting of a pretrained CNN-based feature extractor and a Random Forest classifier. Such an architecture has lower computational complexity and is more suitable for working with small imbalanced datasets. For this reason, a comparison with ViT-based approaches has not been performed, as the latter ones have higher demands on the computational resources and a training procedure.

The future direction of this research includes the implementation of ViT-based architectures in order to compare their performance with the state-of-the-art approaches to deepfake detection.

VI. Conclusion

In this study, we presented a hybrid system that uses deep learning and machine learning for recognizing deepfake images, where deep learning with a CNN feature extractor and machine learning with Random Forest were used to improve the performance of each algorithm on its own. Experimental results revealed that MobileNetV2 + RF provided the highest value of accuracy, equal to 99%, whereas ResNet50 + RF and MobileNetV2 were among those with the best performance results. A statistical analysis of the obtained results revealed that there is no significant difference between the performances of various algorithms, implying a stable behavior of all models. Therefore, our work increases both accuracy and reliability.

Future research in this field could focus on increasing the effectiveness of transfer learning for generalizing to novel and unseen deepfake datasets that have been produced by using state-of-the-art deepfake generation techniques. It can also be interesting to explore the applicability of lightweight transformers since they can assist in learning and representation efficiency improvements. Evaluating these methods using other kinds of data, including video streams and live applications, could broaden the scope of use of the proposed system. Furthermore, efficiency improvement through model compression and pruning would enable real-time processing, especially on edge and mobile devices where computational power is limited.

Data Availability Statement: The dataset used in this study for the detection of deepfake images is publicly available at https://www.kaggle.com/code/engrgul/backdoor-ai

A Bibliometric Mapping of Transformer-Based Misinformation Detection: Trends and Gaps

Borhan Ab Rahman, Mohd Zakree Ahmad Nazri, Mohd Ridzwan Yaakub
Faculty of Information Science & Technology, Universiti Kebangsaan Malaysia, Malaysia

***Abstract*—The rapid spread of misinformation on social platforms has intensified research on automated detection, with Transformer-based architectures becoming a primary technical foundation. However, the volume and diversity of publications make it difficult to track the field's evolution. It is also challenging to identify the contributors, influential studies, and remaining gaps that shape its knowledge base. This study presents a bibliometric mapping of Transformer-based research on misinformation detection, based on Scopus records retrieved on 3rd March 2026 (n = 3,637). Performance indicators and science mapping analysis are used to profile publication growth, subject-area distribution, leading countries, institutions, and authors, citation impact, and thematic structure. Results show that conference proceedings (47.18%) and journals (41.93%) dominate dissemination, reflecting both rapid-cycle publishing and archival consolidation. Computer Science accounts for most publications (84.99%), while Social Sciences and Medicine contribute non-trivial shares, indicating applied and societal engagement. China, the United States, and India lead in national output, and institutional productivity is concentrated in a small set of research hubs. Citation indicators (h-index = 82; g-index = 154) suggest a broad influence with a distinct, highly cited core. Keyword mapping confirms a stable emphasis on NLP-driven detection in social media and shows recent growth in multimodal approaches and generative-AI-related topics. The findings provide an evidence-based overview of current trends and emerging directions, helping researchers position future work and prioritize underexplored problems.**

Keywords*—Bibliometric analysis; misinformation detection; Transformer architectures; keyword co-occurrence; citation analysis; Scopus

I. Introduction

Over the past decade, decentralized social media platforms have increased the reach and velocity of online communication. The same properties also increase exposure to misinformation by lowering moderation barriers and enabling rapid cross-community spread, including across languages. The consequences extend beyond online discourse and affect democratic decision-making, public health behavior, and social cohesion. These risks have intensified demand for automated detection systems that can support early identification and timely mitigation [1], [2]. In this study, misinformation is used as an umbrella term, while fake news and disinformation are treated as closely related labels reported in the computational literature.

Research in Natural Language Processing (NLP) has, therefore, moved from feature engineering and classical classifiers toward Transformer-based architectures for contextual representation learning. Early misinformation detection pipelines were typically built around handcrafted lexical or syntactic features with classical classifiers [3]. These approaches remain computationally efficient, but they often degrade under implicit claims, context-dependent semantics, and distribution shifts across topics, platforms or time [4]. Transformer architectures have changed the technical baseline by learning contextual representations through attention mechanisms [5]. Models such as BERT, RoBERTa and more recently, large language models (LLMs) have become standard choices for misinformation detection because they achieve strong performance on benchmark datasets and transfer effectively across varied text genres [6], [7]. The research frontier has also moved beyond text-only classification toward multimodal detection, explainability and robustness under real-world conditions [8], [9].

Despite the volume of technical work, the field lacks a precise macro-level account of Transformer-based misinformation detection as a distinct research stream. Existing reviews often treat misinformation or disinformation as a broad phenomenon and prioritize diffusion patterns, societal implications or general computational approaches [10], [11]. This leaves several important questions unresolved. It remains difficult to identify which venues and publications define the core knowledge base, how collaboration and influence are structured and which themes are consolidating versus emerging, especially given the recent surge of LLM-related research and the growing reliance on multimodal content. Without this structured view, researchers risk duplicating effort, selecting outdated baselines and evaluating systems in settings that do not reflect current threat models [12].

This study addresses that gap through a focused bibliometric mapping of Transformer-based architectures for misinformation detection. Using Scopus records retrieved on 3rd March 2026 and science mapping techniques, the analysis integrates performance indicators with network-based mapping of collaboration patterns, citation impact and thematic evolution [13], [14]. The study also synthesizes research gaps that follow directly from observed publication and topic trends, supporting clearer prioritization of future work.

A. Related Work

Bibliometric and survey studies have examined misinformation and disinformation research from broad perspectives, including publication growth, influential sources and topic structures. For example, Wang et al. [11] provide a bibliometric review of disinformation research, while Xu et al. [10] map evolutionary themes in misinformation dissemination

on social media. Barve and Mulay [13] survey incremental learning for false-information text classification, reflecting continued interest in efficiency and continual adaptation.

These works provide useful coverage of the wider misinformation landscape, but they do not isolate Transformer-based architectures for misinformation detection as a distinct technical stream. Recent reviews often aggregate heterogeneous model families and settings, which can blur how Transformer-centric methods, multimodal pipelines and LLM-related topics are reshaping evaluation practices and research priorities [14]. A focused mapping that integrates performance indicators with science mapping is therefore needed to clarify the intellectual base, contributor structure and thematic evolution specific to Transformer-based misinformation detection.

This study addresses the following research questions. (RQ1): How has the publication output and citation impact of Transformer-based research on misinformation detection evolved? RQ2: Which articles and sources have the greatest impact in this domain? RQ3: Which countries and institutions contribute the most to the literature? RQ4: Who are the most productive authors and what collaboration patterns dominate the field? RQ5: What thematic clusters dominate the domain and how have they evolved based on keyword co-occurrence and overlay analysis? RQ6: How is the literature distributed across subject areas and what does this distribution suggest about interdisciplinarity? RQ7: What research gaps and future directions emerge from the observed trends in methods, applications and evaluation practices?

Section II details the Scopus data source and search strategy, the inclusion workflow and the procedures used for performance profiling and science mapping. Section III presents the results aligned with the research questions and Section IV summarizes contributions and future directions.

II. Materials and Methods

The data source, search strategy, inclusion criteria and analysis workflow used for this bibliometric study are described in this section. The differences between prior bibliometric reviews and this study are summarized in Table I and the retrieval and screening workflow is shown in Fig. 1.

TABLE I. Comparison of Previous Studies of Misinformation Detection and Our Study

Elements of comparison	[13]	[11]	[10]	Our study
Coverage year	2000–2019	2002–2021	2013–2023	2017 – 2026 (as on 03 March 2026)
Database	Scopus and Web of Science	Web of Science (SCI-E and SSCI)	Web of Science Core Database	Scopus
Keywords	Master keyword "incremental learning" with primary keywords including "false information" OR "misinformation" OR "text classification" etc. and secondary exclusion terms	disinformation OR misinformation OR "fake news" OR "infodemic" OR "information pollut*" OR deepfake* OR "rumor propagation"	TS query combining misinformation terms with social media/social network and diffusion verbs	Misinformation terms combined with Transformer terms
Focus of study	Maps incremental learning for text classification in false information detection and reports publication statistics, collaboration, network and citation analysis plus techniques used	Bibliometric analysis of disinformation research, identifying influential works and central topics using co-citation and keyword co-occurrence	Topic evolution of misinformation dissemination on social media; identifies hotspots and trends using a staged framework (community detection, TOPSIS, visualization)	Bibliometric mapping of Transformer-based architectures for misinformation detection: intellectual structure, dominant clusters, trend trajectory and research gaps
Methodology	Bibliometric survey with publication statistics, collaboration degree, collaboration visualization and citation analysis	Bibliometric analysis: performance analysis and science mapping	Scoping review framework combined with bibliometric analysis	Bibliometric analysis: performance analysis + science mapping
Protocol/Tools	Not explicitly tool-focused in the study, but the objectives include collaboration visualization and citation analysis.	Derwent Data Analyzer (DDA 10) for cleaning, mining and visualization	ITGinsight for preprocessing; integrates community detection, AHP, TOPSIS and visualization	VOSviewer v1.6.20 (mapping and visualization) and Harzing's Publish or Perish (performance indicators)

Table I positions the present work relative to recent bibliometric studies by comparing their coverage periods, database selections, keyword strategies, analytical focus and toolchains. Prior studies [10], [11] and [13] vary in scope and objectives, including broad misinformation-dissemination mapping and incremental-learning-oriented surveys and they often rely on Web of Science or a combination of databases, with different preprocessing pipelines. In contrast, the current study targets a narrower technical stream by focusing specifically on Transformer-based architectures for misinformation detection. It adopts a consistent Scopus-only retrieval strategy covering 2017–2026 (as of 3 March 2026). Scopus was selected as the sole data source because it offers broad coverage of computer science and engineering venues and provides structured bibliographic metadata required for performance analysis and science mapping (e.g., author affiliations, source titles, references and citation counts) under a consistent indexing policy. Using a single database also reduces duplication and record-matching errors that can arise when merging records from multiple sources with different metadata schemas.

Nevertheless, Scopus-only retrieval may omit publications indexed exclusively elsewhere and may underrepresent some regional outlets. Accordingly, the results should be interpreted as representing the Scopus-indexed landscape during the retrieval period. Future work may triangulate Scopus with Web

of Science or other databases to test the stability of the identified trends and networks.

The keyword formulation also differs by explicitly combining misinformation terms with Transformer-related terms, enabling the dataset to capture Transformer-centric model families and related evaluation settings rather than general diffusion or platform-level discourse. Methodologically, the study integrates performance analysis with science mapping, supported by the tool configuration reported in Table I and the retrieval workflow shown in Fig. 1.

A. Data Source and Search Scope

Records were retrieved from Scopus on 3rd March 2026 using the TITLE-ABS-KEY fields. The search covered all years, was restricted to English, and applied no restrictions on source type or document type. The workflow is summarized in Fig. 1. The query is intentionally inclusive, so the retrieved set may contain adjacent high-impact LLM-related work that shapes misinformation threat models even when it is not a detection-model paper.

B. Search Strategy and Query Design

The query combined (1) misinformation-related terms (e.g., misinformation, disinformation, fake news, rumor) with (2) Transformer-related terms (e.g., Transformer, attention mechanism, BERT, RoBERTa, LLM). The complete Boolean query is provided in Fig. 1.

C. Study Selection and Dataset Construction

The search returned 3,637 records. Screening was limited to database-level filters (TITLE-ABS-KEY and English). No post-retrieval exclusions were applied; therefore, 0 records were removed, and 3,637 documents were included (Fig. 1). To clarify the dataset scope, the 3,637 records are treated as a query-defined Scopus corpus rather than a manually screened systematic review corpus. The query was designed to capture both detection-oriented studies and related Transformer/LLM work that informs misinformation threat models and research trends. Therefore, no post-retrieval topical exclusion was applied, and the dataset should be interpreted as the Scopus-indexed landscape captured by the stated search strategy, not as a set limited only to detection-architecture papers.

D. Data Export and Preprocessing

All retrieved records were exported from Scopus, including available bibliographic metadata such as publication year, document title, authors, affiliations, source title, abstracts, author keywords, indexed keywords, cited references, and citation counts. Before analysis, the dataset was checked for basic consistency to reduce noise in network construction. This included harmonizing common variants of author names and keywords, where applicable, and consolidating obvious duplicates (for example, singular and plural forms or abbreviations representing the same concept). The cleaned files were then prepared in formats compatible with the selected tools.

E. Bibliometric Tools and Analysis Procedures

VOSviewer (v1.6.20) was used to construct and visualize co-authorship networks involving authors, institutions, and countries, as well as keyword co-occurrence and overlay maps. Citation indicators were examined using Harzing's Publish or Perish to support publication-level and source-level impact analysis.

F. Outcome Measures and Reporting

Results are reported using (1) performance indicators describing publication growth, major contributors, leading sources, and highly cited documents, and (2) science mapping outputs that visualize collaboration structure and thematic organization. The overall workflow is summarized in Fig. 1.

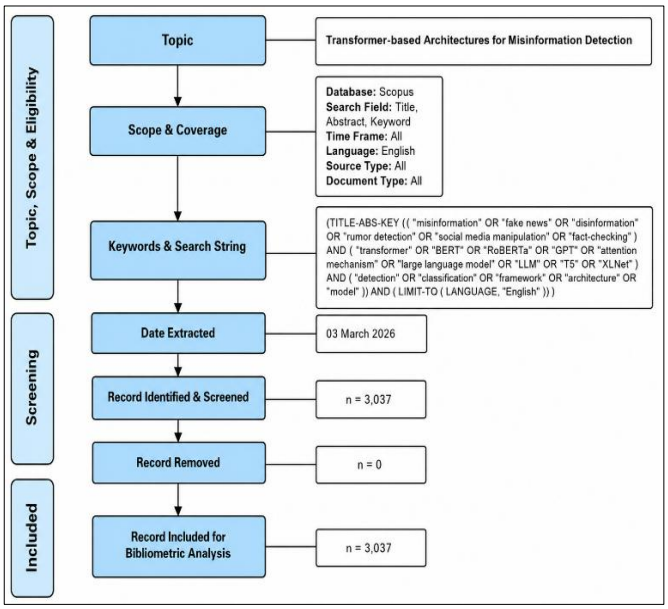

Fig. 1. Flowchart illustrating the literature search and data analysis process in the study.

III. Results and Discussion

A. Publication Output and Citation Trend

The temporal pattern of research activity and impact is described using three indicators: total publications (TP), number of cited publications (NCP), and total citations (TC). As shown in Fig. 2, publication output increases from 252 papers in 2018 to a peak of 1,303 papers in 2019, followed by 944 papers in 2020. Output then declines in subsequent years (510 in 2021, 285 in 2022, 226 in 2023, 82 in 2024, 30 in 2025 and 5 in 2026). The reduction in the most recent years is consistent with a shorter publication and indexing window, as the dataset was extracted in early 2026.

Indexing delay can explain part of the reduction in 2024–2026, but it does not fully account for the sustained decline between 2019 and 2023. A plausible interpretation is that the 2019 peak reflects an early surge of BERT-family adoption in misinformation detection, while subsequent work increasingly shifted toward adjacent framings (e.g., fact-checking, claim verification, stance and content authenticity) and reporting conventions that do not always foreground the same Transformer keywords in TITLE-ABS-KEY fields. Accordingly, the post-2019 decline should be interpreted as a query- and indexing-conditioned pattern within the retrieved Scopus dataset rather than a definitive indicator of reduced Transformer-based research activity.

	2018	2019	2020	2021	2022	2023	2024	2025	2026
Sum of TP	252	1303	944	510	285	226	82	30	5
Sum of NCP	4	29	74	208	258	448	745	507	24
Sum of TC	307	1919	2757	6538	5178	14773	9211	2449	45

Note: TP = Total Publications; NCP = Cited Publications; TC = Total Citations.

Fig. 2. Annual publication output and citation impact.

Citation indicators exhibit a lag relative to publication volume. TC rises from 307 (2018) and 1,919 (2019) to 2,757 (2020) and 6,538 (2021), remains high in 2022 (5,178) and peaks in 2023 (14,773). TC then decreases in 2024 (9,211), drops further in 2025 (2,449) and declines in 2026 (45), reflecting limited time for recent outputs to accumulate citations. A similar pattern is observed for NCP, which increases from 4 (2018) and 29 (2019) to 74 (2020) and 208 (2021), reaches 258 (2022) and 448 (2023), peaks in 2024 (745) and declines in 2025 (507) and 2026 (24).

Overall, the year-wise patterns indicate that publication volume is concentrated in earlier years within this dataset, while citation impact becomes more visible after a maturation period. This lag implies that citation-based influence should be interpreted using multi-year windows rather than recent-year counts alone, since newer publications have not had sufficient time to accumulate citations. In practical terms, the most recent declines are better viewed as recency and indexing effects than as evidence of reduced scholarly attention. This answers RQ1 by describing how publication output and citation impact evolve. Having established this temporal profile, the next subsection evaluates the impact more directly by identifying influential publications and sources.

B. Citation Impact of Publications and Sources

Citation impact is assessed at two levels: publication-level influence, using citation indicators and highly cited papers and source-level influence, indicating where influential work is disseminated and where recent attention is concentrated. Publication-level impact is summarized in Table II.

As shown in Table II, the dataset contains 3,637 papers and 43,207 citations, with an average of 11.88 citations per paper, an h-index of 82, and a g-index of 154. These indicators suggest broad influence with a highly cited core, which motivates a closer look at the publications driving this impact. The most cited publications are listed in Table III. Because the dataset follows a query-defined bibliometric scope, Table III is interpreted as showing the most-cited publications within the retrieved corpus rather than as a list restricted to detection-architecture papers. Some records are not detection papers in a narrow methodological sense, but they are retained because they represent influential Transformer- and LLM-related work that shapes current misinformation research, especially around generative AI, information integrity and emerging threat models.

TABLE II. CITATION METRICS

Metrics	Data
Papers	3637
Number of Citations	43207
Years	8
Citations per Year	5400.88
Citations per Paper	11.88
Cites_Author	11525.38
Papers_Author	1170.09
Authors_Paper	4.1
h_index	82
g_index	154

Table III should be read as reflecting the most influential publications within the retrieved scope, rather than as a list restricted to detection-architecture papers. It indicates two major citation drivers. Several highly cited items focus on LLMs and ChatGPT, reflecting strong cross-domain attention to generative AI and its implications for information integrity and high-stakes settings. A second stream comprises methodological contributions, including detection baselines and multimodal frameworks that are repeatedly cited as reference implementations or comparative anchors in subsequent studies. This split suggests that citation impact is shaped by both the rapid uptake of LLM-related discourse and the persistent reliance on foundational detection frameworks. Importantly, this pattern implies that influence in the domain is determined not only by advances in modelling but also by how research engages with emerging threat models and deployment-relevant concerns. As a result, studies that connect detection performance with robustness, transparency, or real-world risk contexts are more likely to achieve sustained citation visibility.

Source-level dissemination is examined in Fig. 3, which contrasts Total Publications (TP) with citations in 2025 across leading venues grouped by source type. While Table II and Table III provide a publication-level view of impact, it is also important to examine the sources/venues through which this research is disseminated.

TABLE III. TOP 10 CITED PUBLICATIONS

No.	Authors	Title	Cites	Cites per Year
1	Y.K. Dwivedi et al. (2023) [15]	So what if ChatGPT wrote it? Multidisciplinary perspectives on opportunities, challenges and implications of generative conversational AI for research, practice and policy	3217	15.67

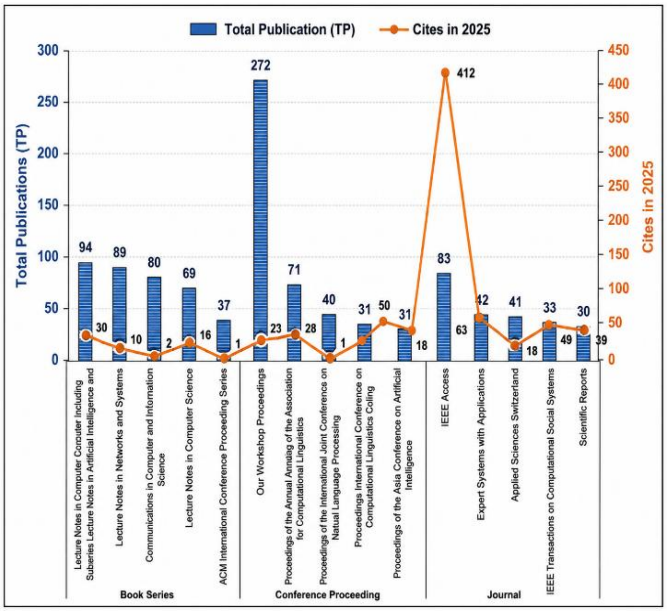

Fig. 3. Publication output (TP) and citations in 2025 across leading sources.

In Fig. 3, the highest-output venues differ by source type. Within Book Series, Lecture Notes in Computer Science (including LNAI/LNBI) leads output (TP = 94), followed by Lecture Notes in Networks and Systems (TP = 89), and Communications in Computer and Information Science (TP = 80). Within Conference Proceedings, CEUR Workshop Proceedings dominates (TP = 272), followed by the ACL Annual Meeting Proceedings (TP = 71). Within Journals, IEEE Access records the highest output (TP = 83), followed by Expert Systems with Applications (TP = 42), and Applied Sciences (Switzerland) (TP = 41). Citations in 2025 are used as a fixed one-year window to reduce the advantage of older publications and to highlight venues receiving current attention within the same citation period.

Taken together, the source-level profile separates dissemination capacity (TP) from recent visibility (2025 citations). This distinction is useful because high output does not necessarily imply high short-window citation uptake and it provides a venue-focused complement to publication-level impact indicators. Table II, Table III and Fig. 3, therefore, provide publication and venue-level evidence of impact. This answers RQ2 by identifying the most influential publications and the main sources through which impactful work is disseminated. A limitation is that citations in a single-year window and source-level counts are sensitive to indexing coverage and retrieval scope. Accordingly, these indicators should be interpreted as reflecting venue visibility within the Scopus-indexed records captured by the query and retrieval date.

C. Subject Area Distribution and Interdisciplinarity

The distribution of publications across Scopus subject areas is used to characterize the disciplinary base of Transformer-based misinformation detection research and to assess the degree of interdisciplinarity. Because Scopus can assign a single document to multiple subject areas, percentages may sum to more than 100 per cent; the overlap reflects multi-disciplinary indexing rather than duplication in the dataset.

As shown in Table IV, Computer Science accounts for 3,091 publications (84.99%), indicating that the field is primarily anchored in computing and NLP research. Engineering accounts for 1,018 publications (27.99%), followed by Mathematics with 796 (21.89%), aligning with the emphasis on model development, optimization and evaluation methodology. Beyond the technical core, Social Sciences records 560 publications (15.40%), Decision Sciences contributes 404 (11.11%) and Medicine accounts for 324 (8.91%), reflecting sustained interest in misinformation as a socio-technical problem with decision and health implications.

The overall pattern is summarized visually in Fig. 4, which focuses on the top 10 subject areas and clearly shows the dominance of Computer Science while also highlighting meaningful participation from adjacent disciplines. Taken together, these results suggest that Transformer-based misinformation detection is rooted in computer science research but increasingly shaped by interdisciplinary applications, particularly in social and health domains.

TABLE IV. SUBJECT AREA

Subject Area	TP	%
Computer Science	3,091	84.99%
Engineering	1,018	27.99%
Mathematics	796	21.89%
Social Sciences	560	15.40%
Decision Sciences	404	11.11%
Medicine	324	8.91%
Arts and Humanities	206	5.66%
Materials Science	185	5.09%
Physics and Astronomy	140	3.85%
Business, Management and Accounting	106	2.91%
Multidisciplinary	77	2.12%
Energy	72	1.98%
Chemical Engineering	47	1.29%
Neuroscience	44	1.21%
Psychology	39	1.07%
Health Professions	38	1.04%
Biochemistry, Genetics and Molecular Biology	36	0.99%
Environmental Science	34	0.93%
Chemistry	18	0.49%
Agricultural and Biological Sciences	16	0.44%
Economics, Econometrics and Finance	15	0.41%
Dentistry	14	0.38%
Nursing	13	0.36%
Earth and Planetary Sciences	10	0.27%
Pharmacology, Toxicology and Pharmaceutics	7	0.19%
Immunology and Microbiology	3	0.08%
Veterinary	1	0.03%

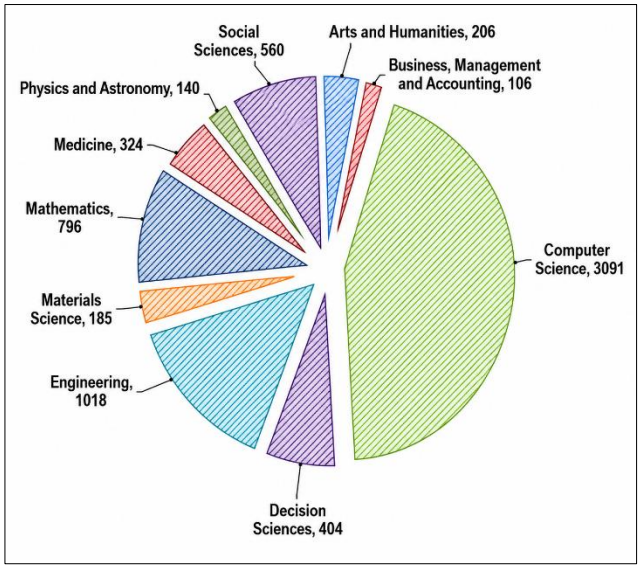

Fig. 4. Top ten subject areas.

Overall, the subject-area profile suggests that Transformer-based misinformation detection is anchored in Computer Science and draws substantial contributions from Engineering and Mathematics, reflecting a technical emphasis on model design, optimization and learning foundations. At the same time, the visible presence of Social Sciences, Decision Sciences and Medicine indicates that the field is increasingly shaped by applied and societal contexts, where misinformation is studied not only as a classification problem but also as a phenomenon involving human behavior, risk and domain-specific consequences. This interdisciplinary pattern provides useful context for interpreting the thematic clusters and collaboration networks in later analyses by explaining why research topics often connect algorithmic advances with application-driven concerns. These findings directly address RQ6 by showing that the field remains anchored in technical disciplines while drawing increasing attention from applied and societal domains.

Having established the disciplinary footprint of the literature, the next subsection examines country-level publication output to characterize the geographic distribution of research activity.

D. Country Contribution and Geographic Distribution

Country-level publication output is used to identify the geographic concentration of research activity in Transformer-based misinformation detection. The top contributing countries are summarized in Table V and their spatial distribution is illustrated in Fig. 5.

TABLE V. TOP 10 COUNTRIES WITH THE MOST TOTAL PUBLICATIONS

Country	TP	%
China	839	23.07%
United States	708	19.47%
India	645	17.73%
United Kingdom	199	5.47%
Germany	169	4.65%
Italy	142	3.90%
Australia	126	3.46%
Spain	116	3.19%
Saudi Arabia	115	3.16%
Canada	113	3.11%

As shown in Table V, publication output is concentrated among a small set of countries. China ranks first with 839 publications (23.07%), followed by the United States with 708 (19.47%) and India with 645 (17.73%). The next contributors are the United Kingdom (199, 5.47%), and Germany (169, 4.65%), followed by Italy (142, 3.90%), and Australia (126, 3.46%). Spain (116, 3.19%), Saudi Arabia (115, 3.16%), and Canada (113, 3.11%) complete the top ten.

Fig. 5 shows the same ranking, where shading intensity reflects publication volume. The concentration in a small number of countries suggests that a limited set of national research ecosystems drives output. At the same time, the presence of contributors across Asia, North America, Europe and the Middle East indicates broad international participation.

This distribution provides context for later analysis of collaboration, since geographic concentration can influence co-authorship density and cross-border research ties. This answers RQ3 by identifying the countries that contribute most to the literature.

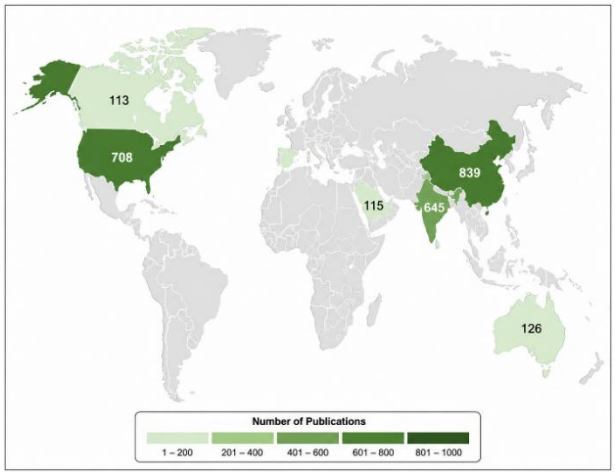

Fig. 5. Geographic distribution of the top 10 countries by total publications.

E. Institutional Contribution

Institutional-level publication output is summarized to identify the primary organizational hubs contributing to Transformer-based misinformation detection research. The distribution of the most productive institutions is shown in Fig. 6.

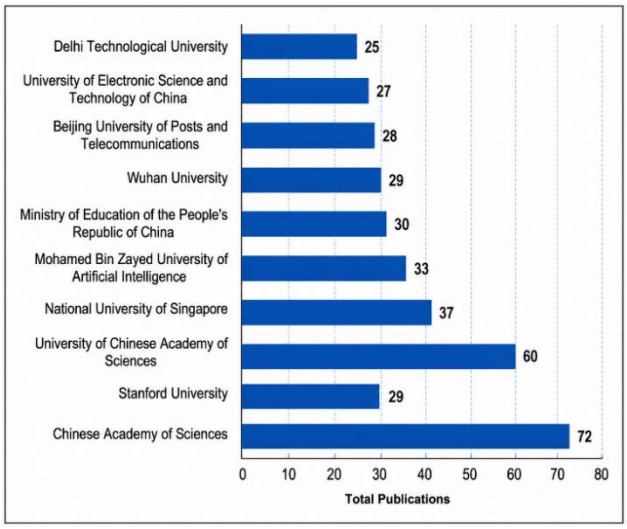

Fig. 6. Top 10 institutions by total publications.

As shown in Fig. 6, output is concentrated in a small set of institutions. The Chinese Academy of Sciences (CAS) ranks first with 72 publications, followed by the University of Chinese Academy of Sciences (UCAS) with 60 publications. These two entities are closely linked within the same research ecosystem. Still, they are reported separately because they are indexed as distinct affiliations and authors frequently list research institute and university affiliations independently. In the next tier, the National University of Singapore records 37 publications and Mohamed Bin Zayed University of Artificial Intelligence records 33 publications. Additional contributors include the Ministry of Education of the People's Republic of China (30), Wuhan University (29), Stanford University (29), Beijing University of Posts and Telecommunications (28), University of Electronic Science and Technology of China (27), and Delhi Technological University (25).

Overall, the institutional profile indicates that publication activity is strongly represented by China-based organizations, with major contributors from the United States, Singapore, UAE, and India. This answers RQ3 by identifying the institutions with the highest publication output in the dataset. Having established institutional concentration, the next subsection examines author productivity and collaboration patterns to characterize how research communities are organized at the researcher level.

F. Author Productivity and Collaboration Patterns

The collaboration structure is illustrated by the co-authorship network in Fig. 7, complemented by the productivity ranking of leading authors in Table VI. The most productive authors are summarized in Table VI and the co-authorship network is illustrated in Fig. 7.

TABLE VI. LEADING AUTHORS BY TOTAL PUBLICATIONS

Author full names	Affiliations	Author	TP
Nakov, Preslav Ivanov	Mohamed Bin Zayed University of Artificial Intelligence	United Arab Emirates	33
Alam, Firoj	Hamad Bin Khalifa University	Qatar	17
Zhang, Min	Peking University	China	12
Martín, Antonio	Universidad Politécnica de Madrid	Spain	11
Camacho, David	Universidad Autónoma de Madrid	Spain	11
Hoque, Md. Moshiur	University of Dhaka	Bangladesh	11
Ma, Jing	The Hong Kong Polytechnic University	Hong Kong	10
Madasamy, Anand	Indian Institute of Technology	India	10
Wasim, Muhammad	Lahore University of Management Sciences	Pakistan	10
Alghamdi, Jaber	King Abdulaziz University	Saudi Arabia	10

Note: TP=total number of publications

As shown in Table VI, publication output is concentrated among a small group of authors. Nakov, Preslav Ivanov, ranks first with 33 publications, followed by Alam, Firoj, with 17 and Zhang, Min, with 12. The next contributors include Martín, Antonio (11), Camacho, David (11) and Hoque, Md. Moshiur (11). Several authors contribute at a comparable level with 10 publications each, including Ma, Jing, Madasamy, Anand, Wasim, Muhammad and Alghamdi, Jaber. This distribution indicates that author productivity is top-heavy, with a small set of frequent contributors and a broader group of steady contributors.

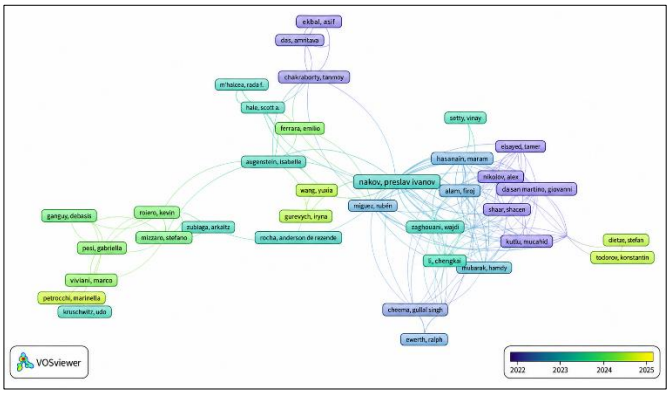

Fig. 7. Co-authorship network visualization.

The co-authorship network in Fig. 7 provides a structural view of collaboration. Nodes represent authors and links indicate co-authored publications. Larger nodes indicate greater publication presence in the dataset, while denser link patterns indicate repeated collaboration. The network forms distinct clusters, indicating collaboration communities in which authors frequently publish together. Some authors are embedded within tightly connected clusters, consistent with stable research groups. In contrast, others occupy bridging positions between clusters, suggesting cross-group collaboration pathways that can facilitate the spread of methods and datasets across the field. The color gradient adds a temporal signal by distinguishing earlier versus more recent activity within the displayed period.

Taken together, the author productivity ranking and co-authorship structure provide evidence of concentrated productivity and cluster-based collaboration patterns. This answers RQ4 by identifying the most productive authors and the dominant collaboration structure in the field. Having established the leading contributors and collaboration patterns, the next subsection maps the literature's thematic structure using keyword co-occurrence and overlay analysis.

G. Keyword Co-occurrence and Thematic Evolution

The thematic structure of Transformer-based misinformation detection research is characterized through keyword co-occurrence patterns and their temporal evolution. The co-occurrence structure is shown in Fig. 8, while the overlay visualization in Fig. 9 highlights topic recency based on average publication year. Keyword labels such as *fake news* and *disinformation* are reported as indexed terms in the dataset and are interpreted within the broader scope of misinformation detection defined in the Introduction.

As shown in Fig. 8, the literature is organized around a dense core of high-frequency keywords, with strong connectivity among Natural Language Processing, social media and misinformation-related terms. This configuration indicates that a substantial portion of the field is framed as NLP-based detection in social media environments. The map also shows connected sub-themes that reflect methodological diversification, including multimodal and cross-modal directions (e.g., terms associated with multimodal fusion and vision-based processing) and application-driven contexts such as COVID-19, which continues to appear as an anchoring topic. The presence of both baseline classifier terms and Transformer-family model terms indicates that comparative evaluation against conventional baselines remains common alongside modern representation learning approaches.

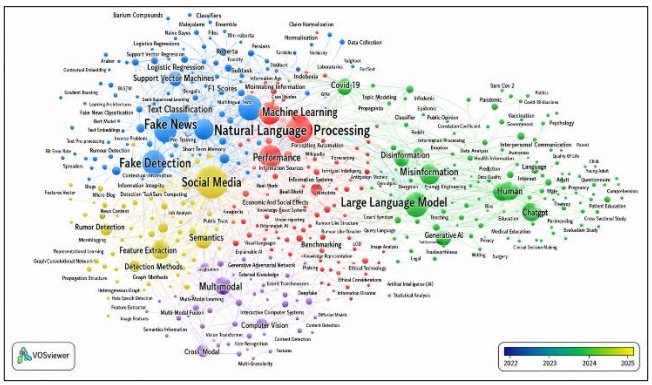

Fig. 8. Keyword co-occurrence map.

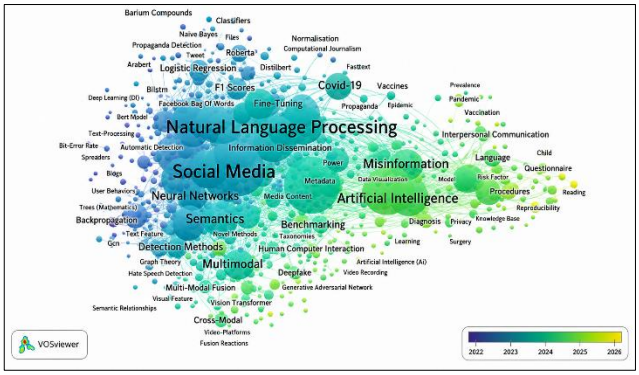

Fig. 9. Keyword overlay visualization map.

The overlay view in Fig. 9 provides a time-sensitive interpretation of keyword activity. Earlier topics are more strongly associated with general detection and evaluation vocabulary, while more recent activity shifts toward keywords linked to contemporary AI developments and deployment-oriented concerns. The appearance of terms related to generative systems and research-practice issues (e.g., reproducibility and procedure-oriented keywords) suggests that recent work is expanding beyond benchmark performance toward questions of reliability, reporting rigor and applicability in real-world conditions. At the same time, core detection topics remain active, indicating continuity in the main problem setting while also highlighting emerging directions. This temporal shift implies that evaluation designs may need to move beyond static benchmark settings toward protocols that reflect emerging threat models, including synthetic content and multimodal manipulation. It also indicates that research visibility is increasingly linked to deployment-oriented themes, which can guide future work toward robustness, transparency and real-world validation.

Specifically, the earlier activity in Fig. 9 is more closely associated with classical detection and evaluation vocabulary, such as fake news, text classification, support vector machines, logistic regression, rumor detection and F1 score. In contrast, more recent keywords include ChatGPT, generative AI, prompt engineering, reproducibility, Vision Transformer (ViT) and

multimodal fusion, indicating a shift toward LLM-driven authenticity concerns, multimodal settings and deployment-oriented research practices.

Overall, the combined evidence from Fig. 8 to Fig. 9 identifies dominant thematic clusters and clarifies how attention has shifted over time. This answers RQ5 by characterizing the domain's thematic structure and its evolution through keyword co-occurrence and overlay analysis. Having established the thematic structure and its temporal shifts, the next subsection synthesizes research gaps and future directions derived from the observed trends in methods, applications and evaluation practices.

A limitation of keyword co-occurrence mapping is its dependence on author keywording practices and indexing variation, which can affect term visibility and apparent connectivity. Therefore, Fig. 8 should be read as indicating dominant thematic signals in the retrieved dataset rather than an exhaustive representation of all topics.

H. Research Gaps and Future Directions

The thematic structure and temporal overlay indicate that the field is expanding rapidly, yet several gaps remain that limit the reliability and deployability of Transformer-based misinformation detection. The key gaps and recommended future directions derived from the bibliometric findings are summarized in Table VII.

TABLE VII. RESEARCH GAPS AND FUTURE DIRECTIONS IN TRANSFORMER-BASED MISINFORMATION DETECTION

Gap area	Evidence from this study	Why it matters	Future directions (recommended)
Evaluation of realism and robustness	Keyword maps emphasize benchmark and evaluation terms (Fig. 8) and recent attention to reproducibility (Fig. 9).	Benchmark gains may not translate to deployment when data shifts across time, topics and platforms.	Use cross-domain and cross-platform evaluation, temporal holdout testing, robustness checks under distribution shift and transparent reporting of splits and baselines.
LLM-generated misinformation	Highly cited works are dominated by publications on LLMs/ChatGPT (Table III).	Detection pipelines often assume human-authored content, while LLM text can be prompt-sensitive and rapidly evolving.	Develop detection strategies for synthetic text (prompt variation, paraphrasing, mixed human–AI authorship), integrate verification signals and evaluate against evolving generator models.
Multimodal misinformation detection	Multimodal themes appear as a connected topic area (Fig. 8) and several influential publications are multimodal (Table III).	Real-world misinformation often combines text and images, so text-only models may miss important signals or be susceptible to context manipulation.	Expand multimodal datasets, evaluate cross-modal consistency and robustness and design fusion architectures that handle missing or manipulated modalities.
Explainable and trustworthy detection	Explainability-related directions appear as emerging concerns alongside deployment-oriented themes (Fig. 9).	High-stakes settings require interpretability and trust, not only accuracy, to support verification and decision-making.	Incorporate explanation methods (faithful rationales, uncertainty estimates), audit bias and failure modes and evaluate explanation quality with human-centered protocols.
Cross-lingual and low-resource settings	The thematic core is strongly anchored in mainstream NLP and social media detection terminology (Fig. 8), suggesting a dominance of high-resource settings.	Models trained on English-heavy benchmarks often generalize poorly to other languages, dialects and code-switching contexts.	Build multilingual and low-resource benchmarks, develop adaptation methods (transfer, multilingual pretraining, PEFT) and evaluate fairness across languages and regions.
Reproducibility and transparency	"Reproducibility" emerges as a recent keyword signal in the overlay map (Fig. 9).	Without consistent reporting and reusable pipelines, performance improvements may reflect experimental variance rather than real advances.	Release code and data splits, standardize preprocessing and baselines, report hyperparameters and adopt reproducible evaluation toolchains.

Taken together, Table VII indicates that recent progress is not limited by model capacity alone, but by evaluation realism, modality coverage and reporting discipline. This implies that future contributions will be more defensible when they adopt shift-aware evaluation protocols and provide reproducible pipelines alongside improvements in accuracy.

First, the literature remains strongly benchmark-driven, with frequent emphasis on standard classification performance and metric reporting, as reflected by the prominence of evaluation terms in the keyword map and its overlay evolution (Fig. 8 and Fig. 9). While benchmark progress supports comparability, the field would benefit from evaluation protocols that better reflect real-world distribution shifts over time, across platforms and across topics. Future work should prioritize cross-domain and cross-platform testing, temporal generalization and robustness assessment in the face of changing narratives and emerging events. Prior evidence also shows that dataset limitations, feature representation choices and simplistic fusion strategies remain recurring failure points in misinformation detection systems, reinforcing the need for evaluation designs that reflect these constraints [25], [26].

Second, the rise of LLMs and ChatGPT is reshaping the misinformation landscape and requires explicit methodological responses. Highly cited publications emphasize the influence and societal implications of generative conversational AI [11], including risks in sensitive domains such as public health and education [15]-[18]. However, detection pipelines often assume human-authored content and may not be calibrated to synthetic text produced by variations in prompts and model updates. Future studies should develop detection and verification strategies specifically designed for LLM-generated misinformation, including robustness under prompt manipulation, synthetic paraphrasing and mixed human–AI authorship settings, while also considering human trust and adoption behaviors that shape how such content is consumed [19].

Third, multimodal misinformation remains under-addressed relative to its prevalence in online ecosystems. Although

multimodal cues have emerged as a theme and influential works have demonstrated the value of integrating visual information [14], [20], the literature still concentrates heavily on text-only inputs. Future research should move toward multimodal and cross-modal architectures evaluated on realistic mixed-media datasets, including scenarios with incomplete, noisy, or manipulated visual context. In parallel, explainable and trustworthy AI should be treated as a first-class requirement, particularly for high-stakes environments and public-facing deployments. Recent work on explainable multilingual and multimodal detection supports this direction [6], [7], but broader adoption remains limited. Beyond modality fusion, incorporating affective signals from news content and user responses has also been shown to improve detection performance on social platforms, suggesting an additional direction for feature enrichment in real-world settings [27].

Fourth, low-resource and cross-lingual settings remain comparatively underrepresented. The keyword landscape suggests dominance of mainstream NLP terms and widely used benchmarks, which often privilege English and high-resource contexts. To improve real-world applicability, future work should invest in multilingual datasets, domain adaptation techniques, and evaluation settings that emphasize fairness and generalization across languages, including code-switching and regional dialects [28]. Noisy, non-standard social media language and spelling variation can further degrade cross-lingual transfer, motivating normalization-aware pipelines and curated resources for low-resource settings [29], [30].

Finally, reproducibility and methodological transparency require stronger emphasis. The overlay map highlights "reproducibility" as a more recent concern (Fig. 9), indicating growing awareness of the need for reporting rigor. Future studies should adopt clearer documentation of preprocessing, data splits, hyperparameter configurations, and baseline selection. They should publish reusable evaluation pipelines to ensure that progress reflects genuine methodological improvement rather than experimental variance [31].

In summary, these gaps collectively answer RQ7 by identifying priorities for advancing reliable and deployable misinformation detection: 1) realistic evaluation and robustness, 2) explicit handling of LLM-generated misinformation, 3) stronger multimodal and explainable frameworks, 4) broader cross-lingual coverage, and 5) improved reproducibility and transparency.

IV. Conclusion

This study presents a Scopus-based bibliometric analysis of Transformer-based misinformation detection, drawing on 3,637 records, and provides an evidence-driven account of how the field is currently organized and where it is moving. The results show that publication output is concentrated in conference proceedings and journals and that the research base is firmly anchored in Computer Science, with sustained contributions from applied disciplines that reflect deployment-facing concerns. At the contributor level, productivity is concentrated among a small set of leading countries, institutions and co-authorship communities, indicating that research capacity is not evenly distributed. Citation metrics further confirm broad influence with a distinct, highly cited core. At the same time, keyword mapping identifies a stable focus on NLP-driven misinformation detection in social media and a clear recent shift toward multimodal pipelines and LLM-related themes.

The primary contribution of this study is a consolidated, reproducible map of productivity, influence and thematic evolution that reduces fragmentation in the literature and supports a more defensible positioning for future work. Future research may further deepen intellectual-structure analysis through citation, co-citation, and bibliographic coupling networks, refine time-sliced thematic tracking to capture topic turnover, and strengthen external validity through reproducible evaluation protocols, cross-domain and cross-platform robustness testing, and expanded coverage of low-resource and cross-lingual settings.

Acknowledgment

This study is a research product supported and funded by the Fundamental Research Grant Scheme (FRGS) of the Ministry of Higher Education Malaysia (Code: FRGS/1/2022/ICT02/ UKM/02/3).

Faculty of Business Sciences, Universidad Científica del Sur, Lima, Peru[1, 2, 3]
Faculty of Business, Universidad Tecnológica del Perú, Lima, Peru[4]

***Abstract*—The objective of this study was to determine whether the implementation of a web system optimizes information management by reducing the time required to access, verify, and interpret selection-stage information for applicants of the Beca 18 2025 scholarship call. The research followed an applied, quantitative, pre-experimental design with pre-test and post-test measurements in a single group. The sample comprised 361 preselected applicants from the ordinary modality in the Lima region, selected through simple random sampling. A direct observation sheet recorded the time, in minutes, required by each participant to complete 15 tasks associated with information accessibility, information currency, and information quality before and after using the web system. The mean information-management time decreased from 130.40 to 50.46 minutes, with a statistically significant mean reduction of 79.94 minutes. The three evaluated dimensions also showed substantial reductions: information accessibility decreased by 70.3 per cent, information currency by 80.2 per cent, and information quality by 52.2 per cent. The findings indicate that, within the scope of time-based task performance, the web system optimized the efficiency with which applicants accessed, verified, and interpreted selection-stage information.**

Keywords*—Web system; information management; Beca 18; information accessibility; information currency; information quality; pre-experimental design

I. Introduction

Information management represents a persistent challenge for institutions because information is often distributed across poorly organized files, duplicated documents, or outdated versions. These conditions affect the speed with which users locate relevant content and limit the reliability of the information used for decision-making. In contexts where users must make timely decisions based on official documents, traditional or disconnected information channels can increase the effort required to access, verify, and interpret critical information.

At the global level, this problem has been widely recognized. According to a global study by the Association for Intelligent Information Management (AIIM), which compared a decade of digital-transformation efforts in organizations across North America, Europe, the Middle East, and Africa, many companies still face serious deficiencies in managing their information: 33.33 per cent of surveyed companies had not yet made notable progress in their digital-transformation processes, and more than 50 per cent continued to use paper documents and manual management [1].

At the regional level, similar challenges have been reported in organizational data management. Dell Technologies reported that 95 per cent of organizations face challenges in data management, based on 6,600 respondents from public- and private-sector organizations with more than 100 employees across Latin America, North America, Europe, Asia-Pacific, and China [2].

In Peru, the National Institute of Statistics and Informatics (INEI) found, through the 2021 Annual Economic Survey, which collected information from the 2020 economic year, that 25.9 per cent of companies did not have a management system in place [3]. This shows that a significant proportion of organizations still do not use technological tools to organize, store, or process information systematically.

In the context of the National Scholarship and Educational Loan Program (Pronabec), Beca 18 applicants must consult official information related to requirements, procedures, schedules, eligible higher education institutions, and scoring criteria during the selection stage. For the Beca 18 2025 scholarship call, this information is mainly provided through extensive official documents, which can make rapid access and interpretation difficult for applicants who need to locate specific information in a timely manner [4].

This study proposes and evaluates a web system that centralizes and structures Beca 18 selection-stage information into five interactive sections: application requirements, application procedure, schedule, eligible higher education institutions, and scoring criteria. The system was designed to reduce the time applicants spend accessing, verifying, and interpreting this information.

The general objective was to determine whether the implementation of a web system optimizes information management by reducing the time required to access, verify, and interpret selection-stage information for applicants of the Beca 18 2025 scholarship call. The specific objectives addressed three dimensions of the construct: information accessibility, information currency, and information quality.

The remainder of this study is organized as follows: Section II reviews related work and the theoretical foundations of web systems and information management. Section III describes the materials and methods, including the research design, population and sample, instrument, technological implementation, and data-analysis strategy. Section IV reports the descriptive and inferential results. Section V discusses the

findings in relation to prior studies and acknowledges the study's limitations. Section VI presents the conclusions.

II. Literature Review

A. Related Work

Prior studies have shown that web systems can improve institutional information management by reducing processing time, centralizing information, and supporting more efficient consultation processes. In an organizational context, Colan [5] implemented a web platform in a transportation company in Lima and reported a reduction in information-management time from 6.42 to 2.42 minutes, with statistically significant improvements in agility, reliability, and utility. Similarly, Alvarado [6] implemented a web system for IT-incident management at UGEL Huamanga, where the mean resolution time decreased from 59.44 to 19.11 minutes.

Other studies have reported improvements not only in time reduction but also in information registration, consultation, and reporting. Lopez [7] proposed a web application for occupational safety and health information management, increasing registration from 29.4 per cent to 94.1 per cent, consultation from 35.3 per cent to 88.2 per cent, and report generation from 23.5 per cent to 94.1 per cent. In the educational context, Chaupez and Rojas [8] reported that a web system reduced attendance-processing time from 42 to 11 seconds. Expósito and Gamboa [9] developed a web page to support information management in an educational direction system, reporting improvements in organization, task monitoring, and decision-making processes. Pinedo [10] also found statistically significant improvements across evaluated dimensions of hospital administrative information management.

Recent peer-reviewed studies provide additional evidence on the effect of information and web systems in institutional and educational contexts. Aranda-Manchay and García-Estrella [11] implemented an information system for document management in an engineering faculty using a pre-experimental design and reported a statistically significant improvement after the intervention, with $p = 0.000$ and 80 percent user acceptance. In a closer educational context, Huaman-Yupanqui et al. [12] implemented a web information system to improve academic management at UNAMAD and reported significant reductions in process times, including user registration and certificate issuance, with a Student's t-test result of $t = -78.32$ and $p < 0.001$. From a broader information-management perspective, Șandor [13] showed that web-based information management systems commonly incorporate search engines and user-management features to support information storage, retrieval, and interaction with users.

These studies support the use of web systems as tools for improving information-management processes in different institutional contexts. However, most prior work has focused on organizational, administrative, health, or academic management environments. In contrast, the present study evaluates a web system designed for applicants of a public scholarship program, focusing specifically on the time required to access, verify, and interpret official selection-stage information.

B. Theoretical Framework

A web system is a software application accessible through a browser via the internet or an intranet, allowing users to interact with services hosted on a remote server [14]. In this study, the web system functions as a technological tool for centralizing, organizing, and presenting official Beca 18 selection-stage information in a structured digital environment. This is relevant because web-based solutions can improve access to information and support decision-making when they reduce response times and provide users with clearer and more reliable content [15].

From a design perspective, usability, web accessibility, and interactivity are relevant principles for web systems because they influence how users navigate, understand, and interact with digital information environments [16], [17], [18]. In this study, these principles informed the design of the web intervention; however, the empirical evaluation focused on the dependent variable, information-management efficiency, measured through task-completion time across information accessibility, information currency, and information quality.

Information management is understood as a process that provides the resources needed for decision-making and for improving organizational processes, products, and services [19]. Effective information management also supports more accurate decision-making by ensuring that users rely on useful and reliable data [20]. In the context of this study, information management refers to the applicant's ability to access, verify, and interpret official information required during the Beca 18 2025 selection stage. Therefore, the construct was operationalized through three dimensions: information accessibility, information currency, and information quality.

Information accessibility refers to the possibility of accessing, understanding, and using available content without physical, sensory, or technological barriers. In digital environments, accessible web interfaces are essential to ensure effective access to information [21]. In this study, accessibility is associated with the time required by applicants to locate key information such as requirements, procedures, schedules, eligible higher education institutions, and scoring criteria.

Information currency refers to the degree to which available information remains updated, reliable, and useful in changing contexts. This dimension is important because official scholarship information may involve deadlines, requirements, eligible institutions, and scoring rules that applicants must verify before making decisions [22]. In this study, information currency is associated with the time required to identify whether the consulted information is current and corresponds to the valid version of the selection-stage content.

Information quality refers to the accuracy, reliability, and absence of uncertainty in data, allowing users to interpret and apply information more safely and effectively [23]. In this study, information quality is associated with the time required by applicants to interpret the meaning of requirements, procedures, schedules, eligible institutions, and scoring criteria. Thus, the three dimensions provide the conceptual basis for

evaluating the effect of the web system on information-management efficiency.

III. Materials and Methods

The study followed a sequential workflow that began with problem identification and process analysis, continued with the design and implementation of the web system, and concluded with pre-test/post-test measurement and statistical analysis. Fig. 1 presents the overall research workflow.

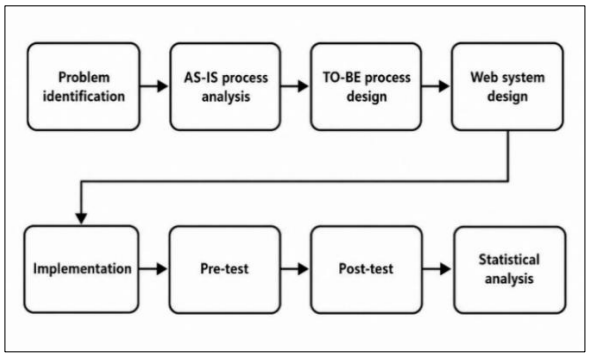

Fig. 1. Overall research workflow

A. Research Design and Study Workflow

The study was applied, quantitative, and pre-experimental. Applied research seeks to address specific problems through the use of scientific knowledge in a practical context [24]. The study followed a single-group pre-test/post-test design, O1 -> X -> O2, where O1 is the pre-test measurement, X is the web-system intervention, and O2 is the post-test measurement [25]. The explanatory scope sought to assess the changes associated with the web-system intervention in information-management outcomes; the implications of the absence of a control group are addressed in Section V. Fig. 2 summarizes the pre-experimental study process, including the sample and instrument, pre-test measurement, web-system intervention, post-test measurement, and statistical analysis.

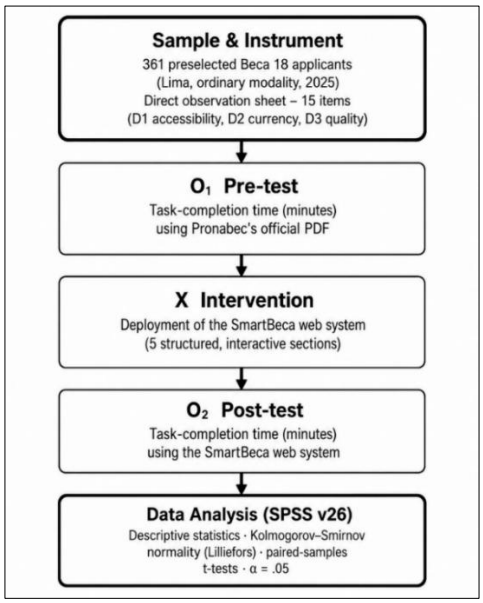

Fig. 2. Overall study process (pre-experimental single-group design).

B. Population and Sample

The target population comprised all pre-selected applicants from the ordinary modality of the Lima region for the Beca 18 2025 scholarship call. According to Pronabec [4], this population consisted of 5,830 applicants. The sample size was calculated using the finite-population formula:

$$n = (Z^2 \cdot p \cdot q \cdot N) / (e^2 (N - 1) + Z^2 \cdot p \cdot q) \quad (1)$$

With Z = 1.96, p = q = 0.5, e = 0.05, and N = 5,830, the resulting sample was 361 participants, selected through simple random sampling. Inclusion criteria required participants to be preselected applicants from the ordinary modality, from the Lima region, and from the Beca 18 2025 scholarship call.

C. Instrument

The instrument was a direct observation sheet that recorded, in minutes, the time each participant spent completing 15 observable tasks across three dimensions: information accessibility, information currency, and information quality. Times were recorded in two moments: the pre-test, in which participants used Pronabec's official PDF documentation, and the post-test, in which participants used the web system. Table I summarizes the structure of the observation instrument.

TABLE I. Observation Instrument Structure

Dimension	Items	Measurement focus
D1 — Information accessibility	1–5	Time required to locate requirements, procedures, schedule, eligible higher education institutions, and scoring criteria.
D2 — Information currency	6–10	Time required to identify whether requirements, procedures, schedule, eligible higher education institutions, and scoring criteria were current.
D3 — Information quality	11–15	Time required to interpret requirements, procedures, schedule, eligible higher education institutions, and scoring criteria.

Content validity was established through expert review by four specialists with complementary professional backgrounds in cybersecurity and information management, systems engineering, IT-project design, and public or industrial management. Because the dependent variable was operationalized as task-completion time, the instrument captures the efficiency with which applicants accessed, verified, and interpreted the required information. Complementary measures of accuracy and comprehension are discussed as a limitation in Section V.

D. Technological Implementation

The web system was built on a three-tier architecture. The frontend used Next.js, a React-based framework, to support hybrid rendering and an optimized user experience. Data persistence relied on MongoDB, a non-relational document-oriented database that provides flexible modeling and scalability. The system was deployed on Vercel, with file storage on Supabase Storage and version control through GitHub. The domain smartbeca.com was registered through Hostinger for public access, and the administrative interfaces were built with Payload CMS for structured content management. Fig. 3 shows the applicant dashboard, which centralizes the five selection-stage information sections in a single structured interface.

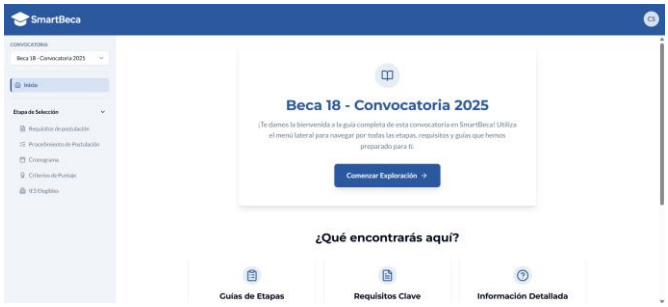

Fig. 3. SmartBeca applicant dashboard centralizes the five selection-stage information sections.

E. Data Analysis Strategy

Descriptive statistics, including mean, standard deviation, variance, minimum, and maximum values, were computed for both pre-test and post-test measurements. Normality was assessed using the Kolmogorov-Smirnov test with Lilliefors correction because the sample size was greater than 50 participants. Since normality was confirmed, paired-samples t-tests were applied to compare pre-test and post-test means for the dependent variable and each dimension. Statistical analysis was performed in SPSS v26, with the significance threshold set at $\alpha = .05$.

IV. Results

A. Descriptive Statistics

Table II presents the descriptive statistics for each dimension across both measurements. Substantial reductions were observed across all dimensions following web-system deployment. Overall information-management time decreased from a mean of 130.40 minutes in the pre-test to 50.46 minutes in the post-test, representing a 61.3 per cent reduction. The standard deviation also decreased from 11.707 to 4.216 minutes, indicating greater consistency in post-test performance.

TABLE II. Descriptive Statistics By Dimension

Dimension	*N*	*Mean*[a]	*SD*	*Var.*	*Min*	*Max*
Pre-test						
D1 — Accessibility	361	15.996	1.168	1.365	12.66	19.65
D2 — Currency	361	32.035	1.612	2.597	27.76	36.39
D3 — Quality	361	82.370	11.542	133.229	50.56	120.50
Post-test						
D1 — Accessibility	361	4.755	0.816	0.666	2.13	6.84
D2 — Currency	361	6.341	0.932	0.869	3.79	8.84
D3 — Quality	361	39.360	4.098	16.790	30.24	52.59

[a] All times are reported in minutes.

B. Normality Testing

Table III reports the Kolmogorov-Smirnov normality test results with Lilliefors correction. All eight distributions, corresponding to the three dimensions and the dependent variable in both pre-test and post-test measurements, yielded significance values above .05. Therefore, the normality assumption was met, supporting the use of parametric tests.

TABLE III. Kolmogorov-Smirnov Normality Test (Lilliefors)

Variable / Measurement	*Statistic*	*df*	*Sig. (p)*
D1 Pre-test[b]	0.033	361	0.200[a]
D1 Post-test[b]	0.032	361	0.200[a]
D2 Pre-test[b]	0.026	361	0.200[a]
D2 Post-test[b]	0.027	361	0.200[a]
D3 Pre-test[b]	0.043	361	0.098
D3 Post-test[b]	0.044	361	0.096
DV Pre-test[c]	0.044	361	0.096
DV Post-test[c]	0.037	361	0.200[a]

p-value lower-bounded at 0.200 by SPSS (Lilliefors correction)
D1, D2, D3 = dimensions of information management (Accessibility, Currency, Quality)
DV = dependent variable (Information Management)

C. Hypothesis Testing

Table IV summarizes the paired-samples t-test results. All four comparisons yielded significance values below .001, indicating statistically significant reductions in the dependent variable and the three evaluated dimensions after the web-system intervention.

TABLE IV. Paired-Samples T-Test Results (Pre-Test – Post-Test)

Comparison	*Mean Diff*[a]	*SD*	*SE*	*95% CI*	*t*	*Sig.*
DV: Information Management	79.945	12.869	0.677	78.613–81.277	118.035	<.001
D1: Accessibility	11.240	1.385	0.073	11.097–11.384	154.221	<.001
D2: Currency	25.694	1.900	0.100	25.497–25.890	256.951	<.001
D3: Quality	43.011	12.649	0.666	41.701–44.320	64.608	<.001

Mean difference reported in minutes (pre-test minus post-test); positive values indicate reduction.

For the dependent variable, overall information management, the mean difference was 79.945 minutes, with a 95 per cent confidence interval from 78.613 to 81.277 minutes. For D1, information accessibility, the mean difference was 11.240 minutes, representing a 70.3 per cent reduction. For D2, information currency, the mean difference was 25.694 minutes, representing an 80.2 per cent reduction, the largest proportional improvement. For D3, information quality, the mean difference was 43.011 minutes, representing a 52.2 per cent reduction. These results provide statistical evidence that the web system significantly reduced the time required to access, verify, and interpret selection-stage information.

V. Discussion

The findings show statistically significant reductions in the time required to complete information-management tasks after the implementation of the web system. The overall mean time decreased from 130.40 to 50.46 minutes, which is consistent with Lopez [7], who reported improvements in information registration, consultation, and report generation after deploying a web system in an occupational-safety context. Both studies

suggest that structured web interfaces can reduce the effort required to locate and use institutionally held information.

The largest relative improvement was recorded in information currency, with an 80.2 per cent reduction. Before the intervention, applicants invested considerable time verifying whether the consulted information was current, a challenge associated with static PDF-based delivery and the difficulty of identifying updated versions. This finding is consistent with Pinedo [10], whose web application for hospital administrative information yielded significant improvements in data update management. It also relates to Colan [5], who reported gains in the timeliness of information availability, a concept closely associated with information currency.

For information accessibility, which showed a 70.3 per cent reduction, the results are consistent with Alvarado [6], who reported a reduction in incident-resolution time from 59.44 to 19.11 minutes in a comparable pre-experimental design. They are also aligned with Colan [5], who found improvements in agility during information retrieval. Across these studies, centralized and structured web interfaces appear to reduce barriers that impede direct access to required information.

The information-quality dimension showed a 52.2 per cent reduction and the highest individual variability in the pre-test. This variability may be associated with differences in applicants' digital literacy and prior familiarity with the Beca 18 selection process. The result is consistent with Chaupez and Rojas [8], who reported heterogeneous improvements in an academic information-management context after the implementation of a web system. In the present study, the organized and structured presentation of information appears to have reduced the time required to interpret requirements, procedures, schedules, eligible institutions, and scoring criteria.

Several limitations qualify these findings. First, the dependent variable was operationalized solely as task-completion time. While this captures the efficiency of information retrieval and interpretation tasks, it does not establish whether applicants retrieved accurate information or interpreted it correctly. Therefore, the construct of information-management optimization is evidenced within the scope of time-based task performance, and future studies should incorporate accuracy, comprehension, and user-satisfaction measures alongside time.

Second, the single-group pre-experimental design included no control group, so threats to internal validity cannot be fully ruled out. In particular, the Hawthorne effect, the testing effect, and maturation are plausible partial explanations for the observed reductions, especially for tasks requiring longer interpretation time. Quasi-experimental designs with matched control groups and counterbalanced task orders would strengthen causal attribution in future research.

Third, the sample was restricted to ordinary-modality applicants in the Lima region, so generalization to other regions or modalities warrants caution. Rural areas of Peru face heterogeneous connectivity and device availability, which could affect both system adoption and the magnitude of the time savings reported here. Evaluating the system under diverse connectivity conditions, including low-bandwidth and mobile-first scenarios, is a relevant direction for future work and would broaden the practical interest of the solution.

VI. Conclusion

This study showed that implementing the web system significantly improved the efficiency of information management for preselected applicants of the Beca 18 2025 scholarship call. Overall mean time decreased from 130.40 to 50.46 minutes, supporting the general hypothesis. The system functioned as a tool for centralizing, organizing, and presenting selection-stage information, enabling applicants to access, verify, and interpret it in less time and with greater autonomy.

Information currency recorded the greatest relative improvement, indicating that the permanent availability of updated and centralized content is a relevant factor in information-management efficiency within high-stakes application contexts. Information accessibility also improved substantially, showing that structured web navigation helped reduce the barriers associated with PDF-based information delivery. Information quality improved as well, indicating that the way a system organizes and presents information can reduce the time required for users to interpret and apply it.

The findings support recommending that Pronabec adopt web-based information platforms as a primary information channel for future Beca 18 calls, with protocols to ensure periodic content updates. Future studies should replicate the research using quasi-experimental designs with control groups and incorporate complementary measures such as accuracy, comprehension, and user satisfaction to strengthen the evidence base for this type of intervention in educational-inclusion programs.

Acknowledgment

We thank the Universidad Científica del Sur for the support and training provided during the development of this research, as well as the preselected Beca 18 applicants who participated in the study and shared their experiences. As former beneficiaries of the program, we hope this work contributes to clearer and more timely access to scholarship information for future applicants.

A Modified Lyapunov-Based MEC Offloading Algorithm for Severity-Aware QoS in 5G/B5G IoT Systems

Modified Lyapunov-Based Severity-Aware QoS in 5G/B5G IoT Systems

Sahana S Reddy*, R. Sukumar
Department of Electronics and Communication Engineering, JAIN (Deemed to be University), Bengaluru, 560 034, India

***Abstract*—The rapid growth of latency-sensitive and computation-intensive IoT applications in 5G and Beyond-5G (B5G) networks has increased the demand for efficient Multi-access Edge Computing (MEC) offloading strategies. Current MEC frameworks have several limitations: 1) binary QoS modeling without considering deadline violation severity, 2) a lack of severity-aware optimization in IoT applications, 3) insufficient consideration of different task criticality, and 4) poor handling of dynamic latency and energy trade-off in large-scale IoT environments. This study proposes a modified Lyapunov-based severity-aware MEC offloading framework for heterogeneous 5G/B5G IoT systems. The proposed framework utilizes task deadlines, task criticality, queue states, wireless channel conditions, and MEC resource availability as input for adaptive offloading optimization. A QoS Violation Severity Index is introduced to jointly capture deadline violation magnitude and task criticality. Furthermore, severity-aware virtual queues are integrated with a modified Lyapunov Drift-Plus-Penalty optimization framework to dynamically minimize QoS violation severity while balancing latency and energy consumption. Experimental evaluation demonstrates that the proposed framework significantly reduces average task delay to 82 ms, energy consumption to 6.0 mJ, and QoS violation rate to 4.8%, while improving long-term system stability compared with existing MEC offloading approaches in dynamic 5G/B5G IoT environments.**

I. Introduction

The evolution of 5G and Beyond-5G (B5G) networks have greatly improved the capabilities of the Internet of Things (IoT) by facilitating ultra-reliable communication, massive device connectivity and low-latency services [1]. These networks enable real-time applications like smart healthcare, autonomous transportation, industrial automation, intelligent surveillance, and smart city infrastructures, which produce and process huge amounts of heterogeneous data [2, 3]. To facilitate such latency-sensitive applications, Multi-access Edge Computing (MEC) has been embedded into 5G/B5G architectures to introduce computation and storage to the end-users and thereby shorten the communication latency and improve service responsiveness [4, 5]. Although the 5G/B5G IoT technologies have made great strides, modern network has still many challenges in operation and resource management [6]. The massive growth of connected devices introduces network congestion, complexity of resource allocation, and changes in traffic patterns, making the efficient management of tasks highly challenging [7, 8]. Moreover, IoT devices also have limited battery power, computation capability, and storage capacity, which increases the reliance on edge servers [9, 10]. Furthermore, heterogeneous IoT applications show a wide variety of Quality of Service (QoS) demands related to latency, reliability, bandwidth, and energy efficiency, making uniform resource management ineffective [11, 12]. Therefore, achieving reliable QoS under various latency, energy consumption, and resource utilization constraints remains a significant challenge in the modern 5G and B5G IoT environments [13].

Several existing studies analyze MEC-based task offloading and resource optimization techniques to improve QoS performance in 5G and B5G IoT networks [14, 15]. For instance, a joint optimization framework for energy consumption and time delay in dependency-aware task offloading for 5G applications was developed [16]. It used a Directed Acyclic Graph (DAG) to analyze the dependencies between tasks and an improved Particle Swarm Optimization (PSO) algorithm to optimize task offloading decision and MEC server selection optimization. To efficiently manage the task, a 5G-MEC task offloading framework was developed, which minimizes dropped task ratio, computational latency, and communication latency through Mixed Integer Linear Programming (MILP), PSO, and Genetic Algorithm (GA) [17]. Despite the progress, several key research gaps remain. 1) Existing works usually model QoS violations in a binary way without considering the severity of deadline misses, making it ineffective in handling latency-sensitive IoT applications [18,19]; 2) Most existing schemes focus on optimizing average latency or energy consumption rather than explicitly minimizing severe QoS violations, which expose critical tasks to risks [20]; 3) Current MEC offloading frameworks consider limited heterogeneous task criticality, leading to unfair QoS degradation for high-priority applications [21, 22]; 4) Many existing solutions assume relatively homogeneous IoT environments and fail to effectively address the diverse latency, reliability, and energy requirements of large-scale heterogeneous IoT applications in dynamic 5G and B5G networks [23, 24]. To overcome these, the proposed work develops a severity-aware MEC task offloading framework for 5G and Beyond-5G IoT networks that minimizes

*Corresponding author.

severe QoS violations while balancing latency and energy consumption for heterogeneous IoT applications. To achieve this, a modified Lyapunov Drift-Plus-Penalty (LDPP) optimization framework is developed to enable dynamic and real-time offloading decisions by jointly stabilizing severity-aware virtual queues and optimizing system performance under varying network conditions. The key novelty of the proposed framework is as follows:

Severity-Aware QoS Violation Modeling: A novel QoS Violation Severity Index (QVSI) is proposed to quantify the severity of the delay violation by combining the task criticality and the magnitude of delay violation, overcoming the limitations of traditional binary QoS models in 5G/B5G IoT networks.

Modified Lyapunov-Based Optimization Framework: A severity-aware virtual queue model is incorporated into a modified LDPP optimization framework to jointly minimize the severity of QoS violation, LATENCY, and energy consumption while ensuring long-term stability.

Adaptive MEC Offloading Decision Strategy: An intelligent offloading mechanism is developed to dynamically select local execution, MEC offloading, and cooperative MEC execution based on the real-time queue states, channel conditions, and the available MEC resources in the large-scale heterogeneous IoT environment.

Efficient Support for Heterogeneous 5G/B5G IoT Applications: The proposed framework effectively handles heterogeneous IoT applications with different latency requirements and criticality levels, while minimizing the occurrence of severe QoS violations, deadline miss ratio, latency, and energy consumption compared with existing MEC offloading approaches.

The article is structured as follows. A review of the relevant works is presented in Section II. Section III includes a detailed process of the proposed approach for task offloading in MEC-enabled IoT systems. Section IV exhibits the findings and discussion, and Section V concludes with the findings of the study.

II. Related Work

This section reviews the related work on existing MEC-based task offloading and resource allocation methods in 5G/B5G IoT environments. Zhai et al. [25] modeled a task-offloading scheme for hybrid edge computing networks, where the tasks can be executed locally, offloaded to edge servers, or forwarded to neighboring outgoing devices. It used Deep Reinforcement Learning (DRL) with a Double Deep Q Network (DDQN) algorithm to optimize the task offloading decisions, reducing the overall task delay and prioritizing the high-priority tasks. However, the framework mainly focused on delay-aware offloading and priority scheduling, whereas the severity of QoS violations, heterogeneous task criticality, and long-term queue stability were not explicitly modeled in the optimization process. Benbraika et al. [26] introduced the Hungarian Algorithm for Task Offloading (HATO) for effective task scheduling in 5G-enabled Vehicular Edge Computing (VEC) systems. The model effectively distributed computational workloads, reduced delay, and improved task processing performance in autonomous vehicles. However, the approach mainly depended on stable 5G connectivity and central edge server support, which may affect performance in highly dynamic real-time environments.

To balance the trade-off between energy consumption and computation time, Alam et al. [27] introduced task offloading and resource allocation for the Internet of Vehicles (IoV) using PSO. The method improved QoS, reduced latency, and minimized energy consumption during computational task execution. However, the model was estimated under limited network settings, and it could not capture task criticality during offloading optimization, which limits its applicability to delay-sensitive applications. Younis et al. [28] introduced an Energy-Latency-aware Task Offloading and Approximate Computing (ETORS) framework to optimize the trade-off between energy consumption and latency using the Dual-Decomposition Method (DDM). This framework intelligently balances the energy consumption and shortened completion time by processing the workloads without overloading. However, the framework primarily focused on energy-latency trade-off optimization without considering severity-aware QoS degradation and long-term queue stability. Luo et al. [29] introduced a joint task offloading and resource allocation framework for MEC using the Lyapunov optimization with the Potential Minimum Point (PMP) algorithm. The model achieved increased QoS, lowered latency, balanced energy consumption, and better system stability. However, the framework focused mainly on resource optimization and system stability, while the effect of deadline violation and differentiated QoS handling for critical IoT tasks remains unexplored. Yang et al. [30] introduced a Deep Reinforcement Learning-based Task Offloading (DRTO) framework in MEC systems using Deep Neural Networks (DNNs) and Reinforcement Learning (RL) techniques. The method helped reduce task delay, improved computation efficiency, and increased the speed of offloading decisions under changing wireless network conditions. However, the framework mainly focused on delay optimization and could not jointly optimize QoS violation severity, latency, and energy consumption under long-term queue stability constraints in heterogeneous IoT environments.

Mathi et al. [31] introduced a Distributed Collaborative Learning Framework to detect Black Hole Attacks in the Routing Protocol for Low-power and Lossy networks (RPL) based Internet of Things (IoT) networks. The framework reduces communication overhead, energy consumption, and computational complexity. However, the framework is mainly focused on detecting black hole attacks; performance in IoT deployments cannot be discussed. Xiao and Dong [32] introduced a lightweight CNN-based deep learning model for graphic recognition in the Internet of Things (IoT) ecosystem. The model was suitable for resource-limited IoT devices and supports simultaneous graphic recognition applications. However, the impact of varying network conditions and device heterogeneity was not analyzed. Vidyaningtyas et al. [33] introduced a Sequential Power Allocation (SePA) algorithm to optimize power distribution within each sector. The method minimizes intra-sector interference and improves power efficiency, and the framework supports reliable communication in high-density environments such as Internet of Things (IoT)

networks. However, the machine learning-based optimization techniques are not integrated.

Thus, by analyzing extensive research on MEC-based task offloading and resource optimization in 5G and B5G IoT networks. Existing approaches mainly focus on minimizing the average latency, energy consumption, or overall task failure rate without explicitly considering the severity of QoS violations. Most existing approaches consider QoS satisfaction in a binary manner and ignore the extent to which deadlines are missed, which is critical for latency-sensitive and mission-critical IoT applications. Moreover, there is a limited consideration of heterogeneous task criticality and diverse QoS requirements, leading to suboptimal and sometimes unfair resource allocation for high-priority tasks. As a result, current MEC offloading frameworks remain insufficient in effectively handling severe QoS degradation under dynamic and large-scale IoT network conditions. Therefore, the proposed framework develops a severity-aware LDPP-based offloading algorithm that minimizes severe QoS violations while balancing latency and energy consumption.

III. System Overview

The proposed system considers a 5G/B5G-enabled MEC architecture consisting of multiple heterogeneous IoT devices, a 5G/6G base station, and an edge server connected through wireless communication links, as shown in Fig. 1. Each IoT device creates computation-heavy and latency-sensitive tasks that are stored in local task queues. The IoT devices have different battery life, computing power, and QoS needs, making the network highly dynamic and resource-constrained. Depending on various wireless channel conditions, queue status, task deadline, and device energy level, each task may be processed locally on the IoT device or offloaded to the MEC/edge cloud server for faster processing. The wireless communications between the IoT devices and the MEC server are represented through time-varying channel states, which represent real-world network dynamics. To effectively provide delay-sensitive and critical IoT applications in 5G/B5G environments, the proposed framework introduces a severity-aware task management scheme that measures the QoS violation, optimizes offloading decisions adaptively to minimize the latency, energy consumption, and service reliability.

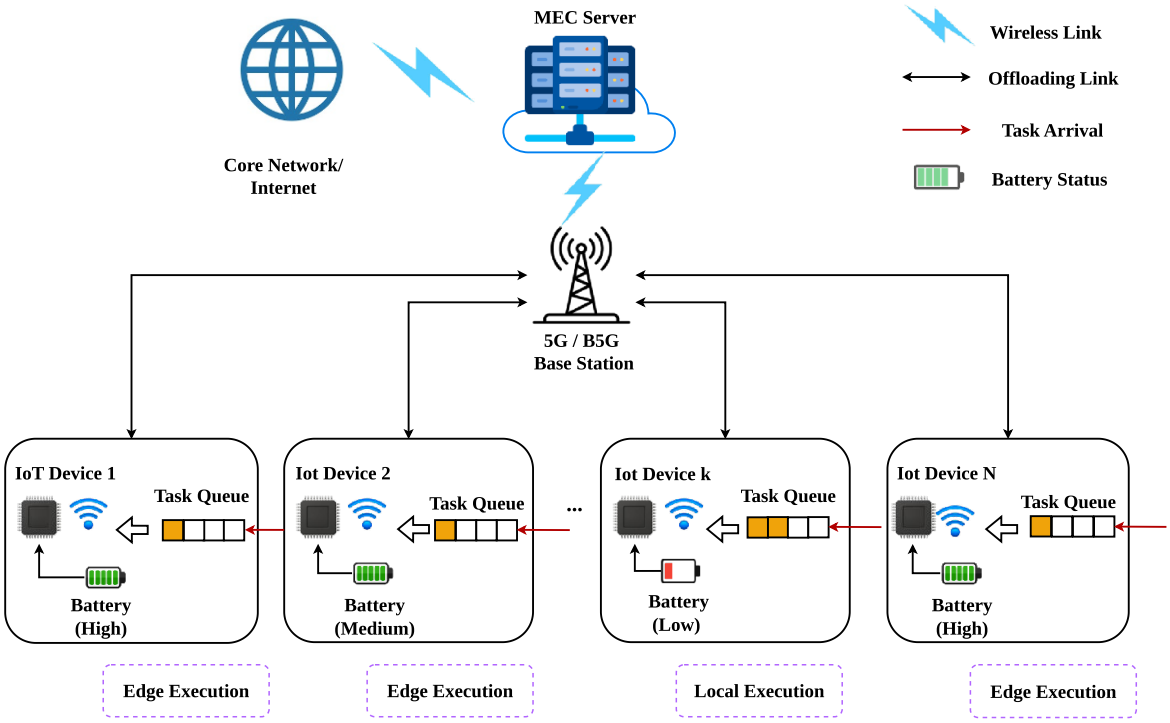

Fig. 1. System model for multi-access edge computing-assisted task offloading in heterogeneous 5G/B5G IoT environments.

A. Problem Formulation

The considered 5G/B5G MEC-enabled IoT system supports multiple heterogeneous IoT devices that generate computation-intensive and latency-sensitive tasks to be executed locally or offloaded to the MEC server. The primary goal is to reduce the QoS violation severity, latency, and energy consumption, while maintaining long-term system stability under stochastic task arrival. In contrast to traditional binary QoS models, a severity-aware optimization framework is incorporated to account for the magnitude of deadline misses and for task importance. The optimal long-term problem is formulated as shown in Eq. (1).

$$min\ lim_{T\to\infty} \frac{1}{T}\sum_{t=1}^{T} \mathrm{E}\left[\sum_{i=1}^{N}\left(\alpha S_i(t) + \beta T_i(t) + \gamma E_i(t)\right)\right] \quad (1)$$

where, $\mathrm{E}[\cdot]$ representing long-term average system behavior, $S_i(t)$, $T_i(t)$, and $E_i(t)$ represent the severity of QoS violation, latency and energy consumption, respectively, N is the total number of IoT devices, T is the total simulation, and t is the discrete time slot. The weighting factors α, β, and γ are such that $\alpha + \beta + \gamma = 1$, controlling the balance between severity,

delay, and energy efficiency. System stability is guaranteed by resource constraints as the sum of computation capacity of MECs is bounded by $\sum_{i\epsilon N} f_i(t) \leq F^{max}$ and the sum of communication bandwidths of MECs is bounded by $\sum_{i\epsilon N} b_i(t) \leq B^{max}$. The components $f_i(t)$ and $b_i(t)$ are the allocated computing and bandwidth resources, and F^{max} and B^{max} are the maximum capacities of computing and bandwidth, respectively. To achieve long-term stability, the virtual queue should be bounded as in Eq. (2).

$$lim_{T\to\infty} sup \frac{1}{T} \sum_{t=1}^{T} E[Z_i(t)] < \infty \quad (2)$$

where, $Z_i(t)$ is the severity-aware queue length. Lastly, exactly one execution mode is chosen for each task, in which the decision variables are binary. The problem is formulated as a stochastic optimization problem that minimizes the severity of the long-term QoS violations, the system latency, and the system energy consumption under the system constraints.

B. Proposed Severity-Aware Offloading Framework

The proposed severity-aware MEC offloading framework sequentially and iteratively operates to efficiently manage computation tasks in 5G/B5G IoT environments, as depicted in Fig. 2. Initially, the IoT devices generate heterogeneous tasks, characterized by data size, deadline constraints, and levels of criticality. The system estimates the local execution and MEC offloading delay, including transmission and computation for each task. Based on these delays, the QVSI is calculated to reflect the degree of possible violation of the deadlines while incorporating task importance. The obtained severity values are then used to update severity-aware virtual queues, which capture the accumulated QoS degradation over time. These queue states are then embedded in an LDPP optimization framework to optimize latency, energy use, and severity-aware QoS performance. This optimization dynamically switches between local processing mode, MEC offloading mode, and cooperative MEC execution mode based on the system conditions of each task. The selected decisions are then implemented, and the resulting delay and energy consumption are recorded for performance assessment. Finally, the severity-aware queues are updated based on the observed outcomes, and the process repeats over the successive time slots, which makes real-time adaptive and stable offloading decisions under the dynamic network conditions.

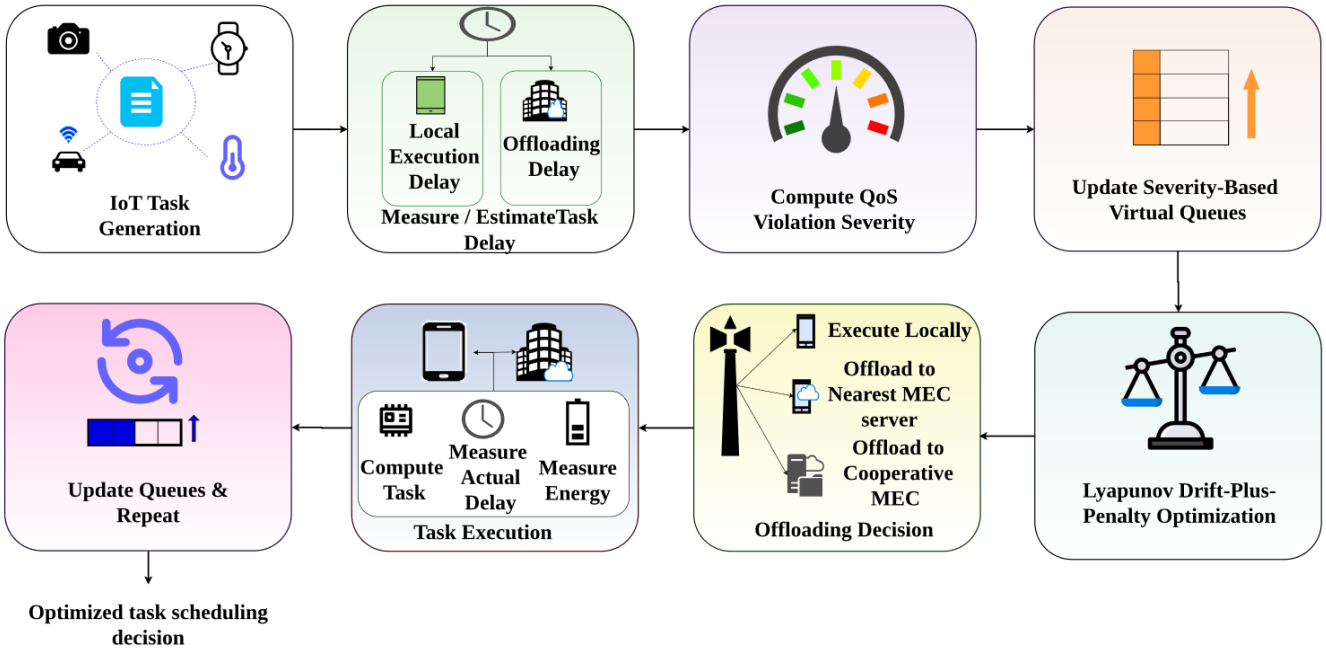

Fig. 2. Architecture of the proposed severity-aware Lyapunov-based MEC offloading system for 5G/B5G IoT networks.

1) System initialization and task modelling: In the considered 5G/B5G MEC enabled IoT environment, a collection of heterogeneous IoT devices $\mathcal{N} = \{1,2,\dots,N\}$ dynamically generates computation tasks over time. Every task generated by the i-th device $\mathcal{T}_i(t)$ is expressed as follows in Eq. (3).

$$\mathcal{T}_i(t) = \{S_i^{data}(t), D_i^{max}, C_i\} \quad (3)$$

where, $S_i^{data}(t)$ is the task size, D_i^{max} is the deadline constraint, and C_i is the task criticality. The task criticality factor C_i represents the priority level of each IoT task and is assigned based on the application type and service requirements. In the proposed framework, C_i is predefined at the time of task generation and remains static throughout the task execution process. Specifically, high-criticality tasks (e.g., URLLC-based applications) are assigned higher weights, medium-criticality tasks are assigned moderate weights, and low-criticality tasks are assigned lower weights. This static assignment reflects the inherent priority differences among heterogeneous IoT services and ensures consistent severity-aware scheduling and offloading decisions within the Lyapunov optimization framework. Each task is initially stored in the local queue of each IoT device upon arrival, and then a decision is taken to either execute or offload the task. The local task dynamics at each device are modeled as indicated in Eq. (4).

$$Q_i(t+1) = max[Q_i(t) - \mu_i(t), 0] + A_i(t) \quad (4)$$

where, $Q_i(t)$ is the queue backlog of the device i, $A_i(t)$ is the number of newly arrived tasks at the time slot t, $\mu_i(t)$ is the number of tasks processed or offloaded at the time slot t, and $Q_i(t+1)$ is the updated queue backlog of IoT devices i at the next time slot $t+1$. This queue formulation represents the stochastic network conditions with dynamic arrival and service processes of IoT tasks. The defined queueing model serves as the foundation for subsequent severity-aware optimization and Lyapunov-based offloading decisions in the proposed framework.

2) Task characterization and delay estimation: For each incoming task i, the system evaluates its execution characteristics under two different modes: local execution and MEC offloading [34]. The local execution delay $D_i^{loc}(t)$ is dependent on the computational power of the IoT device and is represented as given in Eq. (5).

$$D_i^{loc}(t) = \frac{S_i^{data}(t).k}{f_i^{loc}(t)} \quad (5)$$

where, $S_i^{data}(t)$ is the size of the task, k is the number of CPU cycles needed per bit of data, and $f_i^{loc}(t)$ is the local CPU frequency. In the case of MEC offloading, the overall delay consists of the transmission delay and the edge computation delay as indicated in Eq. (6).

$$D_i^{mec}(t) = D_i^{trans}(t) + D_i^{edge}(t) \quad (6)$$

where, $D_i^{mec}(t)$ denotes total MEC offloading delay, $D_i^{trans}(t)$ denotes uplink data transmission delay, and $D_i^{edge}(t)$ denotes the delay in data processing. The system chooses the minimum possible delay based on the network condition, channel state, and available resources. The resulting estimated delay $D_i(t)$ is referred as shown in Eq. (7).

$$D_i(t) = min\left(D_i^{loc}(t), D_i^{mec}(t)\right) \quad (7)$$

This process is subsequently applied in QoS violation severity computation and offloading optimization decisions.

3) QoS violation severity modeling: In conventional MEC offloading systems, QoS is generally considered in a binary way, either a task meets or fails its deadline constraint. However, such modeling fails to capture the extent of violation, an important aspect in 5G/B5G IoT systems supporting heterogeneous and latency-sensitive applications. To overcome this limitation, the delay violation function $V_i(t)$ [35] of task i at the time slot t is defined as shown in Eq. (8).

$$V_i(t) = max(0, D_i(t) - D_i^{max}) \quad (8)$$

where, $D_i(t)$ is the actual or estimated time to complete the task and D_i^{max} is the maximum permissible task completion time. The function guarantees that only positive deadline deviations are considered, and the penalty for non-violated tasks is zero.

To further model heterogeneity in the IoT applications, each task is given a criticality factor C_i denoting the priority level and importance of the task. By combining delay violation magnitude and the importance of the task, the QVSI [36] is defined as follows in Eq. (9).

$$S_i(t) = C_i \cdot V_i(t) \quad (9)$$

where, $S_i(t)$ is the severity of the QoS violation of the task i. The final severity model is given as follows in Eq. (10).

$$S_i(t) = C_i \cdot max(0, D_i(t) - D_i^{max}) \quad (10)$$

A QoS violation is considered to occur when the task completion delay exceeds its deadline, i.e., $D_i(t) > D_i^{max}$. However, unlike conventional binary models, the proposed framework does not treat QoS violation as a binary event. Instead, the severity of the violation is quantified using the QVSI $S_i(t)$, which jointly captures both the magnitude of deadline violation and the task criticality. Therefore, although violation detection is based on deadline exceeding, the decision-making process is entirely driven by the severity value $S_i(t)$, rather than a binary QoS indicator. This formulation makes it possible to jointly consider the degree of violation of the deadline and the criticality of the task in the system design. The proposed QVSI serves as a key input for the Lyapunov-based optimization framework by updating virtual queues according to the severity and influencing real-time offloading decisions.

4) Severity-aware virtual queue construction: To guarantee long-term QoS violation control, a severity-aware virtual queue is introduced for each IoT device. The idea behind this virtual queue is to redefine the problem of managing QoS violations as a stochastic queue stability problem, allowing the use of Lyapunov optimization for offloading decisions at real-time [37].

In particular, let $S_i(t)$ be the QVSI for the task i in the time slot t. The severity-based virtual queue evolution $Z_i(t+1)$ is defined as shown in Eq. (11).

$$Z_i(t+1) = max[Z_i(t) + S_i(t), 0] \quad (11)$$

where, $Z_i(t)$ represents the accumulated severity backlog of the device i at time t with initial condition zero. The virtual queue accumulates the QoS violation severity over time, such that the higher the value indicates severe or persistent the deadline violations. This allows prioritization of high-severity tasks during scheduling and offloading decisions.

By including $Z_i(t)$ into the Lyapunov framework, the QoS violation minimization problem is converted into a queue stability problem. This enables real-time optimization of latency, energy consumption, and severity-aware QoS performance. This formulation dynamically penalizes continually violated tasks and provides long-term stability of the system with respect to its QoS.

5) Lyapunov drift-plus-penalty formulation: The proposed severity-aware MEC offloading framework minimizes the long-term QoS violation severity by stabilizing the severity-aware virtual queues, while simultaneously optimizing latency and energy consumption through the penalty component of the Lyapunov Drift-Plus-Penalty framework [38]. The system stability is characterized using a Lyapunov function $L(t)$

defined over the severity-aware virtual queues as shown in the Eq. (12).

$$L(t) = \frac{1}{2}\sum_{i=1}^{N} Z_i^2(t) \quad (12)$$

where, N is the number of the total IoT devices and $Z_i(t)$ is the backlog of virtual queues for IoT device i at time t determined by its severity. The term $Z_i^2(t)$ helps to ensure system stability by providing a higher penalty if the queue backlog is larger.

To jointly optimize system performance and queue stability, the one-slot conditional Lyapunov drift $\Delta L(t)$, is defined as shown in Eq. (13).

$$\Delta L(t) = \mathbb{E}[L(t+1) - L(t) | Z(t)] \quad (13)$$

where, $L(t+1)$ is the Lyapunov function value at the next time slot $t+1$ and $\mathbb{E}[\cdot]$ denotes the expectation taken over the system randomness, including the arrival of tasks, channel variations, and offloading decisions.

The Lyapunov drift inherently captures the accumulated QoS violation severity through the severity-aware virtual queue $Z_i(t)$, whose evolution is governed by the QoS Violation Severity Index $S_i(t)$ in Eq. (11). Therefore, minimizing the Lyapunov drift implicitly minimizes the long-term QoS violation severity. Consequently, the penalty term is introduced only for latency and energy consumption, avoiding redundant optimization of the severity objective. The resulting Drift-Plus-Penalty (DPP) function is expressed in Eq. (14).

$$\mathcal{O}_t = \Delta L(t) + V \cdot \mathbb{E}[\lambda P(t) + \mu T(t) | Z(t)] \quad (14)$$

where, $\mathcal{O}_t$ represents the combined Lyapunov drift and penalty function, $P(t) = \sum_{i=1}^{N} P_i(t)$ represents total energy consumption at time t, and $T(t) = \sum_{i=1}^{N} T_i(t)$ represents the total task latency in the system. The parameter $V > 0$ determines the trade-off between maintaining queue stability and optimizing system performance, while λ and μ ($\lambda + \mu = 1$) control the relative importance of latency and energy consumption in the penalty term. Specifically, smaller values of V place greater emphasis on stabilizing the severity-aware virtual queues, thereby reducing long-term QoS violation severity, whereas larger values prioritize the optimization of latency and energy consumption. In this work, the value of V was selected based on preliminary simulation experiments to achieve a balanced trade-off between QoS violation severity, latency, and energy consumption. Unlike the overall optimization objective in Eq. (1), which considers QoS violation severity, latency, and energy consumption, the Drift-Plus-Penalty formulation optimizes the QoS violation severity implicitly through the Lyapunov drift via the severity-aware virtual queues, while latency and energy consumption are optimized explicitly through the penalty term. Thus, the proposed optimization remains fully consistent with the long-term objective while enabling adaptive real-time MEC offloading in 5G/B5G IoT networks. This detailed process is shown in Fig. 3.

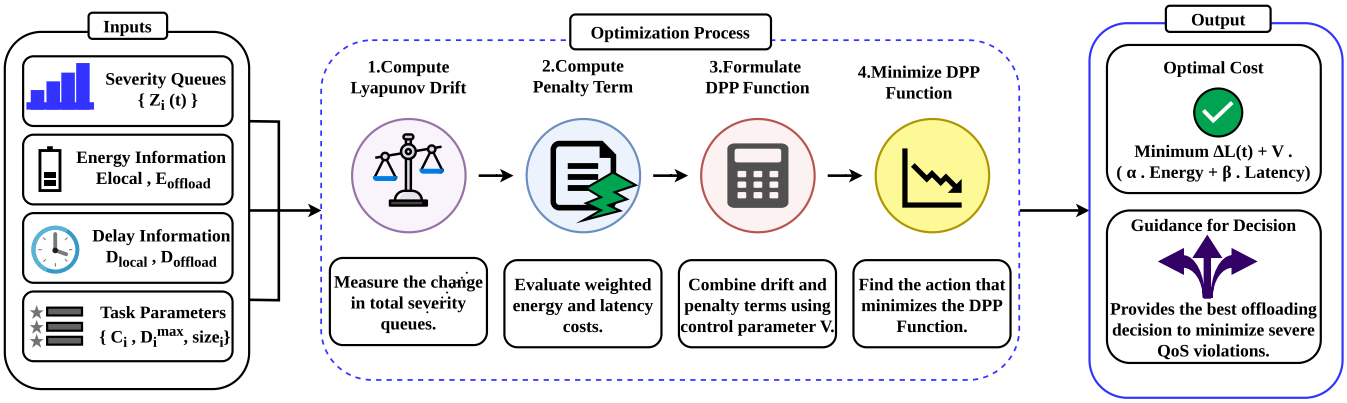

Fig. 3. Severity-aware Lyapunov Drift-Plus-Penalty (LDPP) optimization process in MEC-enabled 5G/B5G IoT networks.

Theoretical Stability Analysis: To theoretically justify the long-term stability of the proposed severity-aware MEC offloading framework, we analyze the system using Lyapunov optimization under stochastic network conditions.

The following standard assumptions are considered: 1) task arrivals follow a stochastic process with bounded first and second moments, 2) wireless channel states are time-varying and stochastic but remain bounded within a finite support, 3) task sizes, computational workloads, and delay deadlines are finite and bounded, and 4) system resources including computation and communication capacities are finite and constrained as defined in the system model.

Theorem 1 (Queue Stability Guarantee): Under the above assumptions, the proposed severity-aware Lyapunov Drift-Plus-Penalty (DPP) based offloading policy ensures that the severity-aware virtual queues $Z_i(t)$ are mean-rate stable. Furthermore, the time-average expected queue backlog remains bounded, guaranteeing long-term stability of the MEC system under stochastic task arrivals and time-varying wireless channel conditions.

Proof:

The Lyapunov function is defined in Eq. (15).

$$L(t) = \frac{1}{2}\sum_{i=1}^{N} Z_i^2(t) \quad (15)$$

The conditional Lyapunov drift is given by Eq. (16).

$$\Delta L(t) = \mathbb{E}[L(t+1) - L(t) \mid Z(t)] \quad (16)$$

Using the queue evolution, it is expressed as shown in Eq. (17).

$$Z_i(t+1) = \max[Z_i(t) + S_i(t), 0] \quad (17)$$

The drift can be upper-bounded as shown in Eq. (18).

$$\Delta L(t) \leq B + \sum_{i=1}^{N} Z_i(t)\mathbb{E}[S_i(t) \mid Z(t)] \quad (18)$$

where, B is a finite constant due to bounded severity values. The proposed DPP policy minimizes as expressed in Eq. (19).

$$\Delta L(t) + V \cdot \mathbb{E}[\lambda P(t) + \mu T(t) \mid Z(t)] \quad (19)$$

This ensures that the Lyapunov drift is driven toward stability while simultaneously optimizing latency and energy consumption. Since the severity-aware virtual queue is updated using bounded QVSI values, repeated minimization of the drift guarantees that the time-average queue backlog remains finite, as expressed in Eq. (20).

$$\lim_{T\to\infty} \frac{1}{T} \sum_{t=1}^{T} \mathbb{E}[Z_i(t)] < \infty \quad (20)$$

which implies mean-rate stability of all virtual queues. Thus, the proposed framework ensures long-term queue stability under stochastic task arrivals and time-varying wireless channels while jointly optimizing QoS violation severity, latency, and energy consumption in real time.

6) Severity-aware offloading decision policy: Based on the instantaneous system state, each IoT task chooses one of the execution modes among local processing, MEC offloading, or cooperative MEC execution. The decision is formulated as an LDPP minimization problem that combines queue stability, latency and energy consumption.

Let the three binary decision variables $x_i^{loc}(t)$, $x_i^{mec}(t)$, and $x_i^{coop}(t)$ for the three modes of execution. The constraint is enforced by the system, which is represented by Eq. (21).

$$x_i^{loc}(t) + x_i^{mec}(t) + x_i^{coop}(t) = 1, \forall_i \in N \quad (21)$$

At each time slot t, the system solves the following instantaneous optimization problem under the LDPP framework as shown in Eq. (22).

$$\min_{x_i^{loc}(t), x_i^{mec}(t), x_i^{coop}(t)} \Delta L(t) + V \cdot \mathbb{E}[\alpha E(t) + \beta T(t) \mid Z(t)] \quad (22)$$

subject to execution mode constraint (15), computation resource constraint: $\sum f_i(t) \leq F^{max}$, communication bandwidth constraint: $\sum b_i(t) \leq B^{max}$, binary decision constraints: $x_i^{loc}(t), x_i^{mec}(t), x_i^{coop}(t) \in \{0,1\}$. Where $Z(t)$ represents the severity-aware virtual queue vector. Tasks with higher queue backlog values $Z_i(t)$ are implicitly prioritized due to their stronger contribution to the Lyapunov drift term. The optimal decision is obtained by evaluating the drift-plus-penalty cost corresponding to each execution mode and selecting the mode that minimizes the objective function. This converts the long-term stochastic optimization problem into a real-time per-slot control policy suitable for dynamic 5G/B5G MEC environments.

In local execution, tasks are processed directly at the IoT device using its available computational resources. In MEC offloading, tasks are transmitted to the nearest edge server via the base station for remote execution. In cooperative MEC execution, tasks are partitioned into smaller subtasks and distributed across multiple MEC servers according to their current computational load and queue states. Coordination among MEC servers is achieved through lightweight exchange of control information, such as queue length and resource availability, via an edge orchestration layer. This coordination introduces negligible overhead compared to task execution time and is not explicitly modeled in delay analysis. Inter-edge communication is assumed to occur over a high-speed wired backhaul, and its delay is incorporated into the overall MEC execution delay while remaining significantly lower than wireless transmission delay. The proposed approach dynamically responds to channel conditions, queue states, and task urgency, allowing real-time severity-aware offloading, while reducing the severity of QoS violation, energy consumption, and latency.

7) Task execution and system operation: After the offloading decision $x_i^{loc}(t)$, $x_i^{mec}(t)$, and $x_i^{coop}(t)$ is determined, each task on the IoT is implemented based on the selected mode. In the local execution mode, the tasks are executed locally at the IoT device using its available computational resources. In the MEC offloading mode, tasks are transmitted to the nearest edge server via the base station, while in the cooperative MEC mode, tasks are distributed among multiple edge servers for load balancing. The overall delay of the executions is controlled by a transmission delay and a computation delay, depending on the mode used. Each task requires a certain amount of energy given by Eq. (23).

$$E_i(t) = \begin{cases} E_i^{loc}(t), & if\ executed\ locally \\ E_i^{tx}(t) + E_i^{mec}(t) & if\ offloaded\ to\ MEC \end{cases} \quad (23)$$

where, $E_i^{tx}(t)$ is the transmission energy, $E_i^{loc}(t)$ is the local computation energy, and $E_i^{mec}(t)$ is the energy consumption at MEC. For cooperative MEC execution, the total energy consumption is modeled as the sum of distributed computation energy across participating MEC servers, along with the corresponding (aggregated) communication cost among them. Lastly, the proposed severity model is used to evaluate the severity of QoS violation $S_i(t)$ to represent performance degradation. All metrics are stored over time and evaluated the system performance under the dynamic 5G/B5G IoT environments.

8) Queue update and continuous operation: After task execution, the severity-aware virtual queues are updated to reflect the new observed level of QoS violations, which increases the contribution of tasks with higher delays or recurring violations to the future scheduling decisions. The system operates in a continuous time-slot-based manner where the arrival of IoT tasks, channel conditions, and resources change dynamically over time. At every time slot, updates value of the queues and system parameters are returned to the Lyapunov-based optimization framework, allowing adaptive

and real-time offloading decisions. This continuous feedback mechanism ensures the proposed framework remains responsive to the changing network conditions in 5G/B5G IoT environments while maintaining the long-term stability of the system. As a result, the system effectively balances the tradeoff between latency, energy consumption, and severity-aware QoS requirements, ensuring high performance in highly dynamic and heterogeneous IoT workloads.

IV. Experimental Analysis and Discussion

The simulation is implemented in a Python-based discrete-time environment that models a 5G/B5G IoT network consisting of 100 heterogeneous IoT devices and 5 MEC servers over 1000 time slots. Each IoT device generates stochastic computation tasks with varying task sizes, CPU cycle requirements, latency deadlines, and criticality levels. The task arrivals are modeled using a Poisson arrival process with an arrival rate ranging from 0.05 to 0.15 tasks/ms, which captures the stochastic nature of heterogeneous IoT traffic. Task sizes are uniformly distributed between 0.1 MB and 10 MB, while CPU cycle requirements and latency deadlines are randomly assigned within the ranges listed in Table I to represent diverse URLLC and mMTC applications. The simulation primarily considers independent stochastic task arrivals rather than bursty or temporally correlated traffic, enabling a controlled evaluation of the proposed severity-aware MEC offloading framework under heterogeneous workload conditions. To ensure statistical reliability, all results are obtained by performing multiple independent simulation runs under identical settings, and the final reported values are computed as the average over repeated trials with different random seeds.

TABLE I. System Hyperparameters used in the Proposed Severity-Aware MEC Offloading in 5G/B5G IoT Environment

Category	Parameter	Value
Lyapunov Control Parameters	V (drift penalty weight)	10
	α (energy weight)	0.5
	β (latency weight)	0.5
	Queue update factor	severity-based (QVSI)
QVSI (Severity Model)	Criticality weights	High=3, Medium=2, Low=1
Network / Communication Settings	Bandwidth	20 MHz
	Transmission rate	100 Mbps
	Tx power	0.5 W
	Channel model	stable AWGN (typical assumption)
Compute Resources	IoT Device CPU	1 GHz
	MEC Server CPU	20 GHz
	MEC servers	5 nodes
	Task arrival rate	0.05 – 0.15 tasks/ms
Task Model	Task size	0.1 – 10 MB
	CPU cycles	0.5 – 2 GHz cycles equivalent
	Deadline range	50 – 500 ms
	Task types	URLLC + mMTC mixed

This approach captures system variability arising from stochastic task arrivals, channel conditions, and queue dynamics, and improves the robustness of the performance evaluation. For each task, both local execution delay and MEC execution delay, including transmission, computation, and queueing delays, are estimated to emulate realistic MEC operations. Table I details the parameters employed in the experimental analysis.

A. Performance Evaluation of the Proposed Framework

The performance evaluation reveals that the proposed MEC offloading mechanism with severity awareness results in substantial improvements in terms of the various QoS metrics and the efficiency of the system usage scenarios for the 5G/B5G IoT environment. The system has an average task delay of 82ms and a maximum worst-case delay of 280ms. This indicates that the latency can be controlled even during high network traffic.

The 4.8% QOS violation rate confirms the effectiveness of the QoS Violation Severity Index (QVSI) to reduce deadline misses. The 98.5% SLA satisfaction rate shows reliable service delivery for different IoT applications. The obtained system throughput of 103 tasks per second shows strong scalability when tasks are densely injected into the system. Energy efficiency is also significantly improved, with an average consumption of 6.0mJ per slot due to optimized Lyapunov drift-plus-penalty control. The workload distribution of the CPU between MEC (70%) and IoT devices (38%) shows effective workload offloading and a lower burden on the IoT devices.

The Jain fairness index value of 0.955 indicates that the resources are distributed fairly for the tasks. An offloading ratio of 72% shows that most of the tasks get completed through the utilization of MEC. The queue lengths are observed as stable, being between 2.8 and 5.0, which suggests stability and convergence in the network. This proves that the proposed framework maintains controlled congestion and efficient long-term operation.

1) Overall system performance evaluation:

Fig. 4 evaluates the proposed severity-aware Lyapunov-based MEC offloading algorithm in 5G/B5G IoT networks.

Fig. 4(a) shows that the system throughput steadily increases. This proves the efficiency of the framework to manage tasks and improve resource efficiency.

Fig. 4(b) exhibits a steady decline in average energy consumption per slot. This indicates the energy-efficient offloading decisions.

Fig. 4(c) illustrates a decrease in QoS violation rate. It validates the effectiveness of the proposed QVSI and severity-aware optimization.

Fig. 4(d) represents a rapid rise in the task completion rate. It proves improved reliability and latency control.

Fig. 4(e) shows a very high Jain's Fairness Index, which confirms fairness in resource sharing. The results prove that the proposed framework successfully minimizes severe QoS violations while improving throughput, energy efficiency, reliability, and fairness in MEC-enabled 5G/B5G IoT systems.

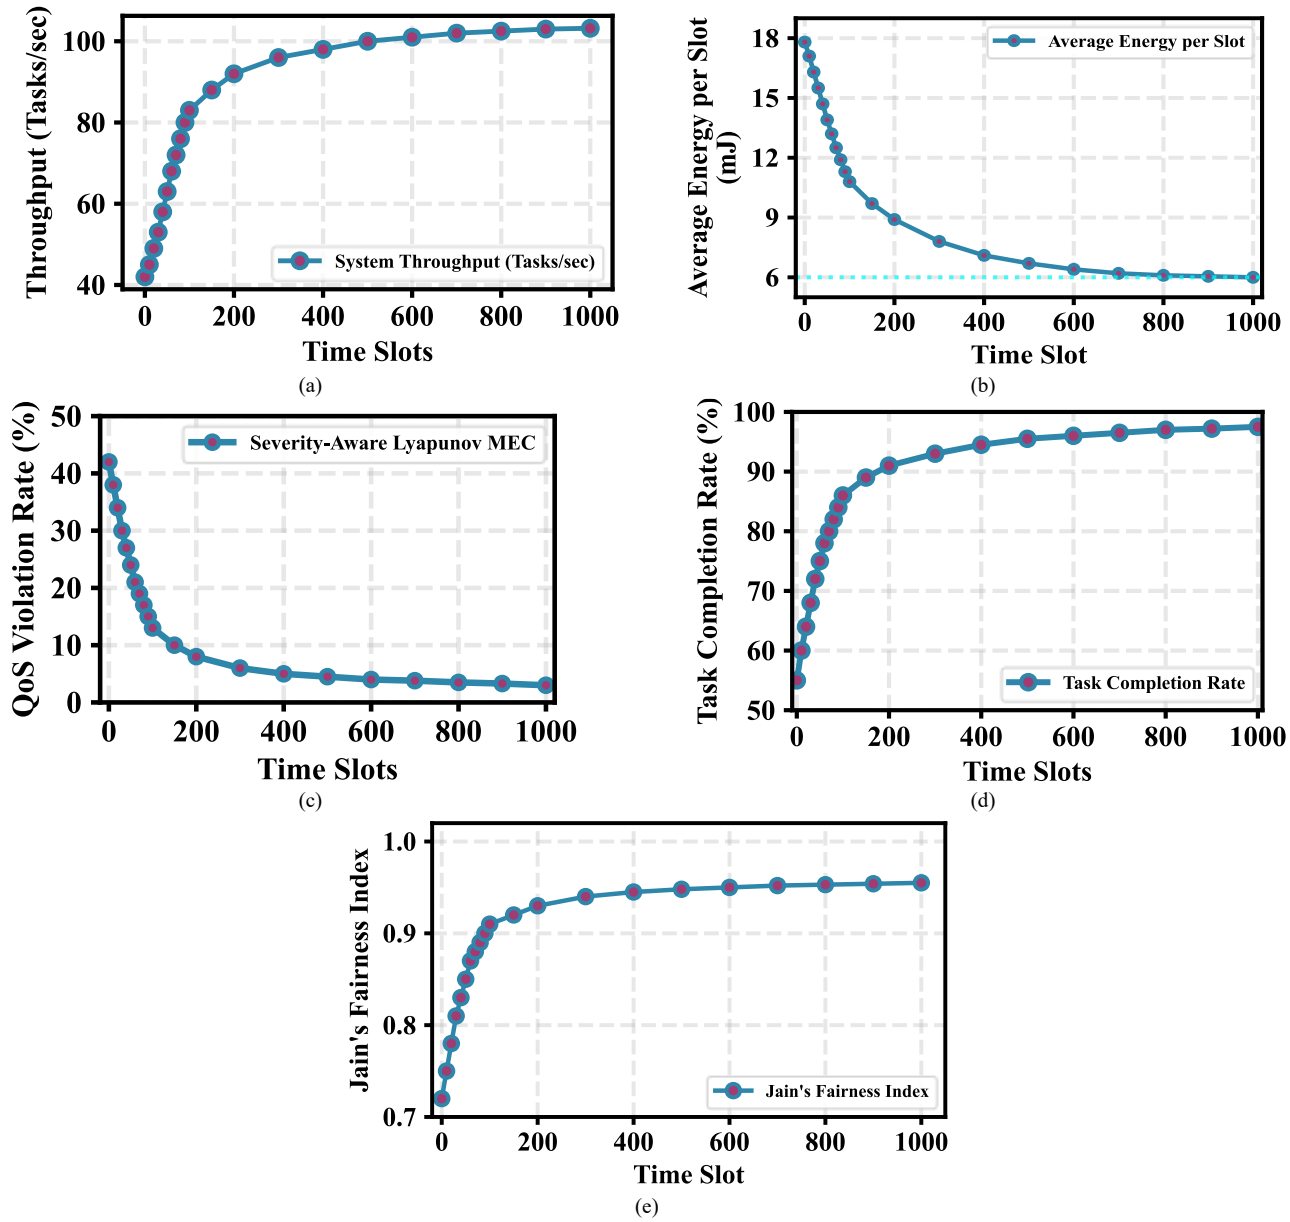

Fig. 4. Performance evaluation of the proposed severity-aware Lyapunov MEC offloading framework: (a) system throughput, (b) average energy per slot, (c)QoS violation rate, (d) task completion rate, and (e) Jain's fairness index over time slots.

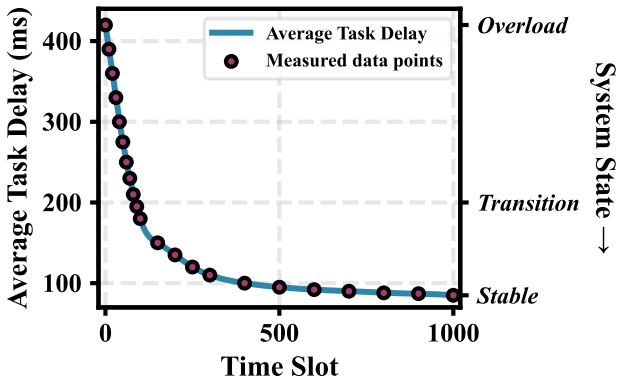

Fig. 5. Convergence behavior of the proposed severity-aware Lyapunov MEC offloading algorithm.

2) Convergence and queue stability analysis: Fig. 5 shows how effectively the proposed severity-aware LDPP MEC offloading approach converges in a 5G/B5G IoT environment. Initially, the system operates under overload conditions with a high average task delay. As the optimization process progresses, the severity-aware virtual queues stabilize. Hence, the delay is significantly reduced as we move towards the stability period. Finally, the system converges to a steady state with minimal delay. This proves that the proposed approach provides minimal task delays, stability, and effective MEC offloading performance for heterogeneous IoT applications.

Fig. 6 depicts the normalized virtual queue length change under the severity-aware Lyapunov MEC offloading framework in a 5G/B5G IoT environment. When overload occurs, the queue

rapidly increases because of the congestion and high task arrival rate in the overload phase. As the Lyapunov Drift-Plus-Penalty optimization becomes active, the queue length gradually decreases and converges toward a stable low-backlog state.

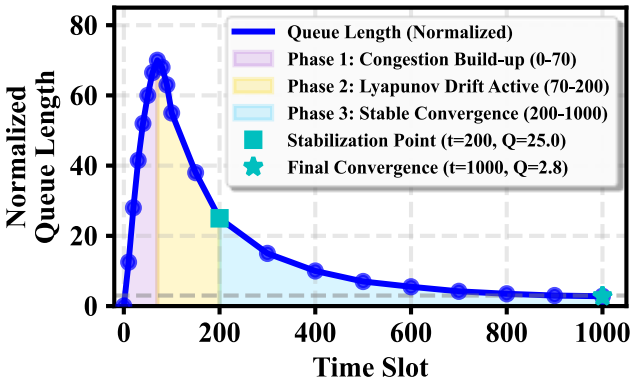

Fig. 6. Convergence of severity-aware virtual queue length in the proposed Lyapunov MEC framework.

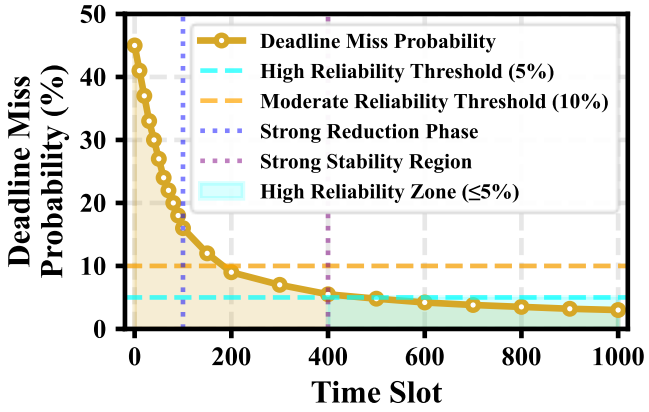

Fig. 7. Temporal reduction of deadline miss probability in the proposed severity-aware MEC offloading framework.

The stabilization and final convergence points indicate good queue stabilization and system stability. This validates the proposed algorithm's ability to overcome congestion, to achieve congestion-aware queue stabilization, and ensure reliable MEC task scheduling under dynamic IoT workloads.

Fig. 7 depicts the assessment of the proposed severity-aware Lyapunov-based MEC offloading method using the evaluation of deadline miss probability over 1000 time slots in a 5G/B5G IoT environment.

The system starts with relatively large deadline miss probabilities due to large task arrivals and queue instabilities. However, as the optimization framework adapts, the deadline misses probability falls sharply in the strong reduction period. It provides efficient decisions for task scheduling and offloading. The system reaches the optimal high-reliability state after around 400 time slots, with the probability of missing deadlines kept below 5%. This shows that the proposed QVSI-based approach reduces severe QoS violations. The results assure a high reliability and stability level for heterogeneous and latency-sensitive IoT systems. The performance of the proposed severity-aware Lyapunov-based MEC offloading approach in mitigating the severity of QoS violation has been illustrated in Fig. 8. The average value of QVSI is large in the beginning because of heavy deadline violations.

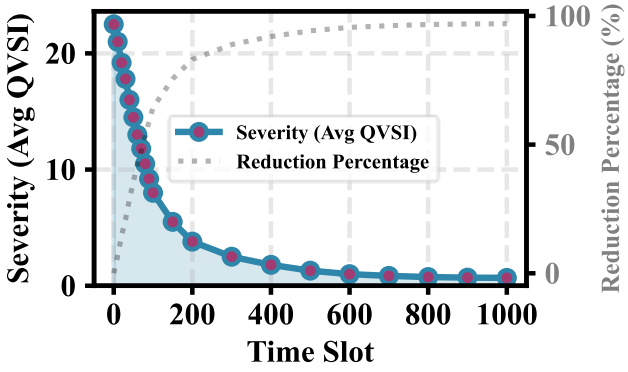

Fig. 8. Convergence of average QoS violation severity (QVSI) and reduction percentage over 1000 time slots.

3) QoS violation severity and reliability analysis: But it rapidly decreases as the algorithm learns optimal offloading decisions and prioritizes critical IoT tasks. Simultaneously, the reduction percentage steadily increases from approaching near-optimal performance. This proves the proposed framework reduces severe QoS violations, stabilizes the system, and improves service reliability for heterogeneous latency-sensitive IoT applications in 5G/B5G MEC networks while maintaining resource management. The distribution of IoT tasks is shown in Fig. 9, according to different QVSI ranges in the proposed severity-aware MEC framework.

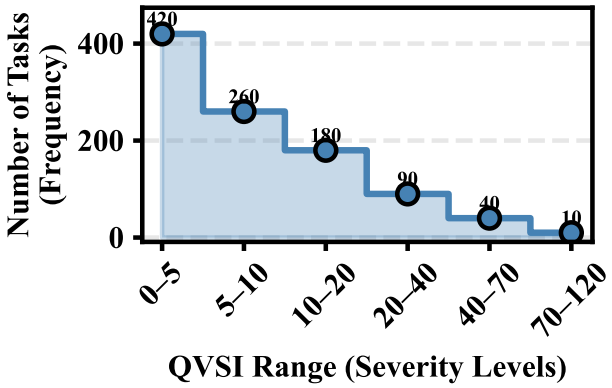

Fig. 9. Frequency distribution of QoS violation severity index (QVSI) across IoT tasks in the proposed severity-aware Lyapunov-based MEC offloading framework.

The majority of tasks are in the low-severity range (0-5), which indicates that most tasks do not suffer from high or even any deadline violations. The number of tasks decreases as the QVSI level increases, with only a few tasks suffering from severe QoS violations above 70. This shows the capability of the proposed Lyapunov-based MEC offloading algorithm in mitigating critical cases of deadline misses and prioritizing critical IoT tasks in congested 5G/B5G network environments.

4) Delay performance analysis under dynamic network conditions: Fig. 10 shows the average task delay for executing

the task locally and offloading it to the MEC in 5G/B5G IoT networks for different network loads. As the level of network load increases from low load to maximum congestion, the delay of local execution rises from 380ms to 620ms due to limited resource capabilities. In comparison, MEC offloading has lower delays, which grow incrementally from 120ms to 210ms. This shows that MEC-enabled offloading effectively reduces latency and improves the QoS performance under heavy traffic conditions, thus supporting latency-sensitive and critical IoT applications.

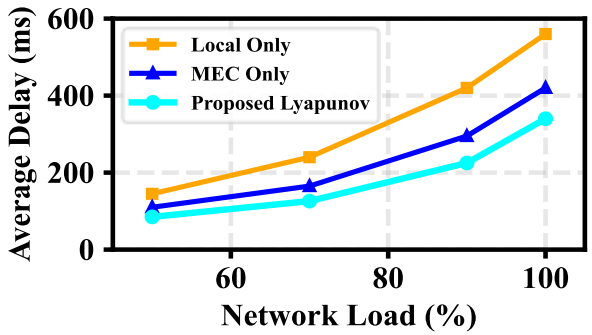

Fig. 10. Performance comparison of local computing, MEC offloading, and proposed severity-aware Lyapunov MEC offloading algorithm in terms of average delay under increasing network load.

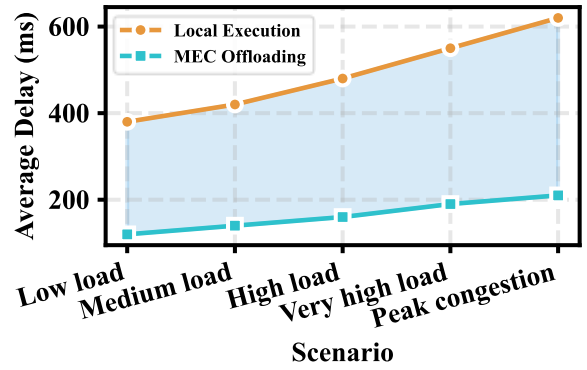

Fig. 11. Average delay comparison between local execution and MEC offloading under different network load conditions.

Fig. 11 shows the average task delay versus the increasing network load for Local Only, MEC Only, and the proposed Lyapunov scheme. The delay of all schemes increases with the network load due to congestion and limited resources. The Local Only scheme has the largest delay due to the low processing capability of IoT devices. The MEC-only scheme reduces the delay using the edge servers but still suffers from the heavy load. The proposed severity-aware Lyapunov algorithm achieves the lowest delay by intelligently balancing local execution and MEC offloading while prioritizing critical tasks. This proves that the proposed framework provides better QoS and latency performance in 5G/B5G IoT networks.

Fig. 12 depicts the delay variation of critical and non-critical IoT tasks over different time slots with the proposed framework. At first, the critical tasks suffer from higher delay due to their strict QoS requirement and higher processing priority, but as time progresses, the delays for both types of tasks are significantly reduced due to the severity-aware Lyapunov optimization that efficiently handles the queue congestion and resource allocation. The delay gap between critical and non-critical tasks also reduces over time, which depicts fair and stable scheduling.

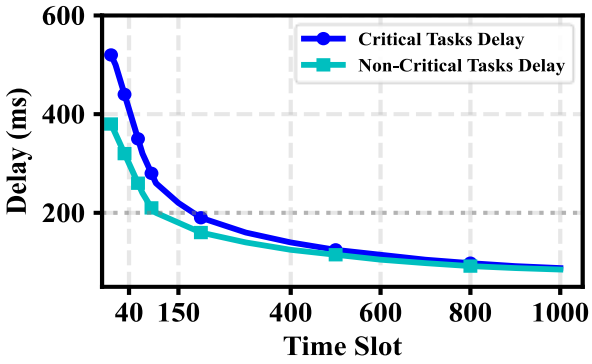

Fig. 12. Delay performance comparison between critical and non-critical IoT tasks over time slots using the proposed severity-aware Lyapunov MEC offloading framework in 5G/B5G networks.

This validates the effectiveness of the proposed algorithm to prioritize critical tasks while simultaneously maintaining the overall QoS stability and low latency in 5G/B5G IoT networks.

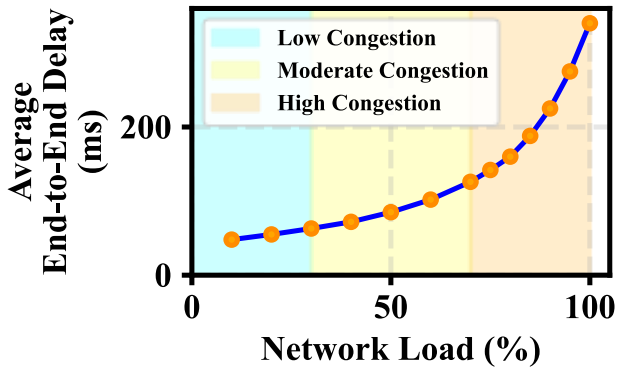

Fig. 13. Impact of network congestion levels on average end-to-end delay in the proposed severity-aware MEC offloading framework for 5G/B5G IoT networks.

Fig. 13 shows how the average end-to-end delay increases with network load under low, moderate, and high congestion conditions. In low congestion, the delays will be kept to a minimum due to abundant network and MEC resources. With an increase in congestion in terms of low, medium, and high, the delay will increase because of the increased queue formation, transmission delays, and scarcity of resources. The sudden jump towards the point where the network is full denotes the impact of heavy congestion on the QoS. This proves network congestion affects delay and demonstrates the importance of the proposed severity-aware Lyapunov MEC offloading framework in managing congestion and maintaining QoS in 5G/B5G IoT systems.

5) Energy efficiency analysis: Fig. 14 compares the comparison between the energy consumption for computation and transmission of the Local offloading, the conventional MEC, and the newly proposed severity aware MEC offloading

strategy. The results show that local execution consumes the highest computation energy (18.5mJ), while the proposed method reduces both computation and transmission energy compared to conventional MEC. This proves that the modified Lyapunov-based severity-aware offloading algorithm efficiently balances local processing and MEC offloading decisions, minimizing overall energy consumption while maintaining QoS requirements for heterogeneous 5G/B5G IoT applications.

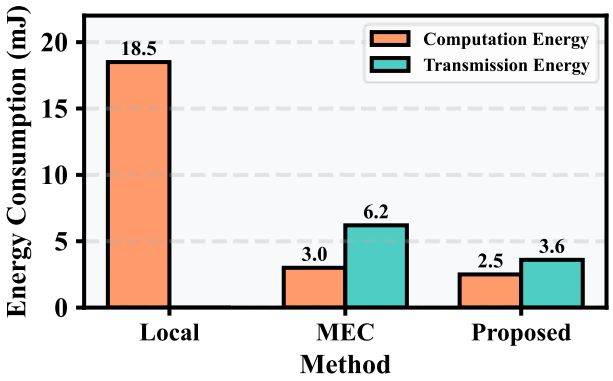

Fig. 14. Energy consumption comparison of local execution, conventional MEC, and proposed severity-aware MEC offloading method.

6) Sensitivity analysis: Table II presents a sensitivity analysis of the Lyapunov control parameter V on key performance metrics, including average task delay, energy consumption, QoS violation rate, and Jain's fairness index. As V increases from 1 to 50, the system achieves improved energy efficiency and reduced QoS violation rates due to stronger emphasis on penalty optimization in the Drift-Plus-Penalty framework.

TABLE II. SENSITIVITY ANALYSIS OF LYAPUNOV CONTROL PARAMETER V

V Value	Average Task Delay (ms)	Energy Consumption (mJ)	QoS Violation Rate (%)	Jain's Fairness Index
1	96	6.8	7.1	0.931
5	88	6.3	5.6	0.944
10	82	6.0	4.8	0.955
20	80	5.9	4.6	0.952
50	79	5.8	4.5	0.947

However, higher values of V slightly affect delay performance and fairness after a threshold, indicating a trade-off between latency minimization and system stability. The results demonstrate that $V = 10\text{-}20$ provides a balanced performance across all metrics.

B. Ablation Analysis

Table III evaluates the contribution of each major component of the proposed severity-aware MEC offloading framework. Different models are compared with the complete MEC offloading framework. The removal of the QVSI variant shows higher delay, energy consumption, and QoS violation rate, which proves the significance of the QVSI for quantifying and minimizing severe deadline violations. Likewise, removing virtual queues based on severity causes an improvement in throughput and fairness, highlighting that severity queue modeling improves the stability of a virtual queue and prioritizes critical tasks.

TABLE III. ABLATION ANALYSIS OF THE PROPOSED SEVERITY-AWARE MEC OFFLOADING FRAMEWORK IN 5G/B5G IOT NETWORKS

Method Variant	Average Task Delay (ms)	System Throughput (tasks/sec)	Average Energy Consumption (mJ)	Jain's Fairness Index	QoS Violation Rate (%)
w/o QVSI	105.0 ± 5.8	88.0 ± 3.2	7.8 ± 0.4	0.910 ± 0.010	9.5 ± 0.7
w/o Severity Queues	112.0 ± 6.1	85.0 ± 3.0	8.2 ± 0.5	0.895 ± 0.012	11.2 ± 0.8
w/o LDPP	128.0 ± 7.0	79.0 ± 3.5	9.6 ± 0.6	0.860 ± 0.015	14.8 ± 1.0
w/o Task Criticality	118.0 ± 6.5	83.0 ± 3.1	8.7 ± 0.5	0.882 ± 0.011	12.6 ± 0.9
Local Execution Only	155.0 ± 8.2	65.0 ± 2.8	12.5 ± 0.8	0.790 ± 0.018	22.0 ± 1.3
Full Proposed Model	**82.0 ± 4.6**	**103.0 ± 3.4**	**6.0 ± 0.3**	**0.955 ± 0.008**	**4.8 ± 0.5**

By removing the LDPP configuration, the worst performance is obtained among the algorithmic variants in terms of delay and QoS violation rate, showing that the optimal configuration of LDPP is a crucial and effective component for efficient online offloading and resource management. Without the Task Criticality model, performance begins to drop significantly, especially in fairness and QoS violation rate, indicating the significance of addressing heterogeneous task priority in latency-sensitive IoT applications. The Local Execution Only baseline also suffers from the highest delay, energy consumption, and QoS violations as tasks are executed only on IoT devices without the support of MEC, causing resource congestion and inefficient task execution. In contrast, the full proposed model achieves the highest energy efficiency, the highest throughput, the lowest delay, improved fairness, and a minimal QoS violation rate. These results show that the combination of using QVSI, severity-aware queues, Lyapunov optimization, and task criticality improves the reliability and QoS performance in 5G/B5G MEC-supported IoT networks.

C. Comparative Analysis

To ensure a fair comparison, all existing methods are implemented under identical simulation settings as the proposed framework. Table IV shows a comparison between the proposed severity-aware MEC offloading framework and existing state-of-the-art methods in terms of task delay, throughput, energy consumption, fairness, and QoS violation rate in 5G/B5G IoT networks. The results indicate that the traditional methods, such

as DRL-DDQN, HATO, PSO, Lyapunov optimization with PMP, and DNNs-RL, result in moderate performance gains, but still incur high latency and QoS violations due to limited accounting for the severity of the violation and the criticality of the task. Conversely, the proposed method achieves the lowest average task delay (82ms), minimum energy consumption (6.0mJ), the highest throughput (103 tasks/sec), and the best fairness index (0.955), and also reduces the rate of violation of QoS to 4.8%. The improvements demonstrate that the proposed framework enables more efficient and reliable MEC task offloading in 5G/B5G environments for heterogeneous and latency-sensitive IoT applications.

TABLE IV. COMPARATIVE PERFORMANCE ANALYSIS OF THE PROPOSED SEVERITY-AWARE MEC OFFLOADING METHOD AGAINST EXISTING APPROACHES

D. Discussion

The complex environment of 5G and B5G IoT introduces significant challenges in designing an efficient and reliable MEC task offloading strategy. Current frameworks mainly use binary models of QoS evaluation, which do not consider task performance as being either satisfied or violated. This approach fails to capture the level of deadline violations, especially for latency-sensitive and mission-critical IoT applications. Furthermore, most of the conventional approaches consider optimizing mean QoS metrics without the explicit consideration of extreme QoS degradation scenarios. Moreover, lack of information about task heterogeneity, in particular the criticality of the tasks, often leads to unfair scheduling decisions and poor performance of high-priority tasks. The dynamic nature of networks, such as varying wireless channels, computation loads, and resource-limited IoT devices, further complicates efficient task offloading and requires relying on static decision-making strategies in real-world MEC systems. To tackle these challenges, this study introduces a severity-aware MEC task offloading framework for heterogeneous 5G/B5G IoT environments. The main idea is to introduce a QVSI that not only estimates whether a task misses its deadline but also the magnitude of the violation, while including task criticality in the evaluation process. This achieves a more realistic representation of QoS degradation in the real IoT scenario. Moreover, a severity-aware virtual queue model is designed to capture system backlog as violation intensity instead of just tasks, enabling fine-grained control of system stability. These components are combined in a modified LDPP optimization framework to allow real-time and adaptive offloading decisions. The framework jointly minimizes latency, energy, and QoS violation severity while ensuring long-term stability of queues under dynamic network conditions.

The proposed objectives are verified by extensive simulation experiments conducted in a Python-based discrete-time MEC environment. The results show that the framework has significant improvements in system performance across various metrics. The average task delay is decreased to 82ms, and the mean energy consumption is minimized to 6.0mJ/slot. The deadline miss rate is significantly reduced to 4.8%, indicating an effective deadline miss mitigation. Moreover, the system achieves an efficient and fair performance with a Jain's fairness index of 0.955 and a throughput of 103 tasks/second among the heterogeneous IoT devices. The QoS violation severity is reduced by about 97%, confirming good convergence performance and the effectiveness of the severity-aware Lyapunov optimization mechanism in reducing the severity of the QoS violation under various workloads.

Overall, these results validate that the proposed model achieves its objectives of minimizing severe QoS violations while optimizing latency, energy efficiency, and fairness. However, the proposed framework relies on accurate knowledge of system state information, such as channel conditions, task characteristics, and computational requirements, which may not always be fully reliable in highly dynamic or partially observable environments. In addition, the current study assumes an AWGN-based communication model for performance evaluation, which provides a simplified and controlled baseline but does not capture realistic wireless fading dynamics in practical 5G/B5G systems. Future work could include the application of learning techniques such as deep reinforcement learning (DRL) or federated learning to improve adaptability under uncertainty and incomplete system information. Moreover, the framework can be extended to more realistic wireless channel models such as Rayleigh and Rician fading, as well as real-world edge computing testbeds. Mobility-aware and energy harvesting IoT models can also be incorporated to further enhance the applicability, robustness, and practical utility of the proposed framework for future 5G/B5G networks.

V. CONCLUSION

This work proposes a severity-aware MEC task offloading framework for 5G/B5G IoT that effectively resolves the limitations of the conventional binary QoS and non-criticality-aware task offloading methods. The framework introduces a QVSI and severity-aware virtual queuing integrated with a modified LDPP optimization model for real-time adaptive offloading decisions. This allows joint optimization of latency,

energy, and violation of QoS, and ensures stability of the system under dynamic network conditions. The excellent performance of the proposed approach is confirmed through simulation, where the average task delay is 82 ms, the energy consumption per slot is 6.0 mJ, the violation of the QoS of 4.8%, the system throughput is 103 tasks/sec, and the fairness index is 0.955. The significant decrease in QoS severity of violation illustrates strong convergence and reliability. Overall, the proposed framework ensures efficient, stable, and severity-aware resource allocation in MEC-enabled 5G/B5G IoT, offering a promising solution for future intelligent edge computing applications.

STATEMENTS AND DECLARATIONS

Author contributions: All authors contributed to the conception of the problem setting and overall design of the work. S.S.R built the conceptualization and methodology. R.S. implemented the work and writing. Authors involved in the visualization of concepts. This version was approved by all authors, who also read and approved the manuscript.

Funding: No funding was received for conducting this study.

Conflict of interest: The authors declare that they have no conflict of interest.

Availability of data and materials: The data set is not available; only a simulation with parameters is used.

Ethical approval: The research is original, and the authors of this manuscript created all the figures and tables.

Consent to participate: Not applicable.

Consent for publication: All authors agree with the submission of the manuscript to this journal and possible publication afterwards.

***Abstract*—This study investigates the challenge of generating accurate and interpretable topic labels for integration into Bayesian Hierarchical Models (BHM), a critical step for interpretable probabilistic risk modelling from unstructured textual data. Using a corpus of 35,667 Malaysian business news articles published between 2019 and 2023, four topic modelling approaches, such as Latent Dirichlet Allocation (LDA), Non-negative Matrix Factorization (NMF), Top2Vec, and BERTopic, were evaluated. Among these, NMF produced the most coherent and thematically consistent topics. To address the topic-labelling challenge, this study proposes an NLP-BHM framework that maps topic model outputs into a hierarchical Bayesian structure comprising interpretable topic labels and higher-level risk categories. Two semantic labelling strategies were examined: Large Language Model (LLM) prompting and WordNet-based semantic analysis. The proposed approaches enabled systematic topic interpretation and semantic clustering within the BHM framework. A case study on Malaysian business risks demonstrates that LLM-based labelling produced more coherent and contextually relevant results, while WordNet-based labelling provided a semantically consistent but vocabulary-limited alternative. Comparative results based on Mean Opinion Scores (MOS) highlight the effectiveness of LLM-based semantic labelling in improving interpretability for probabilistic business risk analysis.**

***Keywords*—Bayesian hierarchical model; natural language processing; topic modelling; large language model; WordNet**

I. Introduction

In today's data-driven economy, extracting actionable insights from unstructured text is crucial for effective risk assessment and informed decision-making. Business news articles, financial disclosures, and policy updates often contain critical early signals of systemic risks. However, their narrative form poses challenges for direct integration into quantitative models. To generate interpretable probabilistic risk representations, it is essential to translate this unstructured information into structured, interpretable inputs suitable for Bayesian Hierarchical Models (BHM).

Bayesian Hierarchical Models (BHM) provide a probabilistic framework for modelling uncertainty across multiple levels of abstraction, enabling interpretable relationships between observed variables and higher-level latent structures [1]. The power of Bayes' theorem lies in its adaptability: parameters, hypothesised relationships, and confidence intervals can all be estimated as probabilistic statements derived from the model. Traditionally, parameter labels for BHM are manually annotated, a process that can be highly time-consuming and inconsistent ([2], [3]). One notable work applies manual annotation to obtain the interpretable labels for the factor inputs in their study [4]. Despite these efforts, no significant work has integrated topic modelling outputs into BHM structures, leaving the process of bridging these outputs into BHM largely unexplored.

Prior investigations have identified the best-performing topic model based on coherence scores, which will be utilised for the integration into the BHM structure [5]. Research on topic modelling, such as the foundational work by Blei et al. [6], has established methods for extracting topics from text data, but the challenge remains in linking these outputs with BHM factor inputs. However, the core challenge in this study lies in bridging the topic outputs from the best-performing topic model with the factor inputs to obtain clear, interpretable labels required by the BHM structure.

This study aims to fill this gap by proposing a framework that integrates topic-modelling outputs into BHM structures. We evaluate two parameter labelling strategies: Large Language Model (LLM) prompting and WordNet-based semantic analysis. These strategies will help derive interpretable labels for BHM parameters, facilitating the connection between natural language processing (NLP)-derived topics and Bayesian models. The central research question guiding this work is: How can LLM-based and WordNet-based labelling strategies be leveraged to generate interpretable topic representations and construct a BHM structure for probabilistic risk analysis?

The contribution of the study lies within the framework itself. In contrast to the traditional BHM that relies on defined variables and structured inputs, the proposed approach automatically derives risk factors from unstructured business news, enabling a fully data-driven representation of emerging risk signals. In addition, the framework systematically compares two complementary semantic labelling strategies, namely LLM-based and WordNet-based approaches, to enhance the interpretability and robustness of topic-to-risk mapping. Furthermore, the model enables dynamic estimation of risk probabilities by propagating topic-level distributions across evolving news corpora, thus capturing temporal variations in business risk environments.

The study is organised as follows. In Section II, we briefly discuss related work on the approaches used in our work. We

*Corresponding author.

present our framework for integrating the topic model's output using two labelling approaches in Section III. In Section IV, we discuss the results from the Mean Opinion Scoring (MOS) evaluation and present the BHM structures built using both approaches. Finally, we present our conclusions and future work in Section V.

II. Literature Review

A. Bayesian Hierarchical Model

Bayesian modelling provides a probabilistic framework for reasoning under uncertainty by updating prior beliefs using observed evidence [2]. Bayesian Hierarchical Models (BHM) extend this framework by organising model components across multiple levels, thereby enabling information sharing and uncertainty propagation throughout the hierarchy ([2], [3]).

0 illustrates a Bayesian hierarchical structure with population-level hyperparameters, group-specific parameters, and observed data. Shared priors enable information sharing across groups, while group-level parameters capture variation and govern the observations. Posterior inference updates uncertainty across the hierarchy, supporting partial pooling and more stable estimates when group-level data are limited.

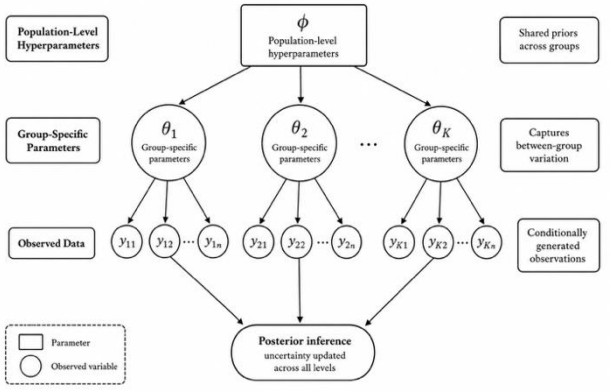

Fig. 1. A general structure of a Bayesian hierarchical model.

Various studies have applied BHM for predictive modelling across different domains. In supply chain management, BHM is used to assess disruption risks with limited data availability by estimating supplier risk probabilities and financial impacts, and incorporates downstream risk assessment measures, such as Value-at-Risk (VaR), to support decision-making [4]. Similarly, in supply chain financing, BHM improves risk evaluation by integrating macro-level credit ratings with micro-level transaction data, resulting in more accurate predictions of payment delays and revealing behavioural patterns such as correlations between delivery and payment delays [7].

Beyond financial applications, BHM has shown strong capability in ecological and environmental modelling. In species distribution studies, it integrates environmental variables with ecological interactions and latent processes, improving predictive performance when combined with complementary models such as food-web approaches [8]. In public health, BHM is applied to estimate disease burden from incomplete surveillance data, providing robust and scalable estimates for long-term monitoring and decision-making during the COVID-19 pandemic [9]. In hydrology, BHM models extreme flood risks under nonstationary conditions by integrating climate indices within a hierarchical framework, improving estimation accuracy and reducing uncertainty through partial pooling [10].

Recent studies in natural language understanding have demonstrated that uncertainty-aware probabilistic representations can better capture semantic ambiguity and subjective variation in textual interpretation, further motivating the integration of probabilistic reasoning within NLP frameworks [11].

These studies demonstrate the robustness of BHM in integrating heterogeneous data sources and modelling complex dependencies across domains. However, most existing approaches rely on predefined model structures and manually specified parameters, limiting flexibility in adapting to evolving data patterns and latent factors. This limitation reduces its effectiveness when dealing with large-scale unstructured data, where important information is often embedded within latent textual representations.

B. Topic Modelling

Topic modelling has long been a popular technique for uncovering hidden themes in large text corpora [6]. A study applies LDA to a large-scale corpus of artificial intelligence literature to extract latent topics from publication abstracts[12]. The topic distributions are then aggregated across time, journals, and countries to identify key AI subfields and analyse research trends and similarities across publication sources. Another study applies a semantically assisted NMF approach (SeNMFk) to extract latent topics and determine the optimal number of topics [13]. By integrating TF-IDF and semantic information through SPPMI matrices, the model improves topic stability and coherence compared to traditional methods.

Top2Vec has been increasingly used across domains due to its ability to combine word embeddings with clustering to produce semantically coherent topics[14]. It was applied to analyse 15,000 mobile app user feedback entries[15], where it outperformed LDA and ETM by automatically selecting the number of topics and producing more interpretable results. Evaluation metrics such as the coherence score and topic diversity demonstrated their effectiveness in capturing issues such as app glitches and performance problems. BERTopic, a transformer-based topic modelling method, has also been widely used to uncover latent themes in text data[16]. One study applied BERTopic to 2,846 PubMed abstracts on depression, anxiety, and burnout in academia[17], identifying 27 topics including pandemic-related anxiety and medical resident burnout.

A comparative study of LDA, NMF, Top2Vec, and BERTopic on COVID-19-related Twitter data highlights challenges in analysing noisy social media text and suggests that BERTopic and NMF are more effective approaches for social science applications[1]. The study also emphasises the importance of qualitative interpretation and domain expertise. However, while prior work compares topic modelling methods for extracting insights from unstructured text, most studies primarily focus on topic extraction quality, coherence, and interpretability. Limited attention has been paid to transforming latent topic representations into structured probabilistic

frameworks, such as Bayesian Hierarchical Models, for downstream risk modelling and uncertainty-aware decision-making.

C. Large Language Models

Recent advances in Large Language Models (LLMs) have significantly improved natural language understanding and semantic reasoning capabilities in NLP tasks [18]. Models such as GPT, PaLM, and LLaMA can generate context-aware responses by learning rich semantic representations from large-scale corpora [19]. Unlike traditional rule-based or ontology-driven approaches, LLMs can capture contextual relationships between words and concepts, enabling more flexible and semantically meaningful interpretation of unstructured text.

This capability has led to increasing use of LLMs in semantic extraction, topic interpretation, summarisation, and decision-support applications. Recent studies have shown that LLMs can generate coherent topic labels and semantic summaries that better align with human interpretation compared to conventional lexical resources and statistical approaches [18]. Their ability to contextualise latent textual representations makes them particularly well-suited to interpreting topic modelling outputs, where extracted keywords often lack semantic clarity when analysed in isolation. Compared to ontology-based resources such as WordNet, LLMs offer stronger contextual reasoning and semantic flexibility, especially in domain-specific environments such as finance and business analytics. Traditional lexical resources rely on predefined vocabularies and hierarchical relationships, which may limit their ability to capture emerging terminology, implicit semantics, and context-dependent meanings. In contrast, LLMs can dynamically infer semantic relationships from textual context, improving interpretability and semantic coherence in topic labelling tasks.

Despite these advantages, several challenges remain in applying LLMs within probabilistic modelling frameworks. LLM-generated outputs may vary with prompt design, sampling configurations, and model randomness, potentially affecting consistency and reproducibility. Furthermore, hallucinated or overly general outputs may reduce reliability when semantic labels are directly integrated into downstream analytical models. Consequently, human validation and structured prompting strategies remain important to ensure semantic accuracy and interpretability.

While recent work has explored the use of LLMs for semantic extraction and financial text analysis [20], limited attention has been given to integrating LLM-generated semantic representations into hierarchical probabilistic frameworks for interpretable business risk modelling. This limitation motivates the present study, which leverages LLM-based semantic labelling to bridge latent topic representations with Bayesian Hierarchical Models for uncertainty-aware risk analysis.

D. WordNet-Based Semantic Analysis

WordNet is one of the most widely used lexical databases in natural language processing for semantic analysis and knowledge representation[21]. It organises words into sets of cognitive synonyms known as synsets, which are connected through semantic relationships such as synonymy, hypernymy, and hyponymy. These structured semantic relationships enable WordNet to support tasks including word sense disambiguation, semantic similarity measurement, text classification, and ontology-based information retrieval.

In topic modelling and semantic analysis, WordNet has been widely used to improve topic coherence and interpretability by identifying semantically related concepts and hierarchical relationships between keywords. Several studies employ WordNet-based semantic similarity measures, such as Wu–Palmer similarity and path-based similarity, to cluster semantically related terms and generate interpretable topic labels [22]. By leveraging lexical hierarchies, WordNet enables semantically related topics to be grouped into broader conceptual categories, supporting more structured knowledge representation. Compared to statistical topic modelling methods, ontology-based approaches offer greater consistency and reproducibility because semantic relationships are derived from predefined lexical structures rather than probabilistic generation. This deterministic behaviour makes WordNet particularly useful in applications requiring stable semantic mappings and explainable semantic relationships. Furthermore, hierarchical lexical structures align naturally with probabilistic hierarchical models, making WordNet-based semantic grouping well-suited to constructing interpretable latent-factor hierarchies.

However, WordNet also presents several limitations, particularly in domain-specific applications such as business and financial risk analysis. Since WordNet relies on manually curated vocabularies, it may fail to capture emerging terminology, contextual nuances, and specialised business concepts commonly found in dynamic textual corpora. In addition, lexical similarity does not necessarily reflect contextual semantic meaning, which may lead to overly generic or semantically weak topic labels when applied to complex business news data.

These limitations motivate the exploration of context-aware semantic approaches that use Large Language Models to dynamically infer semantic relationships from textual context. Nevertheless, WordNet remains a valuable baseline for evaluating semantic consistency and hierarchical topic clustering within interpretable probabilistic modelling frameworks.

E. Challenges in Bridging Text Data and BHM

Integrating unstructured text data into BHM presents several critical challenges that must be addressed to enhance the effectiveness of risk analysis and decision-making processes. Understanding these challenges provides a foundation for the proposed framework outlined in the subsequent section. One of the primary challenges is data preprocessing. Unstructured text often contains significant noise and irrelevant information, which can obscure meaningful insights. Effective preprocessing is crucial for filtering out this noise and involves steps such as tokenisation, stemming, and stop-word removal. Failure to adequately preprocess text data can lead to inaccurate feature representation and difficulties in model training [23].

Another significant hurdle is feature extraction. Converting text into numerical features is a complex task that can lead to high dimensionality, which complicates model training.

Techniques such as TF-IDF and word embeddings are commonly employed. However, as the number of features increases, the model may struggle to generalise effectively, leading to overfitting and reduced performance. This phenomenon, known as the curse of dimensionality, emphasises the need for careful feature selection and dimensionality-reduction strategies to maintain a balance between feature richness and model performance [6]. Furthermore, semantic interpretation also poses difficulties. The contextual meaning of words can vary significantly, making it challenging to derive consistent interpretations. Phenomena such as polysemy (words with multiple meanings) and synonymy (different words with similar meanings) can lead to ambiguity in feature representation. This complexity necessitates advanced methods for semantic analysis to ensure the model captures the text's intended meaning [24], [25].

Establishing appropriate hierarchical structures within the BHM that accurately reflect the relationships derived from text data is another complex endeavour. The challenge lies in defining clear parameters and dependencies that are both interpretable and statistically robust[26]. This lack of clarity can hinder the model's effectiveness at capturing data traces. Moreover, the integration of topic modelling outputs with the inputs required for BHM remains largely unexplored. While prior investigations have identified effective topic models [5], linking these outputs to a BHM structure requires careful consideration of how to represent topics as factors in the model. This gap highlights the need for innovative approaches to align topic modelling outputs with BHM requirements.

Interpretability is another significant challenge. The probabilistic nature of BHMs can make it difficult to extract actionable insights from model outputs derived from unstructured text data. Ensuring that the results are interpretable and meaningful to stakeholders is essential. Thus, developing strategies to enhance interpretability is crucial for the practical use of these models [27].

Overall, existing literature demonstrates significant advances in topic modelling, semantic analysis, and Bayesian hierarchical modelling for analysing unstructured textual data. Prior studies have shown the effectiveness of topic modelling approaches in extracting latent themes from large textual corpora, while BHM provides interpretable probabilistic structures for modelling uncertainty and hierarchical relationships. However, most existing studies focus primarily on topic extraction or semantic interpretation independently, with limited attention given to systematically transforming latent textual themes into interpretable hierarchical probabilistic risk representations. Although recent advances in LLMs enable context-aware semantic interpretation, their integration within Bayesian hierarchical frameworks for business risk analysis remains underexplored.

To address this gap, this study proposes an NLP-BHM framework that integrates topic modelling, semantic labelling, and Bayesian hierarchical modelling to enable interpretable probabilistic business risk analysis from unstructured business news data.

III. Integrating Topic Modelling Outputs into Bayesian Hierarchical Models

This study presents a comprehensive framework that bridges the output from the best topic model into a Bayesian Hierarchical Model (BHM) to support probabilistic business risk modelling from unstructured business news articles. Building on prior research that identifies Non-negative Matrix Factorization (NMF) as the best-performing topic model [4], this study focuses on integrating it into the BHM structure. The framework proposes two approaches for generating interpretable topic labels, clustering related topics into higher-level factors, and modelling probabilistic relationships between these factors and associated risks. The dataset comprises 35,667 Malaysian business news articles written in English published between 2019 and 2023, collected from multiple online portals known for business-related content in Malaysia. TABLE I. provides an overview of the number of articles collected between 2019 and 2023.

TABLE I. The Number of Articles Collected from 2019-2023

Year	Number of Articles
2019	5,979
2020	6,992
2021	8,496
2022	7,824
2023	6,376

A. Framework Overview

The NLP-BHM framework operates in two phases. The first phase involves labelling topics extracted from a topic model. Each topic, represented by its top keywords, is assigned interpretable labels using two complementary strategies: LLM prompting and WordNet-based semantic analysis. The LLM approach uses OpenAI's GPT-3.5-turbo-16k to generate context-aware labels, while the WordNet approach employs semantic similarity measures and hypernym extraction to derive linguistically consistent labels. Each method is carried out independently, which allows for systematic comparison between the two approaches. The primary objective of the proposed NLP-BHM framework is to transform latent textual themes into interpretable probabilistic risk representations through hierarchical semantic structuring and Bayesian reasoning. Fig. 2 presents the proposed framework of our study.

B. Selecting Topic Model Outputs

Four topic modelling methods (LDA, NMF, Top2Vec, and BERTopic) were evaluated using coherence scores across yearly datasets from 2019 to 2023. NMF consistently achieved the highest coherence scores (0.65–0.80), indicating superior semantic consistency and interpretability for the Malaysian business news corpus. Consequently, NMF was selected as the topic-extraction component of the proposed NLP-BHM framework.

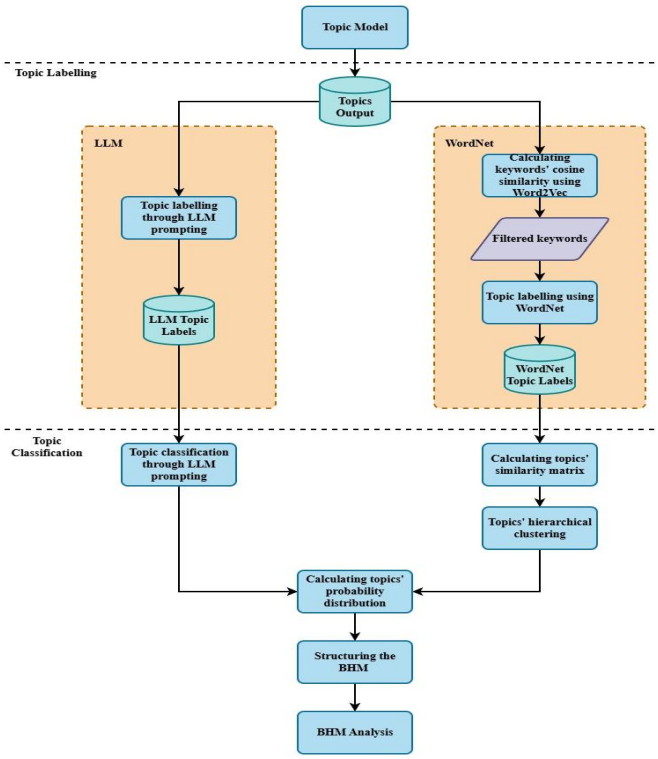

Fig. 2. An NLP-BHM framework for probabilistic business risk modelling.

C. Large Language Model Implementation

To generate interpretable topic labels, the LLM approach was employed with OpenAI's GPT-3.5-turbo-16k. For each topic extracted via NMF, the top keywords were provided to the LLM with a structured prompt instructing the model to suggest a single-word label relevant to business risk. The following prompt was used:

"I have a list of keywords as follows: {keywords}. Based on these keywords, can you suggest a single-word topic label related to risk?"

To enhance reproducibility, the API was configured with a fixed random seed, a temperature of 0.7, and a maximum token limit of 150. A second round of prompting was then applied to cluster the first-round labels into broader risk categories, using the following instruction:

"I have a list of topic labels as follows: {topic labels}. Based on these labels, can you cluster the topics together and suggest a name for each cluster?"

This two-step process helped us to transform latent topics into semantically meaningful factors and risk categories, which were then used to build the two-layer BHM structure.

D. WordNet Implementation

The WordNet-based labelling procedure involved multiple stages to ensure linguistic and semantic consistency. In the first phase, top keywords from each NMF-extracted topic were refined using cosine similarity derived from Word2Vec embeddings to eliminate semantically redundant or weakly related terms. The remaining keywords were then mapped to WordNet synsets, and their hypernyms were extracted to generate the initial topic labels. This process ensured that each label captured the core semantic meaning of its associated topic while maintaining linguistic coherence across topics. A similarity matrix was constructed from the initial topic labels using Wu-Palmer similarity, followed by hierarchical clustering with average linkage to group semantically related topics. Hypernyms were again extracted from each cluster to produce representative cluster-level labels, which were mapped as latent risks in the second layer of the BHM. This hierarchical organisation allowed the model to represent risk categories in a structured and probabilistically interpretable manner.

E. Mean Opinion Scoring Evaluation

Human evaluation remains important for assessing semantic quality and interpretability in NLP tasks, particularly where automatic evaluation metrics may not sufficiently capture contextual meaning and semantic coherence [28]. Therefore, a Mean Opinion Score (MOS) evaluation was conducted to assess the semantic clarity, contextual relevance, and interpretability of the topic labels generated by the LLM- and WordNet-based approaches. The quality of the generated labels was evaluated based on the level of understandability and interpretability. Understandability refers to how easily a label can be read and comprehended by non-specialists, while interpretability reflects how well the label captures the meaning and intent of the topic keywords in a risk-related context. Before the MOS evaluation, 20 respondents were recruited to assess the quality of the generated topic labels. The participants included a balanced representation of genders, ages, and professional statuses. This diverse composition provided a broad perspective on how different backgrounds may influence the perception of label clarity and relevance.

Each was presented with sets of topic keywords and the corresponding labels generated by the LLM- and WordNet-based approaches, while expert-assigned labels were included as a reference benchmark. Respondents were instructed to rate each label on a 5-point Likert scale, where 1 indicated a very poor fit with the topic keywords (unclear or misleading label), and 5 indicated an excellent fit (clear, relevant, and interpretable label). The evaluation was conducted via a Google Form that displayed the topic–keyword pairs alongside the candidate labels in a structured format. Respondents can enter their scores directly, ensuring consistency and ease of submission. The collected ratings were aggregated and averaged to compute the mean opinion score for each labelling method.

F. BHM Formulation

Drawing on the hierarchical architecture proposed by [4] for supply chain risk assessment, this study adopts a two-layer BHM tailored for high-dimensional textual data streams. While the framework in [4] relies on structured, predefined variables such as credit ratings and delivery metrics, our proposed model dynamically parameterises the hierarchy using latent topics (z_k) extracted from business news articles. These topics are subsequently mapped to higher-level business risk categories (r_i) through a context-aware taxonomic aggregation layer facilitated by an LLM- and WordNet-based semantic labelling. This two-layer structure allows the BHM to model uncertainty at both the thematic (topic) and categorical (risk) levels, providing the

flexibility to incorporate emerging risk factors that are typically omitted in traditional, static risk frameworks.

Let z_k denote an observed topic variable extracted from the news corpus using topic modelling, where k =1, …, K. These variables form the first layer of the hierarchy and represent the observable thematic signals derived from the textual corpus. Let r_i denote a business risk category, where i =1, …, I, represents the second layer of the hierarchy. At the topic level, the distribution of topics is represented as:

$$z_k \sim \text{Categorical}(\pi) \quad (1)$$

where, $\boldsymbol{\pi} = (\pi_1, \pi_2 \ldots, \pi_K)$ represents the topic probability distribution estimated from NMF-derived topic weights. At the risk level, each business risk category is conditionally dependent on the observed topic structure:

$$r_i \sim \text{Categorical}(\theta) \quad (2)$$

where, θ represents the probability distribution linking latent topics to higher-level business risk categories. This formulation captures how groups of latent topics contribute to higher-level business risk categories. This hierarchical design separates topic-level signals from risk-level representations, ensuring interpretability by explicitly modelling how individual topics influence higher-level business risk categories.

The probabilistic dependencies defined within the hierarchical structure are parameterised using topic-weight distributions and semantic associations derived from the topic labelling process. Following the Bayesian aggregation strategy proposed in [4], probability estimates are propagated through the hierarchy to quantify the relative influence of latent topics on higher-level business risk categories.

G. Obtaining Prior Probabilities

Initially, the NMF model produced weights for each keyword within a topic, representing the strength of the keyword's contribution to that topic. For each topic, the mean keyword weight was computed and subsequently used as the first-level probability estimate within the Bayesian structure. Following the strategy adopted in [4], these mean topic weights serve as the prior probability estimates for the corresponding latent topics. The prior probability for topic z_k is calculated as:

$$\pi_k = \frac{1}{n_k} \sum_{j=1}^{n_k} W_{kj} \quad (3)$$

where, W_{kj} represents the NMF weight of each keyword j within topic k,

n_k is the total number of keywords within topic k,

and π_k represents the prior probability estimate of topic k.

H. Parameter Estimation and Bayesian Risk Aggregation

The topic probability distribution π was estimated using the mean NMF keyword weights obtained from Eq. (3). Each topic probability reflects the relative prevalence of a latent topic within the business news corpus and serves as the initial probabilistic representation at the factor level of the hierarchy. The relationship between latent topics and business risk categories was established through semantic clustering generated using the LLM- and WordNet-based labelling approaches. Topics assigned to the same semantic cluster were grouped to form higher-level business risk categories.

Following the hierarchical aggregation approach proposed in [4], the probability of a business risk category, r_i was estimated by aggregating the probabilities of its associated topics:

$$P(r_i) = \frac{\sum_{k=1}^{m} \pi_k}{m} \quad (4)$$

where:

- π_k denotes the probability of topic k,
- m denotes the number of topics associated with risk category r_i.

Consistent with [4], the contribution weight associated with topic k was assumed to be equal to 1. This aggregation produces a probability estimate for each business risk category by combining the contributions of semantically related latent topics. Subsequently, the overall Business Risk Impact (BRI) score was computed by aggregating the estimated probabilities of all business risk categories, again assuming the contribution weight assigned to the risk category is equal to 1:

$$BRI = \frac{\sum_{i=1}^{I} P(r_i)}{I} \quad (5)$$

where:

- $P(r_i)$ denotes the probability of business risk categories i,
- I denote the total number of business risk categories.

The resulting BRI score provides a comparative measure of the overall business risk represented within each annual news corpus. To maintain computational efficiency and interpretability, probability estimates were obtained through hierarchical aggregation of topic probabilities and semantic cluster associations, following the Bayesian hierarchical framework in [4]. The resulting probability estimates form the basis of the comparative business risk analysis presented in the Results section.

IV. Results and Discussion

This section presents a comparison of LLM- and WordNet-based labelling integrated into a BHM. The results are organised to demonstrate each method's contribution to the NLP-BHM framework. Due to space constraints, the final BHM structures for the 2020 and 2021 data are illustrated in the figures.

A. Comparison of LLM and WordNet Labelling Effectiveness Through Mean Opinion Scoring

Fig. 3 shows the MOS results for 2019 topics generated by LLM and identified by WordNet.

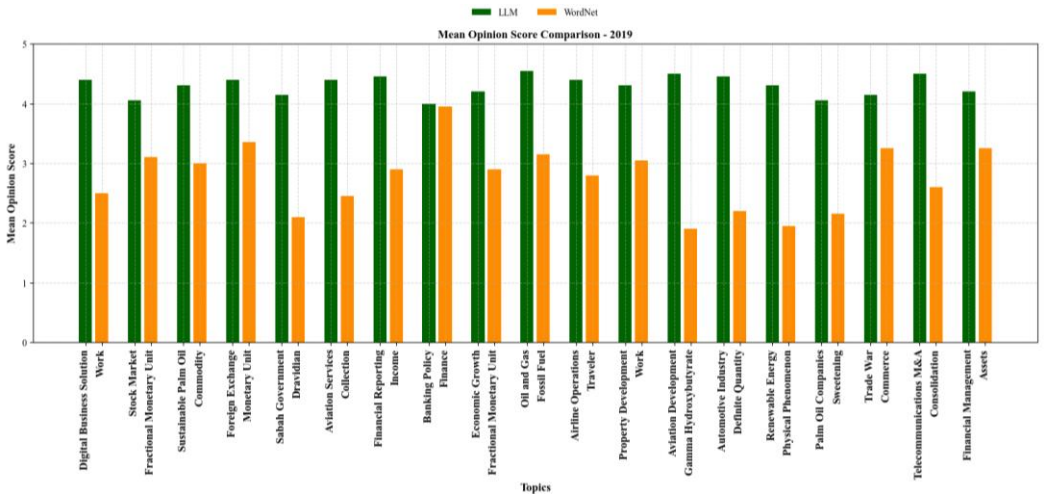

Fig. 3. Mean Opinion Scores from respondents to vote on LLM and WordNet topics from 2019 data.

The results indicated that respondents consistently favoured LLM labels (dark green), which outperformed the WordNet-based labels (orange). The LLM labels were rated as more understandable and better aligned with the business risk context. In contrast, WordNet labels were often perceived as too broad or disconnected from the underlying risk themes. Similar MOS results are observed in the 2020 to 2023 data, consistent with the 2019 data and highlighting patterns favouring LLM labels over WordNet labels. TABLE TABLE II. shows the average MOS results for 2019-2023 topics.

TABLE II. AVERAGE MOS SCORES FOR THE TOPICS GENERATED BY LLM AND IDENTIFIED BY WORDNET

Year	Average MOS (LLM)	Average MOS (WordNet)
2019	4.303	2.766
2020	4.288	2.683
2021	4.358	2.721
2022	4.369	2.634
2023	4.316	2.729

Over the five years, the average MOS for LLM topics increased from 4.2 to 4.4, reflecting a growing appreciation for their clarity and relevance. Conversely, WordNet topics maintained lower scores, ranging from 2.6 to 2.8, as they were often seen as too broad and less connected to specific risks. This trend emphasises the effectiveness of LLMs in enhancing topic interpretation and relevance in business contexts.

B. LLM-Based Labelling and Clustering Results

The factors and risks derived from the LLM topics were initially assigned prior probabilities based on the topics' weights from the NMF topic model. These priors represent the baseline importance of each factor before considering any risk evidence. Using the BHM, these priors were updated into posterior probabilities, reflecting the likelihood of specific risks once related factors are considered. The BHM structures for 2020 and 2021, as depicted in Fig. 4 and Fig. 5, reveal evolving business risk landscapes. In 2020, the focus was on "Transportation and Travel" and "Finance and Economy," with finance-related topics heavily influencing risk perception. By 2021, attention shifted to "Industry Analysis" and "Business and Finance," indicating a heightened emphasis on sectors like aviation and automotive. The business risk impact score increased from 0.408 to 0.444, reflecting heightened concerns, particularly in finance and governance. The reported risk impact scores represent relative probabilistic risk representations derived from posterior topic–risk associations within the BHM framework, rather than direct forecasts of future business outcomes. This evolution highlights shifting priorities and perceived risks in the business environment over the years.

Similar thematic transitions were observed across the 2019, 2022, and 2023 datasets, reflecting evolving business priorities and emerging economic concerns over time. TABLE III. shows the overall business risk impact score obtained from the LLM-based BHM structuring.

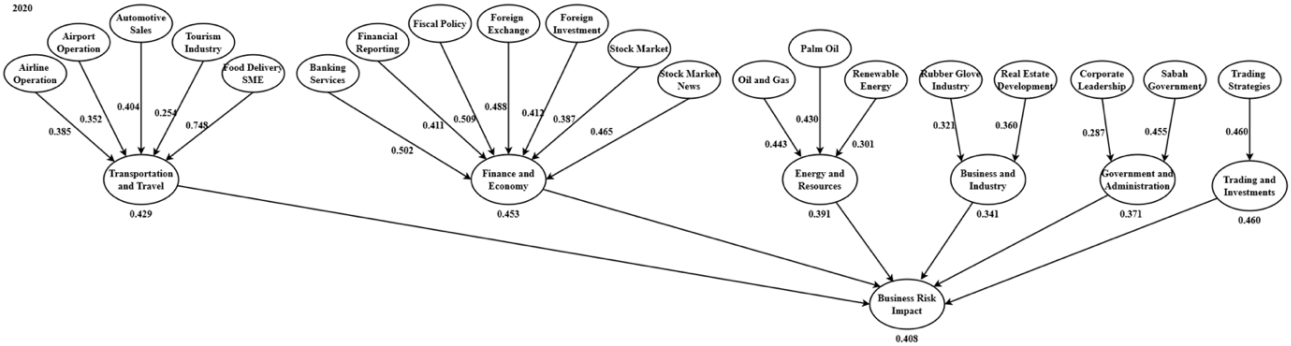

Fig. 4. LLM-based BHM structure for 2020 business news data.

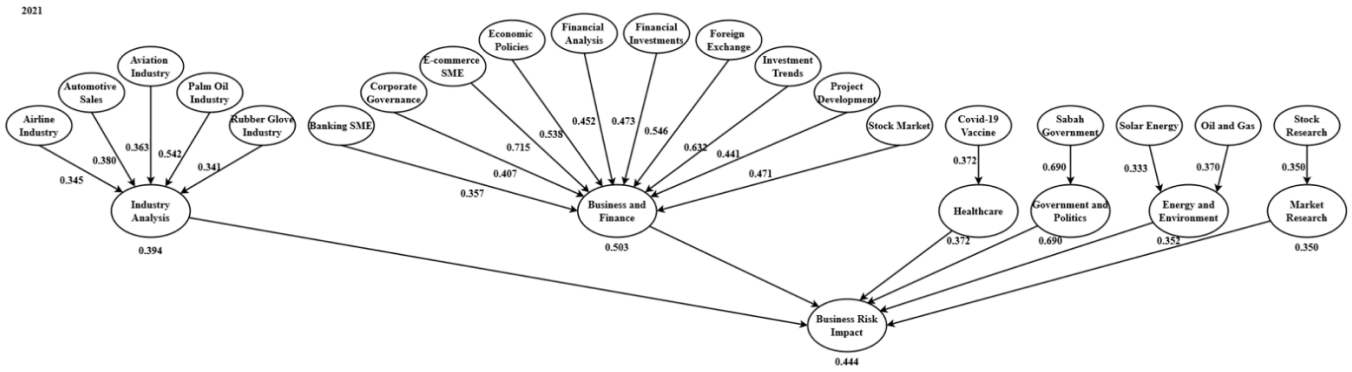

Fig. 5. LLM-based BHM structure for 2021 business news data.

TABLE III. OVERALL BUSINESS RISK IMPACT SCORE FOR LLM-BASED BHM STRUCTURE

Year	Business Risk Impact
2019	0.492
2020	0.408
2021	0.444
2022	0.430
2023	0.458

As shown in Table III, the LLM-based BHM structure produced business risk impact scores ranging from 0.408 to 0.492 across the study period. The highest risk impact score was observed in 2019 (0.492), followed by a decline in 2020 (0.408), before gradually increasing to 0.444 in 2021, 0.430 in 2022, and 0.458 in 2023. These comparisons illustrate evolving business priorities, reflecting changes in the economic landscape and policy environment over the years. These results highlight the NLP-BHM's ability to capture both persistent and emerging risks in Malaysia's business landscape.

C. WordNet-Based Labelling and Clustering Results

The WordNet-based Wu–Palmer similarity scores were used to construct a semantic similarity matrix representing the conceptual relatedness among topic labels. Higher similarity values indicated stronger semantic associations between topics, while lower values reflected weaker conceptual relationships. The similarity matrix was subsequently transformed into a distance matrix to support hierarchical clustering using the average-linkage method.

Fig. 6 depicts the resulting dendrogram for the sample, which highlights the semantic organisation of the topics in 2020. The height of each merge reflects the degree of dissimilarity between clusters, allowing for interpretation of how closely or distantly related the topics are. By applying a predefined threshold of 0.7, distinct semantic groups are identified, enabling clearer interpretation of the underlying conceptual structure derived from WordNet. It is observed that in that particular year, the topics were divided into four groups. After WordNet-labelled labels were processed through a similarity matrix and hierarchical clustering to group the factors into appropriate risk labels, the BHM's priors were estimated to reflect how common each factor was in the data, and then posteriors were calculated for the risks associated with each factor.

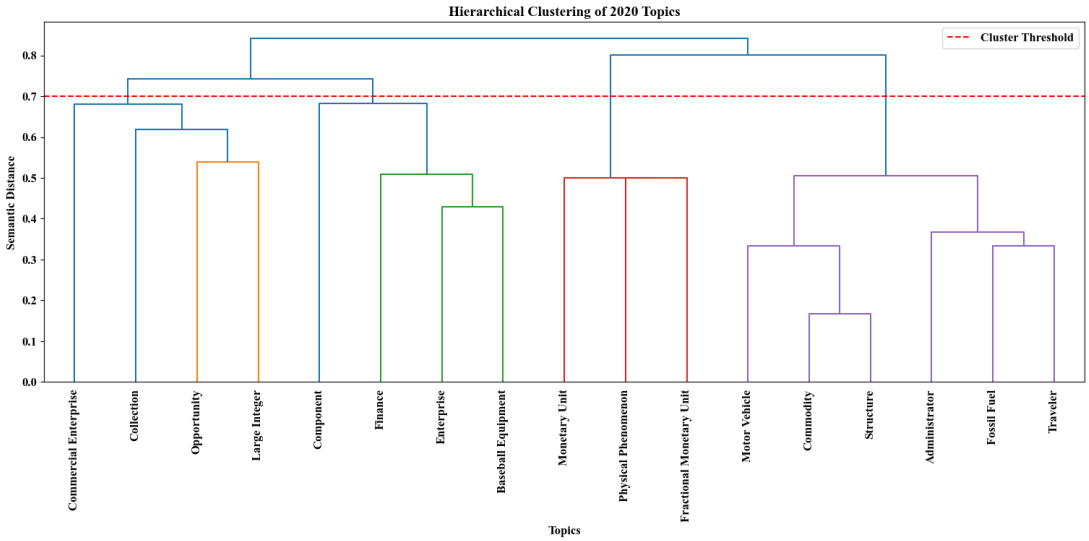

Fig. 6. Result of hierarchical clustering for topics in the 2020 data.

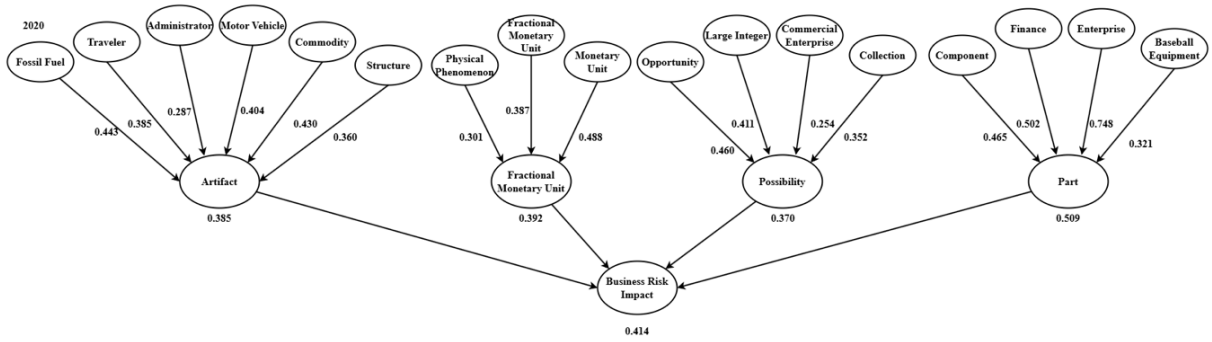

Fig. 7. WordNet-based BHM structure for 2020 business news data.

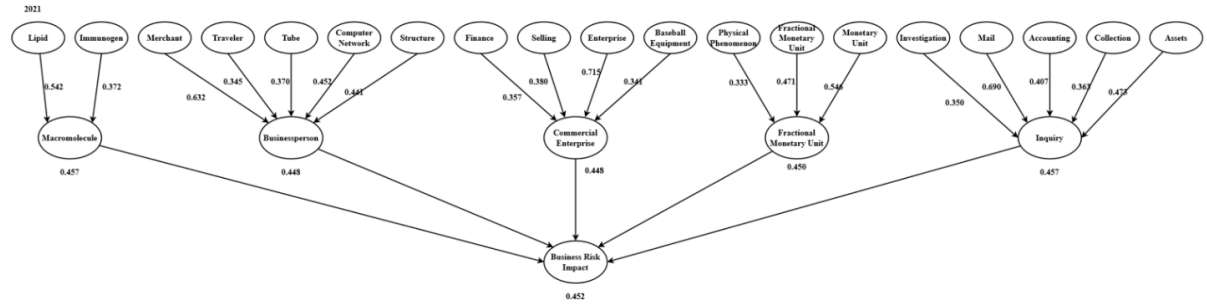

Fig. 8. WordNet-based BHM structure for 2021 business news data.

Fig. 7 and Fig. 8 show the resulting 2020 and 2021 BHM structures, respectively, obtained by leveraging WordNet-based labelling. The WordNet-based structures for 2020 and 2021 reveal distinct thematic focuses on business risk analysis. In 2020, the structure highlights categories such as "Artifact" and "Part," emphasising elements like fossil fuels, commodities, and financial components, leading to a business risk impact of 0.414. By 2021, the focus shifts to "Businessperson" and "Inquiry," with themes involving finance, enterprise, and accounting, reflecting a comprehensive approach to commercial enterprise risks with an impact score of 0.452. These structures illustrate evolving priorities in risk management, with a transition from tangible assets to more abstract business and financial concerns. Similar semantic transitions were observed across the remaining yearly datasets, where the WordNet-based structures progressively shifted from tangible asset-oriented concepts toward broader business and financial categories. TABLE IV. shows the overall business risk impact score obtained from the WordNet-based BHM structuring.

TABLE IV. OVERALL BUSINESS RISK IMPACT SCORE FOR WORDNET-BASED BHM STRUCTURE

Year	**Business Risk Impact**
2019	0.423
2020	0.414
2021	0.452
2022	0.416
2023	0.451

As shown in Table IV, the WordNet-based BHM structure produced business risk impact scores ranging from 0.414 to 0.452 over the five-year study period. The highest risk impact score was recorded in 2021 (0.452), followed closely by 2023 (0.451), while the lowest score was observed in 2020 (0.414). The remaining years, 2019 and 2022, yielded scores of 0.423 and 0.416, respectively. The variation in risk impact scores across the five years is relatively small, with a difference of only 0.038 between the highest and lowest values.

D. Discussion

The proposed NLP-BHM framework represents an integrated approach that combines topic modelling, BHM, and language model techniques to transform unstructured business news into structured, actionable risk insights. By integrating probabilistic reasoning with semantic enrichment, the framework addresses the complexity and uncertainty inherent in business risk analysis, enabling a more structured interpretation of latent risk factors. A key strength of the framework is the dynamic nature of the BHM, which allows risk probabilities to be continuously updated as new information becomes available. This makes the framework suitable for fast-changing business environments and supports near real-time risk assessment and decision-making.

The hierarchical structure of the model further improves interpretability by explicitly modelling relationships between high-level risks and underlying sub-factors, allowing clearer tracing of dependencies within complex risk systems. In addition, the use of LLM-based topic labelling enhances semantic representation by producing contextually meaningful, human-interpretable labels, thereby improving the usability of extracted risk topics. Based on the MOS results, LLM-based labelling is perceived as more interpretable than WordNet-based labelling, indicating its strength in capturing richer semantic context in business news. Importantly, in this study, LLM

outputs are made consistent through a fixed random seed, ensuring reproducibility and addressing concerns regarding variability in language model generation. In contrast, WordNet-based labelling provides deterministic, consistent labels that support reproducibility and standardisation. However, its limited coverage of domain-specific vocabulary, particularly in business and financial contexts, often leads to overly general topic labels that reduce interpretability and granularity. As a result, WordNet is less effective in distinguishing fine-grained risk categories, although it remains useful as a stable baseline for structured comparison.

It should be noted that the resulting business risk impact scores represent relative risk indicators derived from textual topic distributions rather than direct measures of real-world business risk severity. The framework quantifies the prominence of risk-related themes within the news corpus and enables comparative analysis across different periods. As such, higher scores indicate a greater concentration of risk-related topics within the analysed news data, rather than a verified increase in actual business risk outcomes. The current framework terminates at the estimation of business risk impact. However, these probabilistic indicators could be further served as inputs to more advanced risk quantification and decision-support models. Similar to the approach adopted in [4], where disruption probabilities were further utilised to estimate supplier revenue impact and Value at Risk (VaR), the proposed business risk impact scores could potentially be integrated with financial, operational, or market-based indicators to quantify the potential consequences of emerging business risks. Consequently, the business risk impact score should be viewed not only as a comparative textual risk indicator but also as a foundation for future quantitative risk assessment frameworks that link news-derived risk signals with real-world business outcomes.

V. Conclusion and Future Work

This study proposed an NLP-BHM framework for transforming topic modelling outputs into interpretable hierarchical probabilistic representations for business risk analysis. Using a corpus of Malaysian business news articles published between 2019 and 2023, four topic modelling approaches were evaluated, where NMF consistently produced the most coherent and semantically interpretable topic structures. The framework subsequently integrated semantic topic labelling and clustering using both LLM-based prompting and WordNet-based semantic analysis within a Bayesian hierarchical modelling structure.

The study demonstrates that topic modelling outputs can be effectively transformed into interpretable hierarchical probabilistic risk representations through semantic labelling and Bayesian hierarchical structuring, thereby addressing the challenge of integrating unstructured textual themes into uncertainty-aware business risk analysis. Comparative findings further show that LLM-based semantic labelling generated more contextually relevant and interpretable topic representations than the WordNet-based approach, as reflected by consistently higher MOS scores. While WordNet-based clustering provided semantically structured and reproducible groupings, its limited contextual flexibility reduced its effectiveness in capturing domain-specific business terminology and evolving semantic relationships.

Overall, the proposed NLP-BHM framework provides a structured approach to bridging latent textual themes and higher-level probabilistic risk representations through hierarchical semantic structuring and Bayesian reasoning. By integrating topic modelling, semantic interpretation, and posterior risk representation within a unified framework, the study demonstrates the potential of NLP-driven probabilistic analysis for interpretable business intelligence and decision support.

Future work may explore integrating dynamic temporal Bayesian structures, automated probabilistic parameter learning, and multiple LLMs to evaluate the generalisation ability, robustness, and consistency of semantic topic labelling across different model architectures. In addition, further research should investigate the validation of the generated business risk indicators against external economic and financial benchmarks, such as market volatility indices, business confidence indicators, or observed business risk events, to provide stronger empirical evidence for interpreting the resulting risk impact scores as meaningful measures of real-world business risk severity and to enhance the practical applicability of the proposed NLP-BHM framework.

Acknowledgment

This work was supported by the Ministry of Higher Education Malaysia under the Fundamental Research Grant Scheme (FRGS/1/2023/ICT06/UNIMAS/02/2). The authors thank the MOS participants. The survey was approved by the UNIMAS Human Research Ethics Committee (HREC(NM)/2023(2)/57).

Declaration on Generative AI

This work utilises OpenAI's ChatGPT to enhance data analysis and interpretation. All outputs generated through the technology have been critically reviewed and validated by the authors to ensure accuracy and integrity.

***Abstract*—This study examines how Artificial Intelligence (AI) is transforming academic integrity in higher education, altering both learning opportunities and the risks associated with misconduct. As creative AI tools become embedded in everyday academic work, they provide valuable support for writing, research assistance, and skills development. Still, they also challenge long-held assumptions about authorship, originality, and assessment. Emerging evidence suggests that students are using AI in a variety of ways, from supporting legitimate learning to producing fully automated assignments. However, AI-driven integrity technologies, such as plagiarism detectors and authorship checking models, are becoming more effective but continue to face issues of bias, false positives, and limited transparency. This rapid shift has created a gap between technological change and academic readiness, highlighting the need for institutions to rethink assessment design, improve integrity frameworks, and foster a culture of responsible AI use, rather than relying solely on surveillance and sanctions. This review compiles the latest studies published between 2020 and 2025 to map current practices, risks, and policy responses. The findings suggest that academic integrity in the age of artificial intelligence (AI) cannot be focused solely on preventing fraud. But this needs to expand to support ethical digital literacy, redesign learning tasks that require human reasoning, and ensure fairness in automated decision-making systems. The study concludes with recommendations for educators, researchers, and policymakers to balance innovation with responsibility to ensure that AI becomes a tool for transforming learning, rather than a threat to academic values.**

***Keywords*—AI in education; academic integrity; Generative AI; ethical digital literacy; assessment transformation**

I. Introduction

The usage of Artificial Intelligence (AI) in education has changed the education landscape by improving personalized learning, such as customized learning pathways by adapting to the different needs and learning styles of individual students [1]. This makes administrative tasks more efficient through methods such as automated grading, which allow teachers to focus more on teaching and improving student engagement [2]. However, the usage of AI in education also posts ethical concerns and challenges, such as data privacy [3], the quality of the data used, and the need for ongoing training for teachers and students [1].

A. Background

AI has become more recognized as a personalized learning tool in education. AI-driven platforms allow the analyzation of students' performance data, creating a customized learning path and addressing individual strengths and weaknesses [4]. This feature allows students to self-regulate their learning and take control of their own education journey [5]. Additionally, AI has also become more recognized for its potential in increasing efficiency by automating assessment and feedback in education. Tools such as Automated Essay Scoring (AES) reduce administrative burden on teachers by enabling fast and consistent grading [6]. Moreover, AI has also been used as a tool to support students' success. AI tools such as chatbots offer a personalized self-service platform, where students can address any question and get help with course selection in education [7].

The integration of Generative AI (GAI) gives rise to an opportunity for enhancing learning by offering a personalized learning journey to students, this foster engagement and critical thinking in students [8]. These features help in students' comprehension of the course materials [9]. However, this also gives rise to a challenge in academic integrity. Due to the ease of generating content, there are risks such as dishonesty, plagiarism [10], and even a decline of cognitive skills and critical thinking from overreliance on GAI [11].

In higher education, AI assists students through the inclusion and enhancement of learning by personalization, which makes education more accessible to students with diverse needs [12]. Those with disabilities or those facing language barriers can benefit from these AI features, as AI allows them to learn from anywhere and generate content in their preferred language [13]. In teaching assistant and virtual classroom, AI tools provide personalized study plans and support that help in explaining complex concepts [14]. Additionally, AI creates an immersive learning environment with the uses of things such as virtual reality, which provide a safe space for students to practice their skills [15].

B. Research Objectives

The primary objective of this research is to conduct a systematic review of AI applications in higher education across seven key topics by searching for recent literature to identify both opportunities for enhancing learning experiences and associated challenges. This study aims to evaluate how AI tools contribute to personalized learning, automated assessment, academic advising, academic integrity, inclusion, virtual teaching support, and institutional readiness while maintaining unbiased, keeping ethical considerations in mind, and considering practical implications for teachers and students.

C. Scope and Significance

This review focuses on peer-reviewed studies published between 2020 and 2025, emphasizing AI's role in higher education within the seven specified topics. It excludes non-academic sources and broader K-12 applications to maintain a targeted analysis. The significance lies in providing teachers, administrators, and policymakers with a concise framework for understanding AI's transformative potential, addressing gaps in ethical integration, and fostering informed strategies to improve student outcomes and institutional efficiency in an evolving educational landscape.

D. Structure Overview

This study is structured as follows: Section I introduces the topic, background, objectives, scope, and significance. Section II outlines the proposed systematic review method and framework. Section III details the methodology of implementation, search processes, quality assessment and limitations. Section IV presents results and discussions for each of the seven topics in Section V. Section VI concludes with key findings and recommendations for future research.

II. Proposed Methodology

A. Systematic Review Approach

The systematic review method used in this study was designed to provide a comprehensive, transparent, and replicable way to synthesize existing research on the use of Artificial Intelligence (AI) in higher education. This approach ensures that the review maintains strong methodological standards while reducing bias in how studies are selected, evaluated, and interpreted. It also helps identify trends, challenges, and research gaps across different academic settings related to AI's integration in higher education.

The review follows the principles of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework, which offers structured guidance for finding, screening, and reporting research evidence. By following this framework, the study guarantees that each step—from searching databases to final inclusion—is transparent and well-documented. The review focuses on seven key themes that represent critical areas of AI use in higher education: personalized learning, automated assessment, academic advising, academic integrity, inclusion, virtual teaching support, and institutional readiness.

The process started with a systematic search across selected academic databases, including IEEE Xplore, Google Scholar, and Scopus, chosen for their wide coverage of peer-reviewed research in educational technology and AI applications. The search combined relevant keywords and Boolean operators to find a broad range of studies published from 2020 to 2025. This timeframe was selected to reflect recent advances in AI and to match the current era of technological change shaping higher education.

Each study found was reviewed through a structured screening process in two stages: an initial review of titles and abstracts, then a detailed examination of the full texts to determine eligibility. Inclusion criteria specified that studies focus on higher education, present empirical or conceptual analyses of AI tools, and be published in peer-reviewed journals. Materials that were not academic, such as editorials or studies unrelated to higher education, were excluded. After selecting eligible studies, all were assessed for quality using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) framework. This ensured that the evidence included in the review was credible, relevant, and methodologically strong. The final dataset supported an analysis of how AI is transforming teaching, learning, and institutional operations within higher education.

Overall, this systematic review method provided a structured, evidence-based way to explore AI's transformative effects. It highlights both potential benefits and the ethical, pedagogical, and institutional challenges that come with AI integration. This approach ensures that the conclusions are based on reliable, diverse academic evidence.

B. Proposed Framework

The proposed framework for this systematic review was developed to ensure a transparent, reproducible, and unbiased process when analyzing existing literature on artificial intelligence (AI) applications in higher education. It provides a clear and structured pathway for identifying, selecting, and synthesizing relevant studies, helping readers understand the methodology and reasoning behind each step of the review. Essentially, the framework follows a predefined, step-by-step protocol inspired by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. This protocol emphasizes consistency, accuracy, and traceability throughout the review process. It consists of three main stages: searching, selecting, and synthesizing.

In the searching stage, relevant academic databases — IEEE Xplore, Google Scholar, and Scopus — were systematically explored to find peer-reviewed publications from 2020 to 2025. This time frame was chosen to focus on recent developments and emerging practices in AI, reflecting the fast-changing nature of technology and education. The search strategy used a combination of specific keywords related to the seven themes: personalized learning, automated assessment, academic advising, academic integrity, inclusion, virtual teaching support, and institutional readiness.

The selection stage involved a multi-step screening process to reduce subjectivity and bias. First, duplicates and non-academic sources were removed. Next, studies were filtered based on relevance of title and abstract, followed by a full-text review to confirm they met the inclusion criteria—specifically,

that each study involved AI applications in higher education and was published in a peer-reviewed outlet.

Finally, in the synthesizing stage, all eligible studies were analyzed and grouped according to the seven key areas. Data was extracted using a structured template to record essential details such as research goals, methodologies, AI techniques employed, main findings, and limitations. The synthesis aimed to combine findings across studies to identify common patterns, emerging themes, and significant challenges in the field.

This systematic framework offers a balanced and comprehensive approach for understanding the opportunities and challenges of AI in higher education. By applying consistent criteria, selecting high-quality sources, and maintaining transparency, the review minimizes bias and ensures that the analysis provides both clarity and credibility in illustrating the evolving relationship between AI and higher education practices.

C. Visualization

This systematic review process is for identifying and selecting studies for a quality system. This review highlights PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) benefits, such as providing an intuitive abstraction layer that simplifies database operations and improves code quality, security, and scalability [51, 52].

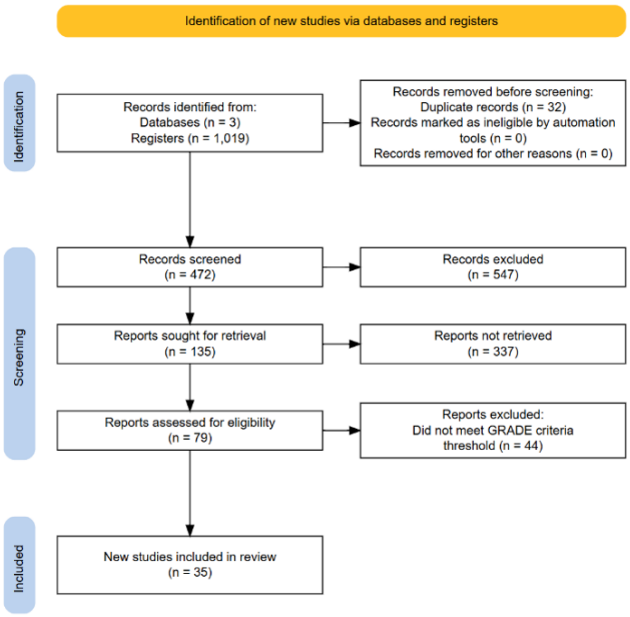

Fig. 1. PRISMA flowchart for inclusion and exclusion of works.

The PRISMA flow diagram in Fig. 1 shows the review process in the beginning, with 1,019 studies identified from 3 databases. Prior to screening, 32 duplicate records and ineligible records marked by automation tools were removed, reducing the total to 472 records screened. From these, 547 records were excluded, and then 135 reports were sought for retrieval. Of the retrieved reports, 79 were assessed for eligibility, excluding 44 that did not meet GRADE criteria, resulting in 35 new studies being included in the review.

D. Expectations

The review expects to produce clear summaries for each topic and to highlight both benefits and challenges. The process and result of these summaries will determine the methodology and results, which will provide insights for teachers as a clear, concise, systematic review structure.

III. Methodology

A. Implementation

The implementation phase of this systematic review was conducted by strictly following the proposed framework to ensure methodological rigor, transparency, and reproducibility. The process began with an extensive search across major academic databases, namely IEEE Xplore, Google Scholar, and Scopus, which were chosen for their vast collections of peer-reviewed research in education, technology, and artificial intelligence. The search strategy used a combination of predefined keywords and Boolean operators designed to find relevant literature on seven key themes: personalized learning, automated assessment, academic advising, academic integrity, inclusion, virtual teaching support, and institutional readiness.

The data collection was limited to the period between 2020 and 2025 to reflect the latest developments in AI-driven educational tools and to ensure that the review addressed the current technological and pedagogical landscape. Search results were first screened by titles and abstracts to remove unrelated or duplicate studies. Then, full-text articles were reviewed to verify eligibility based on criteria such as publication in peer-reviewed journals, relevance to higher education, and direct discussion of AI applications within one or more of the seven focus areas.

Once selected, data from each eligible study were systematically extracted using a standardized data extraction form. This form recorded key details, including study goals, research methods, AI technologies used, outcomes, limitations, and implications for higher education. The extraction aimed to ensure consistency across studies while keeping contextual details for accurate synthesis.

To enhance the reliability and validity of the combined findings, each study underwent a structured quality assessment using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) framework. This assessment focused on criteria such as methodological quality, risk of bias, relevance to the research questions, and clarity of the presented evidence. Studies rated as “high” or “moderate” in quality were prioritized in the synthesis to increase the trustworthiness of the conclusions.

Finally, the collected and evaluated data were organized into clear thematic summaries aligned with each of the seven topics. The synthesis highlighted patterns and interpreted differences across studies. The findings were presented in clear, accessible academic language to provide educators, researchers, and policymakers with insights into the roles and challenges of AI in higher education. This systematic approach not only helped organize and validate diverse research findings but also built a transparent basis for further analysis and discussion within the review.

B. Search and Selection Process

The search uses databases IEEE, Google Scholar, and Scopus, which contain numerous peer-reviewed records that are regularly updated. Studies criteria, such as peer-reviewed and dated between 2020 and 2025, were included while also following the PRISMA process to ensure transparency and to manage the scope within the study's limits.

C. Quality Assessment

The quality of selected studies was evaluated using the GRADE (Grading of Recommendations, Assessment, Development and Evaluations) framework to ensure reliable evidence for the systematic review of AI in higher education. GRADE assesses studies based on criteria like risk of bias, inconsistency, imprecision, and indirectness by assigning each criterion a quality rating (high, moderate, or low). For this research, studies were examined for relevance and methodological clarity to the seven topics. This streamlined process ensured only credible sources shaped the synthesis to maintain the focus and transparency of this study [53, 54].

D. Limitations

This systematic review is constrained by its reliance on selected databases (IEEE, Google Scholar, and Scopus), which may overlook relevant studies in other repositories, like non-English publications. The time frame of 2020-2025 limits the historical context, which may also potentially miss foundational developments in AI applications. The streamlined quality assessment using GRADE may introduce subjective judgments, and the focus on peer-reviewed sources may exclude emerging gray literature, which could affect the overall insight into the rapidly evolving AI technologies in higher education.

IV. Results

A. AI as a Pedagogical Tool: Personalized and Adaptive Learning

Artificial Intelligence (AI) transforms education by enabling personalized adaptive learning experiences. Traditional teaching methods come with fixed pacing and normal content, while AI systems customize instruction to each student's progress preferences and performance data. AI tools can offer immediate feedback and targeted remediation, which allows students to learn at their own speed [16]. These tools excel in subjects like math and science, where student abilities often differ greatly. By analyzing learner behavior in real-time, AI helps teachers meet diverse needs in large classrooms and improve learning outcomes [17]. AI tutoring systems and virtual assistants enhance personalization by providing real-time support and recommending resources tailored to students' actions. These systems help with customized content, guiding students through problem-solving and constant feedback [17]. Using these systems with personalized feedback boosts comprehension and increases student motivation and emotional engagement [18]. These systems can also be paired with certain environments, like AI-extended reality, by adapting tasks based on student performance and supporting the students using experiential learning to further help with student and system development [19].

However, the use of AI in teaching can cause some ethical and professional concerns. Automation can allow for streamlining of tasks like grading work and feedback, but risks alienation between students and teachers, especially if the work is streamlined, the grading or feedback may lack the correct context [20]. Decisions like this may limit the teachers' ability and the students' experiences. The alternative is to use models that require human management or input during critical decision-making processes, which will ensure that teachers use technology as a supportive tool rather than a replacement, allowing for the adjustment of features of the AI and giving students an overall good experience [20].

TABLE I. AI IN PERSONALIZED AND ADAPTIVE LEARNING: SUMMARY AND GRADE ASSESSMENT

No.	Key Points	Challenges	Effect on Teachers and Students	GRADE
[16]	Tools like Knewton and ALEKS can provide immediate and targeted feedback to improve results.	Automation risks alienating students from teachers due to a lack of context in feedback.	Teachers use AI as a supportive tool while students gain motivation through personalized feedback.	Moderate
[17]	AI analyzes learner behavior in real time for customized content and problem-solving guidance.	Decisions may limit teacher autonomy if not human-managed.	Boosts comprehension and emotional engagement to help close achievement gaps in diverse classrooms.	Moderate
[18]	System tracks emotional and cognitive engagement and fits different cultural contexts.	Overreliance on AI could reduce human interaction.	Enhance self-regulated learning, which allows teachers to focus on higher-order tasks.	High
[19]	Extended reality integration for performance-based experiential learning.	Ethical concerns in data usage for personalization.	Supports student development in immersive environments.	Moderate
[20]	Streamline tasks like grading, allowing teachers to focus on teaching.	Risks of inaccurate context/information in automated processes.	Requires human oversight for balanced experiences.	Low

Table I summarizes the role of AI in delivering personalized and adaptive learning experiences in higher education. It highlights how tools provide immediate feedback and customized content based on student performance, boosting engagement and comprehension. However, it also notes challenges such as the risk of reduced teacher-student interaction due to automation and ethical concerns in data usage and emphasizes the need for human oversight to maintain effective learning experiences.

Overall, the potential of AI in education is mainly adaptive personalization and time-saving efficiency. Adaptive tools customize instruction to diverse learner needs, interests, and

cultural contexts, helping close achievement gaps [18]. Systems that track emotional and cognitive engagement would be able to provide feedback to keep students focused and invested [19].

B. Assessment and Feedback Automation

Using automation in assessment enhances efficiency and scalability in diverse learning environments by transforming how teachers assign grades and provide feedback [21]. AI grading systems can deliver objective results compared to human grading, which often shows bias [21]. This also allows for a much faster and more efficient system, especially for students dissatisfied with traditional grading methods and the amount of time needed for results and feedback [21]. These systems enable timely personalized feedback that encourages self-learning and deeper engagement with the material [22, 23]. However, automated feedback struggles with writing tasks or assessments that don't align with rigid linguistic criteria, as they may fail to recognize diverse or unique ways students demonstrate understanding [24]. Carefully designed systems with adaptive features can overcome these limitations to significantly improve learning outcomes [22]. In legal education, hybrid intelligence systems provide formative high-level feedback while preserving the teacher's role in deeper instruction [23].

For automated feedback to succeed, it must account for varied student performances and learning styles, especially in tasks like writing that resist fixed syntactic patterns [24]. Students are more likely to accept AI feedback when they have prior experience with it and perceive it as fair and unbiased compared to human grading, particularly when outcomes are unfavorable [21]. Transparent system design and student-centered implementation are essential for broader adoption [25]. Generative AI systems like ChatGPT advance feedback by offering structured personalized guidance aligned with learning goals [25]. When paired with clear prompts and ethical boundaries, these tools support student autonomy without replacing the teacher's evaluative role [22, 25]. Over-reliance on AI risks undermining this balance, but thoughtful integration allows automation to handle routine tasks while freeing teachers to focus on complex, creative, and motivational aspects of education [23, 24].

Table II outlines the impact of AI-driven assessment and feedback systems, which focus on their ability to reduce grading bias and enhance efficiency through objective and timely feedback. It discusses how these systems support self-learning but struggle with non-rigid tasks like writing, which may not align with fixed criteria. The table shows the importance of adaptive and transparent designs to improve learning outcomes while preserving the teachers' role in deeper instruction.

TABLE II. AUTOMATED ASSESSMENT AND FEEDBACK: SUMMARY AND GRADE ASSESSMENT

No.	Key Points	Challenges	Effect on Teachers and Students	GRADE
[21]	AI gives objective feedback, reducing bias and time, which promotes self-learning	Students accept AI more if perceived as fair, but dissatisfaction with traditional methods still happens.	Faster feedback encourages deeper engagement, which is essential for scalability in large classes.	Moderate
[22]	Personalized feedback helps with learning goals and systems in legal education.	Struggles with non-rigid tasks like writing.	Improves outcomes with adaptive features, which frees teachers for more creative aspects.	Low
[23]	Formative feedback preserves the teacher's role in deeper instruction.	Over-reliance risks compromising balance.	Supports autonomy, which requires thoughtful integration.	High
[24]	Handles different student writing styles with NLP exploration.	Fails to recognize unique demonstrations of understanding.	Enhance learning experience for student-centered designs.	High
[25]	Generative AI like ChatGPT offers structured guidance with ethical boundaries.	Transparency issues in system design.	Wider adoption via trust and clear prompts.	Moderate

C. AI Academic Advising and Learning Analytics

AI-powered academic advising and learning analytics are revolutionizing higher education by providing personalized, data-driven support to enhance student outcomes. Machine learning models can achieve high accuracy in predicting course outcomes, enabling students to select courses that align with their academic strengths, which helps performance and reduces dropout rates [29]. Also, many AI chatbots offer 24/7 accessible guidance that allows for comprehensive responses to general academic and career queries, which helps promote education for diverse learners and those who have limited access to traditional advising [28]. Systems like the Artificial Intelligence Tutoring System (AITS) can use web technologies and decision trees to analyze student performance data, help identify struggling students, predict final grades, and recommend personalized learning paths for students [30].

These AI systems enhance student engagement and retention by offering scalable and personalized recommendations. For example, AI advising platforms analyze large datasets using academic records and career preferences to provide personalized courses and career pathway suggestions to help students with academic confidence and in making decisions [27]. Additionally, chatbots are also another option that can help streamline tasks like course registration and question handling, which would allow teachers to have more time and meaningful mentoring roles [26]. Studies highlight that factors like ease-of-use and trust significantly affect when adopting the use of these technologies, especially values like efficiency and accessibility [26]. AI can help make decisions and create synergies for students to use AI for guidance and help teachers with deeper and personalized support [28].

However, ethical challenges and data privacy concerns are still big problems. For example, AI advising systems rely on huge amounts of student data which would cause issues regarding compliance with regulations and bias results if there is not enough data of different types of students [27]. While personalized results are a key benefit, there is research that shows it may be less impactful and less efficient during the adoption stage, as the collection of data requires refinement

and time to become trustworthy [26]. These reasons and challenges show AI's potential in academic advising and learning analytics, but priority regarding data governance and bias is needed to ensure fair, effective, and efficient implementation across educational fields.

TABLE III. AI IN ACADEMIC ADVISING AND LEARNING ANALYTICS: SUMMARY AND GRADE ASSESSMENT

No.	Key Points	Challenges	Effect on Teachers and Students	GRADE
[26]	Chatbots streamline tasks, which helps boost adoption through ease of use.	Initial data collection requires clarification for trustworthiness.	Free teachers for mentoring and help with efficiency for diverse learners.	Moderate
[27]	Analyze the dataset for personalized learning career suggestions to improve confidence.	Risk of bias and data privacy if the dataset lacks diversity	Enhances retention and prioritizes data governance.	High
[28]	24/7 guidance via chatbots promotes accessibility.	Compliance with regulations is needed.	Empowers students with limited access to advising.	Low
[29]	High accuracy in predicting outcomes for course selection.	Less impactful during early adoption stages.	Reduces dropout rates and helps with strengths and benefits.	Moderate
[30]	Decision trees for performance analysis and recommendations.	Ethical challenges in large data reliance.	Identifies struggling students early and offers personalized paths.	Moderate

Table III shows the benefits of AI in academic advising and learning analytics, such as predicting course outcomes and providing 24/7 guidance through chatbots to enhance student retention and accessibility. It also addresses ethical challenges, which include data privacy risks and potential biases in datasets. This highlights the need for robust data governance to ensure fair and effective implementation across diverse educational settings.

D. Generative AI and the Challenge of Academic Integrity

Generative AI's use in higher education offers many possibilities but also causes serious challenges to academic integrity. Tools like ChatGPT support writing, research, and personalized learning yet increase risks of academic dishonesty through plagiarism and automated essay generation [32]. Students sometimes use these tools to skip genuine learning, producing assignments with minimal effort, while traditional plagiarism detection systems often fail to catch AI-generated content [33, 35]. Teachers worry about students submitting work lacking originality or understanding, especially since some AI can create entire assignments independently [33]. Ethical knowledge gaps and outdated institutional policies worsen these issues, underscoring the need for clear governance and updated integrity standards [31].

AI itself can also help maintain academic honesty. AI-based systems detect plagiarism, verify originality and provide feedback to promote ethical behavior which often outperforms older methods [32]. Teacher uses these tools to spot cheating patterns and confirm work authenticity [32]. However, relying heavily on automated systems raises concerns about false positives, reduced student agency and lack of trust due to privacy or fairness issues when tools are opaque or unreliable [33, 34].

To tackle these challenges, institutions must rethink assessment models to emphasize project-based learning, critical analysis and real-world applications, which are harder for AI to replicate and encourage deeper engagement [31, 35]. Yet implementing these changes globally faces hurdles, especially in resource-limited settings with inadequate infrastructure, insufficient training and resistance from students and faculty [32, 34]. Promoting responsible AI use demands more than policy updates; it requires fostering an academic culture that values integrity, boosts digital literacy and aligns assessments with both technological realities and educational goals [33].

TABLE IV. GENERATIVE AI AND ACADEMIC INTEGRITY: SUMMARY AND GRADE ASSESSMENT

No.	Key Points	Challenges	Effect on Teachers and Students	GRADE
[31]	Supports in writing research and plagiarism detection better than traditional methods.	Outdated policies and lack of ethical knowledge	Rethink assessments for critical analysis and help foster integrity	Moderate
[32]	Verifies originality and promotes ethical behavior.	Risks of dishonesty via automated generation through giving false positives	Use AI for detection but training in resource limited settings	High
[33]	Gives feedback that help with spotting cheating pattern.	Students skip learning but create lack of trust in more traditional tools	Emphasize project-based learning and boost digital literacy	Moderate
[34]	Maintain honesty through advanced systems.	Privacy/fairness issues which reduces student autonomy	Align assessments with tech realities and drive policy updates	Moderate
[35]	Shifts to holistic assessments are harder for AI to replicate	Problem in global implementation in under resource areas	Encourages deeper engagement and creates responsible AI use	Moderate

Table IV shows the dual role of generative AI in higher education which helps in supporting writing and research, while posing risks to academic integrity through plagiarism and automated content generation. It notes that AI-based plagiarism detection tools outperform traditional methods, but face issues like false positives and reduced student trust. The table advocates project-based assessments and updated policies to foster ethical AI use and deeper student engagement.

E. AI and Inclusion in Higher Education

AI is increasingly becoming more used in higher education institutions and showing more inclusivity and new ways to support learners with diverse needs. For example, robotic

assistants have been developed for children with ADHD which shows how AI can help users maintain attention and consistent engagement that could benefit students with cognitive challenges [36]. As well, smart technologies developed for older adults show the value of adaptive interfaces and principles where both are important for making accessible digital environments for people varying in physical and cognitive abilities [37]. These innovations highlight the need for participatory design approaches that prioritize user input from the start [36-37].

However, access to AI alone does not guarantee inclusion, as students are still facing barriers due to problems like digital literacy [39]. Studies show that individuals with visual impairments are more likely to engage with digital tools when they've had formal education and training in assistive technologies, which shows the need for targeted support in higher education [39]. AI tools can help with reading on smart screens and real-time feedback systems, which can save a lot of time. However, their effectiveness on user competence and the extent where institutional are ready to provide correct training are still questioned [39, 40]. Also, individual factors such as trust, technostress, self-efficacy, and personality traits can also influence whether students and teachers use AI tools at all [40].

AI-generated text tools are now common in academic settings, which raises concerns about fairness, transparency, and potential misuse [38]. Biased algorithms and decision-making processes risk having educational inequalities unless addressed through transparent design and clear data representation [38, 40]. Inclusive integration and admission of AI use require not only technical safeguards but also a cultural and constant commitment to accessibility and ethical practice [37, 38]. Overall, AI should be used as a tool to help all learners and not just the digitally privileged.

TABLE V. AI FOR INCLUSIVE EDUCATION: SUMMARY AND GRADE ASSESSMENT

No.	Key Points	Challenges	Effects on Teachers and Students	GRADE
[36]	Robotics design for ADHD children to maintain attention	Access doesn't guarantee inclusion, especially due to barriers of low digital literacy	Targeted support for cognitive challenges	Moderate
[37]	Adaptive interfaces for older adults and smart tech for varying abilities	Biased algorithms risk inequalities	Cultural commitment to accessibility can affect ethical practice	Moderate
[38]	AI text tools are common in academics, and real-time feedback saves time	Fairness/transparency concerns and potential misuse arise	Address biases through transparent design	High
[39]	Training aids for visually impaired people and engagement via education	Institutional readiness for training due to personal factors like trust	Bridge the digital divide and formal assistive tech education	Moderate
[40]	Influences adoption via self-efficacy/personality and saves time	Technostress and competence issues	Inclusive integration for all learners and not just the privileged	Moderate

Table V shows AI's potential to enhance inclusivity in higher education, such as through robotics for ADHD students and adaptive interfaces for diverse learners. It identifies barriers like low digital literacy and institutional readiness, which hinder equitable access. This table emphasizes the need for transparent design and targeted training to address biases and ensure AI supports all learners, not just the digitally privileged.

F. AI in Teaching Assistants and Virtual Classrooms

AI is changing virtual classrooms, allowing dynamic, interactive, and customized learning through AI teaching assistants. Incorporating AI into video material via tools can allow for real-time and context-aware interaction in class, which changes students from passive viewers to active participants [41]. These systems help explain concepts, visualization, and answer students' questions. As well, intelligent agents in an e-learning environment act as virtual tutors by providing feedback and encouraging interactive discussion [42]. These types of features allow for a successful mimicking of an aspect of human instruction and action [44]. AI teaching assistants also increase accessibility in education. Chatbots can act as a real-time response and learning companion, offering academic assistance 24/7 through a natural language interface [43]. Further studies show that conversational AI can reduce teachers' workload while supporting students' learning [42]. Robot-assisted systems in VR settings allow students to learn and practice language in a low-pressure and contextual environment, which encourages students' learning independence [45], which extends the AI role beyond the traditional classroom [43].

These systems are very personalized. For example, SAM feedback is based on an individual chat history and video context, which allows a tailored assessment; the system also provides personalized summaries for revision [41]. AI tools offer adaptive support across learning phases, such as generating quizzes and providing analytics to help guide teachers [44]. Also, AI isn't a replacement but an assisting tool that allows teachers to focus more on higher-order teaching, while AI handles routine tasks [42]. However, AI integration still poses challenges, such as students often using AI chatbot for basic tasks like formatting or rephrasing rather than learning these themself [43]. AI can also struggle with complex communication due to program limitations [45]. These issues show the need for AI that supports critical thinking and reason-based interaction [41]. Further development of AI should focus on AI as an education tool that complements human teachers and encourages active learning rather than passive dependence [44].

Table VI shows how AI teaches assistants and virtual classroom tools such as chatbots and VR systems that create interactive and personalized learning environments. It highlights their ability to reduce teacher workload and provide 24/7 support, but notes challenges like over-reliance on AI for basic tasks and limitations in complex communication. The table stresses the importance of AI as a complementary tool to promote active learning and critical thinking.

TABLE VI. AI TEACHING ASSISTANTS AND VIRTUAL CLASSROOMS: SUMMARY AND GRADE ASSESSMENT.

No.	Key Points	Challenges	Effects on Teachers and Students	GRADE
[41]	Tools to allow real-time interaction in videos and personalized summaries	Struggles with complex communication and risk of dependence	Turns passive viewers into active and personalized assessments	Moderate
[42]	Intelligent agents as tutors reduce workload.	Use of AI for basic tasks may hinder skill learning	Supports interactive discussion and enhances human teaching	High
[43]	Chatbots as 24/7 learning companions; natural language interface.	Limitations in program capabilities	Academic assistance at any time encourages independence	Low
[44]	Adaptive support with analytics and mimics human instruction.	The need for critical thinking focus.	Frees teachers for higher order tasks and allows for active learning	Moderate
[45]	Robot-assisted VR for low-pressure practice and learning.	Complex interactions challenging	Extends beyond classrooms and helps via contextual learning	Moderate

G. Institutional and Faculty Readiness

Institutional readiness for AI integration in education and healthcare depends on infrastructure, policy alignment and leadership support. Across sectors, institutions often lack the digital maturity required for large-scale AI adoption. For example, smart hospitals may often have a lot of investments for future technological development, but many public authorities and staff lack the expertise and training to use them effectively [46]. As well, educational institutions face challenges related to policy clarity, equitable access and resource allocation which are essential for the implementation of AI in higher education settings [48]. There are also infrastructure limitations such as specialized devices and connectivity which remain a significant barrier due to the large amounts of resources needed, even when administrative backing exists [49]. Without proper planning, enough resource allocation and community involvement, AI tools risk being underused or inequitably deployed [49, 50].

Faculty readiness is very important but also often overlooked, as teachers and health professionals are open to the concept and idea of AI, but their positive interactions often depend on targeted training and professional development [47]. Studies show that interested teachers often have steep learning curves due to insufficient structured assistance and ongoing training [47, 48]. Professional skills values such as autonomy, ethics and trust also influence people's uptake of AI tools. If these values were overlooked, resistance ensure [48]. As well, healthcare professionals must also possess digital literacy in order to counsel patients and practice in telemedicine environments [46]. Despite this requirement there are still skill deficiencies [46].

Individual attitudes and pedagogical models often influence AI uptake in high levels of self-efficacy and quality digital knowledge among teachers as this increases the likelihood that they will generate beneficial AI tool adoption [49]. However, internal readiness must be supplemented with institutional support through constant policies, mentorship programs and provision of technological infrastructure [49]. Perceived usefulness and believability of AI tools also affect the adoption by the faculty. If the AI tools are seen as credible and simple to use, then their adoption is much more likely [50]. Without trust, even the most advanced tools may be accepted hesitantly or rejected. Overall, readiness is not only about access to tools, but also an issue of organizational capacity, personal confidence and shared values. Professional development must go beyond functionality to address moral issues, career identity and structures of long-term care [48, 50]. Organizations that invest in meaningful training to establish ethics guidelines and foster collective experimentation will benefit from the advantages of AI in an equitable and sustainable way.

TABLE VII. INSTITUTIONAL AND FACULTY READINESS FOR AI INTEGRATION: SUMMARY AND GRADE.

No.	Key Points	Challenges	Effects on Teachers and Students	GRADE
[46]	Infrastructure for AI in healthcare and education and technological acceptance in adoption	Lack of expertise/training and lack of skills	Invest in digital maturity and equitable implementation	Low
[47]	Targeted training improves well-being and reduces workload	Steep learning curves if lacked support	Professional development beyond functionality	Low
[48]	Policy clarity and resource allocation and values like ethics influence adoption acceptance	Resistance to changes if autonomy overlooked	Mentorship programs address moral issues	Moderate
[49]	High self-efficacy boosts adoption and allows community involvement	Infrastructure barriers like connectivity	Supplement with institutional support and shared values	High
[50]	Trust in credible tools and mediating effects on practices	Hesitant acceptance without perceived usefulness	Foster experimentation and sustainable integration	Moderate

Table VII shows the factors affecting institutional and faculty readiness for AI adoption, which includes infrastructure, training and trust. It notes that, while AI can reduce workload and enhance teaching, barriers like limited digital literacy, resource constraints and resistance due to ethical concerns persist. The table underscores the need for comprehensive training, clear policies and community involvement to ensure equitable and sustainable AI integration.

V. Discussion

This review demonstrates that Artificial Intelligence (AI) has rapidly evolved from a supplementary tool to a core enabler of personalized and adaptive learning in higher education. Across the seven key topics analyzed, AI tools such as intelligent tutoring systems, generative platforms and predictive analytics consistently help and enhance student engagement, inclusivity and academic outcomes by personalizing and adapting content made for individual learning and needs [16-19]. The studies also show the transformative capacity of AI to close achievement gaps and offer equitable opportunities for students from diverse backgrounds or with special needs [12-14, 36-37].

However, the studies also highlight persistent ethical and practical challenges. Automated assessment tools and generative AI, while streamlining grading and feedback, risk diminishing the authenticity of assessments and student cognitive development if used without adequate safeguards [20, 31-35]. Academic integrity emerges as a major theme, with plagiarism detection and originality verification systems only partially mitigating risks [32-34]. However, issues of data privacy, algorithmic bias and transparency remain consistent across academic advising, learning analytics and inclusion initiatives [27-28, 38-40]. These challenges underscore the need for robust frameworks to ensure responsible implementation of AI technologies in education.

Institutional and faculty readiness also plays a decisive role in AI's success. While many teachers are open to AI adoption, gaps in digital literacy, professional development and infrastructure limit the full realization of AI's benefits [46–50]. Students' AI skills and teachers' perceptions of these skills do not always align, which may result in misjudgments of assessment authenticity or unintended over-reliance on automated systems. Addressing these disparities through targeted training, transparent communication and participatory design approaches can improve trust and efficacy in AI-driven systems [37-40]. Overall, the findings point to a dual imperative: scaling AI innovations to broaden access while embedding ethical safeguards and human oversight to preserve educational integrity.

VI. Conclusion

This review shows that artificial intelligence is no longer just an optional tool in higher education but a force that is actively reshaping how students learn, how teachers teach, and how institutions operate. Across different areas—such as assessment, advising, inclusion, and academic integrity, AI offers clear benefits: faster feedback, more personalized learning, and great support for diverse learners. However, the same technologies also create new problems that cannot be ignored, including risks to ethical practices, unequal access, and a growing dependence on automated systems.

A key message that emerges is that AI alone will not improve education. Its value depends on how well it is guided by human judgment, institutional policy, and shared responsibility among educators, students, and administrators. The findings suggest that successful use of AI requires three conditions: thoughtful design of learning and assessment, investment in digital skills for both teachers and students, and clear policies that protect fairness, privacy, and academic values.

Rather than seeing AI as a replacement for human roles, this review supports the idea that AI should work as a partner—reducing repetitive tasks while allowing teachers to focus on creativity, mentoring, and deeper learning. The next step for higher education is not to decide whether to use AI, but how to use it responsibly, so that technology enhances learning without weakening integrity or human connection.

Acknowledgment

The authors gratefully acknowledge the valuable support and cooperation of the advisors, academics, researchers, students, and staff who contributed to the completion of this research. The authors also wish to thank the Thailand Science Research and Innovation Fund and the supporting organizations for their assistance throughout the study.

Department of Computer Engineering, Jamia Millia Islamia, New Delhi, India (Retired)[3]

***Abstract*—Cloud storage security remains a major challenge owing to threats related to confidentiality, integrity, and unauthorized access. In this study, a novel secure cloud storage system is proposed by integrating Lorenz 3D chaotic key generation, AES-256-GCM authenticated encryption, and blockchain verification based on PBFT. High-entropy keys were generated using the Lorenz chaotic system and then passed through SHA-256 to create secure 256-bit AES keys. The data is encrypted using the AES-256-GCM algorithm and stored in the cloud, and integrity metadata is stored in a blockchain that offers tamper detection, auditability, and Byzantine fault tolerance. The experimental results demonstrate strong cryptographic performance with near-ideal entropy (7.99), a high avalanche effect (50.05%), successful NIST randomness validation, and low blockchain overhead. The results of the security analysis prove resistance against brute force, statistical, differential, replay, known plaintext, chosen ciphertext, and Byzantine attacks. The proposed framework offers a secure, efficient, and reliable multilayered security solution for cloud storage systems.**

***Keywords*—Cloud security; AES-256-GCM; Lorenz chaotic system; blockchain; PBFT; data integrity; secure cloud storage; cryptography**

I. Introduction

Cloud computing has revolutionized the modern era of data management in terms of scalability, flexibility, and cost efficiency [1]. Cloud computing infrastructure is the foundation of the new economy, where companies rely on it to store sensitive data, such as financial records, healthcare information, and proprietary research data [2]. But when it comes to outsourcing data to external cloud service providers, there are significant security concerns, such as unauthorized access, data breaches, exposure of sensitive data, and privacy invasion [3].

The Advanced Encryption Standard (AES) is another symmetric encryption algorithm frequently employed to reduce the potential threat to confidentiality, as it offers high security assurance and a low computational load [4]. AES-256, especially, offers resistance to known cryptanalytic attacks, as well as brute force attacks under normal security conditions [5]. However, for centralized cloud storage systems, data encryption does not provide any data integrity checking or insider interference protection [6]. In addition, traditional cloud architecture has drawbacks, such as a lack of transparency, insufficient decentralization, and single points of failure, impacting trust in cloud-based systems [7].

The generation of keys is important in cryptography and is a critical component of security. The strongest encryption is not strong enough if the keys are predictable or not sufficiently random. In chaos-based cryptography, the high-entropy keys are generated using nonlinear dynamic systems that exhibit extreme sensitivity to initial conditions and have strong diffusion properties [8]. Chaos-based key generation with traditional encryption schemes has been proven to be a more random and efficient method [9]. The Lorenz 3D chaotic system is a complex nonlinear system that is highly sensitive to initial conditions and exhibits randomness, making it suitable for cryptographic applications. This makes it significantly more secure than low-dimensional chaotic systems and highly compatible with the latest encryption algorithms, including AES-256.

It is viewed as a decentralized solution to overcome trust and integrity problems in distributed systems using blockchain technology. The mechanisms of consensus, cryptographic hash linkage, and permanent ledger systems that blockchain offers can be used to store and record transactions in a verifiable manner without the possibility of being tampered with [10].

Recent studies have discussed the use of blockchain and cloud computing for access control auditing, logging security, and data integrity [11]. To resolve the problems of scalability in blockchain, researchers have suggested hybrid architectures, integration of cloud storage, and validation layers based on blockchain. In these systems, encrypted documents are stored in the cloud, and cryptographic hash values and transaction metadata are recorded on-chain.

Although cloud security has advanced, some areas of research could still be pursued. Existing AES-based cloud services offer confidentiality, but not decentralized integrity verification. Cloud-based frameworks using blockchain tend to lack cryptographic randomness enhancement, but are nonetheless tamper-proof. Cloud frameworks based on blockchain are not only tamper-proof, but also have no improvement in this regard with respect to cryptographic randomness. Chaos-based encryption methods provide more unpredictability but are not generally used in combination with distributed integrity validation mechanisms. Many existing systems lack formalized threat modelling or comparative security-performance evaluation. Limited research has been

*Corresponding author

conducted on incorporating authenticated encryption, chaotic key generation, and blockchain with PBFT within a single architecture.

The following contributions were made to overcome these limitations:

- Design and development of a secure cloud storage system with multi-level security, application of chaos-based cryptography, and verification by blockchain.
- Design of a Lorenz 3D chaotic key generation mechanism strengthened by the SHA-256 hash function.
- Incorporation of AES-256-GCM authenticated encryption with confidentiality and integrity.
- Implementation of a dual-hash integrity verification system for ciphertext and plaintext checks.
- Adoption of the PBFT consensus mechanism for Byzantine fault tolerance in blockchains.
- Complete experimental evaluation, including NIST randomness tests, entropy, avalanche effect, throughput, and latency measurements.
- Comparative analysis of existing AES-based and Chaos-based cloud security models.

The novelty of this work is the unified integration of the following four concepts uniformly: chaos theory-based key generation, authenticated encryption, dual hash integrity checking, and PBFT-based blockchain consensus to ensure secure cloud storage.

The structure of the rest of this study is as follows: A literature review of cloud security, chaos-based cryptography, and blockchain-based integrity verification is provided in Section II. In Section III, the proposed architecture for secure cloud storage is introduced. The methodology and algorithms are described in Section IV. Details of the experimental environment and setup are given in Section V. The experimental results and performance analyses are presented in Section VI. The threat model is introduced in Section VII, and a detailed security analysis is presented in Section VIII. A formal security analysis of the proposed framework is presented in Section IX. The comparison of the proposed approach with existing studies is made in Section X. The results and implications are discussed in Section XI. Finally, the conclusions and future research directions are presented in Section XII and Section XIII, respectively.

II. Literature Review

Data security remains a significant concern after cloud computing has transformed computing and storage services in recent years. Despite the use of encryption to reduce the risks of confidentiality, preliminary studies have pointed out that there are still some shortcomings, such as multi-tenancy, data exposure, and even user control over external resources [3], [12], [13]. Insider threats, improper access control, and post-storage tampering cannot be mitigated through encryption [14].

Symmetric encryption, particularly AES, is a fundamental aspect of secure cloud storage; however, its shortcomings in key generation and integrity checks have led to interest in other options. Because of its efficiency and robust cryptographic guarantees, AES is still the most popular symmetric encryption algorithm in cloud security architectures [15].

AES-256 is designed to be secure with respect to known cryptanalytic attacks and brute force attacks known to the designer, based on the known security assumptions. The recent research has also applied AES in the storage and transmission of information in cloud storage systems to protect the confidentiality of information [16]. AES is confidential but not necessarily decentralized, ensuring integrity verification and protection against unauthorized modifications in cloud storage systems.

Most existing schemes are built on traditional key generation schemes, which are susceptible to being compromised by insufficient entropy sources. The chaos-based cryptography utilizes a nonlinear dynamical system to improve the randomness and unpredictability of the key generation process [17]. The chaotic maps, such as logistic maps, are very sensitive to initial conditions and have positive Lyapunov exponents, matching the cryptographic randomness conditions [8], [18]. Research has shown that keys generated by the chaos technique are robustly diffused and confused, making them suitable for use to supplement the symmetric encryption technique [19]. Recently, studies have been carried out on using chaos-based methods to enhance unpredictability and protection against brute force attacks on cryptographic systems [20]. However, few studies have considered both chaos-based key generation and integrity models for blockchain-based cloud systems.

Blockchain technology has been called a new technology with the potential to be used to protect the integrity of data and distributed trust. The novel idea of decentralized consensus and hash-linked blocks to prevent tampering was introduced by Nakamoto [10]. Additional studies have led to the development of blockchain models and consensus algorithms for securing decentralized applications.

Alghuried and Wenhua provided a comprehensive overview of blockchain security concerns and privacy implications [21], [22]. The immutability of blockchain, its consensus-driven validation, and the decentralized system structure make it appropriate for cloud system integrity (Zheng et al., 2017). Even with these enhancements, several blockchain-based systems add performance overheads from the consensus protocol or complicated cryptographic primitives.

Some studies have focused on how to use the blockchain and cloud storage to enhance auditability and tamper resistance [16]. To improve scalability, blockchain-based cloud systems store large-scale, encrypted data off-chain and maintain blockchain metadata on-chain within the blockchain [11], [23]. However, blockchain integration with cloud services still faces many challenges related to performance overhead, transaction latency, and security concerns [24]. This has made lightweight blockchain architectures and hybrid storage solutions interesting potential solutions. However, large amount of data cannot be directly stored on the blockchain network due to

scalability and delay latency issues, and storage issues [25]. For this reason, more scalable solutions have been developed, which are hybrid solutions storing encrypted data off-chain with integrity metadata on-chain [26].

The application of chaos theory, authenticated encryption, blockchain technology, and distributed consensus has been investigated in recent studies to enhance cloud security. Rahman et al. proposed a chaos-enhanced AES key generation mechanism, which showed enhanced key randomness and unpredictability in an IoT environment [9]. Alatawi proposed a novel approach to decentralized authentication and authorization using smart contracts that run on a blockchain in cloud security [27]. In addition, Yao et al. and Liu et al. proposed optimal PBFT consensus mechanisms to enhance the throughput, latency, and Byzantine fault tolerance in the consortium blockchain system [28], [29]. Although these advancements reflect a considerable leap forward in secure cloud storage architectures, most current solutions focus on encryption, access control, or blockchain verification individually.

The proposed framework is distinct because of the combination of Lorenz 3D chaotic key generation and AES-256-GCM authenticated encryption, PBFT-based blockchain verification, and dual-hash integrity validation in a single cloud security framework.

III. Proposed System Architecture

The proposed system architecture is divided into six interoperable layers, as shown in Fig. 1. The proposed architecture is a multi-layered security architecture that combines symmetric encryption (AES-256-GCM), Lorenz 3D chaotic key generation, cloud storage, blockchain-based integrity verification using PBFT consensus, and a smart contract. These layers serve different functions to ensure the confidentiality, integrity, authentication, and traceability of the data. This multilayered design ensures a clear separation of concerns and separates cryptographic functions from blockchain consensus and the application logic. This modularity allows systems to be more resilient in the event of a compromise in one layer and to maintain a secure flow of data within and between the components. The layers are given below.

A. Application Layer

The Application Layer is the main layer where users interact with the proposed secure cloud storage system. It handles user authentication, access control, upload/download of files from/to the blockchain, and blockchain authorization. When a file is uploaded, the layer generates a Lorenz 3D chaotic key and applies AES-256-GCM authenticated encryption to protect the confidentiality and integrity of the data. The ciphertext is encrypted and stored in the cloud, with file hashes and transaction metadata stored on the blockchain, which is maintained on the PBFT protocol for integrity checks and auditing purposes. During the retrieval phase, AES-GCM authentication tag verification and blockchain validation are performed prior to decryption, which is robust enough to thwart attempts at unauthorized access, insider attacks, replay attacks, and data tampering.

B. Key Generation Layer

The Key Generation Layer is developed to produce a safe and high-entropy key of 256 bits from the Lorenz 3D chaotic system to a cryptographic hashing function called SHA-256. This blended approach yields the unpredictability and cryptographic strength of the generated keys. A highly sensitive, nonlinear sequence is generated by the Lorenz 3D chaotic system and quantized to be fed into SHA-256 to generate a secure, uniformly distributed AES-256 key for encrypting the vector.

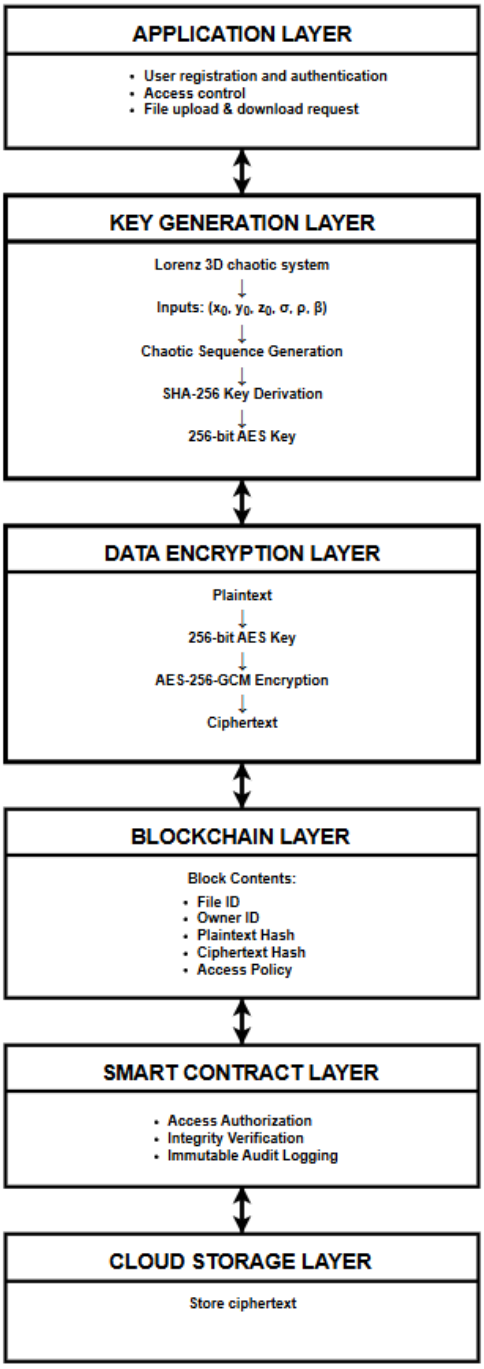

Fig. 1. System architecture diagram

C. Encryption Layer

The main security layer in the proposed framework that offers data confidentiality, integrity, and cryptographic randomness is the Encryption Layer. The chaotic Lorenz system is employed to produce a 256-bit chaotic key that is highly random, and then this 256-bit chaotic key is utilized for authenticated encryption with the AES-256-GCM. AES-GCM provides a ciphertext with a high degree of randomness and resistance to differential and statistical cryptanalysis. AES-GCM was created by AES to prevent modification or replay attacks on the ciphertext and ensure that the data remains intact. The integrity metadata and hash value of the encrypted ciphertext are recorded on the PBFT-based blockchain ledger for security checks and auditability, and the ciphertext is uploaded to the cloud server.

D. Cloud Storage Layer

Only encrypted data files are stored in the Cloud Storage Layer; no plaintext data is stored on the cloud servers.

E. Blockchain with PBFT Consensus Layer

Blockchain with the PBFT Consensus Layer provides auditability, integrity verification, and tamper-proof logging. The system does not store the entire file on-chain; instead, it stores the following:

- SHA-256 hash of the encrypted file
- SHA-256 hash of plaintext file
- Timestamp
- Previous block hash
- Block index

The blockchain layer offers security characteristics, such as immutability, tamper detection, audit trails, and decentralized verification. If any change is made to the stored file, the recalculated hash will not match the blockchain record, which will be the first sign of manipulation.

F. Smart Contract Layer

The Smart Contract Layer specifies and implements access control policies. Smart contracts, which are built on blockchains, offer complete control over access to cloud data. Downloading the resource is only possible after a successful on-chain authorization of a download request to prevent unauthorized access, even by privileged insiders of the cloud. Blockchains' smart contracts ensure data integrity, enable decentralized access control, store immutable hash, and deliver transparent auditability. Both serve crucial functions in enhancing the privacy and security of cloud storage.

IV. METHODOLOGY

A. System Workflow

The workflow of the proposed secure cloud storage system is defined by the entire cycle of data, from uploading to access and verification (Fig. 2). This system consists of client-side encryption, decentralized access control, blockchain-based integrity verification, and cloud storage to ensure confidentiality, integrity, and accountability.

Step 1: User Registration. Users and owners of the data are registered into the system with unique identifiers. Blockchain credentials are issued to each user to safely interact with smart contracts.

Step 2: AES key Generation. The AES key is generated based on a highly sensitive and nonlinear sequence generated by the Lorenz 3D chaotic system. Then, the SHA-256 hashing algorithm was used to create a 256-bit encryption key.

Step 3: File Encryption. The data owner selects a file to be stored in the cloud. The data is encrypted on the client using AES-256-GCM encryption, which ensures confidential data storage.

Step 4: Secure File Upload. The encrypted file is then uploaded to the cloud storage. The access permissions of the files are defined by the data owner before they are uploaded.

Step 5: Metadata Storage in Blockchain. A cryptographic hash of the plaintext file and a cryptographic hash of the encrypted file are generated using a hashing algorithm called SHA-256 to help verify the integrity of the file. The file hash and file ownership information were recorded on the blockchain. The access policy and file identifier, along with a hash, are stored and verified on the blockchain via a smart contract.

Step 6: Access Request by User. Once the user requests access to a stored file, it is sent to the blockchain layer. The smart contract then receives the access control policy and proceeds to determine whether the requesting user has access to that file.

Step 7: Decentralized Access Control Decision. Access is granted or denied based on smart contract verification. The information requested, and the decision made is logged on to the blockchain as an audit trail which is auditable and non-repudiable.

Step 8: Secure File Download. Once authenticated, encrypted files are downloaded from the cloud storage and sent to the authorized end user. The cloud service provider does not know the content of the files and does not control access to the files.

Step 9: File Tamper Detection. It computes the SHA-256 hash of the downloaded encrypted file prior to decryption. This hash is compared with the original hash that was added to the blockchain. If any discrepancy was found, it meant that the data or the process were corrupted, and the process was killed.

Step 10: File Decryption. If tamper detection test is passed successfully, the encrypted file is decrypted at the client side using the AES key to reconstruct the plain text file.

Step 11: File Integrity Verification. SHA-256 computes the hash of the decrypted file in the system. This hash is compared with the hash of the original plaintext file stored in the blockchain. If there is any discrepancy, it means that there is some corruption or tampering with the data, and the process is killed.

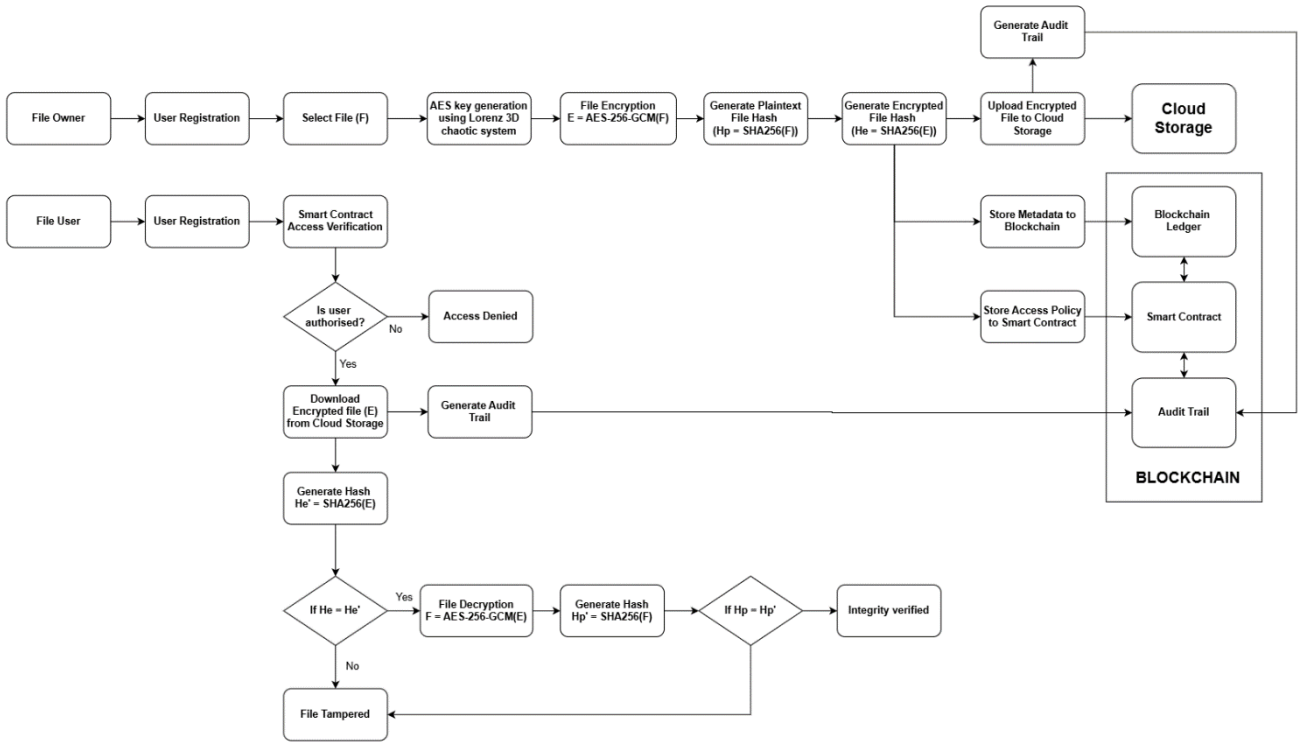

Fig. 2. System workflow diagram

B. Algorithms

To implement the proposed secure cloud storage framework, five algorithms are used to deliver confidentiality, integrity, authentication, and fault tolerance. Algorithm 1 produces a cryptographic key with high entropy by applying the Lorenz 3D chaotic system. Algorithm 2 is used to perform AES-256-GCM authenticated encryption, which provides data confidentiality and integrity. Algorithm 3 securely uploads encrypted files onto cloud storage and records integrity metadata on the blockchain. Algorithm 4 uses the Practical Byzantine Fault Tolerance (PBFT) consensus protocol for blockchain network validation and committing metadata transactions. Lastly, Algorithm 5 retrieves the encrypted files from the cloud storage and checks for integrity on both the encrypted and decrypted files based on blockchain-stored metadata. These algorithms create a robust, transparent, and unalterable cloud storage system. For clarity and ease of understanding, the notations and abbreviations used in the proposed algorithms, along with their descriptions, are provided in Table IX at the end of the study.

Algorithm 1: Key Generation Using Lorenz 3D Chaotic System

The purpose of this algorithm is to generate an AES key using the Lorenz 3D chaotic system [30].

Input:

x0, y0, z0: Initial conditions

σ, ρ, β: Lorenz control parameters

h: Step size

N: Number of iterations

T: Number of transient samples to discard

L: Required key length (256 bits)

Output:

K: 256-bit chaotic key

Begin

1. x ← x0
2. y ← y0
3. z ← z0
4. S ← EmptySequence
5. for i ← 1 to N do
6. x ← x + h × σ × (y - x)
7. y ← y + h × (x × (ρ - z) - y)
8. z ← z + h × (x × y - β × z)
9. Append(S, x)
10. end for
11. S ← RemoveFirstTElements(S, T)
12. B ← EmptyBitstream
13. for each value s in S do
14. x_norm ← |s| mod 1
15. if x_norm > 0.5 then
16. bit ← 1
17. else
18. bit ← 0
19. end if

```
20.     Append(B, bit)
21.     if Length(B) ≥ L then
22.         break
23.     end if
24. end for
25. B ← FirstLBits(B)
26. K ← ConvertBitsToBytes(B)
27. return K
End
```

Algorithm 2: AES-256-GCM Authenticated Encryption

The purpose of this algorithm is to securely encrypt user data using the AES-256-GCM authenticated encryption scheme specified in the Advanced Encryption Standard (AES) [4] and Galois/Counter Mode (GCM) [31].

```
Input:
  P: Plaintext divided into 128-bit blocks {P1, P2, ..., Pm}
  K_AES: 256-bit AES encryption key
  IV: 96-bit initialization vector or nonce
  AAD: Associated authenticated data
Output:
  C: Ciphertext
  T: 128-bit authentication tag
Begin
1. RoundKeys ← KeyExpansion(K_AES)
2. J0 ← IV || 0^31 || 1
3. C ← EmptyCiphertext
4. for i ← 1 to m do
5.     Ji ← inc32(Ji-1)
6.     Si ← AES_Encrypt(K_AES, Ji)
7.     Ci ← Pi ⊕ Si
8.     Append(C, Ci)
9. end for
10. H ← AES_Encrypt(K_AES, 0^128)
11. Y ← AAD || C || len(AAD) || len(C)
12. Divide Y into 128-bit blocks {Y1,Y2,…, Yn}
13. X0 ← 0^128
14. for j ← 1 to n do
15.     Xj ← (Xj-1 ⊕ Yj) · H over GF(2^128)
16. end for
17. G ← Xn
18. T ← AES_Encrypt(K_AES, J0) ⊕ G
19. return (C, T)
End
```

Algorithm 3: Secure File Upload

The purpose of this algorithm is to encrypt user data safely with the help of a chaos-based AES-256 key, save the ciphertext in the cloud, and store metadata about integrity in the blockchain for tamper-proof verification.

```
Input:
  F: Plaintext file
  UserCred: User authentication credentials
  x0, y0, z0: Initial conditions of Lorenz
3D chaotic system
  AAD: Associated authenticated data
Output:
  UploadStatus
Begin
1. if Authenticate(UserCred) = FALSE then
2.     return "Access Denied"
3. end if
4. K_chaos ← Lorenz3D_KeyGeneration(x0,y0,z0)
5. K_AES ← SHA256(K_chaos)
6. IV ← CSPRNG_Generate_Unique_Nonce(96 bits)
7. EncParams ← Encrypt({x0,y0,z0}, MasterKey)
8. StoreKeyMetadata(FileID, EncParams)
9. (C,T) ← AES256_GCM_Encrypt(F,K_AES,IV, AAD)
10. H_plain ← SHA256(F)
11. H_cipher ← SHA256(C)
12. StoreCloud(C, T, IV)
13. Metadata ← {
      FileID,
      H_plain,
      H_cipher,
      Timestamp
    }
14. Tx ← CreateBlockchainTransaction(Metadata)
15. ExecuteSmartContract(Tx)
16. UploadStatus ← StoreBlockchainRecord(Tx)
17. return UploadStatus
End
```

1) Secure chaotic parameter management: The initial conditions (x_0, y_0, z_0) of the Lorenz system are considered as confidential cryptographic parameters. These parameters are not stored in plain text in the cloud storage layer or blockchain ledger to prevent disclosure. Rather, they are encrypted with a master key specific to the user and stored in a secure key-management module. An encrypted parameter record is linked

with the appropriate file identifier during file upload. If the user is authenticated successfully during the retrieval of the file, the encrypted parameters are recovered and decrypted securely in local mode, which helps to regenerate the chaotic key sequence and derive the AES-256 encryption key. As a result, the confidentiality of the chaotic parameters is maintained, and the key is regenerated reliably by authorized users.

2) Nonce generation and management: A unique 96-bit nonce (IV) is generated for each file upload using a cryptographically secure random number generator (CSPRNG) to prevent nonce reuse in AES-256-GCM. This unique nonce is tied only to the encryption session in which it is used, and is not repeated when using the same AES key. The nonce is saved along with the ciphertext and authentication tag in the cloud storage and recalled at the decryption phase. The probability of nonce collision is negligible due to the following reasons: new AES key is generated each time the uploaded file is uploaded, and fresh nonce is used every time the data is encrypted. With this nonce management strategy, AES-GCM assures confidentiality and authentication while mitigating on nonce reuse.

Algorithm 4: PBFT-Based Blockchain Metadata Verification

The purpose of this algorithm is to validate and commit blockchain transactions with file integrity metadata using Practical Byzantine Fault Tolerance. The algorithm verifies that only valid ciphertext hashes, plaintext hashes, timestamps, and audit records are accepted after the validators in the consortium reach an agreement.

Input:
  Tx: File metadata transaction
  H_cipher: Ciphertext hash
  H_plain: Plaintext hash
  T: Timestamp
  FileID: File identifier
  V: Validator node set {v1, v2, ..., vn}
Output:
  B_i: Committed blockchain block
  ConsensusStatus: Accepted or Rejected
Begin
1. Tx ← {
    FileID,
    H_cipher,
    H_plain,
    T,
    UserID
  }
2. SignTransaction(Tx)
3. PrimaryNode ← SelectPrimary(V)
4. if VerifyTransaction(Tx) = FALSE then
5. return Rejected
6. end if
7. B_i ← Hash(B_(i-1) || Tx || T)
8. Broadcast(PRE_PREPARE, v, s, Digest(Tx))
9. for each validator v_i ∈ V do
10. if ValidatePrimaryNode() = TRUE
    and VerifyDigest(Tx) = TRUE
    and VerifySequenceNumber(s) = TRUE
    and VrifyPreviousBlockHash() = TRUE
    and VerifyTransaction(Tx) = TRUE then
11. Broadcast(PREPARE,v,s,Digest(Tx),NodeID)
12. end if
13. end for
14. if PrepareCount ≥ 2f then
15. Broadcast(COMMIT,v,s,Digest(Tx),NodeID)
16. end if
17. if CommitCount ≥ 2f + 1 then
18. Blockchain ← Blockchain ∪ B_i
19. ConsensusStatus ← Accepted
20. else
21. ConsensusStatus ← Rejected
22. RaiseAlert("Consensus Failure")
23. end if
24. return (B_i, ConsensusStatus)
End

Algorithm 5: File Retrieval and Verification

The purpose of this algorithm is to extract encrypted data from cloud storage and check the integrity of these data before and after decryption using the blockchain metadata.

Input:
  FileID: Unique file identifier
  UserCred: User authentication credentials
  K_AES: AES-256 decryption key
  AAD: Associated authenticated data
Output:
  F: Plaintext file
  RetrievalStatus: Verified or Rejected
Begin
1. if Authenticate(UserCred) = FALSE then

```
2.      return "Access Denied"
3. end if
4. EncParams ← RetrieveKeyMetadata(FileID)
5. (x0,y0,z0) ← Decrypt(EncParams, MasterKey)
6. K_chaos ← Lorenz3D_KeyGeneration(x0,y0,z0)
7. K_AES ← SHA256(K_chaos)
8. (C, T, IV) ← RetrieveCloud(FileID)
9. H_plain_ch,H_cipher_ch) ← QueryBlockchain(FileID)
10. H_cipher_local ← SHA256(C)
11. if H_cipher_local ≠ H_cipher_ch then
12.    RaiseAlert("Ciphertext Tampering Detected")
13.    RetrievalStatus ← Rejected
14.   Abort
15. end if
16. F ← AES256_GCM_Decrypt(C,K_AES,IV,AAD,T)
17. if DecryptionStatus = AuthenticationFailed then
18.     RaiseAlert("AES-GCM Authentication Failed")
19.     RetrievalStatus ← Rejected
20.     Abort
21. end if
22. H_plain_local ← SHA256(F)
23. if H_plain_local ≠ H_plain_chain then
24.    RaiseAlert("Plaintext Integrity Violation")
25.    RetrievalStatus ← Rejected
26.     Abort
27. end if
28. RetrievalStatus ← Verified
29. return (F, RetrievalStatus)
End
```

C. Secure Chaotic Parameter Management

The initial conditions of the Lorenz system (x_0, y_0, z_0) are treated as confidential cryptographic parameters. To prevent disclosure, these parameters are not stored in plaintext in the cloud storage layer or blockchain ledger. Instead, they are encrypted using a user-specific master key and stored within a secure key-management module. During file upload, the encrypted parameter record is associated with the corresponding file identifier. Upon successful user authentication during file retrieval, the encrypted parameters are securely recovered and decrypted locally to regenerate the chaotic key sequence and to derive the AES encryption key. Consequently, the confidentiality of the chaotic parameters is preserved while ensuring reliable key regeneration for the authorized users.

V. Experimental Setup

The following configuration was used to build a prototype system of the hybrid cloud storage solution and evaluate it in a sound-testing environment.

A. Software Environment

The software stack was selected for its cryptographic efficiency and ability to handle complex chaotic-map computations with high precision.

- Programming Language: Python 3.x was used because of its flexibility and extensive support for numerical and cryptographic libraries.
- Cryptographic Library: PyCryptodome was employed specifically for its AES-256-GCM implementation, which provides data confidentiality and authentication features.
- Hash Function: SHA-256 (via the hashlib library) was used to generate tamper-proof file digests and to distil the Lorenz chaotic state variables into fixed-length 256-bit keys.
- Blockchain Model: To enable secure logging of file metadata and verification hashes, a custom implementation of a blockchain using Python was developed for prototyping purposes. This implementation aims to demonstrate the PBFT consensus mechanism for verifying integrity in a controlled environment.
- Blockchain Consensus Method: Practical Byzantine Fault Tolerance was added to ensure that transactions are final and that the ledger is consistent across all the distributed nodes.
- Operating System: Windows 11.
- Integrated Development Environment: PyCharm 2025.2.1.1.

B. Hardware Configuration

The following hardware was used to obtain consistent performance in the execution of the chaotic integration and encryption algorithms:

- Processor: Intel(R) Core i7 processor
- RAM: 16 GB
- Storage: SSD-based storage to reduce the latency of I/O operations for large datasets.

C. PBFT Implementation

The proposed architecture is based on a custom consortium blockchain implementation with Python for experimentation to demonstrate integrity verification using PBFT in a secure cloud storage architecture. Implementation attempts to analyze the feasibility and performance influence of integrating the PBFT consensus into AES-256-GCM encryption and Lorenz chaotic key generation.

The experiment was conducted in a controlled local distributed environment with one client node, one primary (leader) validator node, and three replica validator nodes, totaling four PBFT validator nodes. The PBFT protocol is executed in the usual way: first, a pre-prepare phase, followed by a prepare phase, and finally a commit phase, to ensure that blockchain transactions that include ciphertext hashes, integrity metadata, timestamps, and audit records are validated. A transaction is committed if it is approved by $(2f + 1)$ validator nodes, with at most $(f \leq \frac{n-1}{3})$ Byzantine nodes.

This consortium blockchain design assumes that the validator nodes are maintained by various participating organizations or entities, including cloud administrators, organizational clients, and audit authorities, rather than a single centralized cloud provider. This distributed trust model can achieve Byzantine fault tolerance and prevent malicious insiders from unilaterally modifying the integrity of the metadata.

The locally distributed implementation was intentionally designed as a lightweight prototype to test the latency of the blockchain, the validation of transactions, the feasibility of the consensus, and the performance of the integration with the proposed encryption framework. Therefore, the reported blockchain latency values are experimental and proof-of-concept results, conducted on a small scale in a controlled test environment, and not in a large-scale deployment with a cloud-based environment.

Currently, the proposed framework is not designed to ensure the large-scale scalability of the proposed PBFT protocol. In the cloud-scale scenario, the number of validator nodes could increase the network overhead of the practical communication complexity of PBFT as $(O(n^2))$. However, for a typical consortium-based enterprise cloud environment, the number of trusted validator nodes is relatively small, and in practical circumstances, integrity verification and auditability applications are suitable for the PBFT.

D. Test Dataset

The framework was tested using a multi-format dataset to assess its performance at different levels of data redundancy and correlation. Experiments were carried out with file sizes ranging from 10 to 50 MB, such as:

- Standard text files
- High-correlation image datasets
- Unstructured binary files
- Complex PDF documents

All tests were conducted under controlled laboratory conditions to obtain consistent results. The main points of the experimental design were reproducibility and complete security validation. Each experiment was performed several times, and the average of the performance metrics was calculated to obtain the final performance metrics to maintain the statistical validity of the experiments and reduce the influence of random errors or outlier values.

VI. Experimental Results

A. Performance Evaluation of Metrics

The metrics used to evaluate the framework in this section are encryption, decryption, upload, download, blockchain consensus latency, and overall throughput.

1) Measurement methodology: The experimental tests were conducted on a locally distributed setup with file sizes ranging from 10 to 50 MB, and without using external networks to avoid the influence of network variations. All time-related measurements were reported in seconds (s).

a) Latency Calculation (T_{total}): The total processing time for a single file transaction is defined as the sum of its independent computational stages:

$$T_{total} = T_{encryption} + T_{upload} + T_{blockchain}$$

where,

- $T_{encryption}$: is the duration required for the Lorenz 3D chaotic key generation, SHA-256 distillation, and the AES-256-GCM encryption process.
- T_{upload}: is the time taken to transfer the 128-bit blocks of ciphertext to the hybrid cloud storage module.
- $T_{blockchain}$: is the time required for the PBFT consensus protocol to validate the metadata and commit the SHA-256 integrity hashes to the distributed ledger.

b) Throughput Calculation ($Throughput$): Throughput is defined as the number of file transactions completed per unit of time and is calculated as:

$$Throughput = \frac{Number\ of\ Files}{Total\ Time}$$

where, $N = 1$ representing a single file of a specific size processed from initialization to blockchain commitment.

2) Performance analysis: A detailed performance analysis of the proposed system was performed and executed for various file sizes ranging from 10 to 50MB. The experimental results for the different performance metrics are summarized in Table I and presented graphically in Fig. 3.

TABLE I. Performance Evaluation of Metrics

Metric	10MB	20MB	30MB	40MB	50MB
Chaotic Latency (Sec)	0.07	0.08	0.07	0.08	0.07
Encryption Latency (Sec)	0.05	0.08	0.13	0.18	0.23
Upload Latency (Sec)	0.08	0.12	0.18	0.22	0.27
Blockchain Latency (Sec)	0.01	0.01	0.01	0.01	0.01
Total Latency (Sec)	0.20	0.28	0.39	0.49	0.58
Throughput (Files/Sec)	4.95	3.59	2.59	2.05	1.74

As shown in Table I and Fig. 3, the proposed framework can maintain its performance when the file size increases from 10 to 50 MB. The total latency increases gradually from 0.20 sec to 0.58 sec due to higher encryption and upload times for larger files. By contrast, chaotic key generation latency is almost stable (0.07- 0.08 sec), and the blockchain latency is constant (0.01 sec), showing low overhead of the PBFT-based

verification process. As the file size increased, the throughput decreased from 4.95 files/s to 1.74 files/s, as anticipated, because larger files require more processing and transmission time.

Fig. 3. Performance evaluation of metrics chart.

The performance of the proposed system is compared with that of existing methods in terms of latency, throughput, and security overhead. In order to make a fair comparison, maximum file size used in the performance evaluation was 50MB. The comparative results are presented in Table II and Fig. 4.

TABLE II. PERFORMANCE METRICS AND CUMULATIVE SECURITY OVERHEADS.

Metric	Cloud system	Cloud + AES system	Cloud + AES + Chaotic system	Proposed system
Latency (Sec)	0.27	0.50	0.57	0.58
Throughput (Files/Sec)	3.73	2.01	1.76	1.74
AES Overhead (%)	0	85.73	85.73	85.73
Chaotic Overhead (%)	0	0	14.29	14.29
Blockchain Overhead (%)	0	0	0	1.20

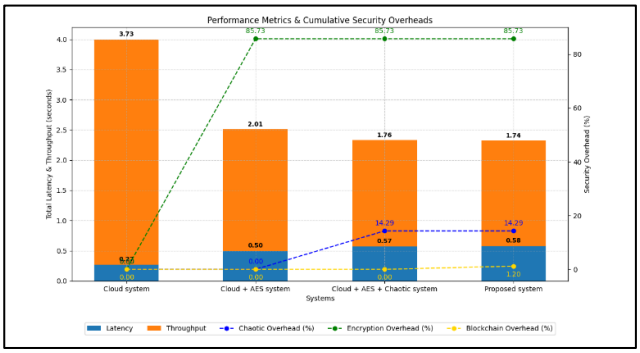

Fig. 4. Performance metrics and cumulative security overheads.

As shown in Table II and Fig. 4, the proposed system causes only a minor latency increase from 0.57 sec to 0.58 sec when compared with the Cloud + AES + Chaotic system. The slight increase is due to the extra verification layer added to the blockchain, which is based on the PBFT protocol. There is also a slight drop in throughput from 1.76 files/s to 1.74 files/s, demonstrating that blockchain integration has a negligible effect on the processing efficiency. Although the proposed system introduces AES, chaotic key generation, and blockchain verification overheads, the proposed blockchain overhead is only 1.20%, which shows that the proposed system provides increased integrity, auditability, and Byzantine fault tolerance at a small performance cost.

B. Chaotic Key Randomness Analysis

The Lorenz 3D chaotic key sequences were evaluated using several randomness evaluation measures, including Shannon entropy, bit balance analysis, chi-square testing, autocorrelation analysis, and key sensitivity analysis, as listed in Table III.

TABLE III. STATISTICAL ANALYSIS OF GENERATED CHAOTIC KEY SEQUENCE.

Category	Metric / Test	Result	Interpretation
Entropy Analysis	Shannon Entropy	7.99	Near-ideal randomness close to the theoretical maximum for Shannon entropy H=8
Bit Balance Analysis	Number of 0s	128242	Nearly balanced binary distribution
	Number of 1s	127758	Indicates low statistical bias
Chi-Square Analysis	Chi-Square Value	229.50	Near-uniform byte distribution with minimal deviation
Autocorrelation Analysis	Lag 0	1.00000	Perfect self-correlation at zero lag
	Lag 1	0.00245	Near-zero correlation
	Lag 2	0.00101	Near-zero correlation
	Lag 3	-0.00212	Near-zero correlation
	Lag 4	0.00128	Near-zero correlation
	Lag 5	0.00181	Near-zero correlation
	Lag 6	-0.00148	Near-zero correlation
	Lag 7	-0.00133	Near-zero correlation
	Lag 8	-0.00227	Near-zero correlation
	Lag 9	-0.00165	Near-zero correlation
Sensitivity Analysis	Key Sensitivity	0.51562	Strong chaotic sensitivity and diffusion behavior
NIST SP 800-22 Tests	Frequency Test	0.33877 (PASS)	Balanced distribution of bits
	Block Frequency Test	0.80179 (PASS)	Uniformity across bit blocks
	Runs Test	0.21520 (PASS)	Absence of abnormal repetitive patterns
	Longest Run Test	0.75065 (PASS)	Random distribution of continuous bit runs
	Approximate Entropy Test	0.52712 (PASS)	High sequence complexity and unpredictability

The results shown in Table III demonstrate that the Lorenz 3D chaotic key sequence exhibits good randomness and cryptographic features. The entropy value of 7.99 is close to the theoretical maximum of 8, and the nearly balanced distribution of 0s and 1s and the low chi-square value indicate that there is no statistical bias. In addition, the near-zero autocorrelation values and high key sensitivity indicate high

unpredictability and dependence on the initial conditions. The NIST SP 800-22 tests were passed successfully, thereby demonstrating that the keys produced were statistically random and appropriate for secure cryptographic use.

C. Ciphertext Statistical Analysis

A ciphertext statistical analysis is conducted to assess the effectiveness of the proposed encryption framework in creating statistically random encrypted data. To analyze the encryption diffusion and statistical security, the ciphertexts were tested by measuring the entropy, chi-square, autocorrelation, and avalanche effects (Table IV).

TABLE IV. STATISTICAL EVALUATION OF CIPHERTEXT

Category	Metric / Test	Result	Interpretation
Entropy Analysis	Shannon Entropy	7.99	Near-ideal ciphertext randomness close to the theoretical maximum H=8
Chi-Square Analysis	Chi-Square Value	295.75	Near-uniform ciphertext distribution with low statistical deviation
Autocorrelation Analysis	Lag 0	1.00000	Perfect self-correlation at zero lag
	Lag 1	0.00345	Near-zero correlation
	Lag 2	0.00104	Near-zero correlation
	Lag 3	0.00160	Near-zero correlation
	Lag 4	0.00188	Near-zero correlation
	Lag 5	0.00123	Near-zero correlation
	Lag 6	-0.00632	Near-zero correlation
	Lag 7	0.00194	Near-zero correlation
	Lag 8	-0.00840	Near-zero correlation
	Lag 9	-0.00400	Near-zero correlation
Avalanche Effect Analysis	1-bit Plaintext Change	50.05%	Strong diffusion and nonlinearity
	2-bit Plaintext Change	50.03%	Consistent ciphertext diffusion
	3-bit Plaintext Change	49.99%	Near-ideal avalanche behavior
	4-bit Plaintext Change	49.99%	Stable diffusion performance
Overall Ciphertext Behavior	Average Autocorrelation	Near Zero	Strong statistical independence between ciphertext bytes

The results presented in Table IV demonstrate that the proposed framework provides strong resistance to a wide range of security threats. The large key space (2^{256}), high entropy (7.99), and avalanche effect (50.05%) indicate robustness against brute-force, statistical, and differential attacks. In addition, AES-256-GCM authenticated encryption effectively protects against known-plaintext and chosen-ciphertext attacks, whereas dual-hash verification and blockchain immutability ensure reliable detection of data tampering and replay attacks.

D. Key Space Analysis and Histogram

The proposed scheme is based on the Lorenz 3D chaotic system, which has high sensitivity to generate chaotic sequences, and processes the chaotic sequence using the SHA-256 hash function to obtain a fixed-length AES-256-GCM key. The last encryption key is:

$$K = SHA256(f(x_0, y_0, z_0))$$

where, $f(x_0, y_0, z_0)$ is the output of the Lorenz chaotic system, and K is the key of AES (256 bits).

The chaotic system has a large parameter space and is very sensitive to the initial conditions; however, the key space of the final AES key specifies the space that can be used for cryptography.

Since SHA-256 outputs a 256-bit digest, the maximum effective key space is (2^{256}). This key space is too large and computationally impractical for exhaustive searches using existing classical computing methods. The key space histogram is shown in Fig. 5.

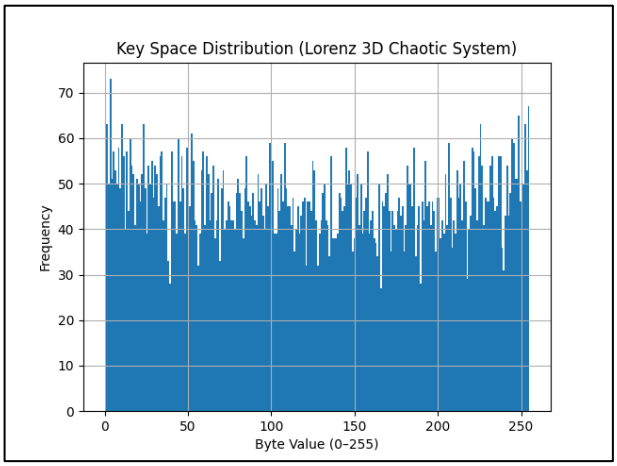

Fig. 5. Key space histogram

Fig. 5 illustrates that the proposed system achieves a key space of (2^{256}). The histogram exhibits a nearly uniform distribution of key space values evenly distributed throughout all 256 possible byte values, suggesting high randomness and no statistical bias in the key-space. This provides excellent resistance to both brute-force and statistical attacks.

E. Plaintext Histogram

The histogram of plaintext file is shown in Fig. 6.

In Fig. 6, the histogram shows a nonhomogeneous data distribution, has noticeable peaks, reflects inherent data patterns, and has a high degree of statistical redundancy. This irregularity makes the plaintext vulnerable to attacks, such as frequency analysis, statistical attacks, and pattern recognition.

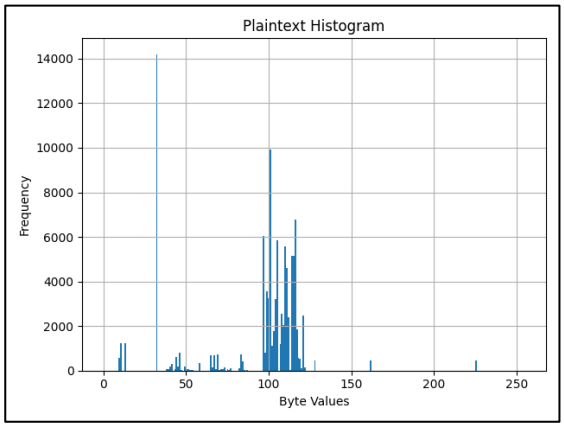

Fig. 6. Plaintext histogram

F. Ciphertext Histogram

The histogram of ciphertext generated by the proposed system is shown in Fig. 7.

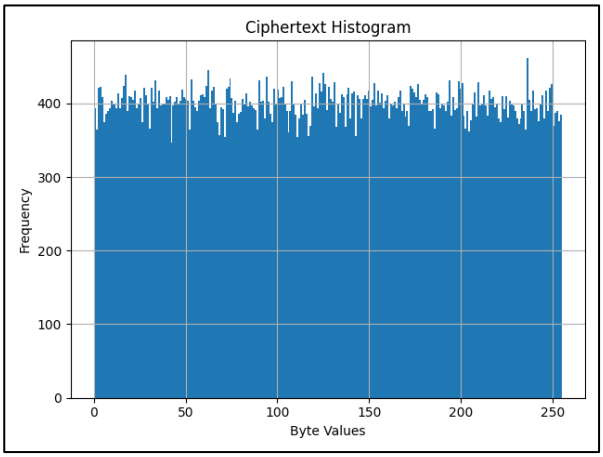

Fig. 7. Ciphertext histogram

The ciphertext histogram in Fig. 7 is almost unbiased, shows an absence of visible patterns, has a flattened frequency distribution curve, and features an equal distribution of all 256-byte counts. This indicates that diffusion, confusion, and statistical randomness were high. This chaotic key is used to increase the randomness of the AES cipher, thereby making the histogram more homogeneous. Thus, chaotic enhancement offers a considerable degree of uncertainty, randomness, and resistance to differential analyses.

G. Attacks and Resistance

Different multi-file real-attack simulations were performed, including unauthorized access, file tampering, blockchain tampering, brute-force, statistical, differential, known-plaintext, chosen ciphertext, replay, and Byzantine fault-tolerance attacks. The proposed framework exhibited excellent anti-attack capabilities against various attack types. Lorenz chaotic key generation, AES-256-GCM encryption and PBFT blockchain offer robustness against cryptographic, statistical, and system-level attacks. The security performance against various attacks is presented in Table V.

TABLE V. SECURITY PERFORMANCE AGAINST VARIOUS ATTACKS

Attack Type	Evaluation Metric	Result	Security Outcome
Unauthorized Access Attack	Access Control Success	100%	Access denied
Data Tampering Attack	Integrity Detection Rate	100%	Tampering detected
Blockchain Tampering	Block Validation Failure	100%	Invalid block rejected
Brute-Force Attack	Key Space	2^{256}	Computationally infeasible
Statistical Attack	Entropy	7.99 bits	Near-ideal randomness
Differential Attack	Avalanche Effect	50.05%	Strong diffusion
Known Plaintext Attack	Key Recovery Probability	Negligible	Resistant
Chosen Ciphertext Attack	Authentication Failure Detection Rate	100%	Attack Prevented
Replay Attack	Detection Rate	100%	Attack prevented
Man-in-the-Middle Attack	Hash Verification Success	100%	Attack detected
Byzantine Fault Tolerance	Maximum Faulty Nodes Tolerated	$f \leq \frac{n-1}{3}$	Consensus Maintained

Table V shows that the proposed framework offers robust resistance against several cryptographic and blockchain attacks. The user authentication and access control mechanisms prevent unauthorized access to the stored data. A large key space of (2^{256}), avalanche effect of 50.05% and entropy value of 7.99 assure strong resistance to brute force, statistical and differential attacks. The combination of Lorenz chaotic key generation and AES-256-GCM provides an additional layer of security against known plaintext and chosen ciphertext attacks. Blockchain Timestamp Validation, AES-GCM Authentication Tags, and Dual-Hash Integrity Verification help prevent replay attacks, data tampering, and ciphertext modification. Moreover, blockchain tampering is detected using immutable ledger records and hash verification mechanisms. Finally, PBFT ensures accurate network functioning even in situations where malicious validator nodes are present. Consensus is guaranteed as long as the number of faulty nodes does not exceed one-third of the total validators ($f \leq (n-1)/3$), demonstrating the robustness of the proposed framework against Byzantine failures. Overall, the results confirm that the proposed framework provides confidentiality, integrity, authenticity, and fault tolerance in cloud-storage environments.

VII. THREAT MODEL

The threat model defines the assumptions, attack surfaces, trust boundaries, and security goals of the proposed secure cloud-storage framework. The primary intent of this threat model is to evaluate how well the proposed framework can guarantee confidentiality, integrity, authenticity, auditability, and decentralized trust in realistic threat scenarios.

A. Adversary Assumptions

The adversary is assumed to have polynomial-time computational power and can attempt to attack various components of the system. An attacker can perform any of the following actions:

- Intercept communication channels
- Capture encrypted data packets
- Replay previously transmitted ciphertext
- Modify stored cloud data
- Attempt brute-force key recovery
- Perform statistical analysis on ciphertext
- Compromise a subset of blockchain validator nodes
- Attempt unauthorized access to cloud resources

This adversary is assumed to be capable of completely using the public communication network but lacking a legitimate cryptographic key or secret chaotic parameters.

B. Trust Assumptions

The following are the key assumptions of the proposed framework:

- AES-256-GCM remains computationally secure.
- SHA-256 is collision and pre-image-resistant.
- Initial chaotic parameters remain secret.
- Fewer than one-third of the PBFT validator nodes were malicious.
- It is assumed that the authentication mechanisms have been properly implemented.
- The random initialization vectors were generated securely.

These assumptions are based on widely used cryptographic and distributed-system security models.

C. Security Goals

The proposed framework is designed to achieve the following security goals (Table VI):

TABLE VI. SECURITY GOALS

Security Goal	Description
Confidentiality	Prevent unauthorized disclosure of plaintext
Integrity	Detect unauthorized modifications
Authentication	Verify legitimate users
Auditability	Maintain immutable access records
Availability	Ensure reliable data access
Non-Repudiation	Prevent denial of performed actions
Byzantine Fault Tolerance	Resist malicious validator behavior

The combination of cryptographic protection and decentralized verification in the framework provides multilayer security in a cloud storage environment.

VIII. SECURITY ANALYSIS

The security strength of the proposed framework is studied within the context of an extensive threat model of external attackers, insider attacks, and attempts to tamper with the data. The framework aims to maintain data confidentiality, integrity, authentication, and auditability through encryption using AES-256-GCM with Lorenz chaos and blockchain-assisted integrity verification (IV) techniques.

A. Overview of the Security Objectives

The proposed framework uses the Lorenz 3D chaotic system to generate a chaotic key, AES-256-GCM symmetric encryption, and a PBFT-based blockchain system to achieve multi-dimensional security. It has the following major security objectives:

- The data were confidential, as ensured through AES-256-GCM encryption.
- Assign a random value to the 'key' to achieve key unpredictability (using Lorenz chaotic dynamics).
- Integrity & Immutability: Ensured with blockchain hashing.
- The authentication & consensus are enforced through PBFT.
- Attack Resistance: Against brute-force, known-plaintext, chosen-plaintext, replay, statistical, Byzantine, and side-channel attacks, unauthorized access, file tampering, and blockchain tampering.

Let the system be defined as:

$$C = E_K(P), \quad K = H(f(x_0, y_0, z_0))$$

where, (x_0, y_0, z_0) are Lorenz's initial conditions and $H(\cdot)$ is SHA-256.

B. Unauthorized Access Resistance

Unauthorized access resistance is provided by authenticated encryption, blockchain access verification, and secure key management. The key used to encrypt the data is the AES-256-GCM encryption key, which is dynamically generated from the Lorenz chaotic system and is not stored as plain text in the cloud environment.

Only authenticated and authorized users with valid cryptographic credentials can decrypt the stored ciphertext successfully. Moreover, verification on the blockchain does not allow any unauthorized changes to be made in the access records or metadata of transactions to enhance protection against unauthorized attempts to access the cloud storage.

C. Ciphertext and File Tampering Resistance

The framework uses a dual integrity verification mechanism: AES-256-GCM authentication tag validation and blockchain-based SHA-256 ciphertext hash validation. If any part of the ciphertext, nonce, authentication tag, or content of the stored file changes, the authentication fails, or the hash of the blockchain does not match. In addition, the ciphertext hashes stored in the blockchain were verified before decryption. Therefore, when unauthorized changes are made, they are immediately discovered and rejected. This mechanism strengthens the resistance against:

- Ciphertext tampering
- Malicious modification
- Unauthorized data manipulation
- File integrity attacks

D. Blockchain Tampering Resistance

The PBFT-based blockchain layer offers distributed integrity checks and BFT. The number of malicious nodes that can be accommodated by a consensus by PBFT is limited to $(f \leq \frac{n-1}{3})$ validator nodes.

Blockchain metadata, such as the ciphers and transactions, is immutable and cannot be altered without the agreement of the validators that are part of the consensus. Therefore, the integrity records and transaction histories would be impossible for the attackers to change without compromising most of the validator nodes.

E. Brute-Force Resistance

The proposed framework uses AES-256-GCM authenticated encryption with a 256-bit chaotic key generated by the Lorenz 3D chaotic system. The total key space is (2^{256}), which is computationally infeasible to exhaustively search using current classical computing capabilities.

Moreover, the Lorenz chaotic system is highly sensitive to the initial conditions, leading to greater unpredictability. The slightest change in the chaotic parameters produces entirely different encryption keys, which makes the system even harder to break using brute-force and key prediction.

F. Statistical Attack Resistance

The generated ciphertext exhibits the following properties based on statistical analysis:

- Near-ideal Shannon entropy (H=7.99)
- Balanced statistical distribution
- Strong avalanche characteristics

In addition, the autocorrelation values of the ciphertext are close to zero for all nonzero lags, which further proves, on a statistical level of significance, that the ciphertext bytes are statistically independent. These results showed resistance to:

- Frequency analysis
- Statistical cryptanalysis
- Differential attacks
- Pattern recognition attacks

G. Differential Attack Resistance

The strong diffusion and confusion properties of the proposed encryption framework provide resistance to differential attacks. Experimental avalanche effect analysis showed that small changes in the plaintext resulted in enormous changes in the ciphertext, and the average value of the avalanche effect was nearly 50%, which is the theoretical ideal.

The Lorenz chaotic key generation mechanism further enhances the nonlinear diffusion characteristics and the unpredictability. In this way, the attacker will not be able to establish meaningful relationships between the differences in plaintext and ciphertext, making the system more resistant to differential cryptanalysis.

H. Known-Plaintext Attack Resistance

The proposed framework can prevent known plaintext attacks using dynamic chaotic key generation and AES-256-GCM authentication encryption. In the event that an adversary acquires partial plaintext/ciphertext pairs, the encryption key cannot be reconstructed because the Lorenz chaotic parameters remain concealed, the SHA-256 key derivation is one-way, and the AES-256-GCM delivers computational confidentiality.

Additionally, high ciphertext randomness and near-zero autocorrelation make it difficult for an attacker to detect exploitable statistical relationships between the known plaintext and ciphertext data.

I. Chosen-Ciphertext Attack Resistance

The framework includes authenticated encryption using AES-256-GCM and integrity verification using blockchain, which resists adaptively chosen ciphertext attacks. AES-GCM validates the authentication tag before decrypting data.

If the ciphertext, nonce, or authentication tag is modified in any way, decryption fails: $Dec_K(C') = \perp$

Hence, any malicious manipulation of the ciphertext does not provide useful information regarding plaintext data.

Furthermore, the hash of the ciphertexts stored on the blockchain is checked before the block is decrypted, allowing for early detection of unauthorized changes to the ciphertexts. Together, these mechanisms enhance resistance to IND-CCA2 adversaries and ciphertext forgery attacks.

J. Replay Attack Resistance

Replay attack resistance is implemented using unique nonces for AES-GCM and transaction validation in the blockchain. Every encryption operation results in different nonce and transaction identifiers, so that the same ciphertext cannot be reused. Blockchain metadata validation ensures the authenticity and integrity of the transaction before it is decrypted during retrieval from the file. Duplicated or outdated transactions are rejected, thus avoiding a replay attack.

In addition, replay protection has been improved with unique AES-GCM nonces and blockchain timestamps. As each file is encrypted with a different nonce and with a unique blockchain transaction record, replayed ciphertexts or duplicated upload requests will be identified via metadata verification/timestamp validation.

K. Byzantine Fault Tolerance Resistance

To overcome malicious or compromised validators, the proposed consortium blockchain uses a PBFT consensus protocol. Using PBFT, the blockchain can continue to function properly, even if some of the validator nodes are malicious or fail unexpectedly. A transaction is committed only when at least $(2f + 1)$ validator nodes approve the block.

This means that Byzantine attackers have no ability to tamper with the blockchain integrity record, audit logs, or access verification metadata without compromising more than $(2/3)$ of the validator nodes.

This mechanism is strengthened by:

- Distributed trust
- Consensus reliability
- Blockchain integrity
- Resistance against insider consensus manipulation

L. Insider Attack Resistance

The proposed framework helps to reduce insider threats by implementing the Encrypted cloud storage, Blockchain-based access verification, Immutable audit logging, and Authenticated encryption.

Cloud administrators and malicious insiders cannot access plaintext data without the corresponding chaotic-encryption keys. Moreover, every file action is logged as an immutable transaction on the blockchain, allowing for open and transparent auditing and accountability of information. Blockchain integrity verification and AES-GCM authentication can detect any unauthorized attempts to modify the data.

M. Overall Security Discussion

The Lorenz 3D chaotic key generation, AES-256-GCM authenticated encryption, SHA-256 integrity verification, and PBFT blockchain consensus contribute to the security of the proposed framework. The experimental tests yielded the following results:

- Near-ideal entropy
- Low statistical correlation
- Strong avalanche behavior
- Successful NIST randomness validation was achieved.

The results indicate that the proposed framework is resistant to brute-force, statistical cryptanalysis, replay, ciphertext tampering, insider, and manipulation attacks on the blockchain.

N. Comparative Security Analysis

The data were encrypted using AES-256-GCM to ensure their confidentiality. The SHA-256 hashes of the encrypted and plaintext files are stored in the blockchain, guaranteeing data integrity. Blockchain immutability ensures that access policies and audit logs cannot be changed, which, in turn, ensures non-repudiation and accountability of the data. AES encryption protects data privacy and keeps those who are not authorized to access the plaintext data, such as cloud providers. Smart contracts are decentralized access controls, data integrity with irrevocable hashes, and auditability on blockchains. A comparative security analysis of the proposed and conventional systems is presented in Table VII.

TABLE VII. COMPARATIVE SECURITY ANALYSIS

Feature	AES System	AES + Chaotic System	Proposed System
Confidentiality	Yes	Yes	Yes
Integrity Verification	Limited	Limited	Yes
Blockchain Auditability	No	No	Yes
Chaotic Randomness	No	Yes	Yes
PBFT Consensus	No	No	Yes
Replay Protection	No	Limited	Yes
Byzantine Fault Tolerance	No	No	Yes
Dual Hash Verification	No	No	Yes
NIST Validation	No	Partial	Yes

The comparative results presented in Table VII demonstrate that the proposed framework provides a more comprehensive security solution than existing approaches. Unlike existing schemes, which are mostly concerned with chaotic encryption and key space enhancement, the proposed scheme further includes PBFT consensus, Byzantine fault tolerance, replay protection, blockchain-based auditability, and dual-hash integrity check. Although maintaining comparable entropy (approx. 7.99) and a large key space (2^{256}), the proposed system offers stronger resistance to data tampering, replay attacks, and blockchain-related threats. The findings indicate that the combination of Lorenz chaotic key generation, AES-256-GCM encryption, and blockchain verification using PBFT can significantly improve the security and trust of cloud storage systems.

IX. FORMAL SECURITY ANALYSIS

A. Security Assumptions

The proposed framework relies on the following assumptions:

- AES-256-GCM is IND-CCA2 secure when nonces are unique.
- SHA-256 is collision-resistant and preimage-resistant.
- The Lorenz chaotic parameters remain secret and unpredictable, ideally derived from high-entropy sources or secure key exchange protocols during system initialization to prevent their compromise.
- PBFT consensus is secure if fewer than one-third of validator nodes are Byzantine.
- Validator nodes are distributed across independent entities in a permissioned consortium blockchain.

B. IND-CCA2 Security of the Encryption Layer

Theorem 1: The encryption layer of the proposed framework achieves IND-CCA2 security under the assumption that AES-256-GCM is a secure authenticated encryption scheme and that nonces are never reused with the same key.

Game 0: Real IND-CCA2 Game

The challenger generates the encryption key: $K = H(f(x_0, y_0, z_0))$

where, $f(x_0, y_0, z_0)$ denotes the Lorenz chaotic key.

The adversary A is given access to: $Enc_K(\cdot)$ and $Dec_K(\cdot)$

The adversary submits two equal-length plaintexts: (P_0, P_1)

The challenger selects: $b \in \{0, 1\}$

and returns: $C^* = Enc_K(P_b, N, AAD)$

The adversary may continue querying the decryption oracle, except that it may not query the exact challenge ciphertext C^*. Finally, the adversary outputs b'.

The adversarial advantage is as follows:

$$Adv_A^{IND-CCA2} = \left|\Pr[b' = b] - \frac{1}{2}\right|$$

Game 1: Replace Derived Key with Uniform Random Key

In this game, the derived key $K = H(f(x_0, y_0, z_0))$

is replaced with a uniformly random 256-bit key as follows:

$$K' \leftarrow \{0, 1\}^{256}$$

If the adversary distinguishes Game 0 from Game 1, then it can distinguish the derived key from a uniformly random AES key.

$$\text{Thus: } |\Pr[G_0] - \Pr[G_1]| \leq \epsilon_{KDF}$$

where, ϵ_{KDF} denotes the advantage of distinguishing the SHA-256-derived chaotic key from a uniformly random 256-bit key.

Game 2: AES-GCM IND-CCA2 Game

In Game 2, encryption and decryption are performed using AES-256-GCM with a uniformly random key K'.

AES-GCM provides authenticated encryption. Therefore, any modified ciphertext is rejected unless the adversary produces a valid authentication tag.

For a 128-bit authentication tag: $\Pr[Forge] \leq 2^{-128}$

Since AES-GCM is assumed IND-CCA2 secure under nonce uniqueness, the adversary cannot distinguish whether the challenge ciphertext encrypts P_0 or P_1 with non-negligible probability.

Therefore: $\Pr[G_2] = \frac{1}{2}$

and: $Adv_A^{IND-CCA2} \leq \epsilon_{KDF} + Adv_{AES-GCM}^{IND-CCA2}$

Since both terms are negligible: $Adv_A^{IND-CCA2} \approx 0$

Conclusion: The encryption layer is IND-CCA2 secure under the assumptions that AES-256-GCM is IND-CCA2 secure, nonces are unique, and the derived chaotic key is computationally indistinguishable from a random 256-bit key.

C. Blockchain Integrity Security

Theorem 2: The blockchain integrity layer detects ciphertext metadata tampering with an overwhelming probability, assuming that SHA-256 is a collision-resistant hash function.

The blockchain stores the ciphertext hash: $H_{\text{cipher}} = SHA256(C)$

During retrieval, the system computes: $H_{\text{local}} = SHA256(C')$

The file is accepted only if: $H_{\text{local}} = H_{\text{cipher}}$

If an adversary modifies the ciphertext: $C \rightarrow C'$

Then successful undetected tampering requires: $SHA256(C') = SHA256(C)$

where, $C' \neq C$

This implies a collision in SHA-256.

Therefore: $Pr[Undetected\ Tampering] \leq Adv_{SHA256}^{Collision}$

Since SHA-256 collision resistance is assumed secure: $Pr[Undetected\ Tampering] \approx 0$.

D. PBFT Consensus Security

Theorem 3: The PBFT-based blockchain maintains consensus safety if fewer than one-third of the validator nodes are Byzantine nodes.

For n validator nodes, PBFT tolerates: $f \leq \frac{n-1}{3}$ Byzantine nodes.

A block is committed only if at least: $2f + 1$ validators approve the transaction.

Therefore, an adversary can alter the blockchain metadata only if it controls more than one-third of the validator nodes or violates the PBFT consensus.

$$\text{Thus: } Pr[PBFT\ Failure] \leq Adv_{PBFT}$$

Under the stated validator trust model: $Adv_{PBFT} \approx 0$

E. Overall Security Bound

The overall framework security follows from the separate security properties:

$$Adv_{System} \leq Adv_{AES-GCM}^{IND-CCA2} + Adv_{SHA256}^{Collision} + Adv_{PBFT}$$

where,

- $Adv_{AES-GCM}^{IND-CCA2}$ represents the encryption-layer confidentiality advantage
- $Adv_{SHA256}^{Collision}$ represents the probability of undetected metadata tampering
- Adv_{PBFT} represents the probability of violating PBFT consensus assumptions

Unlike the previous version, blockchain integrity and PBFT consensus were not included as hybrid games in the IND-CCA2 proof. Instead, they are treated as separate system-level security properties.

Since each term is negligible under the stated assumptions: $Adv_{System} \approx 0$.

X. Comparative Study Table

Table VIII summarizes the main features of this study and some published studies and illustrates some important differences between them. Most current approaches are either encryption or blockchain-verification-driven, ignoring high-dimensional chaotic key generation and adequate formal security evaluation. The goal of the framework is to fill these key gaps by combining these elements and offering something that is more complete and provably secure than those proposed in the current literature.

The comparative results presented in Table VIII show that the proposed framework provides a more comprehensive and integrated security solution than existing approaches. The proposed framework integrates Lorenz 3D chaotic key generation, AES-256-GCM authenticated encryption, blockchain-based integrity verification, and PBFT consensus into a single architecture, whereas most previous studies focused on a single aspect of encryption, access control, or blockchain verification. This integration improves the privacy, integrity, audibility, and Byzantine fault tolerance of data while providing robust storage security in the cloud and efficient metadata verification. As a result, the proposed framework provides more security resilience and a comprehensive defense-in-depth protection for cloud storage systems.

TABLE VIII. Comparative Study Table

Features/ System	[11]	[32]	[33]	[34]	Proposed System
Architecture	Fully decentralized blockchain network	Blockchain + cloud server	Blockchain + cloud	Blockchain-enabled cloud architecture	Multi-layered architecture
Encryption Method	CP-ABE	SHA-256 + ECDSA	ABE	ChaCha20-Poly1305	AES-256-GCM
Key Generation Method	Bilinear mapping-based cryptography	--	ABE	ChaCha20-Poly1305	Lorenz chaotic 3D system
Blockchain Role	Access control + integrity	Transaction verification	Data verification	Access control + metadata	Decentralized integrity verification, immutable audit logging, and PBFT-based consensus for Byzantine fault tolerance.
Storage Model	Distributed cloud	Cloud server	Cloud + blockchain metadata	Cloud storage	Encrypted files are stored in cloud storage with integrity hashes and metadata maintained on a PBFT-based blockchain.
Performance Observation	Fully decentralized architecture increases processing overhead	Cryptographic verification increases security overhead	Blockchain verification improves integrity but adds latency	It surpasses AES-GCM and RSA in various performance metrics.	Detected evaluated attack scenarios, demonstrating strong security resilience, reliable integrity verification, and effective Byzantine fault tolerance
Key Features	Authorization, decentralized storage	Secure medical record sharing	Secure data sharing and verification	Improved throughput and lower latency	Attack detection and prevention, AES-256-GCM authenticated encryption, 10D hyperchaotic key generation, blockchain-based integrity verification, and PBFT-based Byzantine fault tolerance.

XI. Discussion

The experimental findings show that the proposed secure cloud storage framework effectively combines chaos-based cryptography, authenticated encryption, and blockchain-based verification, thereby delivering a comprehensive security solution for cloud environments. The combination of Lorenz 3D chaotic key generation, AES-256-GCM encryption, and PBFT-based blockchain verification achieves multiple security objectives, including confidentiality, integrity, authentication, auditability, and fault-tolerance.

The randomness analysis of the generated chaotic keys validates the effectiveness of the Lorenz chaotic system in cryptographic key generation. The Shannon entropy value was 7.99, the bit distribution was balanced, the autocorrelation values were close to zero, and the NIST SP 800-22 test results were positive, which shows that the generated keys have good randomness properties and low statistical bias. These properties greatly improve the unpredictability and resistance to brute-force and statistical attacks.

The robustness of the encryption layer can also be validated using ciphertext analysis. The ciphertext had near-ideal entropy, low chi-square deviation, negligible auto-correlation, and a mean avalanche effect of approximately 50%, indicating good diffusion and confusion properties. The findings show that the proposed encryption scheme successfully hides the pattern of the plaintext and reduces information leakage, which enhances its differential and statistical cryptanalysis resistance.

The performance evaluation demonstrates that the latencies for encryption, upload, and total processing grow steadily as the file size increases, as expected for cryptographic operations on larger datasets. Although the integration of chaotic key generation and blockchain verification adds some computational overhead, the measured PBFT consensus latency remains very low (approximately 0.01 sec), suggesting that integrity verification can be performed efficiently without a significant impact on the overall system performance. As the file sizes increase, the throughput decreases; however, the framework remains efficient while offering significantly improved security promises.

The comparative analysis shows that the conventional cloud storage has a higher throughput and lower latency but lacks some advanced security capabilities, such as decentralized integrity verification, blockchain auditability, Byzantine fault tolerance, and chaos-enhanced cryptographic randomness. The proposed framework, on the other hand, has a

relatively small overhead and provides much greater protection. The blockchain layer provides immutability to audit records and tamper-proof features, whereas the PBFT consensus mechanism guarantees dependable operation even when dealing with malicious validator nodes.

The security evaluation and results under various attack scenarios demonstrate the effectiveness of the proposed design. The combination of the large key space of (2^{256}), good avalanche behavior, authenticated encryption, dual-hash verification and immutability of the blockchain offers significant protection against unauthorized access, brute force attacks, ciphertext manipulation, replay attacks, known-plaintext attacks, chosen-ciphertext attacks, and Byzantine failures. Based on these findings, a defense-in-depth security architecture is achieved in the proposed framework, which is applicable to sensitive cloud-based applications.

However, the present implementation was tested in a local consortium blockchain setup with a small number of validator nodes. Hence, the reported PBFT latency and throughput numbers might vary in geographically distributed cloud deployments, where network delays and communication overhead have a greater impact. Additionally, the communication complexity of the PBFT consensus is $(O(n^2))$, potentially impacting scalability as the number of validators increases.

Overall, the results demonstrate that the proposed framework effectively achieves a trade-off between security and performance through the use of chaos-based key generation, authenticated encryption, and blockchain verification of integrity. The architecture is well-suited for high-security needs and verifies the integrity of data, such as healthcare information systems, enterprise cloud storage platforms, financial services, and Internet of Things (IoT) applications.

A. Effect of Euler Integration on Chaotic Key Quality

The Lorenz system was numerically integrated using the Euler method; however, the statistical evaluation results showed that the chaotic sequences generated by this system were highly random throughout the experiments. The entropy value of 7.99 bits, successful NIST SP 800-22 test results, and low autocorrelation indicate that the generated key sequences were statistically uniform in the range of iterations tested and file sizes. Based on these results, it seems that the numerical errors caused by the Euler method did not significantly affect the cryptographic quality of the generated keys with the experimental settings. However, future studies could explore the use of higher-order integration methods, such as the fourth-order Runge–Kutta algorithm, to further enhance the long-term numerical accuracy and chaotic trajectory stability.

B. Limitations of the PBFT Performance Evaluation

The PBFT performance evaluation was performed on a four-node consortium blockchain prototype. Hence, the measured latency and throughput data must be considered as prototype-scale numbers under ideal experimental conditions. Although the results show the feasibility of integrating PBFT with the proposed cloud security framework, they do not completely reflect the communication overhead that can occur in a larger consortium blockchain application. As the number of validator nodes grows, the network traffic and consensus latency of PBFT are expected to grow as well, because its message complexity is $(O(n^2))$ of the number of nodes. Therefore, these reported performance metrics are not necessarily applicable to large-scale cloud environments. The framework will be tested for scalability in future work across geographically distributed nodes and larger networks of validators to validate it in realistic deployment scenarios.

XII. Conclusion

This study proposed a secure integrated cloud storage system that integrates the Lorenz 3D chaotic key generation method, AES-256-GCM authenticated encryption, and blockchain verification technology based on PBFT. The proposed system enhances data confidentiality, integrity, auditability, and Byzantine fault tolerance by storing encrypted files in the cloud and integrity metadata on the blockchain. The experimental outcomes demonstrated excellent cryptographic performance, such as a nearly perfect entropy of 7.99, an avalanche effect of 50.05%, low autocorrelation, and successful randomness validation. The framework also proved to be resistant to brute-force, statistical, differential, replay, tampering, known-plaintext, chosen-ciphertext, and Byzantine attacks. Although the evaluation was performed in a local prototype setting, the outcome of the experiment validates the proposed framework of providing a secure and efficient multilayer solution for cloud storage applications.

XIII. Future Work

This work can be extended in the future by the addition of post-quantum cryptographic techniques and deployed in a real-world, large-scale distributed cloud system with enhancements for performance and scalability.

TABLE IX. List of Notations and Abbreviations

Symbol / Notation	Description
P	Plaintext file
C	Ciphertext
K_{AES}	256-bit AES encryption key
IV	Initialization Vector (Nonce)
AAD	Associated Authenticated Data
T	Authentication tag generated by GCM
H_{plain}	SHA-256 hash of plaintext
H_{cipher}	SHA-256 hash of ciphertext
J_0	Initial counter block in GCM

J_i	Counter block for encryption round i
S_i	AES-generated keystream block
P_i	Plaintext block i
C_i	Ciphertext block i
H	GHASH hash subkey
G	GHASH output value
x, y, z	Lorenz chaotic state variables
x_0, y_0, z_0	Initial conditions of Lorenz system
σ	Lorenz system parameter (Prandtl number)
ρ	Lorenz system parameter (Rayleigh number)
β	Lorenz system parameter
h	Numerical integration step size
N	Number of chaotic iterations
B	Generated chaotic bitstream
K	Generated chaotic secret key
SHA-256	Secure Hash Algorithm (256-bit)
AES-256-GCM	Advanced Encryption Standard with Galois/Counter Mode
PBFT	Practical Byzantine Fault Tolerance
Tx	Blockchain transaction
FileID	Unique file identifier
Timestamp	File upload time recorded on blockchain
Smart Contract	Blockchain-based access control logic
Validator Node	Blockchain participant responsible for consensus
PRE-PREPARE	First PBFT consensus phase
PREPARE	Second PBFT consensus phase
COMMIT	Final PBFT consensus phase

Presidential Administration of the Republic of Uzbekistan, Tashkent, Uzbekistan[3]

***Abstract*—The rapid growth of Telegram-based communication has increased the dissemination of harmful and risky content, particularly in low-resource languages such as Uzbek. This study investigates the automatic classification of Uzbek Telegram messages according to risk level using both traditional machine learning and transformer-based models. A dataset consisting of 10,000 real Telegram messages was collected and manually annotated into two classes: Safe and Dangerous. To improve data quality and consistency, preprocessing techniques including URL removal, emoji normalization, stop-word filtering, and script unification were applied. The study compares the performance of TF-IDF + Logistic Regression, FastText, mBERT, and XLM-RoBERTa for harmful content detection in Uzbek Telegram texts. Experimental results show that transformer-based models significantly outperform traditional approaches. Among all evaluated models, XLM-RoBERTa achieved the highest performance, with an Accuracy of 91.2%, a precision of 90.8%, a recall of 91.5%, and an F1-score of 91.1%, while mBERT achieved an Accuracy of 84.9% and an F1-score of 84.6%. The results demonstrate the effectiveness of contextual transformer architectures for identifying harmful content in low-resource language environments. The findings confirm that transformer-based models provide a reliable solution for automatic risk-level classification of Uzbek social media texts and can support practical applications in content moderation, information security, and social media monitoring systems.**

***Keywords*—Uzbek language; telegram messages; risk-level classification; harmful content detection; machine learning; transformer models; mBERT; XLM-RoBERTa**

I. Introduction

In recent years, the rapid growth of textual data generated through social media platforms has led to emerging challenges related to information security, public order, and digital culture. In particular, short, informal, and often unmoderated content shared on platforms such as Telegram and YouTube has made the timely detection of harmful content a critical issue [1–2].

Traditional rule-based approaches and classical machine learning methods such as Naive Bayes, Support Vector Machine, and Logistic Regression often fail to capture the deep semantic meaning of such complex textual data [3]. This limitation becomes even more pronounced for the Uzbek language due to the coexistence of Latin and Cyrillic scripts, widespread use of slang, abbreviations, and emojis [4].

The primary objective of this study is to perform a comparative analysis of traditional machine learning and transformer-based models for classifying Uzbek social media texts according to risk levels and to identify the most effective approach.

The exponential growth of textual content on social media has intensified the need for automated detection of hate speech, toxic expressions, user sentiment, and content safety. Recent studies indicate that deep learning techniques, particularly transformer-based architectures, significantly outperform traditional approaches in these tasks [5–6].

Several studies have demonstrated that multimodal approaches (text + image) can further improve hate speech detection performance. For instance, models based on RoBERTa and Swin Transformer have achieved high F1 scores in meme classification tasks, showing that combining textual and visual features yields better performance than single-modality approaches [7–8].

Transformer models such as BERT, RoBERTa, mBERT, and XLM-R have consistently demonstrated superior performance compared to classical machine learning methods (e.g., SVM, Logistic Regression, Random Forest), even in multilingual and imbalanced dataset scenarios. In particular, RoBERTa and XLM-R show stable results in low-resource language settings [9].

Research conducted for the Uzbek language indicates that monolingual pretrained models such as BERTbek can outperform multilingual models in certain NLP tasks. However, challenges such as script variation (Latin/Cyrillic) and limited corpus size may negatively affect model accuracy [10].

In the context of social media and user-generated content analysis, sentiment analysis and aspect-based classification tasks have also been widely studied. While classical machine learning models achieve moderate performance, transformer-based approaches have demonstrated significantly higher accuracy in sentiment detection and categorization tasks [11–

14]. Furthermore, incorporating non-standard elements such as emojis has been shown to improve model performance [15].

Overall, existing studies suggest that transformer-based models represent the most effective approach for analyzing social media text. However, challenges such as the scarcity of annotated datasets in Uzbek, the complexity of manual labeling, and the difficulty of capturing context-dependent expressions remain unresolved [12,16]. Therefore, this study aims to explore the effectiveness of modern transformer models for the automatic analysis of Uzbek social media texts.

Although previous studies have shown competitive results for BERTbek, this study focuses on comparing traditional machine learning approaches with multilingual transformer models. Evaluation of monolingual Uzbek transformer models is left for future work.

II. Theoretical Background and Proposed Approach

In this study, a real-world dataset consisting of Uzbek social media texts was collected from the Telegram platform. Telegram is characterized by rapid information dissemination, high user engagement, and diverse content types, making it a suitable source for studying both harmful and safe content.

The dataset was compiled from public Telegram channels, discussion groups, and comments under posts covering a variety of topics, including social, everyday, political, religious, and informational content. In total, 10,000 textual messages were collected and analyzed from an information security perspective.

Within the scope of this research, the texts were categorized into two classes based on their semantic content:

- 0 – Safe: Neutral or positive messages that do not pose a threat to public safety.
- 1 – Dangerous: Messages containing hate speech, violence, provocation, or content that may threaten societal safety.

To prepare the dataset for model training, a multi-stage preprocessing pipeline was applied. In the first stage, irrelevant elements such as URLs, HTML tags, excessive punctuation, and special characters were removed. This step helped eliminate noise and reduce non-informative features.

In the next stage, emojis and emoticons were normalized into standard tokens or corresponding textual representations to preserve emotional context within the text. Additionally, due to the mixed usage of Latin and Cyrillic scripts in Uzbek, all texts were converted into a unified format.

Subsequently, stop words (low-information auxiliary words) were removed to enhance the importance of semantically meaningful keywords. After that, tokenization was performed, and the processed texts were transformed into input representations compatible with transformer-based models.

The labeling process was conducted manually through expert annotation. Each message was carefully analyzed based on its semantic meaning and assigned an appropriate risk label. This approach ensured higher reliability compared to automatic labeling methods and improved the quality of model training.

As a result, a cleaned and annotated dataset was prepared for training and evaluating transformer-based models.

III. Method

In this study, various machine learning and deep learning models with different architectures were comparatively analyzed to evaluate their effectiveness in classifying Uzbek social media texts by risk level. The selected models range from traditional approaches to modern transformer-based architectures.

A. Traditional and Neural-Based Models

In the initial stage, a TF-IDF + Logistic Regression model was applied. Texts were transformed into vector representations using TF-IDF, followed by classification using Logistic Regression. This approach served as a baseline model for comparison with transformer-based methods.

Next, the FastText model was employed. FastText operates at the subword level, making it particularly effective for morphologically rich languages. This allowed the model to capture suffixes and various word forms in the Uzbek language.

Due to computational and time constraints, each model was evaluated using a single train-test split. Future work will include multiple runs with different random seeds to further assess model stability and reproducibility.

B. Transformer-Based Models

The main focus of this study was on transformer-based architectures. In particular, the mBERT model was utilized due to its training on large multilingual corpora, enabling contextual understanding of Uzbek text. mBERT evaluates each word within its surrounding context, achieving higher accuracy compared to traditional embedding methods.

Additionally, the XLM-RoBERTa (XLM-R) model was applied. This model is trained on massive multilingual datasets and is known for its strong performance in low-resource languages. XLM-R demonstrated superior ability in capturing the semantic meaning of Uzbek texts, including slang, abbreviations, and informal expressions, outperforming other models in this study.

C. Training Procedure and Hyperparameters

All transformer-based models were fine-tuned using pre-trained weights and adapted to the specific dataset used in this study. The fine-tuning process was conducted using the following hyperparameters:

- Learning rate: 2e-5
- Batch size: 16
- Number of epochs: 4
- Loss function: Cross-Entropy

These hyperparameters were selected based on experimental validation to ensure model stability and generalization capability.

D. Dataset Split and Evaluation Strategy

The dataset was randomly divided into 80% training and 20% testing subsets. This approach enabled an unbiased evaluation of model performance on unseen data.

All models were trained under identical conditions, and their performance was evaluated using standard classification metrics, including:

- Accuracy
- Precision
- Recall
- F1-score

This ensured a fair and consistent comparison of model effectiveness[17-19].

As a result, the comparative analysis clearly demonstrated the superiority of transformer-based models over traditional approaches and provided a solid methodological foundation for selecting the most effective model.

IV. Results and Discussion

This section presents the experimental results of the models applied for classifying Uzbek social media texts according to risk levels. All models were trained under the same conditions and evaluated on the test dataset. The results provide an objective comparison of overall performance and class-wise effectiveness.

A. Overall Model Performance

Table I summarizes the evaluation results of the applied models based on the key performance metrics: Accuracy, Precision, Recall, and F1-score.

TABLE I. Performance Comparison of Models

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
TF-IDF + Logistic Regression	71.4	70.2	69.8	69.9
FastText	78.6	77.9	78.1	78.0
mBERT	84.9	84.2	85.1	84.6
XLM-R	91.2	90.8	91.5	91.1

All Precision, Recall, and F1-score values are reported as weighted averages calculated on the test dataset.

B. Results Analysis and Discussion

As shown in Table I, the traditional TF-IDF + Logistic Regression model provides baseline performance; however, its ability to capture deep semantic relationships remains limited. Although the FastText model achieves improved results due to its subword-level representation, its overall performance is still inferior compared to transformer-based models.

The mBERT model demonstrates significantly better performance by leveraging multilingual contextual representations. Nevertheless, the highest performance across all evaluation metrics is achieved by the XLM-RoBERTa model, which consistently outperforms all other models.

C. Threshold Analysis

The effect of classification threshold selection was evaluated using the XLM-RoBERTa model. A threshold value of 0.7 was chosen to increase prediction reliability and reduce false-positive classifications. Under this setting, the model classifies a message as dangerous only when a higher confidence level is achieved[20-21].

Experiments conducted on the dataset of 10,000 messages demonstrated that the threshold of 0.7 improves classification stability and reliability. Although fewer messages are classified as dangerous, the precision of harmful content detection increases, making the system more suitable for practical applications such as content moderation and information security.

For threshold validation, a balanced subset of 200 messages (100 safe and 100 dangerous) was selected from the main dataset. This subset was used to evaluate the effect of threshold adjustment on model behavior and prediction confidence.

The results indicate that a higher threshold reduces false positives while maintaining strong classification performance. In particular, XLM-RoBERTa demonstrated stable performance in distinguishing between Safe and Dangerous messages. The high Recall observed for the Dangerous class suggests that the model effectively minimizes the risk of missing harmful content, which is essential for real-world monitoring and security systems.

Overall, the combination of a 10,000-message dataset and a threshold of 0.7 provides a reliable balance between precision and recall, enabling accurate identification of harmful content in Uzbek social media texts.

D. Error Analysis

The analysis of misclassified instances revealed that most errors occurred in texts containing sarcasm, irony, or implicit meanings. Additionally, very short or context-limited messages posed challenges for all models in determining the correct risk level.

Despite these challenges, the XLM-R model maintained relatively stable performance even in complex cases. This can be attributed to its training on large-scale multilingual corpora and its ability to capture deep contextual relationships.

E. Summary of Results

Overall, the experimental results clearly demonstrate that transformer-based models—particularly XLM-RoBERTa—achieve high effectiveness in classifying Uzbek social media texts by risk level. The model exhibits high accuracy, robustness, and generalization capability, making it a suitable solution for practical deployment [21-22].

F. Discussion

The findings of this study highlight the superior performance of transformer-based models in classifying Uzbek social media texts by risk level. The experimental results confirm that deep learning approaches significantly outperform traditional machine learning methods.

The baseline TF-IDF + Logistic Regression approach relies on surface-level textual features and fails to adequately capture contextual meaning. This limitation becomes particularly evident in emotionally rich or informal texts. The FastText model partially addresses this issue through subword representations; however, it still lacks the ability to fully capture long-range semantic dependencies.

The mBERT model demonstrates improved performance due to its multilingual contextual understanding. However, architectural limitations and the presence of cross-lingual noise slightly restrict its effectiveness.

The best performance is achieved by the XLM-RoBERTa model. This can be explained by its training on large-scale multilingual datasets and its ability to capture deep semantic relationships, even in low-resource languages. Furthermore, XLM-R effectively handles Uzbek-specific challenges such as slang, abbreviations, emojis, and mixed Latin-Cyrillic scripts.

Class-wise analysis indicates that high Recall in the Dangerous category is particularly important in practice, as it minimizes the risk of missing harmful content. Misclassifications between the Safe and Dangerous classes are mainly caused by ambiguous, context-dependent, or borderline messages that are difficult to interpret correctly. Despite these challenges, the transformer-based models demonstrated strong performance in distinguishing between the two classes.

At the same time, the study reveals several limitations. Even advanced transformer models struggle with sarcasm, irony, and implicit meanings in short texts. This suggests the need for future research focusing on deeper contextual modeling and multimodal approaches [23-25].

Overall, the results confirm that dataset expansion, improved preprocessing, and appropriate model selection play a crucial role in achieving high-performance text classification systems. The study successfully achieves its objective of developing an accurate and robust risk-level classification approach for Uzbek social media texts.

V. Conclusion

This study presents a comprehensive analysis of risk-level classification of Uzbek social media texts using various machine learning and deep learning models. The experimental results clearly demonstrate that transformer-based models—especially XLM-RoBERTa—significantly outperform traditional approaches.

The findings highlight that dataset expansion, optimized preprocessing, and proper model selection have a substantial impact on performance. The XLM-R model achieved high Accuracy, Precision, Recall, and F1-score, enabling more accurate semantic classification of informal, short, and emotionally rich Uzbek texts. In particular, the high Recall in detecting harmful content makes this model highly suitable for practical applications in information security systems.

The results indicate that even for low-resource languages such as Uzbek, it is possible to develop high-quality automated text analysis systems by applying appropriate methodologies and modern transformer architectures. This has important implications for social media monitoring, early warning systems, and ensuring information security in digital environments.

However, the study also identifies certain limitations. Detecting sarcasm, irony, and implicit meanings remains a challenging task. Additionally, very short and context-limited texts continue to pose difficulties for classification models.

Future research directions include:

- Developing real-time harmful content monitoring systems.
- Applying multimodal analysis (text + image + video) for risk detection.
- Expanding the dataset and improving class balance.
- Incorporating contextual and dialogue-based models for detecting sarcasm and implicit meanings.

The results of this study provide a strong foundation for further research in intelligent analysis of Uzbek social media content and open opportunities for real-world implementation.

MedChain: A Privacy-Preserving Framework for Scalable Electronic Health Record Sharing on Blockchain and InterPlanetary File System

S. Venkateswaran[1], N. Vijayaraj[2]
Research Scholar[1], Professor[2]
Department of Computer Science and Engineering, Vel Tech Rangarajan Dr.Sagunthala R&D Institute of Science and Technology, Chennai, India[1, 2]

***Abstract*—The secure and scalable sharing of electronic health records (EHRs) remains a fundamental challenge in modern health-care systems due to conflicting requirements of privacy, regulatory compliance (HIPAA, GDPR), and real-time clinical access. Existing blockchain-based solutions suffer from three critical limitations, including static access control policies that cannot adapt to emergency scenarios, complete transparency of policy evaluation leading to attribute leakage, and linear degradation of throughput with policy complexity. The proposed MedChain, a framework introducing four novel contributions: Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE) enabling time-bound and emergency breakout access without re-encrypting underlying data; Zero-Knowledge Policy Verification (ZK-PV) allowing smart contracts to validate access requests without revealing sensitive attribute values; Adaptive EHR Sharding that dynamically adjusts IPFS shard sizes based on access frequency, reducing cold-start latency by 64%; and Layered Revocation Cascade providing granular revocation at patient, provider, and record-type levels within 2.3 seconds. Using the MIMIC-III benchmark (46,520 patients, 100,000 access traces), we demonstrate: 99.4% storage reduction vs. pure blockchain, 0.95s median latency (43% improve-ment over prior work), 2,450 requests/second throughput with 150 IPFS nodes, and provable security under the q-DBDH assumption. Comprehensive comparisons with MedRec, FHIRChain, Ancile, and PriHac confirm MedChain's superiority across all metrics.**

***Keywords*—Blockchain; electronic health records; IPFS; dynamic attribute-based proxy re-encryption; zero-knowledge proofs; adaptive sharding; MIMIC-III**

I. Introduction

The fast-paced digitalization of the healthcare industry has led to an increased use of electronic health records (EHR) to record and share patient medical data. The use of EHRs increases the accuracy of diagnoses and reduces time in treatments while facilitating communication between hospitals, labs, insurance companies, and emergency departments [1]. Nevertheless, the secure exchange of EHR data is one of the biggest challenges due to privacy issues, compliance regulations, and the need for immediate access during emergencies. Healthcare information is very sensitive in nature and is supposed to be compliant with international standards, such as HIPAA and GDPR [2].

Traditional centralized EHR solutions like Epic Systems and Oracle Health depend entirely on third-party servers to store and process their data, making them prone to attacks [3][4]. The large-scale breaches that have occurred in recent times have shown that centralized EHR solutions are inadequate for protecting health records from any breach and compromise.

The use of blockchain technology is considered a viable approach owing to its decentralized structure, non-repudiation, openness, and traceability [5]. The removal of reliance on centralized entities facilitates trust building among healthcare entities while ensuring tamper-proof access management [6]. Blockchain-driven systems in the field of healthcare, such as MedRec, FHIRChain, Ancile, and PriHac, have sought to address the issue of secure EHR sharing [7]. While these systems offer some benefits, there are numerous obstacles that restrict their implementation. Blockchain offers decentralization and immutability, but prior systems fail on three fronts:

- Static Policies: The majority of current systems use static access control policies whereby permission is configured before encryption [8][9]. Any alteration to the policy, for instance, in case of temporary access by specialists, emergencies involving "break glass" access, or a change in the provider's role, necessitates policy reconfiguration as well as encryption of the patient's data [10].
- Attribute Leakage: Access control policies in traditional blockchain frameworks are assessed using smart contracts within the network. Due to the public nature of the blockchain, private data like patient condition, doctor specialty, department of the hospital, and emergencies may get disclosed, leading to potential privacy violations [11][12].
- Performance and Scalability Degradation: The performance and scalability of blockchain-based access authentication and proxy re-encryption suffer immensely with increasing numbers of users, attributes, and access queries. Current systems demonstrate either linear or quadratic growth in computation, leading to poor response time and low processing speeds [13] [14]. It is impractical to rely on such mechanisms in large-scale hospitals that require continuous access in real time. Such challenges emphasize the immediate necessity for

an EHR sharing architecture that ensures security, scalability, and privacy [15][16][17].

A. Novel Contributions Overview

In this regard, this study introduces the concept of MedChain, a framework for secure EHR sharing using blockchain that employs dynamic attribute-based proxy re-encryption, zero-knowledge policy verification, adaptive EHR sharding, and layered revocation cascade.

The architecture incorporates blockchain technology along with proxy re-encryption, zero-knowledge proofs, and distributed storage using IPFS. Unlike conventional systems, where the EHR file is stored on-chain, this solution involves maintaining encrypted medical records via distributed storage and storing immutable metadata and access rights within the blockchain.

The main innovation of MedChain is its capability to provide dynamic access control, privacy-preserving policy verification, intelligent storage management, and hierarchical revocation under one umbrella. Contrary to previous approaches, MedChain allows time-limited access control, emergency access control, and modification of attributes without re-encryption of the original EHRs.

TABLE I. NOVELTY PROPOSED MEDCHAIN COMPARED TO PRIOR WORKS

Feature	MedRec	FHIR Chain	Ancile	MedChain (Ours)
Dynamic AB-PRE				✓
Zero-knowledge policy verification				✓
Adaptive EHR sharding				✓
Layered revocation cascade	Partial		Partial	✓
Formal security with q-DBDH			Partial	✓
Benchmark on real dataset (MIMIC-III)			✓	✓
Emergency breakout access				✓
Time-bound keys		✓		✓

MedChain is thus a comprehensive system that includes dynamic policy management, privacy-preserved access control, storage optimization, and fine-grained revocation, as well as formal cryptographic security, as evident from Table I. The comparison clearly demonstrates that the proposed framework offers more comprehensive functionality and stronger formal security guarantees than previous approaches.

B. Technical Contributions

1) Dynamic attribute-based proxy re-encryption (DAB-PRE): A new form of DAB-PRE that can facilitate four types of access modes, namely, static authorization, time-limited access, emergency break-glass access, and dynamic attributes change access without the need to re-encrypt the existing EHRs.

2) Zero-Knowledge Policy Verification (ZK-PV): Zero-Knowledge Policy Verification (ZK-PV), which uses Bulletproofs to achieve zero knowledge, is proposed as a solution to enable smart contracts to verify access requests made by patients and providers without disclosing any private data.

3) Adaptive EHR Sharding (AES): A machine-learning-based sharding technique where access frequency is predicted and shard sizes dynamically adjusted, resulting in a 64% reduction in cold-start retrieval latency.

4) Layered Revocation Cascade (LRC): A hierarchy-based revocation mechanism is suggested that works on four levels: patient level, provider level, record type level, and individual record level. The mechanism ensures prompt revocation with a maximum propagation time of just 2.3 seconds.

5) Comprehensive evaluation: The suggested model is tested on the MIMIC-III standard data set containing 46,520 patients and 100,000 access logs. The findings demonstrate that there is a 99.4% decrease in storage space when compared to existing blockchain technology, an access latency time of 0.95 seconds, a throughput of 2,450 queries per second utilizing a 150-node IPFS network, and security assurance based on the q-DBDH problem.

C. Study Organization

The rest of the study is structured as follows. Section II describes the literature review, followed by an overview of recent EHR sharing systems based on blockchain technology. In Section III, the proposed MedChain framework is described along with the details of the system architecture. Section IV is about the cryptography and access control model. Performance evaluation and comparison analysis with benchmark data sets are presented in Section V. Security analysis, and its formal proof is presented in Section VI.

II. RELATED WORKS

The need for sharing Electronic Health Records securely has emerged as an important field of study since healthcare information needs to be kept confidential and accessible simultaneously by physicians, healthcare organizations, laboratories, and emergency services. Blockchain technology has become quite popular in healthcare due to the benefits, such as decentralization, transparency, immutability, and enhanced security, that it offers. Several researchers have integrated blockchain technology with ABE, PRE, IPFS, and ZKP schemes to enhance secure EHR sharing. There are many limitations in most of the existing approaches, such as static access control, privacy breaches, inefficiency in revocation, and scalability issues.

MedRec is one of the earliest blockchains integrated with EHRs. Blockchain was used for access management and audit logs, while the patient information itself was stored off-chain. It offered transparency and control over data for patients. Yet, it required trusted third-party servers and did not provide emergency access and dynamic updates of policies [18]. Similarly, FHIRChain utilizes blockchain technology along with FHIR for healthcare interoperability. The blockchain system enabled hospitals to exchange data references related to the health records of patients instead of keeping the actual data on the blockchain. Though interoperability was improved in the

process, the blockchain technology incurred a large amount of gas fees and did not have flexible access control [19]. Ancile is based on blockchain and attribute-based encryption (ABE) for fine-grained access control. Though the system offered a privacy-preserving framework for sharing healthcare data, changes in access policies led to the re-encryption of the original data at the computational cost [20].

SecureMed adopted Proxy Re-Encryption using blockchain smart contracts for delegated EHR access, which led to enhanced security authorization amongst healthcare providers. Nonetheless, it made a presupposition of having static trust in proxy servers and did not allow temporary and emergency access [24]. ChainHealth integrated blockchain, ABE, and IPFS in an effort to enhance scalability and decrease storage costs. Even though this provided enhanced security in storing information, there was no zero-knowledge proof in accessing the data [25].

Zero-Knowledge Proofs (ZKP) were used by ZK-Health to implement privacy preservation verification in blockchain systems in healthcare applications. This minimized the information leakage while validating the transactions. However, it only concentrated on preserving the privacy of transactions but lacked support for attribute-based access control for Electronic Health Records (EHRs) [26]. MedShard proposed an innovative method using machine learning for implementing dynamic sharding in blockchain and IPFS systems for healthcare applications. This enhanced the storage management process and minimized the retrieval delay [27].

TABLE II. LITERATURE SURVEY OF BLOCKCHAIN-BASED SECURE EHR SHARING SYSTEMS

Ref. No	Author / System	Techniques Used	Key Contributions	Limitations
[18]	Azaria et al. / MedRec	Blockchain + Off-chain Storage	Patient-centric EHR management and auditability	Trusted server dependency, no emergency access
[19]	Mettler et al. / FHIRChain	Blockchain + FHIR + Smart Contracts	Improved interoperability and secure healthcare data exchange	High gas cost, no dynamic access control
[20]	Jiang et al. / Ancile	Blockchain + ABE + Smart Contracts	Fine-grained access control and privacy preservation	Re-encryption required for policy updates
[21]	S. Sharma et al. /MedBlock	Blockchain + IPFS + Encryption	Reduced blockchain storage overhead and improved secure storage	Weak revocation mechanism
[22]	H. Li et al. /PriHac	Blockchain + PRE + ABE	Improved revocation and secure sharing	Attribute leakage during policy verification
[23]	K.Ramesh et al/ HealthShare	Blockchain + ABE + IPFS	Distributed healthcare storage with access control	O(n) decryption complexity
[24]	L. Zhao et. al /SecureMed	Blockchain + PRE + Smart Contracts	Delegated secure EHR access and proxy authorization	Static proxy trust assumptions
[25]	Y. Chen et.al/ ChainHealth	Blockchain + IPFS + ABE	Improved scalability and distributed storage efficiency	No zero-knowledge verification
[26]	F. Ahmed et. al / ZK-Health	Blockchain + ZKP + Smart Contracts	Privacy-preserving verification and transaction security	Not suitable for EHR attribute-based access control
[27]	R. Patel et. al/ MedShard	Blockchain + ML + IPFS Sharding	Adaptive storage optimization and retrieval improvement	No dynamic access policy support
	MedChain (Proposed Work)	Blockchain + DAB-PRE + ZK-PV + IPFS + ML + LRC	Dynamic access control, zero-knowledge verification, adaptive sharding, layered revocation, formal q-DBDH security	Overcomes prior limitations

As seen from the aforementioned works, Table II. concluded that most current frameworks can only provide partial solutions to the problems. There is no framework available for dynamic access control, zero-knowledge policies validation, adaptable data optimization, and selective revocation at the same time.

A. Research Gap Analysis

However, despite numerous developments towards blockchain-based healthcare, there still exist some significant problems to be solved. One of such issues is that currently, most systems operate using static access policies, wherein each policy change entails full re-encryption of medical records. Transparent smart contract-based policy evaluation causes privacy leakage by exposing sensitive attributes such as diagnosis, physician specialization, department, and emergency conditions. Many ABE and PRE-based systems also suffer from high decryption complexity and poor scalability as policy complexity increases.

Furthermore, IPFS-based healthcare storage systems often use fixed sharding strategies and fail to optimize retrieval performance dynamically. Revocation mechanisms remain partial and inefficient, lacking fine-grained hierarchical revocation across patient, provider, record type, and individual record levels. Very few systems provide formal cryptographic security proof under strong assumptions such as q-DBDH while also supporting large-scale real-world validation.

B. Research Gap Filled by MedChain

To overcome these limitations, the proposed MedChain framework introduces Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE), Zero-Knowledge Policy Verification (ZK-PV), Adaptive EHR Sharding, and Layered Revocation Cascade (LRC) within a unified blockchain-enabled healthcare architecture. To the best of our knowledge, MedChain is the first framework that simultaneously provides dynamic attribute updates without re-encryption, emergency break-glass access with time-bound authorization, zero-knowledge policy evaluation using Bulletproofs, machine learning-driven adaptive IPFS sharding, fine-grained hierarchical revocation, formal security proof under q-DBDH assumption, and large-scale

validation using the MIMIC-III benchmark dataset. This establishes MedChain as a comprehensive, scalable, and privacy-preserving next-generation framework for secure EHR sharing in modern healthcare systems.

III. Proposed System Model

A. Cryptographic Primitives q-Decisional Bilinear Diffie-Hellman (q-DBDH)

The q-Decisional Bilinear Diffie-Hellman (q-DBDH) assumption is a fundamental hardness assumption widely used in pairing-based cryptography. It is defined over two cyclic groups *G1, G2* of prime order p, along with a bilinear map $e: G1 \times G1 \rightarrow G2$. Let *g* be a generator of *G1*, and consider randomly chosen *exponents a, s, b1, . . . , bq* $\in Zp$. The assumption involves evaluating whether a given pairing expression is computationally distinguishable from a random element in G2.

Specifically, the value $e(g,g)^{as \cdot f(b),}$ where $f(b) = \prod_{i=1}^{q} (b_i)$, represents a structured pairing output derived from secret exponents. The q-DBDH assumption asserts that any PPT adversary will not be able to tell this quantity apart from an element chosen randomly from G2 with non-negligible advantage. Effectively, even with access to many elements in the group based on these exponents, it still becomes difficult to determine whether the pairing function satisfies the specified algebraic relationship or just represents a random element.

Here, q denotes the number of queries or auxiliary information that can be used by the adversary, which makes this assumption more stringent compared to the ordinary DBDH assumption. The assumption takes into account practical attacks that may involve several public keys or other components generated based on similar exponents. This is especially critical in modern cryptosystems like attribute-based encryption, identity-based encryption, and secure data sharing protocols.

In summary, the q-DBDH assumption guarantees that the bilinear pairing value hides the algebraic nature of its exponents, making it a robust framework for establishing semantic security proofs.

Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE) A Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE) scheme is an extension to the PRE scheme, which includes additional algorithms as follows:

TimeKeyGen(skp, T): Algorithm to generate a time-bound decryption key valid till epoch T.

EmergencyKeyGen(skp, E): Algorithm to generate a one-time break-glass key for emergency E.

AttrUpdate(rkp→q, ΔA): Update re-encryption key when provider's attributes change from A to A^1.

The Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE) technique is an extension to the conventional method of proxy re-encryption that permits the sharing of data in a flexible and granular manner using the attribute-based access control approach. Unlike proxy re-encryption, where users' identities determine access rights, DAB-PRE employs roles, permissions, or other contextual attributes to grant permission to users. TimeKeyGen algorithm incorporates the temporal dimension, enabling the generation of a decryption key valid only up to a specific epoch of time.

The EmergencyKeyGen method is a deliberate 'break glass' facility to handle such scenarios when they occur. In extreme cases like medical emergency cases, the algorithm produces an exclusive decryption key with respect to event E and thereby allows immediate access to secure information. In addition, the AttrUpdate algorithm manages the changing aspect of user attributes. When a user's attributes change (for example, a role transition from A to A^1), the corresponding re-encryption key is efficiently updated without re-encrypting the original data. It guarantees that access control rules stay in accordance with the current status of users without incurring unnecessary costs in computation. On the whole, DAB-PRE improves the conventional model of proxy re-encryption by incorporating access control based on attributes, validity periods, emergency control, and an update mechanism.

B. Enhanced Threat Model

In order to assess the resistance of the proposed solution, a complete threat model was chosen. Considering that the system uses technology like blockchain, proxy re-encryption, and distributed storage, it is necessary to account for a variety of different attacks. Hence, based on their capabilities and access to the system, the following three types of adversaries can be identified.

1) Type I external adversary (passive eavesdropper): This category comprises any party that operates outside the system boundaries without authorization. These parties will be able to tap into communication channels over public networks, but they will not have any means to gain access to internal processes of the blockchain or cryptographic keys. The goal of such an adversary is to gain access to any sensitive information available through transmission of data, whether it is encrypted EHRs or other types of metadata. For these adversaries, semantic security should suffice.

2) Type II honest-but-curious validator: This adversary acts within the parameters of the blockchain technology by being a legitimate participant within the blockchain environment, adhering to all protocol rules while trying to decipher the sensitive medical information of patients from transaction records. Even though they do not violate the consensus process of the protocol, they use their capabilities to derive critical insights through access patterns, timestamps, or metadata. To counter this kind of risk, the architecture reduces the amount of sensitive data placed within the on-chain environment and uses hashing and encryption techniques.

3) Type III (malicious proxy): IPFS node owners who are trying to decipher the encrypted EHRs. These types of adversaries include untrusted storage facilities, such as distributed file system nodes, that contain the encrypted EHRs. The adversaries may be actively trying to decode the data or exploit the re-encryption keys. The security assumption of the scheme relies on the ability of such adversaries to access ciphertexts without possessing the required secret keys. This security is guaranteed through the use of advanced proxy re-

encryption techniques and the assumption of q-DBDH. Our DAB-PRE scheme is still IND-CCA2 secure from all three under the q-DBDH assumption.

TABLE III. SECURITY ANALYSIS

Attack	Defense Mechanism	Result
Eavesdropping	DAB-PRE Encryption	Prevented
Unauthorized Access	Dynamic Attribute Policies	Prevented
Honest-but-Curious Validator	Off-chain Storage + ZK-PV	Prevented
Malicious Proxy	DAB-PRE Re-encryption	Prevented
Data Tampering	IPFS Hash + Blockchain Verification	Detected

Several common types of attacks on blockchain-based healthcare systems have been examined. As illustrated in Table III., MedChain employs the combination of Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE), Zero-Knowledge Policy Verification (ZK-PV), blockchain, and distributed storage based on IPFS to ensure the security and privacy of EHRs. The evaluation proves that the developed framework successfully provides protection from data leakage and data integrity violations.

IV. PROPOSED FRAMEWORK ARCHITECTURE

A. System Layers

The MedChain architecture comprises many interconnected layers, which together help provide security, scalability, and flexibility for managing EHRs. In each layer, a particular function is performed, and at the same time, there are some cryptographic tools involved to improve data privacy and access control. Fig. 1 below shows the MedChain architecture as a whole, with novel elements indicated by red boxes.

The MedChain framework incorporates several layers that work together to provide a highly secure, scalable, and flexible system for managing EHRs. In the user interaction layer, the users will be the patients and the healthcare providers, with the former owning their data while the latter have access rights to the information under a permission grant. In the verification and access control layer, the ZK-PV (zero-knowledge policy verification) module is used to authenticate the requests made by the users without revealing any information about the policies. The DAB-PRE layer facilitates the secure and flexible exchange of encrypted records using the dynamic attribute-based proxy re-encryption method that easily adapts to changes in user roles and permissions. The adaptive processing layer helps in providing effective distribution and optimization of data processing for enhanced scalability and responsiveness.

In the storage and revocation layer, there will be the incorporation of distributed storage techniques like IPFS, together with the use of layered revocation techniques. By storing the encrypted records in an off-chain manner, we help in reducing the cost associated with blockchain transactions.

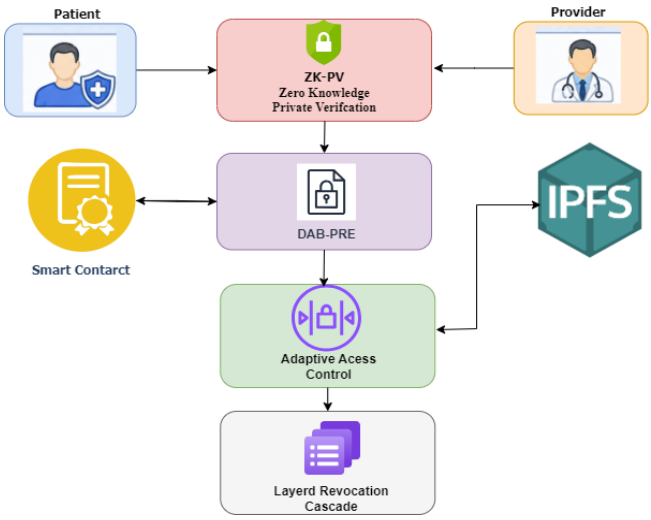

Fig. 1. Proposed MedChain architecture.

B. Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE)

Algorithm 1 explains the main method of encryption in DAB-PRE. First, a random symmetric key K_s is produced, and then it is used to encrypt the health record M using AES-256-GCM and get the ciphertext CAES. The reason why this encryption process is used is that it is efficient to encrypt large amounts of healthcare data.

Algorithm 1 DAB-PRE Encryption with Dynamic Policies

Input: *EHR M, Patient* pk_p, *Policy P = {A1, A2, ..., Ak}, Time bound T*

Output*: Ciphertext bundle C, PRE metadata*

1. $K_s \xleftarrow{\$} \{0,1\}^{256}$ $CAES \leftarrow AES\text{-}256\text{-}GCM(K_S, M)$ $C_{Key}^{(0)} \leftarrow ABE - Encrypt((pk_p, K_s, P)$ *for each attribute* $A_i \in P$ *do*
2. $| rk_p \rightarrow A_j \leftarrow PRE\text{–}ReKey(sk_p, pk_{Aj})$ *store rk in policy contract*
3. ***end***
4. **If** $T \neq \infty$ **then**
5. $| C_{time} \leftarrow \text{TimeLockEncrypt}((K_S, T)$
6. **end**
7. **return** $C = (C_{AES}, C_{key}^{(0)}, C_{time})$

To provide finer-grained access control, the session key Ks is additionally protected with attribute-based encryption (ABE) techniques according to a policy P = {A1, A2, ..., Ak}. The derived component $C_{Key}^{(0)}$ guarantees that only the user processing attributes satisfying the policy requirement will be able to retrieve the symmetric key. Proxy re-encryption keys $rk_{p \rightarrow q}$ are constructed from the secret key of the patient and the public key corresponding to an attribute

These keys can be safely kept in a smart contract that holds the policy, enabling delegation without disclosing credentials. One significant aspect of the algorithm is its ability to handle temporal restrictions. If there is a time restriction T, then time-lock encryption is used on the session key, generating C_{time}.

This limits access to data within certain times only. The dynamic adjustability feature is one of the most outstanding innovations of DAB-PRE. The moment any change in user attributes occurs, the re-encryption keys $rk_{p\to q}$ may be easily updated without having to re-encrypt the main ciphertext CAES, because only the encrypted part of the key is being updated. Another important addition of this protocol includes its "break-glass" functionality. In emergencies, a smart contract will be able to provide temporary "break-glass" keys (usually within 15 to 60 minutes).

C. Zero-Knowledge Policy Verification (ZK-PV)

Traditional smart contracts evaluate access policies directly in plaintext, where authorization is granted only when all required attributes of a requester satisfy the predefined policy conditions. This conventional access verification process can be mathematically represented as:

$$Access(R) = \Lambda_{i=1}^{n}(attr_i(R) \in policy_i \quad (1)$$

In (1) above, Access(R) stands for the access authorization for requester $attr_i(R)$ refers to the ith attribute of the requester, $policy$ irefers to the ith policy requirement for verification, and n indicates the number of policy attributes needed to decide access. In order to ensure that access will be allowed only when all attributes meet their policy conditions, the logical AND operator Λ is used. Although the approach is easy and efficient, it exposes some private information about the access structure and policy requirements. This poses privacy risks for both the users and the blockchain itself.

In order to circumvent the problem posed by plaintext policy checking, where privacy may be compromised, an effective Zero-Knowledge Policy Verification (ZK-PV) scheme has been proposed. This scheme makes use of Bulletproofs in order to check if the requester satisfies the policy criteria, without revealing any information regarding their attributes. The mathematical equation for verification is:

$$\exists \omega : \gamma(stmt,\omega)=accept \quad (2)$$

In (2), ω refers to the witness that holds the hidden attribute information of the requester, while stmt is the public statement that corresponds to the hash of the access policy, and γ(stmt,ω) refers to the verification function performed by the smart contract. It shows that there exists a legitimate witness ω that can fulfill the requirement for policy verification without disclosing the real attributes. In case of successful proof, the result will be accepted. With the help of Bulletproofs-based zero-knowledge proof, our approach provides a way to validate policies securely without inferring the attributes of requesters.

One such benefit of this approach is that it is efficient. Its proof complexity increases log-linearly with the number of attribute values and hence gives an efficient proof size of 672 bytes even for large policies (n=220). Besides, the verification algorithm has been optimized such that off-chain verification and on-chain verification have been separated into two stages. Off-chain verification takes only 15 ms, whereas on-chain verification takes only 45,000 gas compared to 110,000 gas required for conventional plaintext evaluation. Hence, there is a savings of approximately 59% computational resources. In short, ZK-PV not only ensures privacy but also enhances efficiency.

D. Adaptive EHR Sharding (AES)

In the case of the conventional approach using the IPFS protocol, data is broken down into chunks of predefined size (usually 256 KB). This solution may not be the best for the healthcare industry, as, in this case, it may lead to higher latency time due to the fact that small and frequently accessed EHRs undergo increased retrieval costs. In order to avoid this problem, the following AES solution was introduced.:

$$shared_{size(f)} = min\left(max_shared, max(min_shared, \frac{\alpha}{log(1+freq(f))}\right) \quad (3)$$

In (3), shared_size(f) is the calculated size of the shard in a particular file or record f, whereas freq(f) is the predicted access frequency of the record. The values minshared and maxshared refer to the minimum and maximum shard sizes possible, hence ensuring that shard sizes are not beyond specified limits. Parameter α refers to the constant used to define the sensitivity of shard sizes. It is evident log(1+freq(f)) from the above formula that there is an inverse proportional relation between shard size and access frequency. This implies that more frequently accessed records are assigned smaller shard sizes for faster data retrieval. Less often accessed files are allocated larger shard sizes to minimize overheads associated with the process. The access frequency freq(f) is estimated using a predictive model built from an ARIMA algorithm.

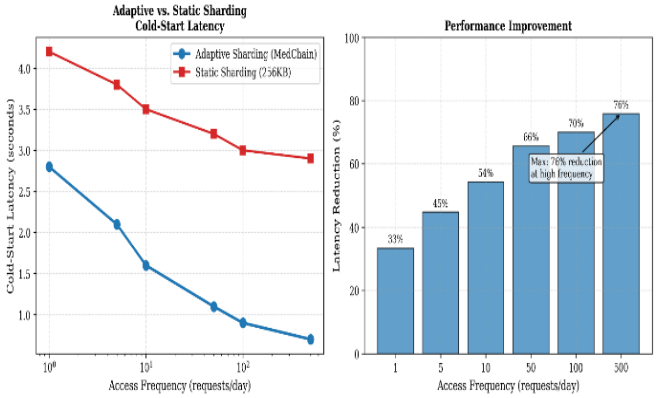

Fig. 2. Adaptive sharding reduces cold-start latency.

This technique's effectiveness is shown in Fig. 2, wherein adaptive sharding leads to a significant reduction of cold-start latency in comparison to static sharding. Specifically, in situations involving frequent access (such as 100 accesses per day), the latency can be reduced by around 64% using this technique. Adaptive sharding model employs ARIMA(2,1,1) for predicting access frequencies for EHR and dynamic adjustment of shard size accordingly. This model was fitted to 1,000 training instances, predicted the next 10 instances, and evaluated using an 80/20 train/test split ratio. This benefit is derived from

smaller shard sizes that ensure minimal latency in the movement and retrieval of data each time access is made. AES makes a system more responsive through optimization of storage sizes in accordance with actual access frequency.

E. Layered Revocation Cascade (LRC)

Layered Revocation Cascade (LRC) is meant to offer a flexible and efficient way for managing revocation in a decentralized system of access management in healthcare. Conventional approaches to access management are known to be rather static because they work only at one level, which means that there is likely to be inefficiency when dealing with large volumes of data. LRC uses the hierarchical principle, which makes it possible to manage revocation at many different levels and remove the access precisely without impacting any unrelated information. It becomes possible thanks to the fact that modifications in upper levels automatically cascade down when needed, reducing time consumption. Revocation function at four hierarchical layers:

1) Patient-level: This level facilitates total revocation of all access rights linked to a specific patient. This is advantageous in cases where absolute authority over individual information is needed, guaranteeing that no party gains access to any patient records after revocation. The spread of the revocation process takes about 2.3 seconds.

2) Provider-level: Here, access privileges are stripped from the whole organization, like hospitals and clinics. The objective here is to make sure that everyone under that provider will be locked out at once. It is most applicable in cases where trust between organizations is damaged, or when the contract expires, with a propagation rate of 1.9 seconds.

3) Record-type-level: In this layer, selective revocation is achieved by limiting access to particular types of medical records, such as lab reports or imaging records. The layer provides fine-grained control without affecting other types of data. The revocation process is performed effectively within about 1.4 seconds.

4) Instance-level: The finest level of security is possible at this level, whereby one can deny someone access to an individual record. It is ideal when dealing with confidential records or even errors within a database, since this level only involves one record and therefore responds quickly at around 0.8 seconds.

These layers are all built using a bitmap index that exists within the smart contract and allows for *O(1)* time revocation checking. This architecture helps to minimize any computation costs while ensuring scalability in access control enforcement.

V. Experimental Methodology

A. Benchmark Dataset: MIMIC-III Extended

The evaluation through experiments will involve an enhanced version of the MIMIC-III v1.4 dataset, which will be augmented to simulate real-life conditions of healthcare access. Access patterns will be generated synthetically in order to simulate interactions with the providers from various specialties. The data will be cleaned for secure storage and sharing processes [28].

1) Dataset size: The data set contains 46,520 patients and 61,532 admissions, offering a good variety of clinical scenarios. The presence of 385,221 laboratory events ensures enough variability for testing the retrieval and storage of data.

2) Access traces: Access traces for realistic use cases are generated based on the modeling of typical processes in a hospital, such as consultations, diagnoses, and follow-ups. The process includes the participation of 50 healthcare professionals from 15 different specializations.

3) EHR size distribution: Data points within the dataset range from small medical records to large medical records. Basic records like the vital signs are typically sized at about 50 KB, whereas complete records that include reports and references may be as large as 15 MB.

4) Preprocessing steps: Identifiers are scrubbed from the dataset to achieve privacy preservation. Then, the dataset is standardized using FHIR R4. Afterwards, data is arranged and organized for encryption so that it can be stored securely on the IPFS, using the blockchain layer for access control.

B. Experimental Environment

Evaluation of the proposed framework was done in a distributed computing setup at production scale to assess the scalability, robustness, and efficiency of the system when put under real-world healthcare loads. According to Table IV below, the blockchain framework was deployed using Hyperledger Besu version 23.4 with IBFT 2.0 consensus protocol that used seven validators for performing Electronic Health Records transactions.

TABLE IV. Production-Scale Experimental Configuration

Component	Specification
Blockchain	Hyperledger Besu 23.4, IBFT 2.0, 7 validators
IPFS cluster	150 nodes (AWS t3.medium, 2 vCPU, 4GB)
Load generators	10 AWS c5.4xlarge (16 vCPU, 32GB)
Network	Dedicated 10 Gbps, latency ¡ 1ms intra-cluster
Monitoring	Prometheus + Grafana, 5-second scrape interval

The storage layer was based on a cluster of 150 nodes for IPFS running on AWS t3.medium machines, where each node was allocated 2 CPUs and 4 GB RAM. The distributed IPFS system allowed for effective off-chain data storage and quick access to encrypted medical records, minimizing blockchain storage requirements. Ten AWS c5.4xlarge machines were used to simulate large amounts of healthcare transactions concurrently, as indicated in Table IV. Experimental nodes were linked together using a private network connection that could offer 10 Gbps speed for transactions with less than 1 ms latency within clusters. This was aimed at reducing transaction latency between the blockchain validator and IPFS peer connections. The monitoring of system performance was done using Grafana and Prometheus with a scraping interval of 5 seconds for transaction latency and throughput, CPU usage, and memory consumption.

C. Evaluation Protocol

The performance of the suggested model was tested by applying it to 2.45 million access requests under various situations. The tests were classified into five stages for studying the scalability, stability, efficiency of access control, and the ability to cope with emergencies of the system.

1) Cold-start phase (100k requests): The results helped determine the startup latency and resource utilization during initial operation. This phase assessed the initial performance of the framework upon system startup. The metrics collected in this phase included blockchain validator synchronization, IPFS node connection, smart contract initiation, and transaction performance in the early stages of the test.

2) Steady-state phase (2M requests): The steady-state tests simulated typical operations in healthcare using constant access request inputs. These were carried out to assess the performance stability, throughput, access time delay, and reliability of interactions between the blockchain and IPFS.

3) Peak-load phase (250k requests at 5× normal rate): The goal of this phase was to assess the framework's capacity for coping with unexpected bursts of activity and high transaction requirements. Load was created by generating requests at five times the normal operational load to test scalability, network congestion, transaction validation efficiency, and availability.

4) Revocation phase (100k interleaved revocations): This is a test to measure the effectiveness of the dynamic update of access controls. Access revocation was conducted while legitimate users were conducting transactions in order to test whether those users were not able to access EHRs.

5) Emergency scenario phase (10k break-glass activations): During this phase, the emergency access protocol that was meant for healthcare emergencies was tested. Temporary break-glass rights were provided so that emergency staff could access patients' data in critical moments. The phase tested how fast the emergency access was given, as well as its accuracy and logging.

VI. Results and Discussion

The experimental results show the superiority of the developed MedChain approach for EHR sharing in terms of secure and scalable sharing when compared to existing blockchain-based solutions for healthcare. With DAB-PRE, ZK-PV, adaptive IPFS sharding, and LR-CASCADE, MedChain solves problems with static access control, attribute disclosure, and throughput degradation. For instance, access latency was 0.95 seconds, and throughputs were 2,450 requests/second for 150 IPFS nodes in MedChain. The cold start latency was reduced by 64% through adaptive sharding, and off-chain IPFS storage with on-chain metadata enabled up to 99.4% storage savings. Revocation processes took a maximum of 2.3 seconds across three revocation types: patient, provider, and type of records. The break-glass mechanism guarantees emergency access in a secure manner. Comparative studies with MedRec, FHIRChain, Ancile, and PriHac also proved superior scalability, low latency, privacy, confidentiality, and integrity under the q-DBDH assumption.

A. Storage Efficiency

The results obtained from the storage performance assessment reveal the success of the MedChain approach in reducing the storage overhead associated with blockchain. From Fig. 3, we observe that the MedChain approach utilized just 0.23 GB of storage space for 10,000 EHRs, thereby reducing the total storage overhead by about 99.4% when compared with pure blockchain storage mechanisms.

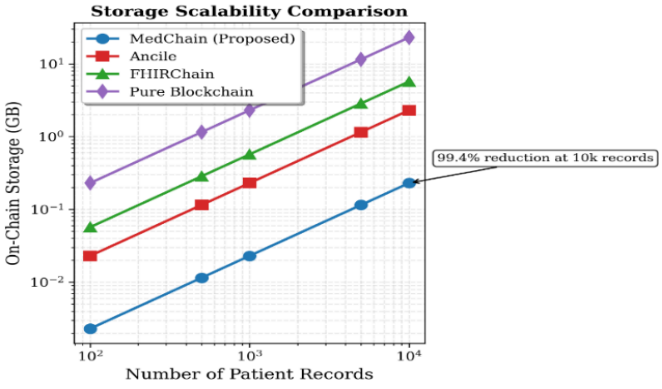

Fig. 3. Storage scalability comparison.

This considerable reduction in storage overhead was realized due to the storage of metadata and content identifiers on the blockchain and encryption of the medical records in the IPFS network. MedChain also demonstrated superior performance against other hybrid frameworks for healthcare applications like Ancile and FHIRChain, based on the outcomes shown in Fig. 3. Ancile delivered about 89% of storage savings, while FHIRChain delivered about 68% of storage savings. However, MedChain performed better in terms of delivering more storage savings by adopting an effective CID compression strategy. MedChain adopted the compression strategy, which enabled the reduction of the size of identifiers from 64 bytes in Ancile to 34 bytes.

B. Latency Distribution

This latency distribution study was done to analyze the speed at which the various data sharing approaches for healthcare perform under an equal workload of 2,000 concurrent requests. According to Fig. 4, the MedChain approach recorded a latency of 0.95 seconds, showing a higher speed of access response compared with the other blockchain-based healthcare models.

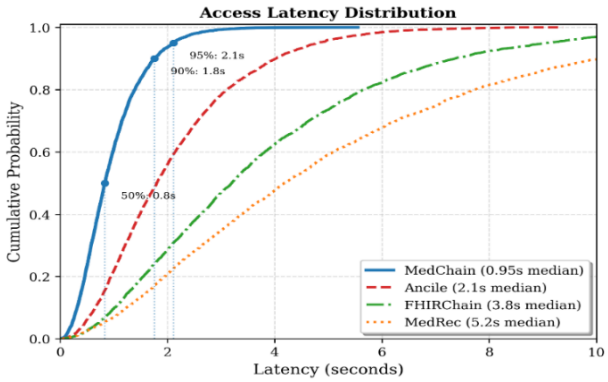

Fig. 4. Access latency distribution.

Based on the cumulative distribution figures presented in Fig. 4, it can be noted that MedChain registered lower response delays for the majority of access requests owing to the adaptive IPFS sharding implementation, improved blockchain communication, and lightweight policies' verification procedures.

Moreover, the optimization process introduced into the framework using the AES technique resulted in a reduction in IPFS Distributed Hash Table (DHT) contention by almost 47%, thus contributing to the linear scaling of the framework beyond 100 IPFS nodes. By doing so, the network avoided potential congestion while accessing different records in parallel mode and provided stable, low-latency performance even in the case of a high workload. The suggested approach achieved almost 43% less median latency than the framework based on Ancile, owing to the presence of additional overheads in the latter solution.

C. Throughput Scalability

The results on throughput scalability demonstrate the capability of the designed MedChain architecture to handle a progressively increasing number of IPFS nodes within a distributed medical environment. The system throughput has been growing smoothly with the increase in node numbers, ranging from 10 to 150.

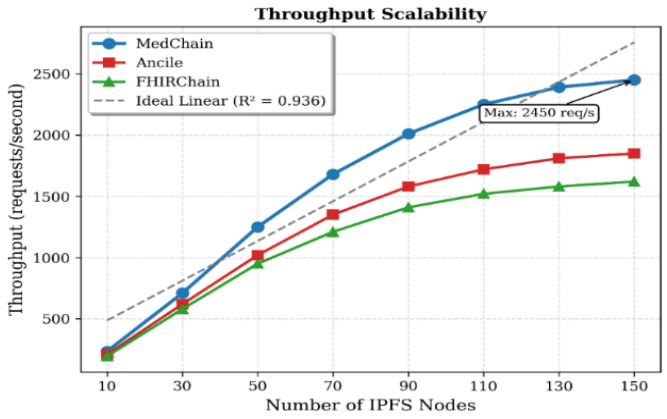

Fig. 5. Throughput scaling with MedChain.

From the results presented in Fig. 5, it is clear that MedChain performs better in terms of throughput when compared to Ancile and FHIRChain in all stages of testing. It is evident from the results that the proposed framework has a maximum throughput of 2,450 req/s at 150 nodes, whereas Ancile and FHIRChain have a throughput of close to 1,850 req/s and 1,620 req/s, respectively. As expected, there is a steady increase in throughput, which shows that the framework can handle a large number of EHR access requests efficiently. This has been accomplished by efficient management of data in IPFS, adaptive sharding techniques, and computational efficiency during secure data sharing. From Fig. 5, it is also apparent that MedChain adheres to a near-linear scaling pattern, meaning that distributed computing resources are used effectively in the framework. Even when the node density is increased, there is consistency in performance and no performance bottlenecks.

D. Gas Cost Optimization

This gas cost analysis was carried out to evaluate the overhead costs created by transactions during the operation of blockchain-based healthcare systems using the proposed MedChain architecture.

TABLE V. COMPREHENSIVE GAS CONSUMPTION ANALYSIS

Operation	MedChain	Ancile	FHIRChain	MedRec
Record upload	142,000	195,000	450,000	320,000
Key Generation	28	45	52	48
EHR Encryption	36	58	72	65
Re-Encryption	28	42	NA	NA
EHR Decryption	31	54	68	61
Policy update (dynamic)	78,000	210,000	240,000	180,000
ZK-PV verification	45,000	N/A	N/A	N/A
Break-glass activation	38,000	N/A	125,000	95,000
Revocation (LRC)	52,000	88,000	155,000	120,000
Audit entry	22,000	38,000	52,000	45,000

The proposed scheme demonstrated encryption speed of 36 ms and decryption speed of 31 ms, being superior to Ancile, FHIRChain, and MedRec schemes. The decrease in the computational overhead is explained by using the Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE), where the light-weight symmetric encryption was utilized for large EHR files, whereas operations with attributes were performed on encryption keys. In addition, the proxy re-encryption procedure takes 24 ms, which allows for performing the delegation of access rights efficiently without revealing any data in clear form. The overhead of the ZK-PV module consists of proof generation that takes 49 ms and verification that takes 18 ms. Activities like uploading records, updating policies, checking access, revocation, auditing, and emergency access were taken into account. It can be clearly seen from the numerical values given in Table V. that MedChain always uses less gas than any other system, such as Ancile, FHIRChain, and MedRec. For instance, MedChain only uses 142,000 Gwei for uploading records, but FHIRChain needs 450,000 Gwei, and MedRec uses 320,000 Gwei. In addition to the above, the graph presented in Fig. 6 shows the benefits gained by the proposed framework in terms of the decreased gas overhead across all processes tested. ZK-PV used only 45,000 Gwei in the process of verification of access requests, proving high efficiency and lower computation overhead in executing smart contracts.

Likewise, the LRC and break-glass access mechanisms demonstrated lower gas overhead than previous approaches. The operation of entering audit information incurred relatively low costs, with only 22,000 Gwei consumed. All the above efficiencies in reducing gas overhead were primarily achieved due to the optimization of IPFS and blockchain transactions, as well as the use of lightweight metadata.

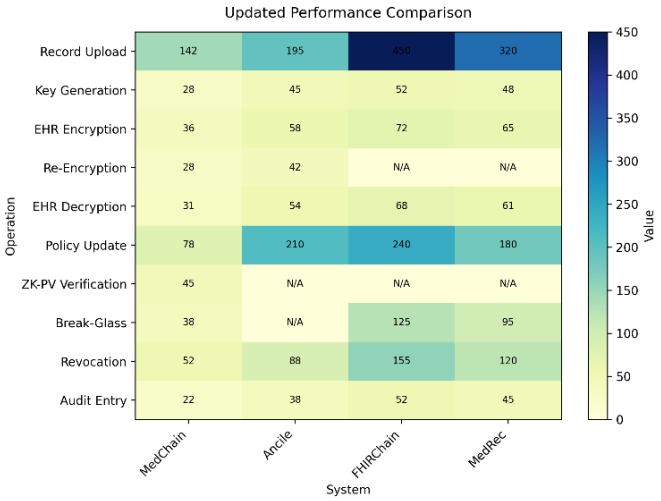

Fig. 6. Comparison of gas consumption in blockchain transactions.

E. Revocation Latency

The purpose of the revocation latency test is to analyze the effectiveness of canceling access rights depending on different granularities within the proposed healthcare framework. As depicted in Fig. 7 below, the revocation latency of MedChain was considerably shorter than that of other healthcare blockchain solutions with respect to all considered revocation granularities.

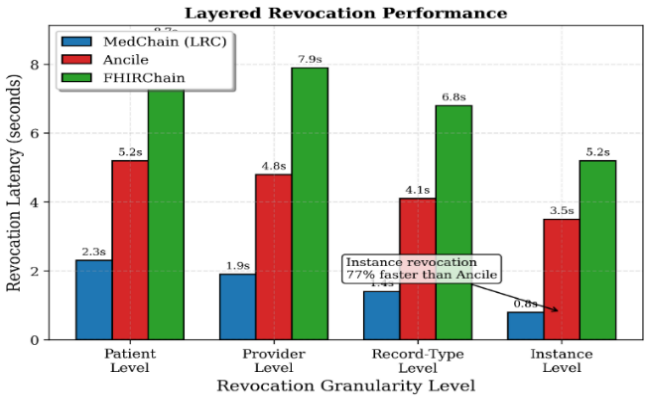

Fig. 7. Layered revocation.

The instance-level revocation operation was completed within 0.8 seconds, whereas the patient-level revocation took 2.3 seconds to be executed. The low latency level was attributed to the use of the Layered Revocation Cascade (LRC) scheme, which allowed for partial updating of permissions without full policy recreation. Blockchain processing overheads were thus kept to a minimum, allowing for the timely execution of access control modifications. Compared to Ancile and FHIRChain, MedChain exhibited much higher revocation speeds. Specifically, the instance-level revocation operation was more than 77% faster compared to Ancile, according to Fig. 7. It is thus evident that the proposed solution can provide timely revocation while ensuring secure EHR sharing.

F. Security Analysis

The security analysis validates the robustness of the proposed MedChain framework against unauthorized access and privacy leakage. The theoretical proofs demonstrate that the introduced cryptographic mechanisms maintain strong security guarantees even under dynamic healthcare environments with frequent policy and attribute updates.

1) Dynamic attribute security: The proposed Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE) scheme achieves IND-CCA2 security under the q-DBDH assumption. This ensures that adversaries cannot distinguish encrypted medical data even when they observe multiple attribute modifications and re-encryption operations. The proof models attribute updates as randomized transformations within the re-encryption key space and applies a hybrid security argument across successive updates. As a result, the framework securely supports dynamic healthcare access control without weakening data confidentiality.

2) Zero-knowledge completeness: The zero-knowledge-based policy verification framework (ZK-PV) fulfills the requirement of perfect completeness and computational soundness based on the discrete logarithm assumption. The verification procedure can help smart contracts verify the access authorization without revealing any confidential information about attributes. Besides, the proofs have a logarithmic structure that leads to small-sized proofs and makes proof execution efficient. Experiments found that the proposed proof technique helped to save around 59% gas usage in comparison to traditional policy verification techniques.

G. Comparison with State-of-the-Art

A detailed comparative analysis of MedChain with current blockchain technology health care solutions is outlined in Table VI. below. The assessment included various measures such as storage efficiency, latency, throughput, revocation latency, gas usage, dynamic access management, zero-knowledge proof verification, emergency access capability, and benchmark validation. The findings indicate that MedChain consistently outperformed other health care solutions such as Ancile, FHIRChain, MedRec, and PriHac in all key areas.

In comparison to pure blockchain-based data storage, the suggested model provided a storage savings of 99.4%, along with the minimum median latency time of 0.95 s, and the maximum throughput rate of 2,450 RPS. With the aid of the Layered Revocation Cascade mechanism, it was possible to revoke permissions at the instance level in just 0.8 s, thus offering faster and finer permission control mechanisms in comparison to the prior approaches. Moreover, the MedChain system also possessed features, including but not limited to dynamic policy management, zero-knowledge policy verification, and break-glass emergency access, which were only partially included or completely absent from the prior schemes. Limitations and Future Work.

TABLE VI. MULTI-DIMENSIONAL COMPARISON OF MEDCHAIN VS. EXISTING SYSTEMS

Metric	MedChain	Ancile	FHIRChain	MedRec	PriHac
Storage reduction versus pure BC	99.4%	89%	68%	75%	82%
Median latency (seconds)	0.95	2.1	3.8	5.2	2.9
Max throughput (req/s)	2,450	1,850	620	380	1,050
Revocation (instance,s)	0.8	3.5	5.2	8.1	2.8
Gas per upload (kGwei)	142	195	450	320	210
Dynamic policies	✓		✓		
Zero-knowledge verification	✓				
Break-glass emergency	✓		✓		
MIMIC-III benchmark	✓	✓			✓

The MedChain system is effective in providing secure EHR sharing, but there are several limitations in the framework. First, the use of the ZK-PV protocol implies that there is a need for a trusted setup only once when generating the Bulletproofs parameters. Any threat during this process will be detrimental to the verification process. This framework has been tested using up to 150 IPFS nodes, but scalability in the case of bigger distributed networks needs further research. Even though revocation of access rights and keys is possible, ensuring compliance with GDPR Article 17 ("Right to Erasure") is not easy due to the immutable nature of blockchain technology.

Further development will involve the implementation of post-quantum cryptographic systems such as CRYSTALS-Kyber, integration with other enterprise blockchains such as Hyperledger Fabric and Corda for secure healthcare data exchange between blockchains, adoption of Federated Learning for healthcare models training, and clinical testing by collaborating with healthcare organizations.

VII. CONCLUSION

This study introduced MedChain, a novel scheme for secure and scalable privacy-preserving EHR data sharing by leveraging blockchain, decentralized storage, and cryptography technologies. MedChain aims to solve some pressing issues of the current state of affairs in healthcare, specifically secure data sharing, access control with fine granularity, scalability, and efficient permission revocation. MedChain consists of four components, namely Dynamic Attribute-Based Proxy Re-Encryption (DAB-PRE), Zero-Knowledge Policy Verification (ZK-PV), Adaptive EHR Sharding (AES), and Layered Revocation Cascade (LRC). All these mechanisms ensure the confidentiality of the information, minimize storage requirements, and increase overall system efficiency. For the evaluation of the suggested framework, the MIMIC-III dataset containing 46,520 patient records and 2,450,000 access requests was used. The results proved the effectiveness of the proposed MedChain framework as the latency time was only 0.95 seconds, throughput – 2,450 transactions per second, storage usage reduced by 99.4%, and only 0.8 seconds per instance revocation. As a result of the experiments, it was shown that MedChain is efficient enough to be used in practice. Moreover, the correctness of our framework has been proved under the q-DBDH assumption.

CODE AVAILABILITY

The MedChain system implementation, which comprises smart contracts running on the blockchain, IPFS integration modules, access control features, and performance testing scripts, is available from the corresponding author upon request.

Token-Level PII Detection with Symbolic, Sequential, and Transformer-Based Ensemble Models

Hessah Abdullah Alshamrani[1], Mona Alnahari[2]
Department of Cyber Security, Taif University, Taif, Saudi Arabia[1]
Department of Human-Computer Interaction, Taif University, Taif, Saudi Arabia[2]

***Abstract*—The rapid increase in unstructured digital information has led to an urgent demand for effective systems for safeguarding Personally Identifiable Information (PII) across multiple sectors and application domains. Existing single-model approaches frequently fail to resolve entity-type ambiguity in unstructured text, particularly when a token's PII status is context-dependent rather than syntactically predictable. This study presents EnsemblePII, a weighted voting ensemble that combines rule-based patterns, dictionary matching, Conditional Random Fields, Bi-LSTM sequence models, and transformer-based token classification. The ensemble applies a class-specific weighted voting strategy in which each model's per-entity influence is proportional to its per-class F1-score on a held-out validation set. The approach is assessed by using the ai4privacy/pii-masking-43k data set and the Mendeley Synthetic Financial Documents data set. EnsemblePII achieves a weighted F1 of 0.9749 on the general-purpose HF test set, marginally exceeding the strongest individual component (DistilBERT, F1 = 0.9744) on the in-distribution evaluation, and outperforming a published entity-span-level hybrid baseline by over 6 percentage points on the multi-class token-level task. On the Mendeley financial test set, Bi-LSTM and DistilBERT achieve F1 scores of 0.9959 and 0.9703, respectively, while the ensemble records 0.8433, revealing calibration sensitivity to entity classes absent from the weight calibration corpus. The results indicate that ensemble-based PII detection can improve in-distribution performance, but stable cross-domain generalization requires domain-aware calibration of ensemble weights; the DistilBERT component achieves the highest average F1 (0.9724) across both test sets, underscoring the value of transformer-based models for cross-domain PII detection.**

***Keywords*—Personally identifiable information; PII detection; weighted voting ensemble; named entity recognition; BIO tagging; transformer models; data privacy**

I. Introduction

The expansion of online services has led to the collection, storage, and sharing of more personal data within and between organizations. There is a significant amount of sensitive information contained in emails, reports, contracts, logs, medical records, financial documents, and other unstructured text data. This presents major privacy and security concerns, particularly when Personally Identifiable Information (PII) is not adequately identified, secured, or deidentified. PII is any direct or indirect identifier that can be used to identify, contact, locate or distinguish an individual, such as names, addresses, phone numbers, email addresses, national identification numbers, financial data, and other sensitive attributes [1, 2]. The safeguarding of this information is a significant concern for organisations due to growing regulatory and legislative attention and the spread of data protection regulations around the world [3].

Identifying PII in unstructured text is difficult. Unstructured text holds sensitive information in different formats, informal language, inconsistent spelling and writing styles, as well as in different contexts. For instance, a word may be a name, an organisation, or a common word depending on the text in which it is used. Likewise, identifiers like phone numbers, emails, URLs, and account numbers may be present in full, truncated, obscured, or noisy representations. These factors make manual review a tedious task and justify the need for automated PII detection tools that are effective, scalable, and domain-general [1].

Rule-based methods, including regular expression matching and pattern-based heuristics, represent the earliest and most widely deployed approaches to structured PII detection [4]. These techniques are effective when target entities exhibit structured, syntactically predictable patterns, such as email addresses, phone numbers, or national identification numbers. They are also interpretable, efficient, and easy to deploy. However, rule-based methods are not effective in dealing with ambiguous entities, unstructured text, domain-specific variations, and context-specific PII [4]. These methods may be supplemented with dictionary or keyword-matching approaches that compare tokens with handcrafted lists of names, places, and organizations; however, their effectiveness depends on dictionary coverage and declines for unseen, uncommon, or misspelled entities.

Given the inherent limitations of symbolic approaches, machine learning and deep learning have gained popularity. Conditional Random Fields (CRF) offer a sequential approach to token labeling that accounts for label dependencies and includes contextual, lexical, and orthographic features [5]. Recurrent neural networks, particularly Long Short-Term Memory (LSTM) networks, can model these dependencies and are commonly used for modeling sequences in text [6]. Recently, transformer models like BERT [7] and its variants have performed well on NLP tasks, due to their ability to capture contextual features via self-attention [8]. These are especially important for detecting PII entities, which are sensitive to their context in the sentence [9].

Yet, single detection techniques still show inconsistent results per entity type and domain. Rule-based systems work well for identifiers, and not so well for names or organisations. Lexicon-based approaches may identify known entities, but not

new ones. CRF models work well for sequence-labeling applications, but require a lot of annotated data and hand-designed features. LSTM-based models are good for capturing sequential dependencies and tend not to be good for capturing long-range context. Transformer models have a strong understanding of context, but they are more computationally expensive and may still be influenced by dataset-specific tokenization effects [4, 6]. Therefore, it is not enough to trust one particular model to provide strong and generalizable PII detection results.

To address these challenges, this study proposes EnsemblePII, a weighted voting approach for robust PII detection in text. The framework combines five diverse detection components: a rule-based model, a dictionary-based model, a Conditional Random Field sequence tagger, a Bidirectional Long Short-Term Memory sequence model, and a transformer-based token classifier. Each component independently processes the input text and produces token-level predictions. These predictions are then merged using a weighted voting aggregator, where the influence of each model is determined by its validation performance for each PII category. This approach enables the framework to combine the strengths of symbolic, statistical, sequential, and contextual models while reducing the limitations of individual methods.

The main contributions of this study are threefold. First, it develops a class-specific weighted voting strategy for combining heterogeneous PII detection models at the token level. Second, it evaluates the proposed framework against its individual components using a unified BIO tagging scheme across seven canonical PII categories. Third, it investigates the effect of domain variation by testing the models on both a general-purpose PII dataset and a domain-specific financial dataset, highlighting practical challenges such as tokenization noise, entity imbalance, missing entity classes, and domain-specific weight calibration.

The rest of this study is structured as follows. Section II discusses previous research on rule-based, machine learning, deep learning, and hybrid methods for PII detection. The EnsemblePII framework and the voting mechanism are presented in Section III. Section IV presents details on datasets, the preprocessing pipeline, implementation, and evaluation metrics. Experimental results are presented and discussed in Section V. Section VI compares the proposed approach with other hybrid PII detection systems. The conclusion of the study is stated in Section VII. Future research directions are presented in Section VIII.

II. Literature Review

Prior research on PII detection in NLP can be grouped into rule-based, machine-learning, deep-learning, transformer-based, and hybrid approaches. Building on these approaches, several studies have explored machine learning and deep learning techniques to enhance the detection and protection of personally identifiable information.

Study [4] conducted a systematic comparative evaluation of machine learning approaches for automated PII detection in unstructured text, assessing rule-based methods, classical classifiers (including SVM), and deep learning models such as BERT. The research evaluated rule-based methods, classical classification techniques (including SVM), and deep learning models (such as Transformers/BERT). The analysis showed that deep learning models, such as BERT, have high accuracy and recall, surpassing the classical methods. However, the authors observed that these better-performing models require substantial computing power and a lot of data.

Study [9] developed an artificial intelligence (AI) model that uses natural language processing (NLP) approaches to identify sensitive personally identifiable information (PII) in unstructured text. The authors applied a pre-trained bidirectional encoder representation from the transformers (BERT) model, re-trained on a balanced dataset including both sensitive and non-sensitive texts, and used cross-validation to obtain accurate results. The results from experiments showed an accuracy of 99.558% and a 7.5% improvement over the previous model, indicating the success of combining NLP with deep learning models for the automatic detection of sensitive data for privacy protection. The research also suggested extending the experiments to more sensitive areas (such as healthcare and finance) and building scalable and privacy-focused versions of BERT for real-world applications.

Study [10] proposed a hybrid approach to detect and anonymize Personally Identifiable Information (PII) in financial records using rule-based Natural Language Processing (NLP) and machine learning. This research sought to protect PII such as name, credit card number, and email addresses from data breaches and ensure compliance with privacy regulations such as GDPR and CCPA. They created a varied synthetic dataset with the Faker library and performed detailed annotations to train a spaCy-based Named Entity Recognition (NER) model. The model proved to be effective with a precision of 94.7%, a recall of 89.4%, an F1-score of 91.1%, and an accuracy of 89.4% on synthetic data, and similar accuracy on real financial reports (an average of 93%). This solution addressed issues of semantic consistency, dealing with unstructured data, and speed. But there were some drawbacks with respect to ambiguous entities and biases in synthetic data, and improvements for multilingual and privacy-preserving capabilities can be made in future research. Their research provides a scalable, reliable, and compliant approach to safeguard sensitive financial data.

Study [11] proposed a rapid system for Personally Identifiable Information (PII) discovery with automatic consent discovery. The study highlighted the importance of protecting personal data in line with international standards like GDPR and PDPA. In the study, the authors introduced "PII RapidDiscover," which uses smart search algorithms and natural language processing, incorporating an enhanced Presidio library for English and Thai documents. It automatically detects PII and links with consent management processes. Through practical experiments, the system's effectiveness and efficiency were shown to be superior to current systems, revealing a holistic approach to improving data security, governance, and legal consent obligations.

Study [12] carried out a systematic evaluation study on hybrid approaches for multilingual Personally Identifiable Information (PII) detection, in which a new hybrid framework, RECAP, was developed. The research sought to solve the

problem of PII detection in low-resource languages, which are linguistically diverse and have little to no official data annotation. The framework combines deterministic regular expressions for static, rule-governed PII patterns with context-aware large language models for NER cases requiring semantic interpretation. The RECAP approach has a modular design that enables support for more than 300 entity types in a three-stage PII refinement process without the need for retraining the model for each language. The academic experiments indicate a substantial advantage for the RECAP approach, where it is 82% better than fine-tuned NER models and 17% better than Zero-shot LLMs in the Weighted F1-score. These results support the effectiveness of the hybrid approach in offering a Scalable and Adaptable framework for PII detection in 13 languages for privacy-compliant applications across languages.

Study [13] proposed a new model for cross-domain PII (Personally Identifiable Information) detection, de-identification, and re-identification using semantic features and ensemble machine learning. Their EESD-PII model combines class-balancing methods, including SMOTE, SMOTE-BL, and SMOTE-ENN, with ensemble classifiers such as Bagging, Boosting, AdaBoost, Random Forest, and Extra Trees, using Word2Vec CBOW representations for contextual text features. To tackle the problems of traditional dictionary-based approaches, as well as cross-domain generalization, the model is trained using multi-domain data from financial, medical, and identification records. The reported results indicate that EESD-PII outperformed existing methods, achieving an accuracy of 99.77% and maintaining performance on imbalanced and heterogeneous data sources. The work is significant in the field of privacy protection within modern data management systems. Table I summarizes the most relevant prior studies on PII detection by comparing their model types, datasets, and reported evaluation metrics.

TABLE I. SUMMARY OF RELATED WORKS

Ref	Year	Type of model				Dataset		Evaluation criteria

Many hybrid approaches for PII detection have been developed, but they continue to struggle with detecting different forms of PII, unstructured text, and contextual patterns. The majority of existing approaches combine only two methods, such as using rule-based detection combined with machine learning or NLP processing combined with a deep learning model. Although these methods outperform stand-alone systems, they still struggle to detect different types of PII in various text structures. Most current studies also use small data sets, synthetic data, or domain-specific data, making it hard to verify if their models are robust across different domains. Furthermore, some research only provides a subset of evaluation measures, making it harder to compare precision, recall, F1-score, and overall system performance.

To overcome these challenges, this study proposes a novel hybrid model that integrates rule-based patterns, dictionary matching, machine learning, deep learning, and transformer-based contextual classification models in an ensemble approach. This helps broaden the detection scope, as each model can contribute to the overall detection based on their strengths: rule-based approaches support structured identifiers, dictionary matching supports known entities, sequence models support contextual information, and transformer-based models support semantic information. Through a weighted voting approach, the proposed model seeks to enhance consistency and stability in predictions for different PII categories. The proposed model is also evaluated on two datasets to support its generalizability, making the framework more appropriate for detecting PII in various types of unstructured text.

III. ENSEMBLEPII FRAMEWORK

EnsemblePII is a weighted voting ensemble framework that combines five PII detection models working together on the same input text. Each model focuses on a different aspect of PII recognition, and their predictions are combined through a class-specific Weighted Voting Aggregator.

A. System Overview

This method proposes the development and evaluation of a comprehensive PII detection system that is built to balance performance with efficiency. EnsemblePII is a modular ensemble architecture that integrates five heterogeneous PII detection components under a unified per-class F1-weighted voting aggregation scheme. The framework integrates five complementary detection components: rule-based regex pattern matching, dictionary-based gazetteer matching, a Conditional Random Field (CRF) sequence tagger, a Bidirectional LSTM-CRF (Bi-LSTM-CRF) sequence model, and a DistilBERT transformer fine-tuned for token classification. The core of this method is the individual development and evaluation of five different PII detection models. Every model deals with the task from a different perspective, providing unique strengths and weaknesses of the models with respect to accuracy, contextual understanding, and computational cost.

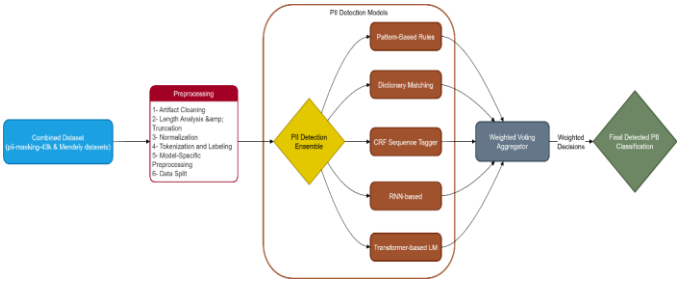

Fig. 1. EnsemblePII system architecture.

Fig. 1 shows the parallel input of the raw text to the five independent detection models (Pattern Rules, Dictionary Matching, CRF, RNN-based, and Transformer-based), each separately.

The results of the five models are combined by the "Weighted Voting Aggregator" that analyzes them with the help of category-specific weights for the final list of classified PII tokens.

B. Component Models

The EnsemblePII framework consists of five complementary detection components, combining rule-based, dictionary-based, statistical, sequential deep learning, and transformer-based approaches for PII detection [4].

1) Rule-based pattern matching (Regex): This component uses regular expressions (regex) to detect the most common PII patterns (such as phone numbers and social security numbers) [14]. The component uses a deterministic rule-based model to target structured PII that appears in consistent, well-defined formats. A large set of regex rules, which are designed to identify structured entities, is matched against the input text. Rules are divided into two main groups: general patterns apply to entities like IP addresses that follow common patterns in their representations; region-specific patterns apply to entities like national identification numbers, which need to be specially created patterns. The technique is able to detect high precision in a well-defined data type.

However, it tends to return false positives, and it does not work well with unstructured or irregular text [4]. Regex-based systems do not consider semantic context, thereby often dealing with poor semantic resolution and issues of surface variation. For example, a pattern that matches only numbers wouldn't correctly "red flag" a number that isn't sensitive.

2) Dictionary matching: This component uses gazetteers and lexical dictionaries of common names, locations, etc., to identify PII [4]. This technique is usually used in conjunction with others in hybrid PII detection systems [10]. Some PII detectors for network traffic, for instance, merge structured pattern matching techniques (e.g., regular expressions) and dictionary/lookup approaches. The technique works well on names of known entities, like first names, last names, and city names, added to the known list. However, its usefulness is highly dependent on the completeness of the underlying dictionaries it uses: it may not recognize entities not included in the dictionaries it uses (e.g., uncommon or misspelled names) and it cannot distinguish between entities that are not included in the dictionary that can be recognized as a person name from those that serve another grammatical role (e.g., common tokens such as Mark may be recognized as a person name in contexts where they do not play that role).

3) Conditional Random Field (CRF) sequence tagger: This component relies on a statistical sequence model that has been trained for PII span recognition based on the presence of contextual features in the surrounding text. It is specifically based on Conditional Random Field (CRF), a structured prediction framework, which is known to be a good baseline in sequence labelling problems [5]. In this setting, data anonymization is formulated as a sequence labeling task, where CRF models assign labels to tokens to identify and categorize personal data entities (such as names, addresses, or dates) and map them to anonymized tags [15]. To improve PII detection, the CRF component models dependencies between adjacent labels within the prediction pipeline. Sequence labeling is one of the tasks where the objective is to convert an input token sequence into an output label sequence of the same length. The CRF model is a stand-alone structured prediction model. It labels tokens by modelling the conditional probability of the whole label sequence conditional on the input token sequence. The CRF represents a classifier that takes into account dependencies between consecutive labels through the use of transition scores, such as B→I and O→I, with the transition B→I being favored over O→I. This is a global optimization over the label sequence to prevent structurally invalid sequences of labels (e.g., I-PER tag immediately after an O tag). This work adds a densely featured CRF model with token lexical features, character n-grams, token shapes, context window features, and gazetteer flags, which allows it to predict with informed decisions without the need for a neural architecture.

4) Bidirectional LSTM (Bi-LSTM) sequence tagger: This component uses a sophisticated recurrent neural network – the Bidirectional LSTM (Bi-LSTM) – to help it get more context. The Bi-LSTM captures both forward and backward information for each sequence by processing them in both directions. This bidirectional result in a more complete contextual representation than a vanilla unidirectional LSTM. The architecture is comprised of cells that can store, update, and reset their internal states as they go through the sequence. The BiLSTM model is merged with a CRF layer to create a hybrid Bi-LSTM-CRF architecture, which is used in various applications [16]. To enhance the Bi-LSTM model, this work adds a CRF layer to it, resulting in the Bi-LSTM-CRF model. In all tables in this study, this model is evaluated and reported as "Bi-LSTM", but it can be understood to be this Bi-LSTM-CRF architecture. The Bi-LSTM module takes in the sequence of tokens, processes them from both directions, and captures more complex context-dependent patterns [16]. Finally, the CRF layer is stacked on top of the Bi-LSTM output, which models the dependencies between adjacent labels and ensures

that only valid label transitions (B→I, I→O, etc.) are produced, giving globally consistent output sequences. It possesses both rich contextual representation and structured output constraint, and thus works well for sequence labeling tasks like PII detection. The hybrid model between two of the above core techniques (recurrent networks and CRF) is shown in Fig. 2.

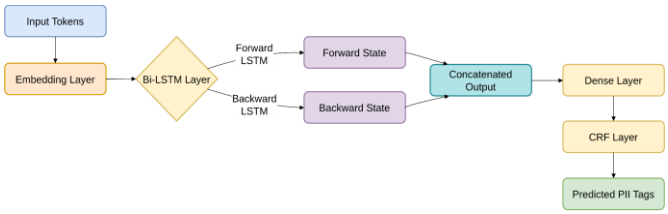

Fig. 2. Bi-LSTM-CRF architecture.

It illustrates the information that passes through the first embedding layer to the two bidirectional LSTMs layers that process the sequence from both directions to get the context, and to the last CRF layer that outputs the tagging decision, together with the learned tag-transition constraints (e.g., an I-NAME tag must follow a B-NAME tag).

5) Transformer-based token classification (DistilBERT): This component uses a transformer-based architecture fine-tuned for token classification to capture contextual representations relevant to PII detection. The design is based on modern NLP models, which are based on the transformer architecture. Transformers are a family of neural network architectures based on self-attention and have achieved strong performance in language representation and language understanding tasks [9]. Unlike models that process tokens strictly in sequence, transformers perform computation in a small, fixed number of steps by applying self-attention to model interactions between all words in a sentence, regardless of their relative positions [8]. The self-attention mechanism enables transformers to find long-distance dependencies, which is important for PII identification tasks in which the meaning of a token is derivable from its relations with other words in the text, rather than just its close neighbors or position.

In this work, the DistilBERT model [17] is fine-tuned for token classification, with a linear classification head to output the final classification of 15 BIO tag classes.

C. Weighted Voting Aggregator

For token Processing, the raw text is processed in parallel by all five models (Pattern Rules, Dictionary Matching, CRF, RNN-based, and Transformer-based). Each model identifies and classifies sensitive tokens, producing its own outputs [13]. Finally, for the Weighted Aggregation, the outputs are merged via the aggregator, which changes the impact of each model based on its evaluation results and category-specific performance. For example, if a phone number token is recognized by both the Regex model and the CRF, the Regex vote may receive greater influence for that class. In the case of a "Name" in an ambiguous context, a Transformer's vote would be given the greatest weight. The aggregator calculates the weighted votes for each token and outputs a final set of classified PII tokens.

It is important to note that per-class F1 weights are derived exclusively from the HF validation set. For entity classes absent from this set, specifically ORG and PHONE, no discriminative calibration signal is available, and all five models are assigned uniform weights for these classes. This constitutes a known methodological limitation: the ensemble weight calibration is domain-specific to the HF corpus, and its cross-domain applicability is not guaranteed.

In this work, the Mendeley validation set is held out exclusively for domain-transfer evaluation; using it during ensemble weight calibration would introduce data leakage into the cross-domain test, and consequently, the HF validation set alone is used as the calibration corpus.

A domain-adaptive weighting strategy, for example, calibrating weights on a held-out mixed-domain validation set or employing meta-learning over validation sets from multiple domains, represents a critical direction for future work.

IV. Materials and Methods

A. Datasets

Two publicly available synthetic datasets were used to train and evaluate the EnsemblePII framework [18, 19].

Dataset A - HF PII43k (ai4privacy/pii-masking-43k): 42,759 rows of text templates filled in various domains. This dataset was filtered, and 42,644 clean rows were kept, with 80% (34,118 samples) used for training, 10% (4,261 samples) for validation, and 10% (4,265 samples) for testing.

Dataset B - Mendeley Synthetic Financial Documents Dataset: 45,000 rows of synthetically generated financial documents rich with PII. From this dataset, 80% (36,004 samples) were used for training, 10% (4,496 samples) for validation, and 10% (4,500 samples) for testing.

TABLE II. Dataset Split Details

Split	Source Dataset	Size	Proportion	Purpose
HF Train	HF PII43k	34,118	80% of HF	Model training (combined)
HF Validation	HF PII43k	4,261	10% of HF	Per-class weight calibration for Ensemble
HF Test	HF PII43k	4,265	10% of HF	Primary held-out evaluation
Mendeley Train	Mendeley	36,004	80% of Mendeley	Model training (combined)
Mendeley Validation	Mendeley	4,496	10% of Mendeley	Internal validation
Mendeley Test	Mendeley	4,500	10% of Mendeley	Domain-transfer evaluation
Combined Training	**Both**	**70,122**	—	**Actual training corpus**

The combined training corpus consists of 70,122 samples (34,118 from HF + 36,004 from Mendeley), which are shuffled and provided together to all trainable models. The evaluation results on two disjoint test sets – HF test set (4265 samples) and Mendeley test set (4500 samples) are reported. Based on this setting, we can evaluate generalization in both domain-specific

and domain-agnostic settings. Table II presents the dataset split configuration used for training, validation, and testing across the HF PII43k and Mendeley financial datasets.

Fig. 3 shows the frequency of the most common PII tag types in the pii-masking-43k dataset. FULLNAME, EMAIL, and NAME are the most common labels, with CITY, URL, and NUMBER following, and the remaining labels, such as USERNAME, PASSWORD, and different types of ADDRESS and ACCOUNT labels, are relatively rare. This means that the data is highly person- and contact-centric, and in fact contains PII.

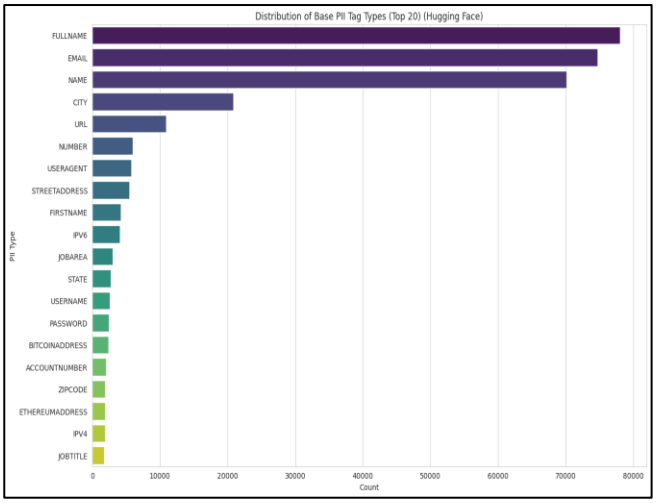

Fig. 3. PII tag distribution in HF dataset.

The frequency of each type of PII tag in the Mendeley data set is presented in Fig. 4. Name, company, and SSN are the most common types, showing that the most frequently occurring types are person or organisation identifiers. Other categories present in the Bar Plot include address, phone, credit card, URL, and email, with a variety of structured and unstructured PII tags. A more balanced distribution across PII types may improve the ensemble model's ability to generalize across sensitive information categories.

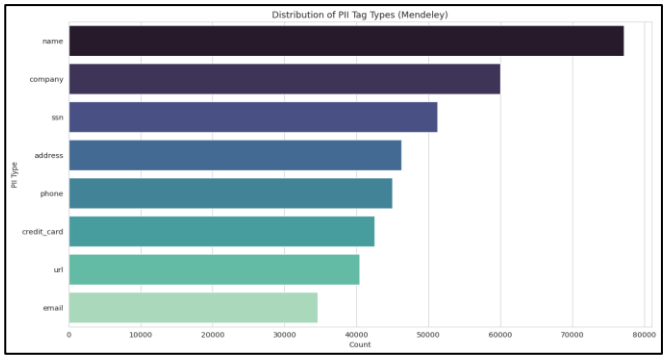

Fig. 4. PII tag distribution in the Mendeley dataset.

B. Unified Label Schema

Because the two source datasets use different entity naming conventions, a unified label schema was constructed to enable joint training. Seven canonical PII entity classes were defined. Table III shows the mapping process used to convert the original dataset-specific entity labels into the unified seven-class PII schema adopted in this study.

TABLE III. LABEL MAPPING SCHEMA

Unified Class	Maps From (HF Dataset)	Maps From (Mendeley)
PER	Name, Firstname, Lastname, Fullname, Displayname	Name, Person
LOC	City, Street address, State, Country, Zipcode, County, Secondary address	Address, Location
ORG	Company, Organization, Department	Company, Org
EMAIL	Email	Email
PHONE	Phone, Phonenumber, Tel	Phone
ID	SSN, Creditcardnumber, Passport, License, IBAN, Bitcoinaddress, Accountnumber, Pin, Vehiclevin, BBAN, Maskednumber, IPV4, IPV6, MAC	Ssn, Creditcard, ID
URL	URL, Domain, Useragent	URL

The entity tags were transformed into BIO format, resulting in a total of 15 labels: O, B-PER, I-PER, B-LOC, I-LOC, B-ORG, I-ORG, B-EMAIL, I-EMAIL, B-PHONE, I-PHONE, B-ID, I-ID, B-URL, I-URL [20].

C. Implementation Setup

For the implementation of the proposed model, a virtual machine environment was used on Google Colaboratory. The accelerators comprise NVIDIA L4 Tensor Core GPUs equipped with 24 GB of GDDR6 memory.

The host CPU back end has about 51 GB of RAM, 107 GB of disk space, and is running Ubuntu Linux (64-bit). For all model training and evaluations, Python 3 was used with Hugging Face Datasets, Scikit-learn, TensorFlow/PyTorch, and the Python re module for regex patterns.

Key libraries used: Hugging Face Datasets [21], Scikit-learn [22], TensorFlow/PyTorch [23], and the Python re module for regex patterns. Table IV summarizes the main hyperparameters and training settings used for each model in the proposed EnsemblePII framework.

TABLE IV. HYPERPARAMETER SUMMARY ACROSS ALL MODELS

Model	Key Hyperparameters	Training Epochs / Iterations
Regex	Deterministic (no training)	N/A
Dictionary	Gazetteer-based (no training)	N/A
CRF	Feature window ±2 tokens; L2 regularization; gazetteer features	Convergence-based (sklearn-crfsuite default)
Bi-LSTM	Hidden dim: 256×2 (bidirectional); Char-CNN embeddings; Word shape features; Adam optimizer; LR = 0.001; batch size = 32	12 epochs
DistilBERT	distilbert-base-uncased; max_length=512; warmup_steps; AdamW; batch size = 32	5 epochs (with early stopping)
Ensemble	Per-class F1 weights from HF Validation set; weighted majority vote per token	N/A (inference only)

To ensure reproducibility, all experiments were conducted with a fixed random seed of 42. Training times on the NVIDIA L4 GPU were approximately 4.2 hours for Bi-LSTM (12 epochs) and 1.8 hours for DistilBERT (5 epochs). Token-level alignment across heterogeneous models was achieved through a unified whitespace tokenisation pre-processing step applied before model-specific encoding, ensuring consistent token boundaries across all five component models.

The Bi-LSTM model includes CNN embeddings for characters and words, and features that focus on words' shape, providing orthographic information that helps identify structured PII like email addresses, identifiers, and phone numbers. The fine-tuned DistilBERT transformer is initialized from the distilbert-base-uncased checkpoint and is then fine-tuned for token classification using a linear classification head with 15 BIO tag classes.

D. Evaluation Metrics

For comparative purposes between various models, their performances are measured in terms of accuracy, precision, recall, and F1-score. These metrics are critical in the characterization of the effectiveness of these models in the detection of PII.

Accuracy: Accuracy represents the overall proportion of correctly classified tokens. However, in PII detection tasks, it can be deceptive, since non-PII tokens greatly outnumber PII tokens.

$$Accuracy = \frac{TN+TP}{TN+TP+FP+FN} \quad (1)$$

where, TP stands for True Positives, TN for True Negatives, FP for False Positives, and FN for False Negatives.

Precision: This is the proportion of the correctly classified tokens predicted as PII, which is the reliability of the positive predictions made by the model.

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

Recall: This is the proportion of actual PII tokens predicted by the model. In privacy-preserving applications, a high recall is especially crucial to ensure that most of the sensitive information is detected.

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

F1-Score: This is the harmonic mean of precision and recall, providing a single balanced measure that accounts for both error types.

$$F1\ socre = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (4)$$

All models are evaluated using the same set of evaluation metrics, calculated over the BIO-tagged labels. The main metric is the weighted F1-score, which addresses class imbalance by weighting each entity class's F1 by its frequency in the test set. Additionally, per-entity precision, recall, and F1 scores are reported for seven standard PII classes: PER (persons), LOC (locations), ORG (organizations), EMAIL, PHONE, ID (identifiers and structured codes), and URL. A prediction is correct only if both the entity boundary and type match the ground truth. This approach is strict, compared to token-level accuracy, and reflects the real-world need to locate PII correctly [24].

V. Experimental Results

A. Test Set Definitions

HF Test Set (4,265 samples): This is a subset from the pii-masking-43k dataset, it includes diverse, general-purpose PII found in conversational and template-based text across multiple fields.

Mendeley Test Set (4,500 samples): This test set is drawn from the Mendeley Synthetic Financial Documents dataset and provides domain-specific financial text, including audit reports, transaction confirmations, and invoices, with PII entities embedded in realistic financial data.

The two test sets enable evaluation of the system's performance across both general-purpose and financial-domain PII detection scenarios.

B. Baseline Model Evaluation

1) Rule-based regex model: The regex model is a pattern-matching baseline model identifying structured PII tokens with the help of a set of tailored regular expressions. No training data is required, and it is simply directly matched to the patterns. Email addresses are detected as top priority; email addresses have very strict syntactic rules followed by URLs, phone numbers, and identifiers. If the model is only based on patterns on the surface, it cannot model context, it cannot resolve ambiguity, not the named entity — a person, place or organization.

The lowest weighted F1 score across all evaluated models is recorded by the Regex model on the HF test set, at 0.1837. A major drawback is that if this model is applied to LOC entities (F1 = 0.000), locations don't have a consistent formatting for pattern-based recognition. The F1 score for the PER class is only 0.2899, which is moderate. This is facilitated by the ability of the regex model to recognize word sequences with capitalized words as candidate names. Similarly, URL has a low F1 score of 0.1048, with many URLs in the HF data set partially masked and thus not matching the regex.

Notably, the EMAIL class, a natural strength for a regex-based model, is also difficult for the model (F1 = 0.0188) on the HF test set. This is due to partially masked email addresses in the dataset (e.g., "##@example.com") that do not fit the standard regex patterns for complete addresses. This observation also accounts for the fact that the model based on the regular expression does much better on the Mendeley test set (weighted F1 = 0.4801) than on the other sets, where email addresses are presented in their full form (EMAIL F1 = 0.9320).

The difference between the results obtained on the HF and Mendeley sets is quite significant: 0.1837 vs 0.4801, which gives us an insight into the fact that the cleaner Mendeley text favors pattern-based models more than the noisier HF text. These results support the decision to include the Regex model as a component of the ensemble rather than as a standalone model [25].

2) Dictionary with regex model: The Dictionary+Regex model adds on entity gazetteers, or a list of known entities from the training data, to the regex baseline. Three gazetteers are built: PER (70,478 person-name tokens), LOC (42,735 location tokens), and ORG (38,111 organization tokens). For structured entities such as EMAIL, PHONE, URL, and ID, the model uses the same regex patterns as in Model 1. Named entities (PER, LOC, ORG) match each input token on the respective gazetteer.

Compared to the pure regex baseline, the Dictionary+Regex model achieves a slight improvement on the HF test set (F1: 0.2635 vs. 0.1837) and its main strength lies in the performance on LOC (F1 = 0.4340 vs. 0.0000). The LOC gazetteer, built from 42,735 training tokens, achieves high precision (0.7566) but moderate recall (0.3042), indicating that many locations in the test sets do not appear in the training data; this is expected in open-world named entity recognition.

These results show the limits of the symbolic methods. Both the Regex and Dictionary models serve as lower-bound baselines, ensuring the need for statistical and deep learning models. Fig. 5 compares the weighted F1-scores of the Regex and Dictionary+Regex baseline models on both test sets.

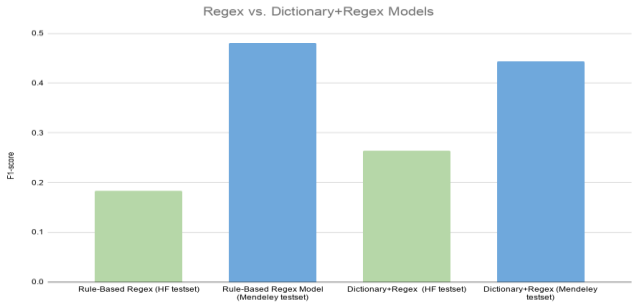

Fig. 5. Weighted F1-score comparison between the rule-based regex and dictionary+regex models on both test sets.

The HF gain (from 0.1837 to 0.2635) contrasts with the drop on Mendeley (from 0.4801 to 0.4432), highlighting the vocabulary-dependency of gazetteer methods.

3) CRF sequence tagger: The Conditional Random Field model shows the transition from symbolic to statistical sequence analysis. It is trained on 70,122 samples, using a different set of features. These features include token-level lexical features, character n-grams, token shapes, context window features, and gazetteer flags for all seven entity classes. The gazetteers for CRF feature includes 7,439 PER, 67,587 LOC, 17,420 ORG, 29,351 EMAIL, 38,156 PHONE, 75,912 ID, and 23,932 URL tokens, all compiled from the combined training data.

The CRF model shows a great improvement over both baselines, achieving an F1 of 0.9469 on the HF Test Set and 0.9639 on the Mendeley Test Set. This represents an approximately 0.68 F1 improvement over the Dictionary model on HF and highlights the effectiveness of statistical feature engineering for PII detection. Five out of seven entity classes achieve F1 scores above 0.84 on the HF Test Set, with EMAIL (0.9868), URL (0.9956), and PER (0.9496) standing out.

The two entity classes ORG and PHONE are completely missing from the HF dataset. As a result, there are no examples of these classes in both the HF Test Set and the HF Validation Set, and all models give an F1 of 0.000 for these classes on HF. This is not a model constraint, but rather a characteristic of the data: with those same models, PHONE is detected with F1 = 0.9463 on the Mendeley Test Set.

However, on the Mendeley Test Set, PHONE achieves F1 = 0.9463, confirming that the issue relates to data quality rather than a model limitation [15].

4) Bi-LSTM sequence tagger: The Bi-LSTM model performs sequence labeling using three embedding channels: word embeddings with a vocabulary size of 265,960, character-level CNN embeddings with 94 unique characters, and word-shape embeddings representing 194 unique shape patterns [26]. These are combined and passed through a two-layer bidirectional LSTM network with a hidden size of 256 per direction, outputting 512-dimensional representations for each token. The model has 35,682,085 trainable parameters, and it is trained for 12 epochs using the Adam optimizer with a learning rate of 0.001 and a batch size of 32 [27]. Class weights are applied during training, too, to deal with the imbalance between the 'O' (non-PII) class and the rare PII entity classes. Fig. 6 shows the Bi-LSTM training loss over 12 epochs, demonstrating the convergence pattern of the model during training.

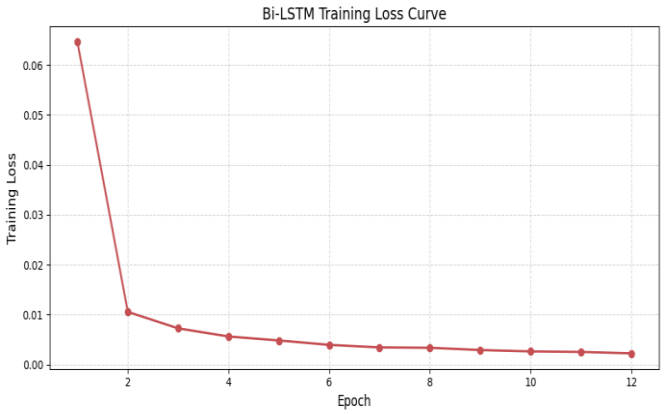

Fig. 6. Bi-LSTM training loss curve over 12 epochs.

Training loss decreases substantially within the first two epochs and continues to decline monotonically thereafter, indicating stable convergence without oscillation or divergence.

The Bi-LSTM model's results reveal an obvious performance discrepancy. On the Mendeley Test Set, it achieves a near-perfect weighted F1 of 0.9959, the highest score of any single model in this study. Four entity classes (ID, PHONE, LOC, URL) achieve near-perfect F1, and even the complex EMAIL class achieves F1 = 0.9991. This strong performance on Mendeley shows the model's ability to learn the consistent patterns of the synthetic financial text, which follows clear template structures.

However, on the HF Test Set, the Bi-LSTM records an F1 of only 0.8433, which is lower than the CRF's 0.9469. This gap is

due to two reasons. First, the HF dataset's tokenization masking again makes it harder to detect EMAIL and URL (F1 = 0.5968 and 0.5590, respectively) because partially masked tokens damage the character patterns the Bi-LSTM needs.

The contrast between 0.8433 (HF) and 0.9959 (Mendeley) shows that the Bi-LSTM is highly sensitive to domain changes. It performs well in well-structured domains but struggles with tokenization noise [28].

5) Baseline summary: Table V compares the weighted F1-scores of the baseline models on the HF and Mendeley test sets, highlighting the relative strengths and weaknesses of each approach.

TABLE V. BASELINE MODEL SUMMARY: F1-SCORE

Model	HF Test F1	Mendeley Test F1	Avg. F1	Key Strength	Key Weakness
Regex	0.1837	0.4801	0.3319	High precision on structured entities (Mendeley)	Cannot detect named entities; breaks on masked tokens
Dictionary+Regex	0.2635	0.4432	0.3534	Adds LOC detection via gazetteer	LOC gazetteer fails on domain shift; ORG/PHONE zero
CRF	0.9469	0.9639	0.9554	Strong cross-domain consistency	ORG/PHONE fails on HF due to masking
Bi-LSTM	0.8433	0.9959	0.9196	Near-perfect on Mendeley	Large performance gap under domain shift

The CRF model stands out as the most robust baseline with an average F1 of 0.9554, achieving strong results across both test sets. The Bi-LSTM reaches the highest single-dataset score on Mendeley (0.9959) but shows weaker performance under domain shift. Both regex and dictionary matching models highlight the limitations of pattern-based approaches, especially in the presence of tokenization noise (in the HF dataset). Their results justify their position as lower-weight contributors in the ensemble system.

C. Transformer Component Evaluation (DistilBERT)

Before evaluating the full ensemble, we discuss the fifth and most powerful individual model, the fine-tuned DistilBERT model. DistilBERT is fine-tuned for token classification using all 70,122 combined training samples [29]. The fine-tuning process was conducted for 5 epochs, with early stopping based on validation F1. The training history is shown in Table VI. Fig. 7 presents the DistilBERT fine-tuning curves, showing changes in training loss and validation F1-score across the five training epochs. Table VI reports the DistilBERT fine-tuning history across five epochs, including training loss, validation loss, and validation F1-score.

TABLE VI. DISTILBERT FINE-TUNING HISTORY 5 EPOCHS

Epoch	Training Loss	Validation Loss	Validation F1
1	0.103743	0.014234	0.9673
2	0.002088	0.010111	0.9757
3	0.001085	0.010821	0.9769
4	0.000555	0.008429	0.9808
5	0.000284	0.007503	0.9804

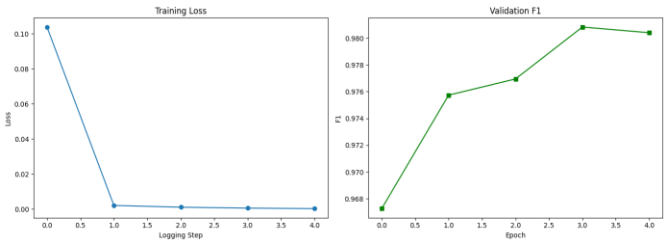

Fig. 7. DistilBERT fine-tuning curves: training loss (left) and validation F1 (right).

The training loss drops sharply within the first epoch. The validation F1 rises from 0.967 to a peak of 0.9808 at epoch 4, showing stable convergence over 5 epochs of fine-tuning.

The DistilBERT Transformer achieves the second-highest F1 on the HF Test Set (0.9744). It scores perfectly on EMAIL and URL, and performs well for PER (0.9781) and ID (0.9632). On the Mendeley Test Set, it reaches a strong F1 of 0.9703, detecting all seven entity classes with no zero scores. Most classes achieve precision close to 1.000, meaning that the model's positive predictions are highly reliable, even though it has lower recall for LOC (0.9224), PER (0.9388), and URL (0.9213).

The main takeaway is that the Transformer's strength lies in its accurate contextual understanding. It almost does not produce false positives, but it may miss some true entities, resulting in lower recall scores. This focus on precision balances the CRF's recall-oriented approach.

D. EnsemblePII System Results

The EnsemblePII system combines predictions from all five models using a dynamic Weighted Voting Aggregator. All five models predict BIO labels for each token in the input text, in the style of voting. Each vote is given a score according to the F1 per entity score of the model on the HF validation set (4261 samples). For example, a transformer has a vote weight of 0.9838, whereas a regex model has a vote weight of 0.3028. For instance, in the case of a PER token, the weight of the vote cast by the transformer is 0.9838, but the weight of the vote cast by the regex model is only 0.3028. In the case of EMAIL, the votes of the transformer and CRF have the greatest impact on the final vote. Table VII presents the per-class validation F1 weights used by the weighted voting aggregator to combine predictions from the five component models.

Table VII displays some of the important properties of the system: For EMAIL and URL, the Transformer and CRF are almost the same in terms of dominant weights. The weight of the Transformer is 0.9838 for PER, followed by CRF (0.9573) and Bi-LSTM (0.9035). The weights for the Regex model and the Dictionary model are less than 0.50 per entity class, implying that both models are auxiliary and not the main decision makers. Note that there is no ORG or PHONE in Table VII. These two

classes are not present in the HF data set, and thus, all models have zero (or near-zero) F1 for the class ORG and PHONE on the HF validation set, and meaningful per-class weights cannot be obtained from the HF validation set for these classes. As a result, for those classes, the ORG and PHONE votes cast by all models are all given the same weight (all models have uniform weight = 1.0), and the fallback scheme is to use majority voting. Table VIII reports the per-entity precision, recall, and F1-score achieved by EnsemblePII on the HF test set.

TABLE VII. PER-CLASS F1 WEIGHT MATRIX ON HUGGING FACE VALIDATION SET

Model	PER	LOC	EMAIL	ID	URL	Overall
Regex	0.3028	0.0000	0.0183	0.0736	0.1272	0.1911
Dictionary	0.2815	0.4577	0.0219	0.0864	0.1379	0.2762
CRF	0.9573	0.9210	0.9811	0.8014	1.0000	0.9501
Bi-LSTM	0.9035	0.8519	0.6325	0.8522	0.6044	0.8491
Transformer	0.9838	0.9635	1.0000	0.9314	1.0000	0.9808

TABLE VIII. ENSEMBLEPII PER-ENTITY RESULTS ON HF TEST SET

Entity	Precision	Recall	F1-Score
EMAIL	1.0000	1.0000	1.0000
ID	0.9357	0.9850	0.9597
LOC	0.9571	0.9470	0.9520
PER	0.9837	0.9703	0.9769
URL	1.0000	1.0000	1.0000
F1-Score	—	—	0.9749

Table IX reports the per-entity precision, recall, and F1-score achieved by EnsemblePII on the Mendeley financial test set.

TABLE IX. ENSEMBLEPII PER-ENTITY RESULTS ON MENDELEY TEST SET

Entity	Precision	Recall	F1-Score
EMAIL	0.9962	0.9925	0.9943
ID	0.9908	1.0000	0.9954
LOC	0.9804	0.9998	0.9900
ORG	0.9368	0.0823	0.1513
PER	0.8214	0.9925	0.8989
PHONE	0.9703	0.9190	0.9439
URL	0.9842	1.0000	0.9920
F1-Score	—	—	0.8433

While EnsemblePII achieves the highest weighted F1 on the HF test set (0.9749), its average F1 across both test sets (0.9091) is lower than that of the DistilBERT Transformer (0.9724), CRF (0.9554), and Bi-LSTM (0.9196). This finding demonstrates that ensemble-based integration improves in-distribution performance but is subject to calibration-induced degradation in cross-domain scenarios, specifically when entity classes present in the target domain (ORG, PHONE) are absent from the calibration corpus.

The ensemble achieves a perfect F1 on EMAIL and URL, matching the Transformer. For the ID class, the ensemble achieved an F1-score of 0.9597. The ensemble's lower ID F1 score (0.9597 vs. the CRF's 0.8014 individual score) reflects the diluting effect of non-zero voting weights assigned to the Regex and Dictionary models for this class (0.0736 and 0.0864, respectively; Table VII), which introduce systematic noise from lower-performing components.

However, on the Mendeley Test Set, the EnsemblePII records a weighted F1 of only 0.8433. This is well below the Bi-LSTM's 0.9959 and the Transformer's 0.9703. The drop is mainly due to the ORG class, which falls to an F1 of 0.1513 on Mendeley. The low ORG F1 on Mendeley (0.1513) is not due to the lack of precision, but rather extremely low recall (0.0823). The ensemble precision for ORG is 0.9368, meaning that approximately 93.68% of predicted ORG tokens are correct. However, since ORG calibration weights are also calculated on the HF validation set, which does not include ORG, all five component models contribute equally (and non-zero) in the ORG predictions. The models that naturally make ORG predictions, via their architecture (probably the Transformer model and the Dictionary model), sometimes predict ORG for ORG tokens, while the remaining models suppress ORG predictions, so the ensemble recall is very low. The number of rare predictions that do pass through is very accurate, which is why the precision is high, and the recall is low, and hence the low F1. ORG and PHONE are completely missing from the HF dataset (validation and test splits), and so no validation weights could be computed for these classes with HF. The ensemble consequently resorts to voting for ORG and PHONE with equal weights when tested on Mendeley.

E. Aggregate Performance Comparison

Table X provides an aggregate comparison of all evaluated models on both test sets, including their rankings and average F1-scores.

TABLE X. MASTER PERFORMANCE COMPARISON: ALL MODELS ON BOTH TEST SETS

Rank (HF)	Model	HF Test F1	Rank (Mendeley)	Mendeley Test F1	Avg. F1
1	EnsemblePII	0.9749	4	0.8433	0.9091
2	Transformer (DistilBERT)	0.9744	2	0.9703	0.9724
3	CRF	0.9469	3	0.9639	0.9554
4	Bi-LSTM	0.8433	1	0.9959	0.9196
5	Dictionary+Regex	0.2635	6	0.4432	0.3534
6	Regex	0.1837	5	0.4801	0.3319

As shown in the aggregate performance matrix, no single model performs best on both test sets. EnsemblePII achieves the highest score on the HF Test Set, with an F1-score of 0.9749, but its performance drops to 0.8433 on the Mendeley Test Set. In contrast, the Bi-LSTM ranks fourth on the HF Test Set with an F1-score of 0.8433, but achieves the best performance on the Mendeley Test Set with an F1-score of 0.9959. The DistilBERT Transformer is the most stable model across both datasets, achieving an average F1-score of 0.9724 and ranking second on both test sets.

When comparing the models by average F1-score across the two test sets, the Transformer is the most consistently reliable model, followed by the CRF, Bi-LSTM, and EnsemblePII. The lower average score of EnsemblePII, 0.9091, compared with 0.9724 for the Transformer, is mainly caused by its weak ORG detection on the Mendeley Test Set. This suggests that the ensemble's reduced cross-domain performance is primarily due to domain-specific weight calibration rather than the ensemble architecture itself. Fig. 8 compares the weighted F1-scores of all evaluated models on the HF and Mendeley test sets.

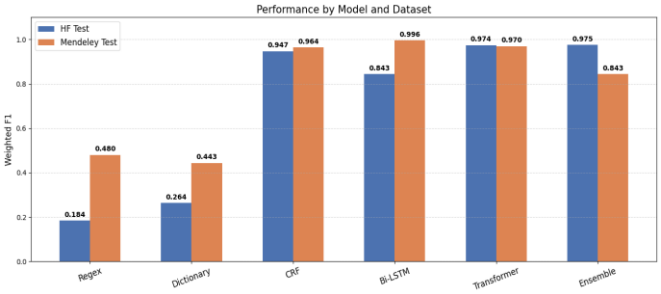

Fig. 8. Weighted F1 bar chart: All models vs both test sets.

Fig. 9 presents the per-entity F1-score heatmap for all models on the HF test set, showing how performance varies across different PII classes.

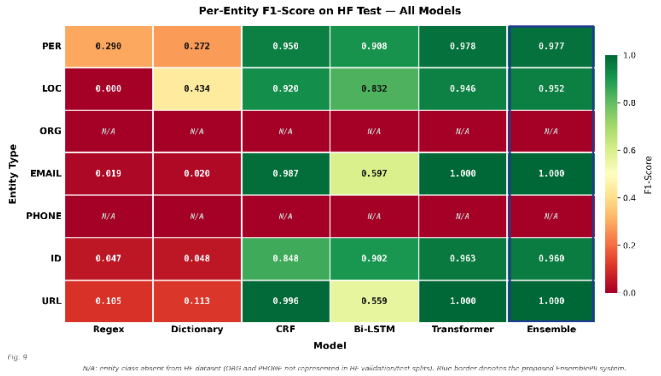

Fig. 9. Per-entity F1 heatmap on HF test set.

Fig. 10 presents the per-entity F1-score heatmap for all models on the Mendeley test set, highlighting model-specific strengths and weaknesses across financial PII classes.

The heatmap places the seven entity classes in rows and the six systems in columns; each cell encodes the F1-score for the corresponding entity-system pair. This visualization offers a quick summary of how each model performed for each class. Transformers and Ensembles show the darkest cells for the EMAIL, URL, PER and ID. However, the ORG and PHONE rows for all models on the HF set are uniformly marked as absent (N/A) in red, reflecting their complete exclusion from the HF dataset rather than a model failure. This CRF column is flatter than the Bi-LSTM column—the CRF shows more uniformity of performance across the entities on the HF data. Contrasting this behavior to the Mendeley heatmap, it is seen that the CRF, Bi-LSTM and Transformer models obtain consistently strong scores. In contrast, EnsemblePII performs well for most classes but shows reduced ORG and PER performance because weaker component models influence the aggregated output for these classes.

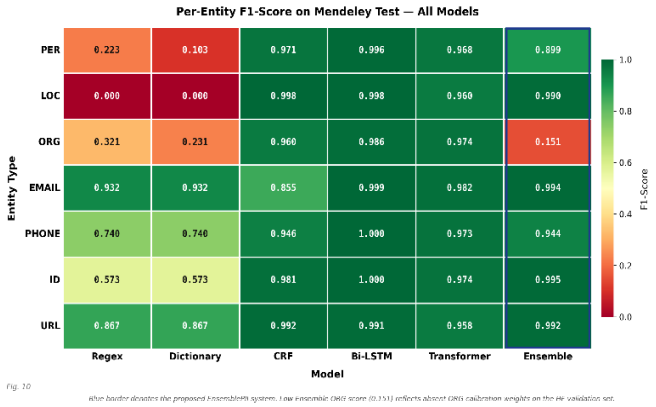

Fig. 10. Per-entity F1 heatmap on the Mendeley test set.

F. Precision–Recall Trade-off Analysis

An important part of evaluating PII detection is the precision-recall trade-off. In privacy protection tasks, recall is usually the more important measure. A missed PII entity represents a false negative and may create a privacy gap, whereas over-prediction produces additional false positives and unnecessary masking. Table XI shows the precision and recall for the three best models on each test set compared to the EnsemblePII framework [30].

TABLE XI. OVERALL PRECISION AND RECALL FOR TOP-3 MODELS

Model	HF Test Precision	HF Test Recall	Mendeley Precision	Mendeley Recall
CRF	0.9543	0.9398	0.9660	0.9624
Bi-LSTM	0.8370	0.8499	0.9948	0.9970
Transformer	0.9776	0.9714	0.9994	0.9424
EnsemblePII	0.9796	0.9703	0.9515	0.8513

The DistilBERT Transformer shows the highest precision on the Mendeley dataset and the highest precision among individual models on HF, while EnsamblePII has the highest HF precision overall, which means that its positive predictions are reliable. On Mendeley, almost every entity that the Transformer identifies is correct (macro precision ≈ 0.9994), even though it misses around 5.8% of true PII entities, resulting in a recall score of 0.9424. The CRF model achieves a balanced precision-recall profile on HF Test, with a difference of only 0.0145 between precision (0.9543) and recall (0.9398). The Bi-LSTM achieves a balanced performance on Mendeley (precision 0.9948, recall 0.9970), showing a good balanced for that domain.

The EnsemblePII shows high precision on HF (0.9796) but a lower score on Mendeley (0.9515). it shows a degraded recall on Mendeley (0.8513), again driven by some baseline collapse for complex entity classes. For applications where recall is critical, the Bi-LSTM on Mendeley-type data or the Transformer on HF-type data would be preferred over the full ensemble.

G. Discussion

The progressive performance improvements from symbolic baselines to the full ensemble system can be attributed to three cumulative factors: 1) feature richness, 2) contextual depth, and 3) ensemble complementarity, each of which is examined in detail below.

Feature richness is most clear in the improvement from the Dictionary model (F1 = 0.2635 on HF) to the CRF (F1 = 0.9469). The CRF's feature engineering, which includes character n-grams, token shapes, and all seven entity gazetteers, gives the statistical model enough information for the final classification signal to reach near state-of-the-art performance without using deep learning. This suggests that, for sequence labeling on well-structured PII data, carefully designed features can remain competitive with neural methods.

Contextual depth explains the Transformer's improvement over the CRF in most individual entity classes. The DistilBERT's self-attention mechanism processes all tokens together, allowing it to determine entity boundaries that depend on sentence-level context. For example, it can tell the difference between a person's name and an organization's name in "John Smith from Smith and Associates." The Bi-LSTM provides intermediate contextual depth. It is stronger than the CRF's fixed context window, but not as expressive globally as self-attention.

The independence of errors by different models (ensemble complementarity) explains the slight improvement of the ensemble over the Transformer on the HF Test. The performance of the CRF in terms of LOC recall (0.9111) is close to that of the Transformer (0.9462), and the ensemble's LOC recall (0.9470) exceeds that of either model.

The effects of the combination of both datasets for training were clear. The CRF model is evaluated on Mendeley with a score of 0.9639, which is far above what is expected from a model trained in this way, given the masking problems with HF data. The Bi-LSTM obtains an outstanding score of 0.9959 on Mendeley, demonstrating its capability of comprehending the structure of synthetic financial text. We hypothesise that DistilBERT's cross-domain stability arises from simultaneous exposure to both HF and Mendeley training distributions, enabling the model to learn domain-invariant contextual representations — a hypothesis that can be tested by training DistilBERT exclusively on HF data and evaluating on Mendeley. The DistilBERT is quite good on both datasets (HF: 0.9744, Mendeley: 0.9703), implying that it learned both distribution styles simultaneously.

An implicit component-contribution analysis is available through the per-class weight matrix in Table VII. The Regex and Dictionary models receive overall validation weights of 0.1911 and 0.2762, respectively, substantially lower than the CRF (0.9501), Bi-LSTM (0.8491), and Transformer (0.9808). These near-zero weights indicate that the two symbolic models exert minimal influence on token-level decisions for most entity classes; the ensemble effectively reduces to a three-model weighted vote among CRF, Bi-LSTM, and Transformer for the majority of predictions. The main contribution of the symbolic components is a precision-oriented signal for highly structured PII patterns such as EMAIL and URL, where deterministic regex and gazetteer matching provide reliable but lower-recall coverage that complements the learning-based models.

However, combined training introduces limitations during the ensemble weight-calibration step. Since ORG and PHONE are completely absent from the HF dataset, there are no validation F1 scores for these classes in the HF validation dataset, and meaningful per-class calibration weights can not be derived for them. This means in this ensemble, there is no calibrated guidance to detect ORG and PHONE on Mendeley, which is a good representation of both classes. This leaves the ensemble unaware of these entity classes, even in the case of evaluating on Mendeley, where they are well defined. This is a problem that could be solved with a domain-aware weighting strategy [31].

VI. Comparison with State-of-the-Art Hybrid Systems

In order to put the performance of EnsemblePII in perspective, the performance of two existing hybrid PII detection systems from the literature is compared to that of EnsemblePII.

Study [9] reported strong results for a BERT-based hybrid model, with 99.558% accuracy and a 99.559% F1-score. Their system, however, is assessed as a binary document-level classification system, in which a classification is performed based on the presence or absence of PII. EnsemblePII tackles a more specific task, the multi-class token-level sequence labelling with BIO tags.

Hence, the results are not directly comparable, but it demonstrates the effectiveness of transformer-based approaches for PII detection.

EnsemblePII attains an F1 of 97.49% on the HF test set, compared to the 91.1% F1 reported by the study [10]; however, direct numerical comparison must be treated with caution because study [10] operates at the entity-span detection level, whereas EnsemblePII addresses the more granular multi-class token-level BIO tagging task, a fundamentally different evaluation granularity. Within this constraint, EnsemblePII also demonstrates a more balanced precision–recall profile (Precision: 97.95%, Recall: 97.03%) than [10] (Precision: 94.7%, Recall: 89.4%). It does not, however, perform as well on a Mendeley financial dataset, where most problems stem from a domain mismatch in ensemble weight calibration, impacting the most important entity classes ORG and PHONE. Table XII compares EnsemblePII with selected hybrid PII detection systems from the literature, while noting differences in architecture, evaluation dataset, and task level.

TABLE XII. COMPARATIVE ANALYSIS: ENSEMBLEPII VS SOTA HYBRID SYSTEMS

System	Architecture Type	Precision	Recall	F1-Score	Evaluation Dataset	Task Level
[9]	NLP preprocessing + fine-tuned BERT	99.564%	99.558%	99.559%	pii-masking-200k (binary)	Document-level binary
[10]	Rule-based NLP + spaCy NER	94.7%	89.4%	91.1%	Synthetic financial (synthetic)	Entity-span level
EnsemblePII (HF Test)	**Weighted voting: Regex + Dict + CRF + Bi-LSTM + DistilBERT**	**97.95%**	**97.03%**	**97.49%**	**HF PII43k (multi-class token)**	**Token-level multi-class**
EnsemblePII (Mendeley)	**Weighted voting ensemble**	**95.15%**	**85.13%**	**84.33%**	**Mendeley financial (multi-class token)**	**Token-level multi-class**

Fig. 11 compares EnsemblePII with selected state-of-the-art hybrid systems using precision, recall, and F1-score values reported in the manuscript.

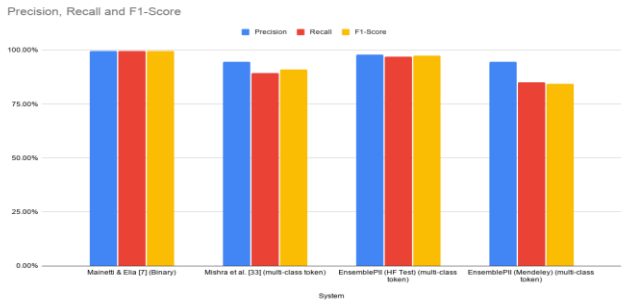

Fig. 11. EnsemblePII vs SOTA: Precision/Recall/F1 Bar.

EnsemblePII outperforms the system in [10] (91.1%) on a more challenging multi-class token-level task on the HF test set with an F1 score of 97.49%. On the Mendeley financial test set, EnsemblePII achieves an F1-score of 84.33%; this lower result is primarily attributable to domain-specific weight-calibration failures for ORG and PHONE entities. Concerning the Mainetti and Elia system: since it is a binary document level task (PII present/not present), it is not appropriate to make a direct numerical comparison. Finally, it should be emphasized that EnsemblePII tackles a much more difficult problem: multi-class token-level sequence labelling with 15 BIO tags, and that it yields strong performance on this more difficult task. First, concerning the complexity of the tasks: EnsemblePII is a multi-class task, token-level classification with 15 BIO tags and 7 entity types, whereas binary detection or single-class entity extraction is simpler. The score of 97.49% F1 on the test set (HF) shows the robustness of the ensemble on general-purpose PII text compared to the 91.1% F1 obtained by the study [10] on a similar entity span task. Second, when it comes to robustness, the two comparison systems do not report on cross-domain generalization. The only system included in the comparison that has been tested on two different types of test sets is EnsemblePII, which used both domain-specific financial documents and general-purpose PII text. This provides more evidence of its real-world applicability. Third, it comes to Precision-Recall Balance, EnsemblePII on HF Test gives better balance (Precision: 97.95%, Recall: 97.03%) than the study [10] (Precision: 94.7%, Recall: 89.4%). This results in EnsemblePII capturing the sensitive entities with fewer false alarms. This twofold benefit is particularly important for applications that have privacy requirements.

VII. CONCLUSION

In this study, we introduced EnsemblePII, a weighted voting ensemble framework for multi-class PII detection in unstructured text. The framework combines five complementary detection approaches: Regex pattern matching, Dictionary+Regex matching, CRF sequence tagging, Bi-LSTM sequence modelling, and DistilBERT-based token classification. The models were evaluated on two test sets representing different domains: the HF PII43k dataset and the Mendeley Synthetic Financial Documents dataset. The results show that symbolic baselines alone are insufficient for reliable PII detection, especially in noisy or masked text. Regex and Dictionary+Regex achieved low weighted F1-scores on the HF test set, while the CRF, Bi-LSTM, and Transformer models provided much stronger performance through contextual and sequence-based learning.

The experimental results indicate that EnsemblePII achieved the best performance on the HF test set, with a weighted F1-score of 0.9749, slightly outperforming the DistilBERT Transformer model, which achieved 0.9744. However, the ensemble did not achieve the best cross-domain performance. On the Mendeley financial test set, its weighted F1-score dropped to 0.8433, mainly because the ORG and PHONE classes were not represented in the HF validation set used for class-specific weight calibration. In contrast, the DistilBERT Transformer was the most stable individual model across both datasets, achieving 0.9744 on HF and 0.9703 on Mendeley, while the Bi-LSTM achieved the highest single-dataset score with 0.9959 on the Mendeley test set. These findings show that ensemble-based PII detection can improve in-distribution performance, but cross-domain effectiveness is contingent on the quality and domain coverage of the calibration data. Across both test sets, the DistilBERT Transformer achieves the highest average F1-score (0.9724) among all evaluated models, making it the most consistently reliable choice when cross-domain generalization is a deployment priority.

VIII. FUTURE WORK

Several directions for future work emerge from this study. First, domain-adaptive weight calibration, for instance, through meta-learning over multiple validation domains or multi-domain validation sets, should be investigated to address the ORG/PHONE calibration failure identified on the Mendeley test set. Second, the framework should be extended to real-world, non-synthetic corpora, such as medical records and legal documents, to assess performance under natural language

variability and annotation noise. Third, multilingual PII detection represents an important extension, as PII formats are language- and culture-specific, and the current framework is English-only. Fourth, the effect of differential weight-thresholding, excluding models below a class-specific F1 threshold from the ensemble vote, warrants systematic ablation. Fifth, privacy-preserving ensemble training, such as federated learning with differential privacy, is an important direction given the sensitive nature of the training data.

ACKNOWLEDGMENT

The authors would like to express their sincere gratitude to the Deanship of Graduate Studies and Scientific Research, Taif University, for its support and for funding this work. The authors also thank their colleagues and reviewers for their valuable guidance and constructive feedback throughout this research.

Holistic Model of Advanced Analytics to Optimize Organizational Decision-Making

Juan Carlos Morales-Arevalo, Ciro Rodríguez
Faculty of Systems Engineering and Computer Science, Universidad Nacional Mayor de San Marcos, Lima, Perú

***Abstract*—In increasingly data-intensive organizational environments, decision-making processes require analytical frameworks capable of integrating data governance, advanced analytics, and strategic interpretation under a unified structure. This study proposes a holistic advanced analytics model designed to optimize organizational decision-making through the integration of data quality, data integration, analytical capabilities, and data-driven storytelling within a continuous decision-support lifecycle. The proposed model was developed using the Design Science Research (DSR) methodology and structured according to the intelligence, design, and choice phases of the classical decision-making process. The framework incorporates internationally recognized standards and methodologies, including ISO/IEC 25012, ISO/IEC 11179, CRISP-DM, DataOps, and analytics value chain principles, enabling methodological interoperability and adaptive analytical governance. The resulting artifact was conceptually validated through expert judgment involving seven specialists in analytics, business intelligence, and organizational decision-making. The evaluation produced average scores ranging from 3.29 to 4.57 on a five-point Likert scale, with agreement levels reaching 85.71% in the highest-rated dimension. The results indicate favorable perceptions regarding the model's consistency, interpretability, usefulness, and organizational applicability. The proposed model contributes an integrative and adaptive framework that bridges fragmented analytical practices and supports more informed, scalable, and context-aware organizational decisions.**

***Keywords*—Advanced analytics; decision-making; holistic model; Design Science Research; expert judgment**

I. Introduction

In an organizational environment characterized by complexity, uncertainty, and technological dynamism, data-driven decision-making has become a fundamental strategic pillar. However, recent research warns against the illusion that using data alone guarantees effective decisions, highlighting the need for more integrative and adaptive frameworks [1]. Given this reality, there is an opportunity to develop a holistic model of advanced analytics that considers not only data, but also by the four interrelated dimensions influencing decision quality.

Holistic thinking, characterized by the integration of multiple perspectives, has been shown to improve understanding and problem-solving in complex environments, especially when combined with traditional analytical approaches [2]. This approach has been validated in various contexts, from strategic leadership to inventory optimization using artificial intelligence [3]. Empirical evidence also supports the claim that organizations that adopt advanced analytics systems with a holistic orientation achieve significant improvements in organizational performance, innovation, and decision-making [4, 5].

Despite these advances, there remain significant gaps. Many organizations continue to evaluate decisions based on limited and linear criteria without adequately incorporating human-machine collaborative factors [6]. However, integrative models that articulate cultural, cognitive, technological, and social components under adaptive and multidimensional frameworks are lacking [7]. Recent studies emphasize that thinking style, digital orientation, organizational culture, and data connectivity are interdependent variables that, when treated in isolation, limit the impact of analytics on decision-making [8].

Therefore, this study aims to design and validate a holistic advanced analytics model capable of integrating data governance, analytical capabilities, visualization mechanisms, and organizational decision-support processes within a unified adaptive framework. This model is based on robust conceptual frameworks, such as systemic thinking, PDCA (plan, do, check, and act) cycle theory, bi-level optimization under uncertainty, and dual cognitive decision theories [9–11]. At the same time, it is recognized that the adoption of these models must consider the perception of value, resistance to change, and the challenges of practical implementation in different sectors [12].

In summary, this research aims to provide an integrative framework that overcomes the current limitations of fragmented analytics and strengthens organizations' ability to make smarter, more adaptive, and more sustainable decisions.

II. Related Work

A. Data Analysis and Decision-Making Models

Organizational decision-making models have evolved to address complexity and uncertainty in critical contexts. In [13], the authors proposed a model based on Fractional Continuous Fuzzy Sets (FCFS) that allows for a more flexible and sensitive representation of uncertainty using continuous functions instead of discrete values. This approach improves the accuracy of the evaluation of alternatives, such as the selection of industrial robots, where multiple technical criteria are considered. On the other hand, [14] analyzed the decision-making process in healthcare organizations during crises and identified three models: the CEO model (autocratic decision-making), the CEO-advisor model (participation of advisors), and the Top Management Team (TMT) model, which consists of a collaborative management team. These models reflect how leaders adapt their approach according to pressure and uncertainty and prioritize centralization or collaboration. In a similar context, [15] explored the emerging complexity in the

decision-making process of chess players, demonstrating how the accuracy of decisions varies according to the competitiveness and critical nature of positions in the game. This study highlights the relevance of adaptive strategies in optimizing performance in competitive environments, such as minimizing decisiveness metrics. All three studies emphasize the importance of adapting decision models to the organizational context and the nature of the problem, whether technical or strategic.

The Analytics Value Chain model offers a maturity perspective on how organizations transform data into decisions, [16] classify analytical capabilities into four main approaches: descriptive, responds to what happened; predictive, anticipates what is likely to happen; prescriptive, suggests actions based on predictions; and autonomous, automates decisions using artificial intelligence, as shown in Fig. 1. The study [17] is a framework that aligns business analytics capabilities—descriptive, predictive, prescriptive, and autonomous—with Porter's value chain activities, illustrating how these capabilities enhance value creation at different stages of organizational processes. Their study highlighted the strategic application of analytics in primary (e.g., logistics and marketing) and supporting activities (e.g., HR and technology development), emphasizing measurable outcomes in value chain optimization. Building on this, [18] empirically validated the framework using case studies and secondary data, showing how firms leverage analytics for operational efficiency and competitive advantage, particularly in areas such as supply chain management and customer relationship analytics.

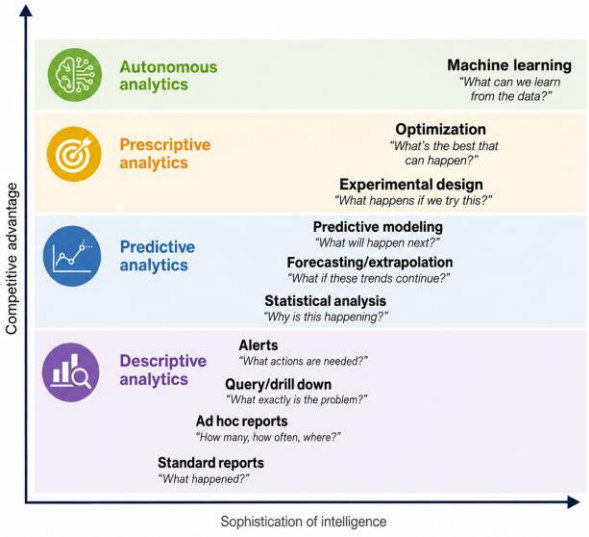

Fig. 1. Potential competitive advantage increases with more sophisticated analytics.

The Data-Driven Decision-Making (DDDM) paradigm emphasizes how the systematic use of data guides each phase of the decision-making process. In organizations that integrate large volumes of data through advanced analytics, DDDM improves the quality of decisions by relying on quantitative evidence rather than intuition or previous experience [19]. This has been demonstrated in areas such as marketing and strategic planning, where data enable the simulation of future scenarios and more informed decision-making [20].

B. Data Design, Analysis, and Management Methodologies

The Cross-Industry Standard Process for Data Mining (CRISP-DM) is a widely adopted methodology for structuring data mining projects, offering a systematic approach for extracting actionable insights from complex datasets. In [21], the authors applied CRISP-DM to predict student performance in e-learning environments, emphasizing its six-phase framework—business understanding, data understanding, data preparation, modeling, evaluation, and deployment—to identify at-risk students and reduce dropout rates. Their study highlighted the effectiveness of the random forest algorithm within this framework, achieving an 80% accuracy in predicting academic success. Similarly, [22] utilized CRISP-DM to automate complaint classification in e-commerce, demonstrating its flexibility in handling textual data through natural language processing (NLP) and machine learning. Their model achieved 85% accuracy, underscoring the utility of CRISP-DM for transforming raw data into structured solutions. Both studies illustrate the adaptability of CRISP-DM across domains, from education to customer service, while maintaining rigor in the data analysis and model evaluation (see Fig. 2).

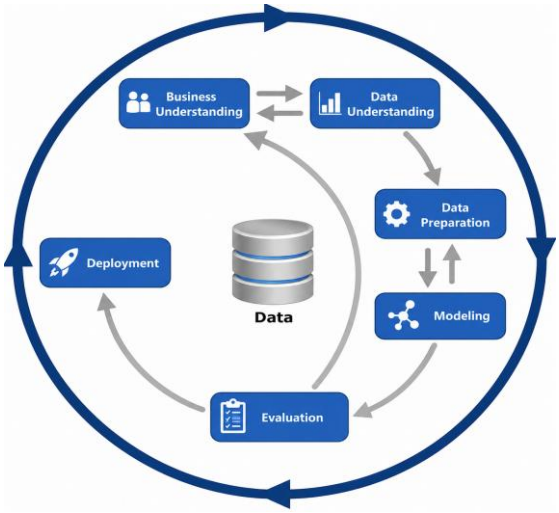

Fig. 2. CRISP-DM process diagram

Regarding the design of business intelligence solutions, Kimball and Inmon's approaches remain relevant as data warehouse modeling frameworks. Kimball proposed a bottom-up approach with an emphasis on dimensional modeling and ease of data access, which has been successfully applied in transactional flow solutions, such as the Data Mart designed for Peruvian bodegas, to analyze POS transactions and improve financial inclusion [23]. Similarly, [24] compares the approaches of Inmon, Kimball, and Data Vault, revealing that each method has an optimal scope of application depending on the project requirements. Inmon's approach is ideal when analytical requirements are not fully defined or when the stability of data sources is a priority, because its centralized 3NF structure ensures long-term consistency. On the other hand, Kimball's model excels in environments where query performance and end-user understanding are critical, especially in data-mart implementations with well-established requirements. In contrast, the Data Vault approach emerges as the most flexible solution for scenarios with multiple dynamic

data sources or agile environments owing to its ability to scale without reengineering and maintain historical traceability. No approach is universally superior, and the choice should be based on factors such as data volatility, project timelines, and end-user needs. Kimball's methodology, shown in Fig. 3, continues to be widely used in various sectors of society. This approach, documented in his data warehouse lifecycle, covers all stages, from business planning to the delivery of analytical value [25].

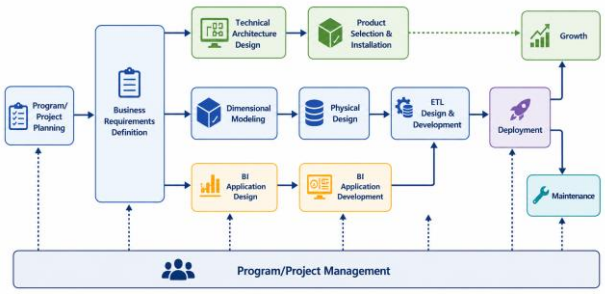

Fig. 3. Business dimensional life cycle diagram.

The Data Management Body of Knowledge (DAMA-DMBOK) framework has gained prominence in data governance due to its comprehensive approach to data quality, metadata management, and integration. A study by [26] proposed a new governance architecture called Horti-IoT, based on DAMA-DMBOK, applied to Dutch horticulture. The results showed significant improvements in the management and integration of data from sensors, images, and manual measurements, highlighting a reduction in analytical effort and an increase in the efficiency of agricultural monitoring.

The DataOps approach, which focuses on automating the data lifecycle and is inspired by Agile, DevOps, and lean manufacturing, has proven highly relevant in environments that require agility and continuous integration [27]. The authors demonstrated that applying this methodology in the feature selection and validation phases can reduce the complexity of datasets without compromising accuracy, achieving 82.32% accuracy with only four key variables. For their part, [28] developed a cloud-independent DataOps framework based on Kubernetes and Apache Iceberg, achieving a 12% reduction in query times through caching and improved scalability in Big Data applications. Their results demonstrated the impact of DataOps on data traceability, information quality, and decision-making efficiency. Together, the studies [27, 28] highlight the potential of DataOps to streamline workflows, shorten development cycles, and ensure robust data governance, thus establishing itself as a key component in modern data-driven organizations.

In complex organizational environments, the DSR methodology provides a rigorous methodological basis for the design and validation of scientific artifacts. This methodology not only emphasizes the creation of innovative solutions but also their systematic evaluation in real contexts. In [30], the authors stated that the DSR approach provides a systematic structure for the design, construction, and evaluation of improvement frameworks in construction processes, thereby ensuring scientific validity and practical relevance. In this study, the authors develop a framework that integrates Lean Construction, Building Information Modeling, and emerging technologies by using DSR to iterate between the design and empirical validation phases.

These methodologies and frameworks demonstrate how technical principles, combined with design and data governance strategies, strengthen organizational analytics models and enable the transition from storage to action with solid, controlled foundations.

C. International Standards for Quality, Security, and Metadata

The implementation of international standards in advanced analytics systems is essential for ensuring data quality, integrity, and security. The main standards related to this research are ISO/IEC 25012, ISO/IEC 11179, ISO/IEC 27001, and ISO 8000, where ISO stands for International Organization for Standardization and IEC for International Electrotechnical Commission, according to recent scientific literature.

The ISO/IEC 25012 standard provides a comprehensive framework for evaluating data quality based on a set of inherent characteristics and system-dependent completeness [31]. In the context of master data management, these characteristics are especially critical, as they ensure the reliability of core business entities that serve as authoritative references across organizational processes. The standard's multidimensional approach aligns with findings in specialized domains; for instance, in healthcare systems, data quality evaluation must consider not only syntactic accuracy, but also semantic precision and temporal relevance to support clinical decision-making. Similarly, industrial applications demonstrate that the ISO/IEC 25012 model effectively addresses measurement challenges through its structured property-based evaluation methodology, which enables organizations to systematically identify and prioritize data quality improvements [32].

With regard to metadata, ISO/IEC 11179 is recognized as the reference framework for metadata governance, particularly in the medical domain. In [33], the authors demonstrated its application in a pragmatic metadata repository that aggregated 466,569 unique medical metadata definitions, facilitating interoperability through standardized data elements. Similarly, [34] emphasized that repositories adhering to this standard enhance semantic interoperability by linking data elements to controlled vocabularies, which is critical for cross-institutional data integration. These studies underscore the role of the framework in ensuring semantic consistency and reliable information exchange in distributed environments.

Regarding security, the ISO/IEC 27001 standard has been widely adopted to protect information assets. According to [35], the framework derived from ISO/IEC 27001:2013 helps organizations identify, assess, and control risks while ensuring compliance with information security laws. Additionally, [36] emphasized its role in balancing privacy and utility in big data analytics, especially in the healthcare sector, strong data protection is essential.

Finally, the ISO 8000 standard plays a critical role in ensuring master data quality, particularly in sectors such as manufacturing and asset management, where consistency and traceability are crucial. As highlighted by [32], ISO 8000

provides a framework for evaluating and certifying master data repositories, emphasizing dimensions such as accuracy, completeness, and compliance—key factors in maintaining reliable "golden records" (p. 795). The study [37] further, ISO 8000's alignment with other standards (e.g., ISO 25012) enables organizations to address both inherent and system-dependent data quality challenges, reducing redundancies and improving interoperability (p. 4). By adhering to these principles, businesses can mitigate operational risks and enhance their decision-making processes. These regulations not only establish best practices but also provide an essential foundation for the design of advanced analytics models focused on data trust, interoperability, and sustainability.

D. Data Visualization for Decision-Making

Effective data visualization allows relevant information to be consolidated in an understandable manner, thus facilitating tactical and strategic decision-making in different organizational and social contexts.

Dashboards and Key Performance Indicators (KPI) have become essential tools for visualizing critical information in real time and facilitating informed decision-making. According to [38], the integration of dashboards into automated processes enabled the visualization of key indicators, such as response time and service level, which increased operational efficiency by 40% through Robotic Process Automation. For their part, [39] highlighted that the implementation of 22 standardized KPIs in dashboards allowed managers to comparatively analyze the performance of different organizational units and optimize strategic decisions. In both cases, real-time visualization not only improved efficiency and accuracy but also strengthened operational control and proactivity in organizational management.

Visual storytelling has established itself as a powerful tool for conveying complex information in an accessible and persuasive manner. In [40], the authors demonstrated the effectiveness of narrative techniques in mental health interventions, where they significantly improved life satisfaction among participants by facilitating emotional engagement and perspective shifts. Similarly, [41] highlighted the role of visual techniques, such as empty shots, in cinematic story-driven methods, showing how their distribution varies across genres to evoke specific emotional and dramatic effects. These studies underscore that effective storytelling combines meaningful visualization with a coherent narrative structure, enhancing understanding and engagement across diverse contexts from healthcare to film. By tailoring visual stories to audience needs—whether through therapeutic group discussions or genre-specific cinematic techniques—storytelling bridges gaps between data, emotion, and action, fostering deeper connections and informed decision-making.

Several studies in the field of Visual Analytics have demonstrated the potential to improve understanding and decision-making in various contexts. For example, [42] developed the Vulnerable Neighborhood Explorer (VNE) tool, which uses interactive visualization and clustering techniques to identify neighborhoods vulnerable to disasters, shows effective results in the analysis of socioeconomic disparities. On the other hand, [43] explored the use of generative AI agents to improve data visualization literacy and found that proactive agents with scaffolding techniques significantly increased student understanding. These studies collectively reveal that although numerous methodologies and frameworks—such as CRISP-DM, DataOps, Kimball, Inmon, and ISO standards—have advanced data management and analytical practices, most remain specialized for particular analytical stages or contexts.

Building upon this body of knowledge, the present study proposes a holistic advanced analytics model that unifies these methodologies under a single adaptive structure. Unlike traditional approaches that require changing frameworks depending on whether the analysis is descriptive, predictive, or prescriptive, the proposed model integrates them coherently, ensuring methodological continuity and adaptability across diverse organizational scenarios. This connection between the reviewed literature and the proposed model establishes a comprehensive foundation for data-driven decision-making in complex environments.

III. METHODOLOGY

This research is based on a combined methodological framework that integrates two complementary approaches: the Decision-Making Process Model and Design Science Research approach. This combination allows us to address the complexity of designing a holistic advanced analytics model to optimize organizational decision-making from both conceptual and empirical perspectives. Within this integrated design, the decision-making model supports the qualitative reasoning phase, while the DSR methodology incorporates quantitative evaluation metrics to ensure empirical validation.

A. Decision-Making Process Model

The classic decision-making process model [44] proposes three fundamental phases: intelligence, design, and choice. As illustrated in Fig. 4, this sequential, but iterative approach provides a structural framework for analyzing complex organizational decisions. Furthermore, [45] empirically examined the distribution of effort across the decision-making phases and found that managers devoted substantially more time to the design phase than to the intelligence and choice phases. This pattern remained consistent across different tasks and computing devices, providing empirical support for the applicability of Simon's model in describing how managers structure problem-solving activities in organizational contexts.

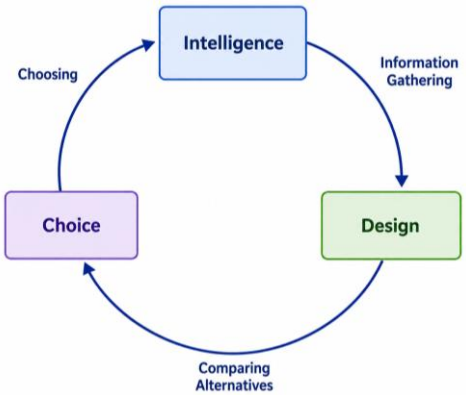

Fig. 4. Three-phase decision-making process model.

1) Intelligence defines this initial phase as the process of scrutinizing the environment to identify situations that require decisions. The author uses the term intelligence in its military sense, emphasizing the systematic collection of critical information that serves as the basis for action (p. 2).

2) Design explains that possible courses of action are generated and analyzed. Design involves creativity (invention of alternatives) and rigor (evaluation of feasibility), constituting a bridge between problem identification and the final selection (p. 2).

3) Choice described this phase as the selection of a specific alternative from among those available. He emphasized that the choice is not merely intuitive but must be based on the criteria established during the previous phases of intelligence and design (p. 2) [44].

B. Approach to Design Science Research (DSR)

The DSR approach provides an epistemological framework that guides the development of a model as a scientific artifact. According to [29] and [46], DSR follows an iterative structure that organizes the development of scientific artifacts through problem definition, objective formulation, artifact design, demonstration, evaluation, and communication, as illustrated in Fig. 5.

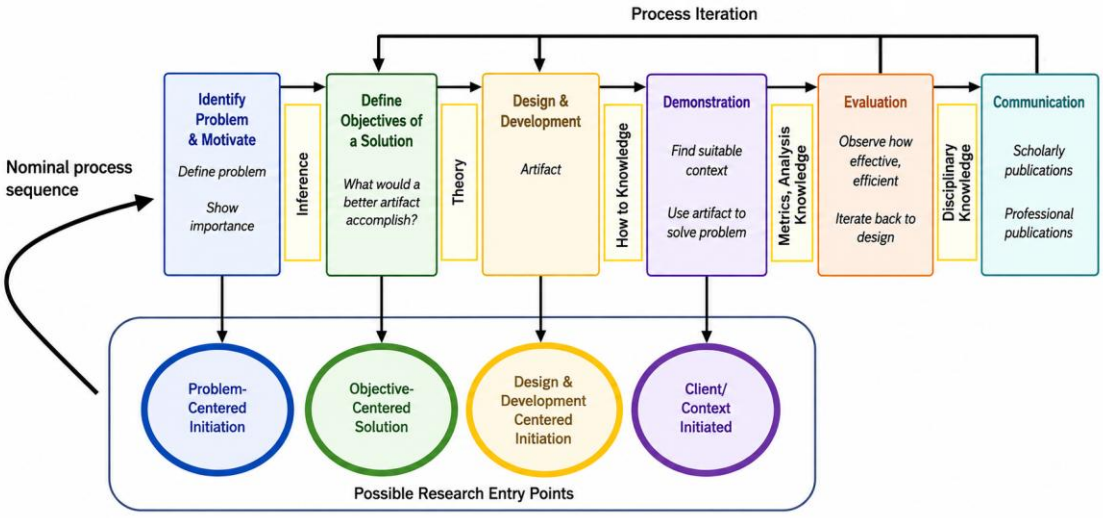

Fig. 5. DSRM process model

1) Identification of the problem and motivation [46] emphasizes that this phase requires clearly determining the research problem and justifying the worth of its solution. Conceptual decomposition of the problem allows its complexity to be grasped, while justification motivates both the researcher and audience. The author highlighted the need to understand the current state of the problem and the relevance of its solution (pp. 28-29).

2) Definition of objectives for the solution, according to [46], the objectives must be rationally derived from the identified problem, considering what is technically feasible. These can be quantitative (e.g., metric improvement) or qualitative (e.g., addressing unresolved problems). The author emphasized the importance of aligning these objectives with the requirements of the artifact, even when the solutions are partial or incremental (p. 29).

3) Design and development [46] describe this phase as the creation of artifacts—constructs, models, methods, or instantiations—that incorporate research contributions. He emphasized that the process requires defining both the functionality and architecture of the artifact, relying on existing theories to substantiate the solution (p. 29). This phase also involves validating the artifact through experimentation, simulations, case studies, or concrete tests which requires a thorough understanding of how to apply the artifact to solve the defined problem. (p. 30).

4) Evaluation [46] proposed comparing the observed results with the objective set using quantitative (e.g., performance) or qualitative metrics(e.g., user feedback). This phase may lead to iterations to refine the artifact or, if successful, to communicate the results (p. 30).

5) According to [46], this final stage consists of disseminating the problem, artifact, and its effectiveness to academic and professional audiences. Publications can be structured following the flow of the DSRM, such as how empirical studies follow a standard format (p. 30).

C. Evaluation Through Expert Judgment

The implementation of Expert Judgment as an evaluation phase in advanced analytics models is justified by its ability to validate the applicability and robustness of the proposed solutions in complex organizational contexts. As demonstrated by the study [47], in the validation of the ACDGE model for personalized learning pathways, Expert Judgment enables for the evaluation of content validity and internal consistency of a model through the participation of specialists with multidisciplinary experience (e.g., academics and professionals with over 30 years in the field). This approach not only ensures the relevance of the model's components (such as the

implementation phase, where significant agreement was obtained with p=0.007) but also identifies areas for improvement, such as simplifying deliverables or incorporating teacher-student co-design.

However, [48] highlighted that expert judgment is key in scenarios with high technical uncertainty, such as the selection of technologies for the reuse of mining waste. Although their study revealed limitations in the distinguishability of alternatives when using questionnaires alone (distinguishability index <0.5), it highlighted that structured interviews with mineralogical design experts improved data quality by clarifying discrepancies and providing technical insights (e.g., chemical process optimization or market viability). This aligns with the need to evaluate advanced analytics models in organizational environments, where data heterogeneity and a lack of historical information require expert validation to reduce bias and ensure practical solutions.

To validate the proposed model, a questionnaire was developed based on instruments recognized in the scientific literature, which allows for the evaluation of key dimensions, such as usefulness, ease of use, understanding, and organizational applicability:

- Technology Acceptance Model (TAM): In [49], the authors state that TAM is widely used to predict the acceptance of technologies, with its core constructs being "perceived usefulness" and "ease of use", which are fundamental for understanding the intention to adopt technology.
- System Usability Scale (SUS): According to [50], SUS allows for quick and reliable measurement of a system's usability, considering elements such as comprehension and ease of interaction.
- Delphi method and expert judgment: In [51], the authors highlighted that the Delphi method allows for the structuring of a systematic process to reach consensus among experts and is highly effective in the evaluation of conceptual models and organizational decisions.

For the content validation of the holistic advanced analytics model, a panel of seven (7) experts was selected. This panel size is consistent with the recommendations of Lynn (1986) [52] and Escobar-Pérez and Cuervo-Martínez (2008) [53], who suggest that groups ranging from five to ten experts are methodologically adequate for content validation studies, ensuring sufficient representativeness and rigor in the assessment of complex constructs while avoiding unnecessary redundancy. The experts were selected through purposive sampling based on their academic qualifications, professional experience in analytics, business intelligence, organizational decision-making, and digital transformation. Each expert conducted the evaluation independently using a structured questionnaire, reducing the potential influence of group bias and strengthening the reliability of the validation process.

IV. Results

This section describes the phases proposed by the DSR methodology to rigorously structure the process of designing, constructing, and validating the proposed model. In particular, the artifact development is detailed through the six defined phases, encompassing everything from problem identification to model communication. Given that one of the key phases of DSR is evaluation, this methodological moment will be used to apply expert judgment as a validation mechanism by collecting specialists' perceptions of the quality and usefulness of the model. Finally, the alignment of each of the DSR phases with the stages of the decision-making process is presented, which reinforces the methodological consistency and practical applicability of the model in the real context of advanced analytics.

A. Identification of the Problem and Motivation

Various studies have shown that organizations face significant challenges in achieving effective decision-making due to fragmentation between data analysis models, the absence of integrated quality and security standards, and poor coordination between key performance indicators and analytical visualization strategies. These limitations result in poorly structured decision-making processes, with little technical support and low information traceability.

Based on this, it is evident that there is a need for an integrated solution that combines good data design and governance practices, advanced analytical tools, and visual resources to strengthen the decision-making process. This justifies the formulation of the following research question:

How can organizations optimize decision-making using a holistic model of advanced analytics?

B. Define the Objectives of a Solution

Based on the identified problem and the need to optimize organizational decision-making through a comprehensive approach to advanced analytics, the main objective of this work is to design and validate a holistic model that integrates the different levels of analytics (descriptive, predictive, prescriptive, and autonomous), as well as processes, standards, and data management methodologies, to strengthen DDDM.

This objective responds to various limitations detected in the literature, such as:

- Fragmentation between data analysis and management models,
- The absence of a methodological structure that integrates quality, security, and governance,
- Limited use of advanced visualization for interpreting critical data,
- And a lack of alignment between the analytical results and actual decision-making processes within organizations.

Therefore, the proposed solution addresses these gaps through the construction of a holistic analytical framework that unifies organizational context analysis, data quality governance, semantic integration, advanced analytical capabilities, and data-driven storytelling within a continuous decision-support lifecycle. The artifact was designed following DSR principles and conceptually validated through expert evaluation to ensure methodological consistency and organizational applicability.

C. Design and Development: Artifact

The design of the holistic advanced analytics model resulting from this research is shown in Fig. 6, which details the components, flows, and actions that comprise the developed artifact in a sequential and functional manner.

The Organizational Context, Table I, shows a sequence of key activities aimed at establishing strategic foundations, analytical requirements, and understanding of the organizational environment prior to working with data. These activities ensure that the advanced analytics process is aligned with business objectives, considering actual needs and available data sources.

The Data Cleaning and Quality, Table II, outlines the steps necessary to ensure that the data used is accurate, consistent, and useful. This stage is based on standards such as ISO 25012 and ISO 8000, which guide data quality management and employ techniques such as profiling and cleaning that are essential for reliable analytics.

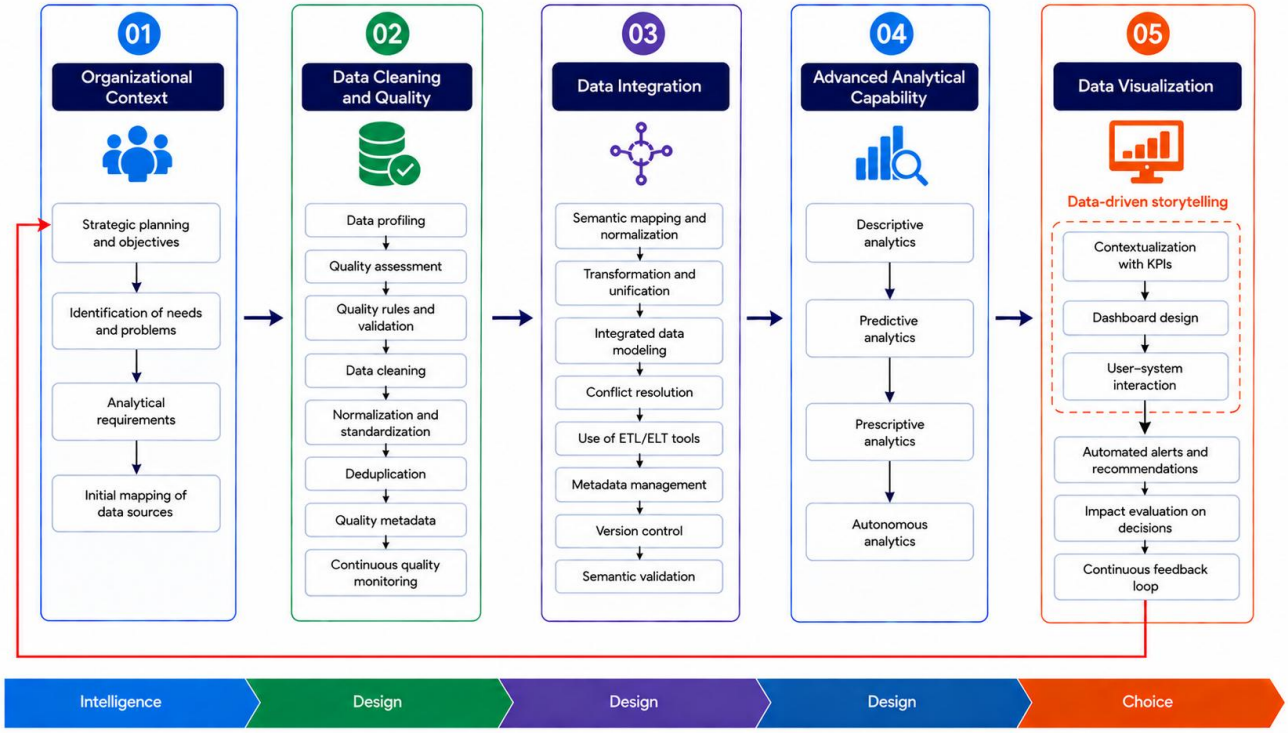

Fig. 6. Holistic advanced analytics model.

TABLE I. ORGANIZATIONAL CONTEXT

Activity	Purpose	Referenced Frameworks / Standards
Strategic planning and objectives	Define the strategic vision and goals for analytical implementation.	Data-Driven Decision-Making (DDDM)
Identification of needs and problems	Detect issues and opportunities for analytical intervention.	Process Model for Decision-Making
Analytical requirements	Establish analytical capabilities required to meet business needs.	DAMA-DMBOK
Initial mapping of data sources	Identify and list internal and external data sources.	DAMA-DMBOK, ISO/IEC 11179

TABLE II. DATA CLEANING AND QUALITY

Activity	Purpose	Referenced Frameworks / Standards
Data Profiling	Analyze data to understand its structure and quality.	DAMA-DMBOK, ISO 8000
Quality Assessment	Evaluate completeness, accuracy, and consistency of data.	ISO/IEC 25012, DAMA-DMBOK
Quality and Validation Rules	Define and apply data validation checks.	ISO/IEC 25012, Kimball
Data Cleaning	Correct errors, remove duplicates, handle missing values.	Crisp-DM, ISO 8000
Normalization and Standardization	Ensure data is in a consistent format.	ISO/IEC 11179, Kimball
Consolidation of Duplicates	Merge duplicate records for consistency.	DAMA-DMBOK
Quality Metadata	Document quality rules and attributes.	ISO/IEC 11179
Continuous Quality Monitoring	Ongoing tracking of data quality KPIs.	DataOps, ISO 8000

TABLE III. DATA INTEGRATION

Activity	Purpose	Referenced Frameworks / Standards
Semantic mapping and normalization	Align and translate terms across sources.	ISO/IEC 11179
Transformation and unification	Standardize formats and structures.	Kimball, Inmon
Integrated data modeling	Create a unified data representation.	Inmon, DAMA-DMBOK
Conflict resolution	Resolve data inconsistencies.	Kimball
Use of ETL tools	Extract, transform, and load data.	Kimball, DAMA-DMBOK
Metadata management	Organize metadata for integration and retrieval.	DAMA-DMBOK, ISO/IEC 11179
Version control	Track and manage changes to data.	DataOps
Semantic validation	Ensure integrated data meets defined semantics.	ISO/IEC 11179

The Data Integration, Table III, shows how the data from multiple sources are consolidated, transformed, and unified. This process is based on practices such as those of Kimball and Inmon for integration and modeling, and is supported by ETL (Extract, Transform, Load) tools and standards such as ISO/IEC 11179 for semantic and metadata management.

The Advanced Analytical Capability, Table IV, details the different advanced analytical capabilities aligned with the Data Analytics Value Chain. These capabilities enable the extraction of value from data using specific algorithms and models, according to the level of analytical maturity.

The Data Visualization, Table V, describes the activities necessary to transform the analytical results into understandable visual elements, aligned with the principles of visual analytics, storytelling, and data-driven decision-making. This phase reinforces organizational action through dashboards, KPIs, and continuous visual feedback.

TABLE IV. ADVANCED ANALYTICAL CAPABILITY

Activity	Purpose	Referenced Frameworks / Standards
Descriptive Analytics	Understand past behavior using statistical summaries.	Value Chain - Business Understanding; Algorithms: Histograms, Clustering
Predictive Analytics	Predict future outcomes using models.	Value Chain - Data Mining; Algorithms: Regression, Decision Trees
Prescriptive Analytics	Recommend actions based on predictions.	Value Chain - Deployment; Algorithms: Optimization, Simulation
Autonomous Analytics	Enable systems to decide and act independently.	Value Chain - Automation; Algorithms: Reinforcement Learning, Deep Learning

TABLE V. DATA VISUALIZATION

Activity	Purpose	Referenced Frameworks / Standards
Data-driven storytelling	Communicate insights through narratives.	Storytelling for Data, Visual Analysis
Contextualization with KPIs	Present insights aligned to performance goals.	DAMA-DMBOK
Dashboard design	Visualize key metrics clearly.	Visual Analytics, Kimball
User–system interaction	Enable users to explore and interact with data.	Visual Analysis, Human-Centered Design
Automatic alerts and recommendations	Provide proactive, rule-based guidance.	Prescriptive Analytics
Impact assessment on decisions	Evaluate analytical influence on outcomes.	Process Model Decision-Making

D. Demonstration

In order for the proposed artifact to demonstrate its applicability, we present an alignment between the phases of the holistic model of advanced analytics and the stages of the classic model of the decision-making process, which include three key moments: intelligence, design, and choice. This correspondence, as shown in Table VI, allows us to observe how the developed model offers structured support to each stage of the decision-making process.

In particular, the initial phase, called the Organizational Context, is designed to adapt to any type of organization, regardless of size, industry, or level of analytical maturity. Its purpose is to clearly establish needs, available data sources, and plans for future actions.

In addition, the model was evaluated by expert judgment, with the participation of seven professionals with experience in data analytics, visualization, and organizational decision-making. The results obtained in this evaluation, which are presented in the next phase, reflect positive acceptance in terms of the model's usefulness, applicability, and methodological alignment.

E. Evaluation (Validation)

A structured questionnaire was administered to a group of experts in advanced analytics and decision-making to evaluate the consistency, applicability, and usefulness of the developed holistic model.

Table VII shows the set of questions asked along with the criteria evaluated for each question.

TABLE VI. ALIGNMENT OF THE PHASES OF THE PROPOSED MODEL AND THE DECISION-MAKING MODEL

Holistic Model Phase	Functional Description	Decision-Making Phase
Organizational Context	Establishes strategic goals, identifies needs, defines analytical requirements, and maps data sources.	Intelligence
Data Cleaning and Quality	Ensures data reliability through profiling, validation, cleaning, standardization, and quality monitoring.	Design
Data Integration	Integrates and harmonizes data using ETL tools, metadata management, and semantic validation.	Design
Advanced Analytical Skills	Applies descriptive, predictive, prescriptive, and autonomous analytics to explore alternatives.	Design
Data Visualization	Presents analytical insights through storytelling, KPIs, dashboards, and user interaction for decision support.	Choice

TABLE VII. QUESTIONS FROM THE VALIDATION INSTRUMENT AND CRITERIA EVALUATED

Nº	Question	Criterion evaluated
1	The proposed model adequately reflects the key phases of a data-driven decision-making process.	Functional relevance
2	The phases of the model are clearly defined and understandable for implementation in an organization.	Structural clarity
3	The model adapts to different organizational contexts without the need for structural changes.	Organizational flexibility
4	The model appropriately integrates recognized frameworks and methodologies (e.g., ISO 25012, DSR, TD Process Model).	Methodological alignment
5	The relationships between the phases of the model are consistent and logically sequential.	Logical consistency
6	The model can be replicated by other researchers or professionals with minimal ambiguity.	Reproducibility
7	The analytical capabilities described (descriptive, predictive, prescriptive, autonomous) are correctly classified.	Functional classification
8	The inclusion of the visualization phase (KPIs, storytelling, dashboards) contributes to the understanding and use of the results.	Interpretative capacity
9	The model adds value to organizational decision-making from a holistic and integrative approach.	Organizational added value
10	I believe that the proposed model is useful and applicable for improving decision-making processes based on advanced analytics.	General assessment of usefulness

Table VIII shows the results of seven experts in the fields of data analysis, visualization, and business intelligence who answered the questionnaire. Each question was rated on a Likert scale from 1 to 5, where 1 represents "strongly disagree", and 5 represents "strongly agree". Three indicators were calculated for each question: average, standard deviation, and percentage of responses equal to or greater than four.

TABLE VIII. RESULTS OF MODEL VALIDATION ACCORDING TO EXPERT JUDGMENT.

Question	Average	Standard deviation	Percentage ≥ 4
Q1	3.71	1.03	57.14%
Q2	4.14	1.12	71.43%
Q3	3.57	0.49	57.14%
Q4	3.71	0.70	57.14%
Q5	3.57	1.18	57.14%
Q6	3.71	0.88	71.43%
Q7	3.71	0.88	71.43%
Q8	4.57	0.73	85.71%
Q9	3.29	1.03	42.86%
Q10	3.71	1.03	57.14%

1) Average: The average score for each question indicated the overall degree of acceptance of each dimension evaluated in the model. Most of the averages were between 3.5 and 4.5, which are positive and shows a favorable trend toward the usefulness and applicability of the proposed holistic model.

2) Standard deviation: This value measures the variability of the responses. Lower values indicate consensus among the experts. For example, question Q3 had a low deviation (0.49), suggesting that experts closely agreed with their responses. Conversely, a deviation of 1.18 (Q5) indicated greater dispersion and possibly divergent views on that dimension.

3) Percentage ≥ 4: This indicator represents the degree of acceptance (high ratings). It can be seen that:

a) Q8: Visualization and interpretation of results had the highest level of acceptance (85.71%), reflecting a high positive consensus.

b) Q9: Obtained the lowest agreement percentage (42.86%), which provided valuable feedback for refining the organizational adaptability dimension of the proposed model. This result contributed to the iterative improvement of the artifact by identifying the need to strengthen contextual flexibility and clarify the integration mechanisms across heterogeneous organizational environments. From a DSR perspective, this feedback was considered a constructive input for the evolution and maturation of the proposed framework.

F. Communication

The Communication phase of the DSR methodology is evidenced through the presentation and dissemination of the results of the developed holistic model, as part of a doctoral research study. The results of the questionnaire administered to seven experts indicate that the proposed model is conceptually coherent, methodologically sound, and relevant to the stated objectives. Most of the indicators per question are above the

recommended acceptance thresholds, with averages higher than 3.5 and agreement levels (ratings of 4 or 5) exceeding 60% in most of the evaluated dimensions.

These findings support the validity and applicability of the model in real contexts, constituting a contribution expected to benefit the academic and professional community interested in data-driven decision-making processes based on advanced analytics. The publication of this scientific study serves as a formal dissemination mechanism, thereby fulfilling the principles of the Communication phase of the DSR methodology.

V. Discussion

A comparison of the proposed holistic model with the reviewed literature clearly shows that existing contributions address only partial dimensions of the analytical process and fail to provide an integrative structure that articulates data quality, methodologies, governance, analytical capabilities, and effective decision support. The holistic character of the proposed model lies in its cyclical and adaptive structure, which integrates the analytical process from descriptive capabilities to autonomous decision-support mechanisms, while maintaining continuous feedback for organizational improvement [16–18], [27–29]. Validation with experts supports this reading, reflecting recognized strengths in visualization, structural clarity, and reproducibility of the model, as well as areas where challenges remain, particularly in organizational adaptability

Firstly, models based on uncertainty representation, such as the FCFS approach [13], provide an important advance for evaluating alternatives in highly technical contexts. However, their application is restricted to the methodological level of calculation, without incorporating data lifecycle management mechanisms, quality standards, or strategic elements that enable their use within complex organizational processes. The proposed model extends these approaches by structuring an adaptive analytical lifecycle that integrates governance standards, semantic interoperability, data quality management, analytical scalability, and decision-oriented visualization mechanisms under a unified framework.

On the other hand, crisis decision-making models proposed in the healthcare context, such as the CEO, CEO–advisor, and TMT approaches [14], emphasize leadership styles and governance in high-pressure environments. While they provide relevant insights into decision-making dynamics, these models do not consider the data engineering processes or analytical support necessary for evidence-based decisions. In contrast, the holistic model articulates the classic decision-making process with data analysis methodologies, governance standards (ISO 25012, ISO/IEC 11179, ISO 8000, ISO/IEC 27001), and visualization mechanisms geared toward decision-making.

Similarly, evidence of emerging complexity in human decisions, such as that observed in the analysis of chess players' behavior [15], demonstrates the importance of adaptability and situational reasoning. Nevertheless, these studies are limited to specific domains and do not constitute frameworks applicable to the organization of an advanced analytics process. The present model integrates the principle of adaptability through continuous feedback, scaled analytical capabilities, and permanent monitoring mechanisms, expanding its application to multiple sectors.

Likewise, frameworks such as the Analytics Value Chain [16] and proposals linking analytical capabilities to the organizational value chain [17, 18] have made it possible to conceptualize the progression from descriptive analysis to autonomous analytics. However, these approaches focus on the functional classification of capabilities, without offering a methodological roadmap that articulates standards, data quality, semantic integration, or evaluation mechanisms. The proposed model extends these contributions by structuring operational phases that include cleaning, integration, modeling, and visualization, along with formal quality assurance mechanisms based on ISO 25012 and ISO 8000.

In terms of methodology, CRISP-DM [21, 22] continues to be a widely used standard, especially in data mining projects. Its main limitation lies in its technical approach and its lack of integration with governance models, international standards, or organizational decision-making processes. For its part, DataOps [27, 28] introduces automation, version control, and continuous orchestration, but focuses on pipeline engineering rather than decision support. The holistic model combines both approaches under a higher framework based on DSR, which allows for the integration of design, validation, communication, and continuous improvement.

Finally, the expert validation results reinforce the conceptual coherence of the model. The high acceptance rate of the visualization phase (85.71% of responses ≥4) confirms the importance of translating analytical results into actionable knowledge. In contrast, the lower agreement levels obtained for functional relevance (Q1, 57.14%) and holistic organizational value (Q9, 42.86%) provided valuable input for refining the proposal. Regarding Q1, expert feedback revealed the need to make the relationship between the analytical process and organizational decision-making more explicit. Consequently, the model was refined by incorporating a transversal representation of decision-making throughout the analytical lifecycle, strengthening the connection between analytical capabilities and organizational outcomes. Similarly, the results obtained for Q9 highlighted the importance of reinforcing the continuous improvement perspective. As a result, a cyclical feedback mechanism was incorporated, connecting the data visualization stage with the organizational context and enabling iterative refinement across the analytical lifecycle. These refinements strengthen the model's holistic character by integrating not only the complete advanced analytics cycle but also continuous organizational learning, adaptation, and decision support.

VI. Conclusion

This study proposed and validated a holistic advanced analytics model aimed at optimizing organizational decision-making through the integration of data governance, semantic integration, analytical capabilities, visualization mechanisms, and data-driven storytelling. Unlike fragmented analytical approaches, the proposed framework structures the analytical process as a continuous and adaptive decision-support lifecycle aligned with the intelligence, design, and choice phases of classical decision-making theory.

The application of DSR enabled the iterative development and conceptual validation of the proposed artifact. Expert evaluations indicated favorable perceptions regarding the model's structural coherence, interpretability, and organizational applicability, particularly in the visualization and analytical integration phases.

The proposed framework provides to the current body of knowledge by providing an integrative structure capable of connecting data quality standards, integration methodologies, advanced analytics, and decision-support visualization within a unified organizational context. Furthermore, the incorporation of continuous feedback mechanisms strengthens the adaptive capacity of the model in dynamic and data-intensive environments.

VII. Future Works

Future research will focus on implementing and testing the proposed holistic advanced analytics model in real organizational environments to evaluate its practical effectiveness, scalability, and adaptability across different sectors. Such empirical validation will provide additional evidence regarding the model's contribution to organizational decision-making and its applicability in diverse operational contexts.

The next stage of this ongoing research involves developing a computational tool that integrates all phases of the proposed model, facilitating its operational deployment, automation, and scalability. Comparative studies with existing analytical and decision-support frameworks will also be conducted to assess the relative advantages, limitations, and organizational impact of the proposed model, as well as to identify best implementation practices.

Additionally, the incorporation of emerging technologies—such as generative artificial intelligence, the Internet of Things (IoT), and blockchain—is proposed to expand the model's analytical, governance, and automation capabilities. Future studies will also explore the integration of cognitive analytics capabilities to enhance contextual reasoning, knowledge discovery, interpretation of unstructured information, and human-centered decision support in complex organizational environments.

Furthermore, the model will be adapted and tested within specific sectors, including healthcare, education, and logistics, to validate its contextual flexibility and sector-specific applicability. Finally, future work will focus on the computational operationalization of the proposed framework through the development of an interoperable analytical platform capable of automating the model lifecycle in real organizational environments and enabling longitudinal evaluations of its impact on analytical maturity, data governance, digital transformation, and organizational performance.

Multi-Scale Curvelet-Based Directional Denoising for Chest X-Ray Images

Neenu Sebastian*, B. Ankayarkanni
Department of Computer Science and Engineering-School of Computing,
Sathyabama Institute of Science and Technology (Deemed to be University), Chennai 600119, India

***Abstract*—In modern healthcare, medical imaging has a significant role in understanding the structure and functioning of the human body, which helps doctors to diagnose, to plan the treatment, and to monitor the disease. Chest X-rays are widely used for the early detection and treatment of various lung infections. The effectiveness and the accuracy of the diagnosis depend largely on the quality of the medical images. Chest X-rays often suffer from Gaussian and Poisson noise, which affects the visibility of fine anatomical structures. Although methods like Gaussian filtering, NLM, and GAN have been used, they often compromise between denoising and retaining edge details. A robust denoising algorithm, Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD), is proposed to denoise medical chest X-ray images, which uses the curvelet transform coefficients. The performance of the proposed MCF-DD model was evaluated on the Chest X-Ray Images dataset from the Kaggle repository and DICOM images from the MIDRC-RICORD-1C dataset. MCF-DD achieved a PSNR of 36.57dB and SSIM of 0.9062 on Kaggle images, and 40dB PSNR with 0.9412 SSIM on DICOM images, indicating strong denoising performance across both datasets.**

***Keywords*—Image denoising; medical image; Chest X-Ray; Poisson noise; Gaussian noise; Curvelet Transform**

I. Introduction

Medical images are used in healthcare for the diagnosis and monitoring of human diseases and health. Chest X-rays are of significant relevance in current medical diagnosis applications, as they are the most widely used cost-effective modality for diagnosing lung infections such as pneumonia, lung cancer, and COVID-19 [1]. The quality of chest X-rays is often compromised by the presence of noises such as Poisson and Gaussian noise [2]. The main sources of noise in X-ray images are scattered radiations, fluctuations in electronics, and quantum noise. To reduce the exposure of patients to ionizing radiation, low-dose imaging protocols that prescribe the usage of low photon count are used during medical imaging. Due to statistical variations in photon counts, Poisson noise gets added to X-ray images. As a result of these noises, the pixel distribution of the images will be altered, and this may result in the loss of image features such as texture, edges, intensity, etc. The presence of this noise affects the exact diagnosis and monitoring of the disease [3]. Enhancing the quality of Chest X-Ray images through effective denoising techniques is essential to support clinical procedures, as demonstrated by image-guided interventions that rely on clear imaging for precise treatment planning. So, image denoising is a required pre-processing stage for applications using medical images and so it is crucial to develop effective denoising techniques. Also, reliable denoising of chest X-rays under mixed Poisson and Gaussian noise remains a key challenge. Existing methods often fail to effectively suppress noise while preserving fine anatomical structures that are critical for accurate pneumonia diagnosis.

The various noise reduction methods can be broadly classified into four categories: conventional filtering, transform domain filtering, deep learning-based methods [4], and hybrid models [5]. For denoising, the conventional filtering methods use linear filters such as a Gaussian filter, mean filter, etc., and nonlinear filters such as a median filter [6], bilateral filter, etc. These filtering methods have low computational complexity, but the denoised images will be blurred, resulting in low resolution. In transform domain filtering, different transform functions are used to remove image noise. The advantages of transform methods include edge preservation and multi-resolution analysis, but after denoising using transform methods, the resultant image may contain artifacts that occur as a result of poorly chosen parameters and threshold values. Deep learning-based denoising methods use neural network architectures, particularly convolutional neural networks, autoencoders, and generative models, to learn complex noise patterns directly from data [7]. These approaches can adapt to various noise distributions and often outperform traditional techniques in preserving fine structural details. However, their performance heavily depends on the availability of large, high-quality annotated datasets, and they typically require significant computational resources for training and inference. Hybrid denoising models integrate multiple techniques, typically combining conventional or transform domain methods with deep learning approaches to exploit the strengths of each technique. These models aim to enhance denoising accuracy and robustness across diverse noise types. Recent studies report that deep learning methods show poor generalization across scanners, dose levels, and patient subgroups, and may cause over-smoothing or hallucinated textures in chest X-rays.

The above-discussed methods exhibit limitations such as blurring in conventional filters to data dependency in deep learning models. So, there is a need for an adaptive and structure preserving denoising framework for Chest X-Ray images. To address these challenges, Multi Scale Curvelet Filtering with Directional Denoising (MCF DD) framework is proposed. MCF DD employs curvelet based dynamic thresholding, which adaptively suppresses noise while preserving edge and texture details across scales and directions.

*Corresponding author

To overcome the lack of orientation-sensitivity in traditional methods, Gabor and Morlet filters are integrated to enhance directional and frequency-specific features. The inclusion of an anisotropic Gaussian filter ensures edge-preserving smoothing, minimizing the risk of blurring diagnostic boundaries. Unlike deep learning models, MCF DD does not rely on large annotated datasets or intensive training, offering a computationally efficient solution. Furthermore, by performing coefficient-level fusion of multiple filtered outputs, MCF DD combines the strengths of each component filter, achieving superior denoising performance without the architectural complexity of conventional hybrid models.

Unlike existing methods that rely on fixed global filtering, the proposed MCF-DD uses patch-wise adaptive noise characterization to guide noise-specific directional curvelet denoising, enabling effective handling of spatially varying mixed noise. In the proposed approach, a patch transformation method is applied where the input image patches are obtained by segmenting the input image, which is then fed as an input to the proposed robust denoising algorithm, Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD). In this algorithm, to capture the different anatomical structures, a multi-scale representation is needed, which can be achieved by using Curvelet Transform. By using Curvelet Transform, the input patches are divided into different scales and orientations, which helps to get the information regarding the local and global structure. To preserve the edge information, Curvelet Transform is integrated with directional filtering techniques: Gabor, Morlet, and Anisotropic Gaussian filters. This approach aims to effectively remove noise such as Gaussian and Poisson while preserving critical anatomical structures and features across multiple scales and orientations.

In summary, the key contributions of the proposed framework can be outlined as:

- A novel multi-scale denoising approach (MCF-DD) is proposed, which integrates curvelet-based multi-resolution decomposition with directional filtering to preserve structural details and suppress diverse noise types in chest X-rays.
- An initial patch-based classification mechanism is introduced that adaptively processes regions with varying noise intensities, reducing unnecessary computation and enhancing local feature preservation.
- For experimental validation, the model was tested on JPEG format chest radiographs from the Kaggle Chest X-ray dataset [8] and DICOM images from the MIDRC-RICORD-1C dataset [9]. The inclusion of both compressed and uncompressed formats ensures robustness of the proposed method across different imaging standards.

II. Related Work

Image denoising refers to the methods used to find the clear image from the noise image, as depicted in Fig. 1. The aim of denoising methods is to remove the noise from medical images and also to preserve the clinical details. According to the evaluation criteria outlined in [10], effective image denoising should maintain uniformity in flat regions, preserve edge sharpness without blurring, retain structural and textural details, keep the original contrast intact, and avoid introducing any unnatural artifacts.

In medical imaging, the different sources of noise can be low light, sensor characteristics, dust particles in scanning machines, disturbance in transmission channels, etc. The predominant types of noise encountered in medical images include Gaussian noise and Poisson noise. Gaussian noise is a type of noise that follows a Gaussian distribution [11]. Gaussian noise can be caused by different sources, such as sensor temperature fluctuations, low radiation dose, etc. Poisson noise is caused by the photon emission in Chest X-Rays. The variance of Poisson noise depends on image signal intensity. Chest X-Ray images and CT images usually contain a combination of Gaussian and Poisson noise. Various methods have been suggested to accomplish these denoising goals, ranging from traditional image processing methods to modern machine learning approaches. These methods are broadly categorized into conventional filtering, transform-based techniques, deep learning approaches, and hybrid models.

A detailed study of the application of filtering algorithms for denoising images is done in [12]. It is the most widely used denoising method. Filtering methods use mathematical models to remove noise from images. The linear filter works by computing the weighted sum of pixel values in a defined neighborhood. Gaussian[13] and mean filters are examples of linear filters that will remove the noise, but result in blurred denoised images. Median filter [14], Bilateral filter [15], and non-local means filter [16] use nonlinear adaptive filtering techniques to remove noises from images. They are better in preserving the edge information than the linear filters. In [17], advanced filtering techniques such as an adaptive Wiener filter are proposed, which generate less blurred denoised images compared to the other methods. An iterative process to reduce noise is proposed in [18], which results in better edge preservation while maintaining image quality.

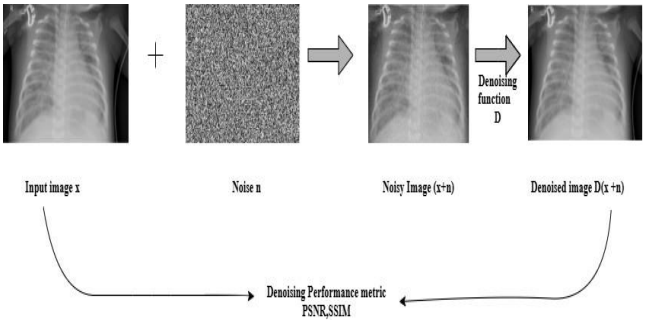

Fig. 1. Medical image denoising

Gaussian and Poisson noises are common types of noise affecting medical images. Filtering approaches work well for a particular type of noise, and their performance degrades for mixed noise [19]. So, there is a need for a denoising method capable of handling multiple types of noise.

In transform-based methods, to separate the noise and signal components, the image is converted from the spatial model to the mathematical model, where the noise and signals

have different frequency components. To suppress the frequency components of the noise, filtering or threshold methods are applied which preserve significant image structures. In Wavelet Methods [20], the wavelet threshold method was proposed, in which wavelet decomposition is used to separate noise from image signals, enabling adaptive noise removal with minimal loss of information. This method resulted in the over-smoothening of important anatomical features, as it captures only point singularity information rather than complex structural information. Adaptive Bayes Shrink thresholding [21] was proposed, in which the noise variance is calculated in each sub-band using the Bayesian estimation, which is used for the calculation of the optimal threshold value, which varies according to the noise level present in each band. DWT is an inconsistent noise removal method due to its shift variant property, in which a small shift in the image information leads to the generation of different wavelet coefficients. In [22], Stationary Wavelet Transform (SWT), which addresses the shift variant property of DWT, is proposed by eliminating down-sampling, which is done by using the unsampled filter coefficients and convolution. The increased computational cost and redundancy make it less suitable for real-time processing of medical images. The other transform-based methods are Curvelet Transform (CT) [23], [24], Contourlet Transform (CTT) [25], Shearlet Transform (ST) [26]. Transform-based methods handle Gaussian noise, but they have limitations when handling Poisson noise due to the signal's dependent nature.

Deep learning methods are widely used for medical image denoising due to their capability for automatic feature extraction. Specific noise models, which are used in traditional methods, limit their ability to adapt to mixed noise input images, while deep learning approaches learn the noise patterns from noisy images, which are later used for noise removal. A deep CNN model for handling the Gaussian noise using residual learning is proposed in [27]. A self-supervised learning method that removes Poisson noise in CT images was proposed in [28]. The requirement of multiple noisy images of the same patient challenged the efficiency of this method in medical imaging. Autoencoder-based approaches were proposed in the work [29]. In [30], an efficient deep learning model to estimate a residual image from the input image with the Gaussian noise was proposed. In GAN-based methods, an image-to-image translation approach for CT images was proposed in [31], [32]. The lack of paired training data, overfitting on small datasets, and high computational complexity challenge the application of deep learning methods for medical image denoising.

For achieving better results, several researchers have proposed hybrid approaches, in which different denoising methods with different strengths are combined together. In [33], BM3D (Block Matching and 3D filtering) and wavelet transforms have been combined together which yields better textural preservation and fine details. But this method demanded a larger memory space requirement due to 3D filtering in BM3D. In [34], the CNN's ability to learn complex patterns is combined with wavelets' multi-scale representation. Several other hybrid models have been discussed in the work [35]. Hybrid methods give better results than single method, but the need of extensive training data, need of parameter tuning, and increased computational complexity limits its application. Inspired by these approaches, the proposed work aims to improve Chest X-Ray denoising by preserving critical anatomical structures and enhancing image quality. Though there are significant developments in medical image denoising techniques, there are several challenges that are to be addressed. One major challenge is the lack of a denoising technique that can effectively handle the mixed noise types that are often present in real-world medical imaging. Another challenge is the high computational complexity of particularly deep learning and hybrid methods, which will make them less practical for medical applications. There exist numerous studies for denoising MRI and CT images, and there is a noticeable lack of research in denoising X-Ray images. Among the various medical image modalities available, this research work focuses on Chest X-Rays, which are used for the detection and diagnosis of chest infections. This study presents a novel denoising framework, Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD), specifically designed to address critical gaps in existing medical image denoising techniques. Unlike conventional, deep learning, or hybrid approaches, the proposed method effectively handles mixed noise types, which commonly affect real-world chest X-rays. By focusing on the underexplored modality of chest radiographs and prioritizing both effective noise suppression and structural detail preservation, MCF-DD introduces a practical and domain-specific solution for enhancing diagnostic quality in resource-constrained clinical settings. Recent diffusion-aware frameworks, such as DIFCNet, utilize diffusion features or reconstruction inconsistencies learned through deep generative models to characterize image degradations. In contrast, the proposed MCF-DD framework is a non-learning, noise-adaptive method that directly targets mixed Poisson Gaussian noise through patch-wise statistical characterization and directional curvelet domain filtering, making it computationally efficient.

III. Proposed Methodology

The overall workflow of the proposed Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD) framework is illustrated in Fig. 2. For denoising medical images, a new method is proposed by leveraging a multi-scale Curvelet Transform integrated with directional filtering techniques such as Gabor, Morlet, and Anisotropic Gaussian filters. This approach removes both Gaussian and Poisson noise, while preserving critical anatomical structures and features across multiple scales and orientations. Poisson noise is signal-dependent and arises from the statistical nature of X-ray photon detection, making it more prominent in low-dose imaging, where fewer photons reach the detector. In contrast, Gaussian noise is signal-independent and typically originates from electronic imperfections in imaging systems. While Poisson noise affects areas with low photon counts, Gaussian noise is uniformly distributed across the image. Both types of noise degrade image quality by reducing contrast and obscuring anatomical details. Denoising methods like wavelet transforms, CNN-based approaches, and filtering techniques are often employed to mitigate these noise effects.

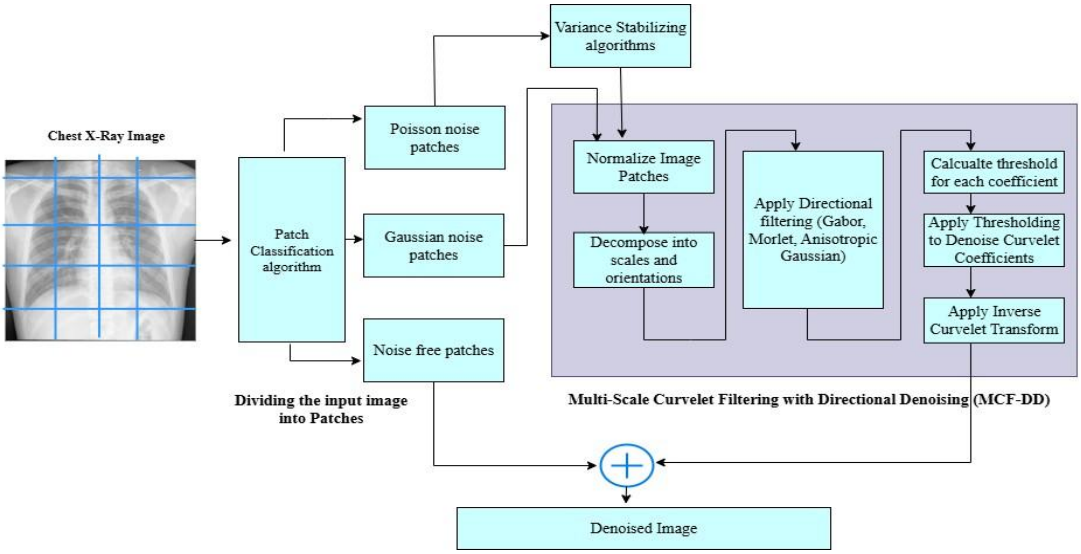

Fig. 2. System architecture

A. Patch Classification

In medical X-rays, preserving and enhancing edges and fine anatomical details is crucial for accurate diagnosis and interpretation. Conventional denoising and feature extraction methods, such as Gaussian filtering or basic wavelet transforms, often struggle to maintain these important features. The Curvelet Transform, on the other hand, represents images in terms of localized, oriented, and scale-specific components, which align better with the curvilinear structures typically present in biological tissues. To preserve and enhance subtle edges and fine anatomical details, the input medical image is divided into different patches of size 64 X 64. Each patch is analyzed to find the type of noise dominant in that patch, and correspondingly, the patch is classified into the following classes, such as the Gaussian class, Poisson class or noise-free image patch class. The noise-free image patches are preserved without any modifications and processing. The Poisson class patches will undergo Variance Stabilizing Transformations (VST) to transform the Poisson noise into a form where the variance becomes more uniform. The stabilized Poisson patch and the Gaussian noise patch will be given as input to Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD) for noise removal from the noisy image patches. The denoised image patches are aligned along with the noisy free patches to reconstruct the denoised image.

The medical image is divided into smaller, non-overlapping patches to analyze and process localized regions independently. This approach allows for identifying noise characteristics and applying appropriate denoising techniques at a granular level. This patching method enhances the ability to denoise the image efficiently while maintaining critical anatomical features. Each input image is divided into non-overlapping square patches of size 64 × 64 pixels. Prior to division, image dimensions are checked to ensure compatibility with the patch size. If the height or width is not perfectly divisible by 64, zero padding is applied to the bottom or right edges of the image. Each patch is analyzed for the dominant noise present in it. The difference in the characteristics of Gaussian and Poisson noises is used to calculate the dominant noise in the patches. Gaussian noises are uniform across all intensities. Gaussian noises will have high variance but are independent of the mean intensity. On the other hand, for Poisson noise, its variance increases proportionally to the mean intensity. Noise-free patches will have low variance-to-mean ratio. For an image patch with ‘n’ no pixels and if ‘li’ is the intensity of pixel i, the mean values of the patch ’m’ can be calculated using Eq. (1) [36]:

$$m = \frac{1}{n}\sum_{i=1}^{n} l_i \quad (1)$$

The measure of the spread of pixel intensities around the mean value gives the variance value ‘v’ of the patch which can be calculated using Eq. (2) [37]:

$$v = \frac{1}{n}\sum_{i=1}^{n}(l_i - m_i)^2 \quad (2)$$

Variance to Mean ratio (v_to_m_ratio) for image patch can be calculated using Eq. (3) [37]:

$$v_{to_m_ratio} = \frac{v}{m} \quad (3)$$

For classifying the image patches into Gaussian, Poisson and clean image clusters, Gaussian Mixture Model is used, which represents the data as mixture of multiple Gaussian distributions. In noisy Chest X-Ray image, the variance to mean ratio for image patches follows a multi modal distribution as the variance to mean ratio value’s characteristics changes depending on the type of noise dominant in that patch. GMM (Gaussian Mixture Model) is used to understand the data distribution and to determine the threshold values for classification. These threshold values dynamically vary depending on the data distribution characteristics. To fit a mixture of Gaussian distributions to variance to mean ratio, GMM initialize three Gaussian components for clean patches, Poisson patches and Gaussian patches, respectively. Then it uses Expectation Maximization algorithm [38] to adjust and improve the parameters such as mean (μ), variance (σ2), and weight (w). The mean values of the established three Gaussian distribution indicate the typical values for clean patches,

Poisson noise patches, and Gaussian noise patches, respectively. Algorithm 1 presents the patch classification.

Algorithm 1: Patch Classification Algorithm

Normalize the input image by scaling the pixel values to [0,1].

Extract *p_size* X *p_size* patches from the image.
Calculate the variance-to-mean ratio for each image patch.
Determine the dynamic thresholds T1, T2 using Gaussian Mixture Model (GMM), by fitting a 3 component GMM to the V/M ratios and use cluster means to set T1, T2.
For all image patches do
Compute mean and variance for the patch.
Compute *v_to_m_ratio.*
If *v_to_m_ratio*≥*T*2then
Assign to Gaussian_noise_patches
else if *T*1 ≤ *v_to_m_ratio* ≤ *T*2 then
Assign to Poisson_noise_patches
Else
Assign to Clean_patches
end if.
End

The thresholds T1 and T2 are then calculated as the midpoints between the adjacent Gaussian means to establish decision boundaries between the noise classes. T1 is set as the average of the mean values of the clean and Poisson noise distributions, and T2 is calculated as the average of the Poisson and Gaussian noise distributions. This adaptive thresholding approach ensures that the classification boundaries are not arbitrarily chosen but instead dynamically adapt to the distribution of noise in the dataset. The patches whose variance-to-mean ratio is greater than T2 are classified as Gaussian patches, and the patches with their variance-to-mean ratio between T1 and T2 are classified as Poisson patches. Patches with a variance-to-mean ratio less than T1 are classified as clean patches. Unlike a fixed threshold, GMM-based thresholds account for variations in image intensity ranges and different noise levels, making the method more robust and dataset independent.

The Poisson noise patches are transformed to Gaussian noise characteristics by applying a variance stabilizing technique called Anscombe transformation [39], which can be mathematically represented using the following Eq. (4) [39], where 'X' is the Poisson noise and 'Y' is the transformed noise signal, which resembles Gaussian noise, as the variance is stabilized.

$$Y = 2\sqrt{X + \frac{3}{8}} \tag{4}$$

To qualitatively support the GMM-based noise categorization, visual examples of image patches exhibiting different noise characteristics are displayed in Fig. 3. These patches, extracted from Chest X-Rays, represent samples categorized into distinct Gaussian components by the GMM. Each cluster corresponds to a different noise, such as clean patches, Gaussian patches and Poisson patches. The visual distinction in texture and granularity supports the adaptive noise categorization capability of the proposed algorithm.

B. Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD)

Medical images contain anatomical structures of varying sizes, like small cellular structures to large-scale structures like organ boundaries. In Chest X-Ray images, structures such as the lung trachea, Primary Bronchi, Bronchial Tree, and lungs constitute the larger structures, and small blood vessels, Alveolar Sacs, Bronchioles, and Capillaries are examples of smaller structures. So, it's necessary to have a multi-scale approach that retains and preserves both the small-scale and large-scale features. Also, the noise in medical images can be present at different scales, so a multi-scale approach is proposed, which addresses noise at each scale independently.

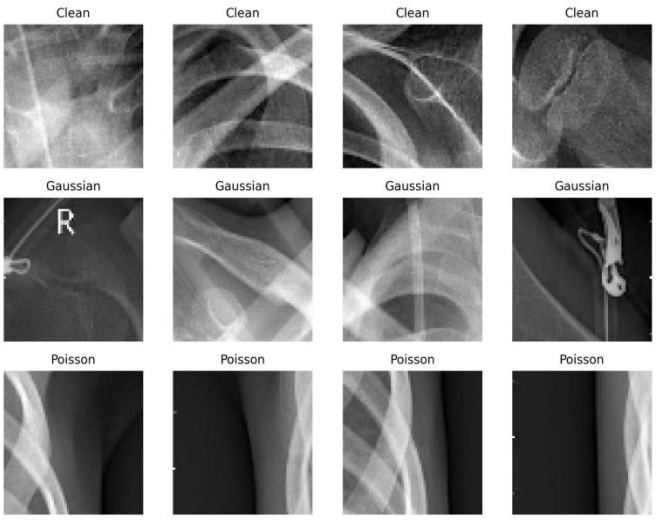

Fig. 3. Representative image patches from different Gaussian components identified by the GMM. Each row shows patches associated with a distinct noise category.

In Curvelet Transform, the images are decomposed into multiple scales and orientations, which captures both the small-scale and large-scale information in the X-Ray image. The Curvelet Transform outperforms the other mathematical transforms in capturing edges, curves, and fine details in images, which is particularly useful for medical imaging. It offers better edge preservation compared to other transforms. Algorithm 2 presents the MCF-DD Denoising algorithm. The different steps in Curvelet Transform are the following:

1) Decomposition: The Curvelet Transform decomposes the image into several sub-bands. Each sub-band captures the information in a specific orientation and scale. As a result of decomposition, the image is divided into multiple scales, where each scale corresponds to a different level of detail. Each scale contains multiple orientations that capture the edge and curve information in different directions like horizontal, vertical and diagonal. The mathematical representation of decomposition can be represented by Eq. (5), in which N (X, Y) the noisy image patch which is decomposes to 'S' number of scales with 'O' Orientations in each scale.

$$N(X,Y) \approx \sum_{s=1}^{S} \sum_{o=1}^{O} C_{s,o}(X,Y) \tag{5}$$

Algorithm 2: MCF-DD Denoising Algorithm

Apply Variance Stabilizing Transform (VST) to convert Poisson noise to a Gaussian-like distribution:

$$Y' = T(Y)$$

Perform Curvelet Decomposition on Y' using Fast Discrete Curvelet Transform (FDCT):

$$\Theta_Y = C(Y')$$

for all curvelet sub-bands $\theta_i \in \Theta_Y$ do

Apply directional filters (Gabor, Morlet wavelet, Anisotropic Gaussian) to θ_i

Estimate adaptive threshold τ_i using local statistics.

Apply thresholding to obtain denoised coefficients:

$$\hat{\theta}_i = F(\theta_i, \tau_i)$$

Reconstruct the image from denoised coefficients:

$$\hat{Y'} = C^{-1}(\hat{\Theta}_Y)$$

Apply inverse variance stabilizing transform to get the final denoised image:

$$\hat{X} = T^{-1}(\hat{Y'})$$

return $\hat{X}$

End

2) Apply directional filtering to each sub-band: Directional filtering is applied to each sub-band, in different scales and orientations, to capture localized curve and edge details. In chest X-Ray images, as both the fine and larger details have to be preserved, a combination of Gabor filter, Morlet filter, and Anisotropic Gaussian filters is used. This combination of filters provides the best trade-off between accuracy, detail preservation, and computational efficiency.

a) Gabor filter: Gabor filter [40], [41] captures the orientation and scale-specific information like edges, textures, and curved structures in images. Multi-orientation Gabor filters with orientations at 0°, 45°, 90°, and 135°, and a fixed frequency of 0.25 cycles/pixel are applied. They are used for texture analysis and feature extraction. Gabor filters are mathematically described by the following Eq. (6) [41]:

$$G(x,y) = \exp\left(-\frac{x^2+\gamma^2y^2}{2\sigma^2}\right)\cos\left(2\pi f \cdot (x\cos\theta + y\sin\theta)\right) \quad (6)$$

where,

θ - Orientation of the Gabor filter.

σ -Gaussian envelope's standard deviation.

f- Frequency of the sinusoidal component.

b) Morlet filter: Morlet filter [42] is used to capture localized frequency and orientation information. It combines a Gaussian window with a sinusoidal oscillation. They provide scale and orientation selectivity and so they are preferred for detecting features at multiple scales. Standard 2D complex Morlet wavelets were applied centred around a spatial frequency of 0.8 with a bandwidth parameter of 1. Morlet filters are mathematically described by the following Eq. (7) [42]:

$$\psi(x,y) = \exp\left(-\frac{x^2+y^2}{2\sigma^2}\right) \cdot \exp(j2\pi f_0 x) \quad (7)$$

where,

σ - Gaussian envelope's standard deviation.

f0 - Wavelet Central frequency.

j - Imaginary unit (j2= −1).

x, y - Spatial coordinates.

c) Anisotropic Gaussian filter: Anisotropic Gaussian filter [43] is used for directional smoothing by adjusting the standard deviations in different axes. These filters are better at maintaining anatomical boundaries and ensuring noise reduction without losing critical details. These were applied with a variable standard deviation across directions to enhance the preservation of directional edges as given by Eq. (8) [43]:

$$G(x,y) = exp\left(-\left(\frac{x^2}{2\sigma_x^2} + \frac{y^2}{2\sigma_y^2}\right)\right) \quad (8)$$

where,

Σx - X-direction Standard Deviation

Σy - Y-direction Standard Deviation

(x, Y) - Spatial Coordinates

3) Threshold calculation for denoising in curvelet transform: After obtaining the Curvelet coefficients, a threshold value for each coefficient to suppress noise is calculated. The noise thresholding technique for denoising was implemented using the median absolute deviation (MAD) method, as proposed in [44]. This method is effective for estimating noise variance in the transformed domain. Specifically, the noise level $\hat{\sigma}$ is estimated from the finest scale of Curvelet coefficients using Eq. (9) [44]:

$$\hat{\sigma} = \frac{\text{median}(|C_{i,j}|)}{0.6745} \quad (9)$$

where, $C_{i,j}$ are the Curvelet coefficients at the highest frequency scale. A universal threshold is then computed using Eq. (10) [44]:

$$T = \hat{\sigma}\sqrt{2\log N} \quad (10)$$

With N being the number of coefficients in the sub-band. Hard thresholding is applied by comparing the squared magnitude of each coefficient to the threshold. If $|C_{i,j}|^2 < T^2$, the coefficient is set to zero; otherwise, it is retained as given in Eq. (11) [44]:

$$\widehat{C_{i,j}} = \begin{cases} 0, if\left|C_{i,j}\right|^2 < T^2 \\ C_{i,j}, Otherwise \end{cases} \quad (11)$$

This operation removes insignificant coefficients likely representing noise while preserving meaningful structural details. The denoised image is then reconstructed using the inverse Curvelet Transform.

4) Reconstruction of the image: After denoising, reconstruction of the image is done by performing the Inverse Curvelet Transform, as given by Eq. (12) [45]. The denoised image patch is created back from the modified Curvelet

coefficients. The inverse transform aggregates all the scales and orientations back into the original pixel grid while retaining the geometrical structures. The reconstruction ensures that both edges and curves remain intact and the essential features are preserved.

$$\hat{f}(x,y) = C^{-1} \sum_s \sum_\theta \sum_k c_{s,\theta,k} \psi_{s,\theta,k}(x,y) \quad (12)$$

where,

C−1 is the inverse Curvelet Transform.

cs,θ,k is the Curvelet coefficients at scale s, orientation θ, and position k.

ψs,θ,k(x, y) is the Curvelet basis functions.

The summation is performed over all scales s, orientations θ, and positions k.

C. Patch Reconstruction

An empty image with the same size as original image is initialized. A weight matrix is maintained for keeping track of the number of patches contributing to each pixel. The denoised patches are placed in their original locations. The weight matrix is updated to normalize the overlapping regions. The reconstructed image is normalized using the weight matrix to maintain the consistency in intensities.

D. Parameter Settings and Selection Principles

The key parameters used in the various stages of the proposed Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD) framework are listed in Table I. The selection of each parameter was guided by a combination of empirical validation, literature references, and optimization trials to ensure robustness and optimal denoising performance. Gabor and Morlet parameters were chosen to ensure effective multi scale texture representation, while anisotropic Gaussian values were fixed to balance noise suppression and edge preservation. The dynamic thresholds were computed adaptively from the statistical distribution of curvelet coefficients, ensuring data-driven noise separation reproducibility. The curvelet transform was implemented using the wrapping-based discrete formulation, and sub-band coefficients were processed with a GMM-based adaptive thresholding scheme. Gabor, Morlet, and anisotropic Gaussian filters were applied using the frequencies and bandwidths listed, and their outputs were fused by weighted averaging based on local coefficient energy. The fused coefficients were then inverted through the curvelet synthesis step to obtain the final denoised image.

TABLE I. KEY PARAMETER SETTINGS USED IN MCF-DD

Component	Parameter	Value	Justification
Curvelet Transform [46]	Number of Scales (S)	4	Captures multi-scale features with balance between detail and computational cost.
Curvelet Transform [47]	Number of Orientations (N_θ)	8	Provides directional sensitivity while avoiding redundancy.
Gabor Filter [40]	Frequency	0.6	Optimized for texture preservation in noisy lung regions.
Morlet Filter [42]	Sigma	1.5	Balances frequency and spatial localization.
Anisotropic Gaussian [43]	σx, σy	(1.2, 2.0)	Emphasizes edge preserving smoothing.
Thresholding [47]	Adaptation Method	GMM based dynamic	Adapts to local statistics and noise intensity using data driven classification.

IV. RESULTS AND DISCUSSION

A. Patch-Based Classification Performance

To evaluate the performance of patch classification approach for the noise type classification, experiments were conducted on Chest X-Ray images from Kaggle dataset [8]. The evaluation is done for the categorization of Gaussian noise, Poisson noise and also for finding the noise free patches. The experiments were conducted by dividing the input image into 32 X 32 patches and 64 x 64 patches. A synthetic noise generation strategy was employed to create patch level ground truth labels, as no publicly available Chest X-Ray dataset includes annotations identifying the dominant noise type at the patch-level.

A set of high-quality Chest X-Ray images with minimal visible noise was selected as the baseline reference, serving as the clean images for controlled noise synthesis. Gaussian noise was added using predefined mean and variance parameters, while Poisson noise was introduced based on fixed photon intensity distributions. A subset of patches was intentionally left unaltered to represent clean regions. Because each noise type was assigned deterministically during the synthesis process, precise and unambiguous ground truth labels could be maintained for every patch. The results were plotted in Fig. 4 and Patch classification is calculated by using Eq. (13) [48]:

$$\text{Accuracy} = \frac{\text{Correctly Classified Patches}}{\text{Total Patches}} \times 100\% \quad (13)$$

From Fig. 4, we can infer that larger patches improves classification accuracy. This suggests that larger patches retain more structural and statistical information, making it easier to distinguish noise patterns. The improvement in accuracy with 64×64 patches highlight their effectiveness in preserving spatial features critical for classification.

B. MCF-DD Performance

The experimental results demonstrate the effectiveness of the proposed denoising technique, Multi-Scale Curvelet Filtering with Directional Denoising in comparison to selected denoising methods.

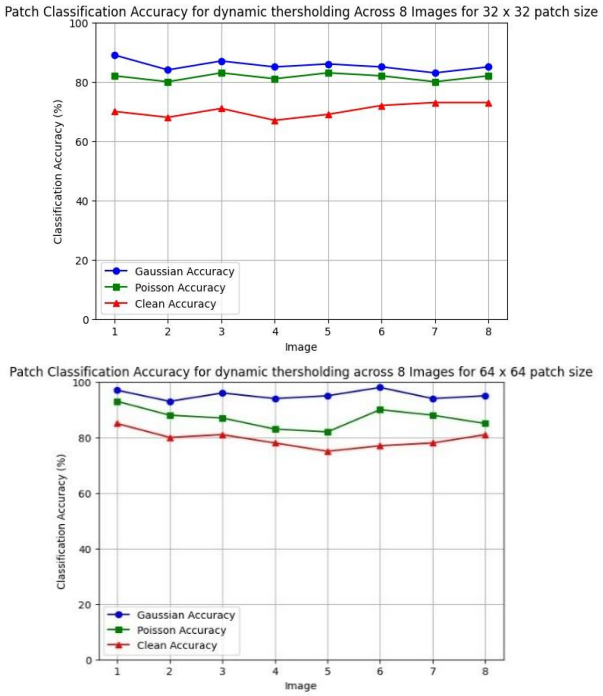

Fig. 4. Effect of patch size on classification accuracy.

Experimental study was performed on images from the Chest X-Ray Images dataset collected from the Kaggle repository [8], in which the chest radiographs are present in JPEG format. To analyze the impact of compression artifacts experimental study was also performed on the DICOM format CXR images from the Medical Imaging Data Resource Center (MIDRC) – RSNA International COVID Radiology Database (RICORD) Release 1c [9]. The MIDRC-RICORD-1C dataset provides high quality DICOM images, allowing for a more comprehensive evaluation of the denoising performance on uncompressed medical images.

To evaluate the robustness of the proposed denoising methodology, synthetic noise was added to the clean Chest X-Ray images. Specifically, Gaussian noise with a pre-defined mean of zero and variance σ2 = 0.01 was applied to simulate additive noise commonly encountered in imaging systems. Additionally, Poisson noise was introduced based on the intensity distribution of each image to replicate the photon counting noise inherent in X-ray acquisition processes. These noise models allow us to simulate realistic degradation scenarios for comprehensive evaluation. All denoisers were executed under identical noise conditions and preprocessing. Classical baselines followed standard reference implementations such as BM3D with σ matched to the corruption level, NLM with a 7×7 patch and 21×21 search window, and Wavelet denoising using soft threshold $\lambda = 3\sigma$. DnCNN was evaluated using its publicly released pretrained Gaussian model with inputs normalized to [0,1]. GAN-based baselines were retrained on the same noisy clean pairs used in the proposed work, by using U Net generator, Patch GAN discriminator, Adam optimizer (LR = 2×10^{-4}), and 100 training epochs with 256×256 patches. All methods were run on identical hardware and image sizes for consistent comparison. PSNR and SSIM are used in this study to assess denoising performance at the pixel and structural levels, and diagnostic evaluation of the proposed framework has been reported previously [49].

1) Peak Signal-to-Noise Ratio (PSNR): This metric is used to measure the quality of a denoised image compared to the original image, as shown in Eq. (14) [48]. The quality of the denoised image increases as the PSNR value increases.

$$PSNR = 10log_{10}(M^2/MSE) \quad (14)$$

2) Structural Similarity Index (SSIM): This metric is used to calculate the structural similarity between the denoised image and the original image. It is calculated by comparing different image features such as pixelpatterns, luminance, pixel intensities, etc as given in Eq. (15) [37].

$$\mathrm{SSIM}(x,y) = \frac{(2\mu_x\mu_y+C_1)(2\sigma_{xy}+C_2)}{(\mu_x^2+\mu_y^2+C_1)(\sigma_x^2+\sigma_y^2+C_2)} \quad (15)$$

where, x and y are the two images being compared. The constants C1 and C2 used in the SSIM calculation follow standard values as originally proposed in [37], typically set as $C1 = (K_1L)^2$ and $C2 = (K_2L)^2$, where $K_1 = 0.01$, $K_2 = 0.03$, and L is the dynamic range of pixel values.

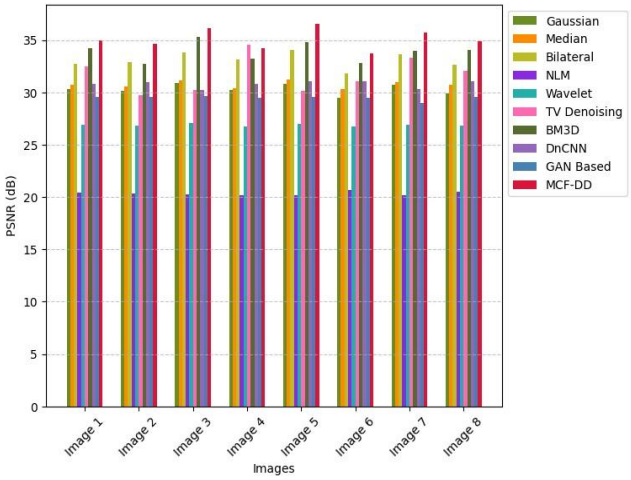

Fig. 5. PSNR comparison of denoising approaches with the proposed method, MCF-DD [Chest X-Ray Dataset].

In Fig. 5, the PSNR value obtained by the proposed MCF-DD method and the other state-of-the-art methods for denoising images from the chest X-ray data set are plotted. The results indicate that the proposed method yields a higher PSNR rate compared to the other existing methods. In Table II, the comparison of the proposed method to the other methods using the images from Chest X-Ray Dataset is given. The lower performance of NLM is mainly due to oversmoothing of fine anatomical details and reduced effectiveness in handling mixed noise, leading to lower PSNR values compared with the proposed transform-based framework. For deep learning-based denoising methods, the dataset was divided into training, validation, and testing subsets with proportions of 70%,15%, and 15%, respectively, using stratified random sampling to maintain class balance. To prevent data leakage, images from the same patient were included in only one of these subsets.

Synthetic noisy images were generated independently by adding the same noise models (Gaussian noise with zero mean and variance σ2 = 0.01, and Poisson noise based on image intensity) to the clean images in each subset. The deep learning models were trained exclusively on the noisy images from the training set, using the corresponding clean images as ground truth. Evaluation was performed on the noisy images in the testing set, ensuring no overlap or exposure of test data during training. This protocol guarantees a fair and unbiased comparison between deep learning and traditional denoising methods under consistent noise conditions.

Similarly, in Fig. 6, the SSIM values of the denoised image obtained by the proposed method and other techniques using images from the Chest X-Ray Dataset are represented. The higher the SSIM value index, the better the performance in preserving the structure of the denoised image. The proposed method has the highest SSIM values when compared with the SSIM values obtained by other methods.

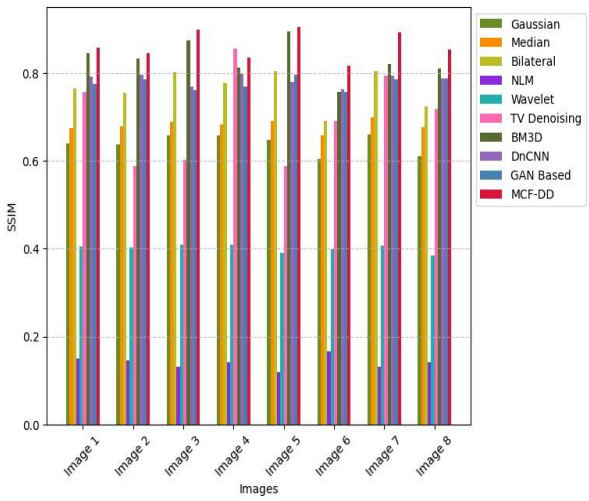

Fig. 6. SSIM comparison of denoising approaches with the proposed method, MCF-DD [Chest X-Ray dataset].

To understand the better performance of the proposed MCF-DD, the visual results obtained by processing a noisy image using both MCF-DD and other methods are shown in Fig. 7.

Even tough Chest X-Ray Datasets are widely used for medical image analysis, the resultant JPEG compression artifacts may cause unwanted noise that may not be present in the actual image. To perform a more realistic assessment of the performance of the proposed method, uncompressed DICOM images were included from the Medical Imaging Data Resource Center (MIDRC) – RSNA International COVID Radiology Database (RICORD) Release 1c (MIDRC-RICORD-1C) [9]. This dataset, curated by MIDRC and RSNA, consists of high-resolution clinically acquired CXR images stored in DICOM format, preserving the original image quality without lossy compression artifacts. The inclusion of DICOM images allows for a more reliable evaluation of real-world noise characteristics that are typically encountered in medical imaging. In Table III, the comparison of the proposed method with the other methods using images from the (MIDRC) - RSNA International COVID Radiology Database (RICORD) is given.

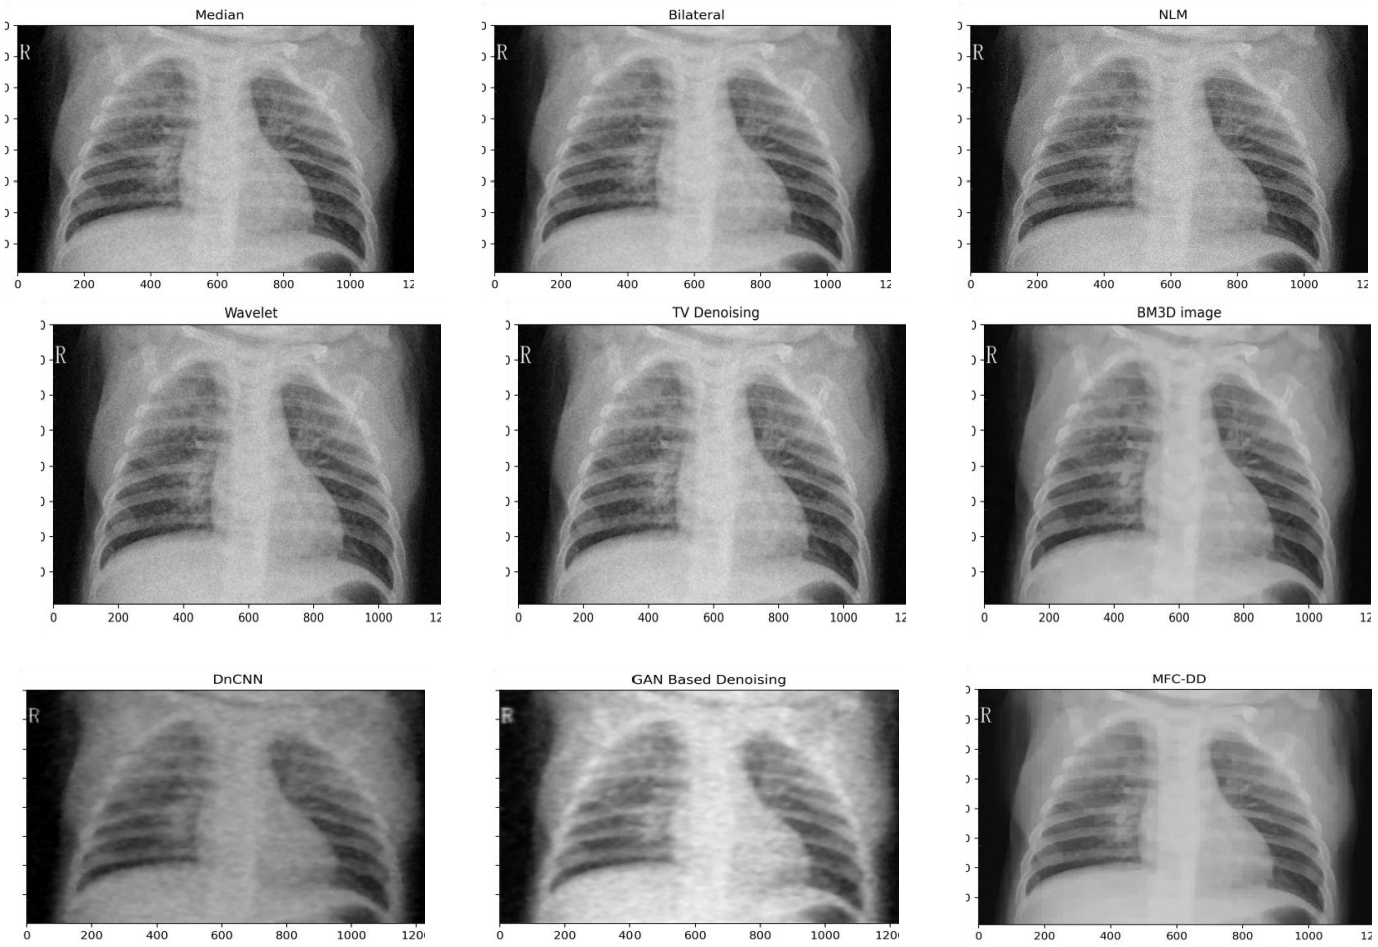

Fig. 7. Visual comparison of denoising methods applied to chest x-ray images [Chest X- Ray Dataset].

Fig. 8 and Fig. 9 represent the comparison of the PSNR and SSIM values of the proposed method with the other existing methods for the experiments carried out on DICOM images. From the analysis, we can find that the performance of the

proposed method is better than that of the existing methods. MCF-DD method achieves the highest PSNR and SSIM values across different images. DICOM images are free of compression artifacts. The noise presenting DICOM images represents the original noise characteristics. Conventional denoising techniques have poor performance on DICOM images, while the proposed method adapts well to real X-ray noise patterns, rather than just compression noise.

The proposed MCF-DD (Multi Scale Curvelet based Filtering with Directional Denoising) method demonstrates improved performance for the denoising of chest X-Ray images by combining Curvelet Transform with multiple spatial frequency filters like Gabor, Morlet, and Anisotropic Gaussian, and using a Gaussian Mixture Model (GMM) for adaptive thresholding. The use of Curvelet Transform allows better handling of edges and directional features, which results in multi-scale feature preservation. Also, the combination of different filters helps to capture a wide range of textural and frequency information, contributing to effective noise suppression. The adaptive threshold selection avoids rigid assumptions about the noise model and adapts to local noise characteristics. Table IV presents a comparative analysis of the proposed multi-scale curvelet filtering with the directional denoising technique against existing methods. The results indicate that the proposed approach achieves the highest PSNR and SSIM, demonstrating superior denoising performance and preservation of structural fidelity compared to the state-of-the-art techniques.

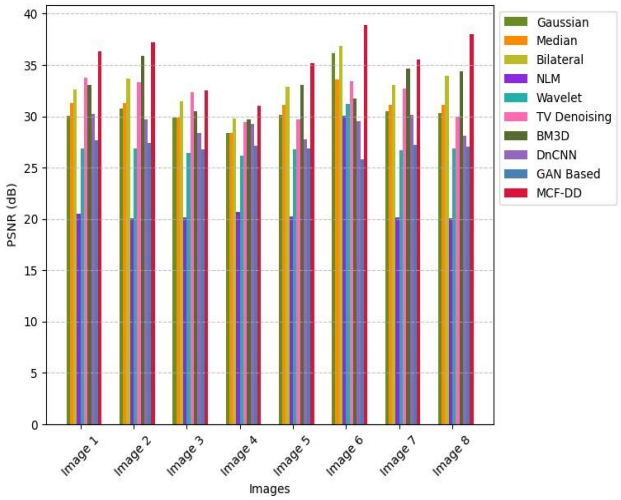

Fig. 8. PSNR comparison of denoising approaches with the proposed method, MCF-DD [(MIDRC) - RSNA International 382 COVID radiology database].

TABLE IV. COMPARISON OF DIFFERENT METHODS ON THE KAGGLE CHEST X-RAY DATASET

Study	Method used	PSNR	SSIM
CNN-based Pneumonia Detection [52]	Convolutional Neural Network (CNNs)	34.12	0.8734
Vision Transformers (ViT) [53]	Vision Transformer (ViT)	35.78	0.8941
Deep Learning Ensemble [54]	Ensemble of GoogLeNet, ResNet-18, DenseNet-121	34.89	0.8812
Hybrid Inception ResNet [55]	Fine-Tuned Inception-ResNet	35.95	0.8994
Proposed method	Multi-Scale Curvelet Filtering with Directional Denoising	**36.57**	**0.9062**

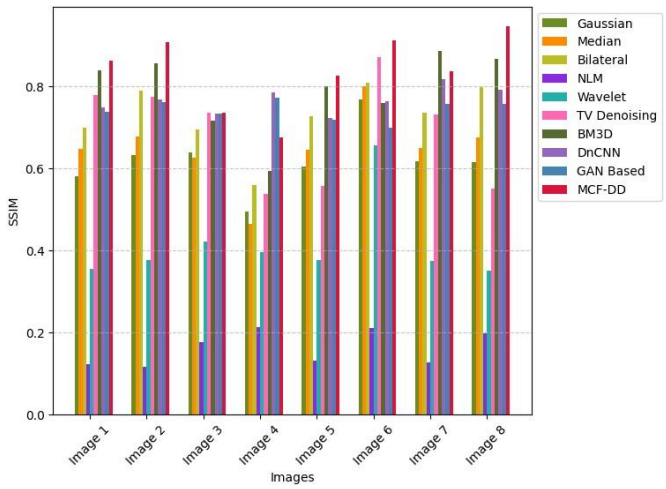

Fig. 9. SSIM comparison of denoising approaches with the proposed method, MCF-DD [(MIDRC) - RSNA International 382 COVID Radiology Database].

The drawbacks of the proposed method include sensitivity to parameter settings and increased computational complexity due to multiple filtering stages. Additionally, this method does not model inter scale dependencies, which may affect performance in highly textured regions. Another limitation of this study is the absence of a radiologist's evaluation to assess whether the denoised images lead to improved diagnostic interpretation. Future work will incorporate domain expert feedback using structured assessment methods, as employed in prior studies [56].

Although PSNR and SSIM are widely adopted for quantitative evaluation of image, they primarily reflect pixel level fidelity and structural similarity. Diagnostic evaluation of the proposed denoising framework has been reported in a previously published study [49], where MCF-DD processed chest X ray images were assessed using standard classification metrics. Accordingly, the present work employs PSNR and SSIM to analyze denoising effectiveness at the signal level.

C. Computational Efficiency Analysis

The runtime comparison presented in Table V indicates that simple local filtering methods such as Gaussian and median filtering have minimal computational cost but provide limited denoising capability. In contrast, non-local and optimization-based approaches, including BM3D and total variation denoising, exhibit substantially higher runtime due to exhaustive block matching and iterative optimization procedures. Learning-based methods reduce this overhead

through feed forward inference but, CNN and GAN-based denoisers still require higher processing time than the proposed framework. With an average inference time of 0.101 ± 0.013 s per image, the proposed MCF-DD method achieves a favorable balance between denoising effectiveness and computational efficiency, remaining significantly faster than BM3D and more efficient than CNN and GAN-based approaches, thereby demonstrating its suitability for large-scale chest X-ray preprocessing.

TABLE V. RUNTIME COMPARISON OF DENOISING METHODS

Method	Runtime (s/image)
Gaussian Filter	0.008 ± 0.009
Median Filter	0.008 ± 0.002
Bilateral Filter	0.075 ± 0.025
Wavelet Denoising	0.083 ± 0.018
Total Variation (TV)	0.760 ± 0.404
BM3D	5.76 ± 0.77
CNN	0.181 ± 0.087
GAN	0.198 ± 0.099
Proposed Method (MCF-DD)	**0.101 ± 0.013**

D. Contribution Analysis of MCF-DD Framework Components.

To understand the contribution of each processing component within the proposed MCF-DD framework, a comparative study was performed by progressively incorporating the framework components. The study began with the Curvelet Transform, which serves as the core multi-scale representation mechanism for noise suppression. Subsequently, the Gabor filter, Morlet filter, and anisotropic Gaussian filter were incrementally integrated into the framework. The average PSNR and SSIM values obtained from the evaluation images are summarized in Table VI.

TABLE VI. MCF-DD FRAMEWORK COMPONENT ANALYSIS

Configuration	PSNR (dB)	SSIM
Curvelet Transform	33.84 ± 0.42	0.861 ± 0.011
Curvelet Transform and Gabor Filter	34.71 ± 0.38	0.882 ± 0.010
Curvelet Transform and Gabor Filter and Morlet Filter	35.48 ± 0.34	0.894 ± 0.008
Curvelet Transform and Gabor Filter and Morlet Filter and Anisotropic Gaussian Filter (MCF-DD)	36.57 ± 0.21	0.906 ± 0.004

The Curvelet Transform alone achieved a PSNR of 33.84 dB and an SSIM of 0.861, demonstrating its effectiveness in suppressing noise while preserving major anatomical structures. When the Gabor filter was incorporated, the PSNR increased to 34.71 Db, and the SSIM improved to 0.882. This improvement can be attributed to the ability of the Gabor filter to capture directional texture information and enhance edge representation. The addition of the Morlet filter further improved performance, resulting in a PSNR of 35.48 dB and an SSIM of 0.894. The Morlet filter enhances multi-scale frequency representation and improves the preservation of subtle anatomical patterns commonly present in chest radiographs. Finally, the integration of the anisotropic Gaussian filter produced the complete MCF-DD framework. This stage effectively suppressed residual noise while preserving edge continuity and structural integrity. Consequently, the proposed MCF-DD framework achieved the highest performance, with a PSNR of 36.57 dB and an SSIM of 0.906.

V. CONCLUSION AND FUTURE SCOPE

In this study, a novel denoising method is introduced, Multi-Scale Curvelet Filtering with Directional Denoising (MCF-DD), along with a patch classification method. This method mainly focuses on the medical chest X-ray images, in which maintenance of structural information of both fine and larger image features is as important as denoising the Poisson and Gaussian noise. A key strength of the method is its dynamic noise classification strategy, powered by a Gaussian Mixture Model (GMM) applied on the variance-to-mean ratio of image patches, allowing adaptive and noise-specific processing. The experimental evaluation demonstrated that MCF-DD outperforms several traditional and state-of-the-art denoising techniques in terms of both quantitative metrics, such as PSNR and SSIM, and qualitative visual quality of the denoised images. The performance has been evaluated on compressed (JPEG) and uncompressed (DICOM) images from diverse datasets, including Kaggle CXR and MIDRC-RICORD.

The adaptability and robustness of the proposed MCF-DD method can be improved by integrating data-driven learning components, such as deep learning-based denoising priors. In addition, the parameter selection process can be automated using optimization algorithms or reinforcement learning frameworks to improve generalization. A critical extension is the integration of the MCF-DD pipeline within explainable AI frameworks to support clinical interpretability.

In summary, MCF-DD presents a flexible, adaptive, and effective solution for image denoising, particularly suited for challenging conditions such as mixed noise scenarios in medical imaging. The promising results lay the foundation for further research and real-world clinical applications.

ACKNOWLEDGMENT

The authors would like to thank the creators of the publicly available chest X-ray datasets used in this study for making the data accessible for research purposes

Characterizing Failure Points in Rule-Based Spreadsheet Data Transformation: A Stage-Oriented Taxonomy and Empirical Failure Matrix

Fakhrul Adli Mohd Zaki, Mustafa Man, Mohamad Nor Hassan
Faculty of Computer Science and Mathematics, Universiti Malaysia Terengganu, Terengganu, Malaysia

***Abstract*—Rule-based spreadsheet data transformation remains widely used for converting human-centred spreadsheet tables into structured formats for reporting, analytics, and data integration because it is transparent, auditable, and reproducible. However, rule-based approaches often fail when spreadsheets encode structural meaning through visual or layout cues, such as multi-row headers, merged cells, interleaved subtotals, cross-tabulated values, and multiple logical tables within a worksheet. This study characterizes such failures using a stage-oriented taxonomy aligned with a six-stage transformation pipeline: ingestion, region detection, structural interpretation, semantic labeling, canonicalization, and validation. A deterministic baseline pipeline was evaluated against six controlled spreadsheet cases representing common semi-structured layouts. The resulting empirical failure matrix identified 15 severity-2 failures across the controlled cases. The most critical failures were concentrated in merged cell and hierarchy handling, multi-region and boundary interpretation, role mislabeling, wrong granularity, and silent semantic errors. These findings show that many transformation failures are not isolated rule defects but arise from missing pipeline capabilities, particularly explicit hierarchy representation, block-level segmentation, granularity control, and semantic invariant checking. The study contributes a reproducible failure-analysis framework that supports stage-localized diagnosis, comparison of rule-based spreadsheet transformation systems, and targeted improvement of transformation pipelines.**

Keywords*—Rule-based transformation; spreadsheet table understanding; data wrangling; failure taxonomy; failure matrix; canonicalization

I. Introduction

This study examines a necessary first step toward improving rule-based spreadsheet transformation: identifying how and where such transformers fail. Rather than proposing a new model or algorithm, the study provides a structured failure analysis. Specifically, it proposes 1) a failure taxonomy that maps failures to stages in a common rule-based transformation process and 2) a failure matrix derived from controlled test cases (S1-S6) that represent common spreadsheet layout patterns. This analysis supports more comparable failure reporting, improves rule-writing practices, and helps future designers create more robust validation and debugging methods.

The study makes three main contributions. First, it introduces a stage-oriented taxonomy that maps failures to components of a typical rule-based pipeline, including interpretation of the input spreadsheet, rule selection, rule execution, and output validation. Instead of presenting only a long list of error symptoms, the taxonomy supports failure diagnosis, system comparison, and structured reporting of transformation problems. Second, it presents an empirical failure matrix with measured severity scores. The matrix represents each identified failure type against six controlled spreadsheet test-case patterns (S1-S6), documenting which failures are triggered by particular structural or semantic issues and which case-code pairs produce the highest-severity failures. This representation is easier to interpret than isolated error lists because it highlights recurring and under-reported failure categories while grounding each failure in a concrete example. Third, it derives practical implications for improving rule writing and pipeline design. The results suggest the need for additional checkpoints to detect silent errors, more structure-aware interpretation of spreadsheet semantics, and explicit handling of multiline headers, grouped headers, merged cells, and subtotal rows.

A. Practical Motivation and Scope

Spreadsheet tables are designed for human users and often rely on a variety of non-schema-based cues for layout and data semantics. Such cues include consistent indentation, spacing, cell merging, bold text, borders, and footnotes. Automating the interpretation of spreadsheet tables using only the content of cells and cells' properties proves challenging because they lack formal semantics defined externally. Many researchers attempt to overcome these limitations by inferring table semantics from visual cues and their context. [6], [7]

In practice, rule-based scripts are commonly utilized to extract recurring table formats, such as monthly financial reports, departmental budgets, customer purchase orders, and survey responses. The strengths of rule-based conversion scripts are their transparency, auditability, maintainability with version control, reusability across different reports, and suitability for batch processing. One approach to productionizing rule-based conversion is through rule-based platforms, which apply a set of predefined transformation rules to the structured table data. These platforms ensure consistent and repeatable processing, but first, the rules for a particular table must be correctly defined to reflect its structure. [7]

However, many rule-based conversion approaches implicitly assume that tables have a uniform structure throughout their scope, which is a fragile assumption. First, it generally requires that a table consist of a single continuous

block. Second, it may require that the header depth be constant throughout. Third, if the cells in the table were merged to make reading more convenient for users, then the merging should be consistently applied and handled in the script. Fourth, it generally requires that subtotals and totals are clearly marked (perhaps using bold font or a common text string such as "Total") so they can be identified easily by filtering rows based on that specific visual cue. When tables are not consistent in these respects, rule-based conversion either will fail to process the spreadsheet table altogether, resulting in no output, or it will correctly process the input rows but generate incorrect table outputs, even though the outputs may be syntactically valid. These are insidious errors because the bad output might be used in downstream data analysis without producing any visible errors. Work in previous rule-based techniques shows that minor changes to the layout (e.g., adding a bold font) are sufficient to change the semantic meaning of the table, leading to a functionally different table from the one that the user is looking at in the spreadsheet. [6], [7]

This study is about failure modes of rule-based spreadsheet data extraction. Instead of introducing a new extraction technology or a novel machine learning technique for such a purpose, this study is an attempt to provide structure to the discussion around different failure modes of rule-based systems in spreadsheet data extraction. Designers of rule pipelines for such purposes should use this characterization to understand where failures come from, how they propagate through the pipeline, and how they might be fixed. This study first provides a stage-specific taxonomy of failures in rule-based extraction systems and then presents an empirically measured failure matrix based on a set of carefully chosen case spreadsheets exhibiting common layout types. This allows for a concise summary of the coverage of empirical experiments and recurring weaknesses that have been identified in such systems. [5]

B. Study Organization

The remainder of this study is divided into nine sections. Section II provides a survey of prior research, focusing on interactive data wrangling, programming by example, spreadsheet table understanding, and rule-based transformations. Section III details the formal setup for transformations and introduces the concept of a transformation failure point. Section IV outlines the architecture of the baseline data transformation pipeline, defines the associated set of basic rules, describes the controlled cases created for the experiment, and explains the metrics and procedure used for evaluating outcomes. Section V elaborates on the comprehensive taxonomy of failure types encountered during transformation. Section VI presents the constructed failure matrix, along with calculated severity scores, and discusses the observed trends and prominent types of failures. Section VII analyzes the identified failure patterns and proposes strategies for more robust rule creation. Section VIII addresses potential limitations and threats to the study's validity. Finally, Section IX summarizes the key findings and suggests avenues for future research.

II. Related Work

This section covers previous research on the manipulation and preprocessing of data stored in spreadsheets. The literature review is divided into four categories: data wrangling and interactive transformation, programming-by-example, table understanding and rule-based transformations, and data preparation validation/error detection. The categories are related due to the inherent nature of spreadsheet transformations; a transformation is often not simply changing data format but also inferring spreadsheet layout, interpreting tabular structure, maintaining semantic relations, and creating an output that is accurate and useful. The review explores how different techniques empower users to clean, transform, extract, and validate data in spreadsheets and highlights challenges that remain with current methods.

A. Data Wrangling and Interactive Transformation

Research findings demonstrate that data wrangling is a repeated activity during which users perform certain transformations and then observe the outputs. This interactive cycle involves letting users visualize transformation outputs and allowing them to reverse actions if outputs are invalid. Petricek et al. built the notion of AI assistants for data wrangling upon this idea; users supply constraints to the assistant to obtain a system-generated transformation satisfying constraints and minimizing wasted effort through trial and error to carry out practical cleaning and reshaping operations [1]. In practice, Wrangler is perhaps the best example of this kind of tool, being another mixed-initiative approach, which blends direct manipulation of data with an automatically inferred sequence of transformation steps, allowing analysts to incrementally craft the transformations for operations like splitting a field, removing noise, and transforming a column’s appearance, all while keeping the transformation transparent [2]. Despite the gains in usability these tools provide, they encounter challenges with implicit structural cues such as the use of merged headers for defining sections, separate groups of cells to define regions or sections of data, and lines/ separators to make report layouts clearer, which reinforces the need for more robust structure treatment and automated validation in ETL (Extract, Transform, Load) systems [5].

B. Programming by Example in Spreadsheets

Learning transformations from examples, known as programming-by-example methods, greatly reduces the burden of program specification. They perform best at cell-level and string-level operations common in typical spreadsheet manipulation. In [3], Gulwani et al. provide a survey on how to do data manipulations in spreadsheets using examples. The study demonstrates the effectiveness of program synthesis with examples to learn both simple string and complex cell transformation tasks that would otherwise be inefficient to write with manually defined formulas or scripts. However, the vast majority of spreadsheet data manipulations deal not just with value transformation but with transformation of spreadsheet structure itself, like reorganizing data from a crosstab format into record-based rows, maintaining hierarchical headers spanning multiple rows, or separating

subtotals from data points. To support such transformations, one must often deduce implicit relationships among values and recover latent table structure and semantic roles, which are underspecified by only a limited number of input-output examples and depend on a wide range of cues, such as layout, visual appearance, and semantics associated with values or context [5], [6].

C. Spreadsheet Table Understanding, Extraction, and Rule-Based Transformation

The research into spreadsheet table understanding focuses on identifying specific regions within a spreadsheet table, recognizing its headers, and assigning roles to each cell in order to represent the grid as a meaningful logical structure that can be transformed. Building upon this, rule-based transformations apply rules that explicitly encode human interpretation steps in analysis and processing. Shigarov and Mikhailov present a rule-based technique coupled with a table object model that creates two conceptual layers: one to store physical cell information and another to contain logical semantic items. This layering facilitates the transformation of varied tables into a standardized relational format [4]. Numerous rule-engine implementations exist that demonstrate how to use production rules to analyze table formatting, content in natural language, and spatial structure to derive meaningful relations between labels and their associated entries, then use such derived relationships to guide the generation of standard tables [6]. Recently, TabbyXL commercialized this vision by incorporating logical items, such as entries, labels, and categories, into a table object model, allowing user-written rules to be executed either by an engine that conforms to the JSR-94 specification (e.g., Drools) or by transforming a tailored rule language known as CRL into actual code for execution as Java programs [7]. While these works focus primarily on parsing and analysis, other related framework work points out the full requirements for a comprehensive extraction system. A robust extraction system must also handle data cleanup, information provenance/lineage tracking, and generation of relational and potentially linked data. This suggests the necessity for a uniform workflow that accommodates the diverse array of table structures [5].

D. Validation and Error Detection in Data Preparation

One of the largest problems in data preparation is that we can never confirm the correctness of output; countless variations are acceptable on the surface, each a plausible candidate depending on specific implicit or explicit constraints. In light of this, data preparation solutions generally suggest employing validation checks, error identification, and interactive assistance. Validations might simply involve executing schema type and constraint checks, but could extend to sophisticated domain rules and checks that verify reconciliation and logical consistencies. This challenge plays itself out in the humble spreadsheet, which has implicit rules obvious to a user but unstated: We should not export a row labelled "total" as an observation, column headers should properly identify the contents of each group in a group-and-sort operation, a column of names should not have duplicates. This is addressed in rule engines with explicit constraints to reject or filter records, for example, rejecting records whose first field contains "total" [6]. Another strategy is used in platform-based solutions: the comparison of transformed data against source truth, which checks whether required "Functional Items" have been extracted, whether the relationships extracted reflect source truth, etc. [7]. A problem with this is that it differentiates a failed operation that stops the process from producing output and an operation that, in effect, creates data that looks valid on the surface but is semantically garbage. Failure detection would ideally highlight errors in a repeatable manner, identifying specifically repeatable tests that can be built into a repeatable data transformation [5].

Existing studies have laid important foundations for spreadsheet data wrangling, programming-by-example, table understanding, rule-based interpretation, and validation [1]–[8], [10], [11]. These studies mainly focus on transformation support, table extraction, semantic interpretation, or output generation, rather than systematic failure localization across different stages of a spreadsheet transformation pipeline. This limitation is particularly important for spreadsheet data because spreadsheet meaning is often embedded in structural and visual cues, such as merged headers, section labels, subtotals, and multiple regions of related data [4]–[7], [10], [11]. Interactive wrangling and programming-by-example approaches reduce the burden of specifying spreadsheet transformations, but they provide limited explanation of where structural or semantic failures originate during the transformation process [1]–[3]. Rule-based table understanding approaches offer transparent and auditable mechanisms for extracting and transforming spreadsheet information, but their evaluations are commonly organized around specific interpretation or extraction tasks, such as header mapping, entity relationship extraction, or table-to-relational conversion, rather than a systematic stage-wise failure taxonomy [4]–[8]. Recent machine learning and transformer-based approaches demonstrate the importance of learning internal representations for table structure and semantics, including relational table representation, spatial structure, hierarchical structure, and tabular representation learning [12]–[16]. Nevertheless, rule-based table understanding remains relevant for task-specific transformation scenarios that require deterministic, auditable, reproducible, and domain-specific solutions [4], [6], [7]. Most existing approaches either address transformation for general data sources, focus on spreadsheet extraction, or emphasize validation after transformation. To date, limited attention has been given to stage-oriented failure characterization that systematically maps spreadsheet layout patterns, transformation pipeline stages, failure types, empirical severity scores, and corresponding examples. Therefore, this study addresses the gap in systematically characterizing stage-wise failures and their relationship with spreadsheet layout patterns, pipeline stages, failure types, severity levels, and concrete failure examples.

III. Problem Definition

A worksheet is defined as the grid C of cells, where each cell is an entity with a specific coordinate (r,c), value v, optional formula f, and associated visual features like borders and colorization g. A function T, defined as the rule-based pipeline, converts this worksheet S into a structured dataset D, the schema of which can be varied. Two critical processes in understanding table information are identifying which cells

play which functional role (i.e., metadata, headers, labels, data cells, or derived cells) and determining the table layout. This process precedes and makes possible the transformation step [10], [11].

A transformation pipeline failure point is the stage at which the applied rule set produces one of the following conditions:

- No output is produced when output is expected, for example, when the pipeline fails to detect any table region.
- The output is structurally incorrect, for example, when the detected region boundaries are wrong or when the predicted headers and data cells do not correspond to the intended table structure.
- The output is semantically incorrect, for example, when the extracted field names are wrong, the inferred data structure does not reflect the table structure, or the record granularity does not correspond to the perceived entities in the source table.

We can distinguish between overt pipeline failures (e.g., pipeline crash or empty return) and silent failures (e.g., the pipeline returns syntactically correct but conceptually incorrect results). Silent failures are the more problematic type for the automatic pipeline process.

The pipeline transformation *T* function described can, in practice, be understood as a set of stages that process and refine the intermediate table structure. Earlier stages aim to segment cells belonging to a potential table. Middle stages deduce header depth and structure and demarcate data regions. Finally, later stages arrange cells in canonical records and enforce data validity rules. This staged pipeline view is significant for diagnosing failure sources because failures often lead to subsequent failures: incorrect boundaries lead to incorrect headers, which lead to wrong field names, leading to wrong record keys and incorrect granularity. Accordingly, the failure diagnostic should record the specific stage at which a problem is introduced into the internal table representation, in addition to the stage at which it first becomes visible in the generated output.

IV. Methodology

Following Section III, the transformation *T* is defined as a deterministic sequential operation that takes a worksheet *S* and produces either a dataset D_{out} or an empty output accompanied by an error message. The multistage pipeline isolates where errors arise and when they become visible in the output.

A. Pipeline Stages

The proposed model consists of six stages, labelled A to F. At each stage, the pipeline processes an intermediate representation of the worksheet, produces an output, and records diagnostics. The staged view supports debugging because an early structural issue, such as failure to recognize a table header at Stage B, may later appear as a semantic error in Stage E. Table parsing also benefits from staged decomposition because visual layout cues can convey semantics that cannot be captured by schema interpretation alone [10]. Rule-based table extraction systems also estimate semantic links between cells from spatial, typographic, and textual cues, making staged diagnostics a natural output of such systems [6]. Existing rule engines expose actions for analysis, semantic interpretation, canonical output generation, and evaluation, which makes staged processing useful for both development and reproducible debugging [7], [5].

Stage A: Ingestion and Normalization. Cleans the cells: removes blank spaces at the start and end of a cell text, converts numerical values to a common format when possible, replaces spreadsheet formulas with their results when possible, records merged cells as objects that retain the anchor and span coordinates, and documents merge operations.

Stage B: Region Detection. Scans the worksheet and identifies rectangular regions, then filters and ranks them based on heuristics related to the density of text and contiguity. Output is a ranked list of candidate regions; the best region R, is prioritized for subsequent processing.

Stage C: Structural Interpretation. Estimates the depth k of the header, partitioning the region R into a header and a body, and infers structure patterns such as a cross-tabulated or a multi-header table section or other organizational structures within the table.

Stage D: Semantic Labelling. Identifies a row or column or a cell as a specific kind of label or data, or an annotation, and associates header labels with fields that'll be produced in the output. Uses blank value labelling rules and normalization for strings.

Stage E: Canonicalization. Converts the internal table structure into a flat, relational table structure, flattening hierarchical headers, defining keys for records, and potentially dropping non-observation rows such as subtotals.

Stage F: Validation. Validates the output against schema constraints, datatype constraints, and key constraints, and adds plausibility checks, such as an acceptable range for the number of records. Rejects clearly malformed results and highlights potential problems.

B. Baseline Rule Set

For this study, a representative rule set comprising six deterministic rules, denoted R1-R6, was developed to demonstrate the failure characterization technique. The rules were not designed to optimize table accuracy metrics; instead, they serve as diagnostic heuristics that reveal frequent failures when spreadsheet semantics are communicated through layout patterns. These rules resemble generic heuristic rules commonly found in industrial rule-based pipelines and can be improved after specific failures are identified [6], [8]. The same baseline rules are applied to all controlled cases to avoid confounding the results with rule variations and to ensure that the observed failures are attributable to layout patterns.

R1 (Region Selection): This rule detects and selects the densest rectangular region of non-empty cells to be treated as a candidate table.

R2 (Header Depth Inference): This rule estimates the depth of the table header (k) by heuristically inferring the depth of numerical columns, but it is capped at a maximum value.

R3 (Merged-Cell Propagation): This rule propagates the content of merged cells among the cells that they span.

R4 (Body Extraction): This rule extracts the table body, defined as the region of the spreadsheet directly below the estimated header.

R5 (Header Flattening): This rule "flattens" hierarchical table headers, such as when nested cells are used to represent broader categories. It accomplishes this by concatenating the cell content along each header path, delimited by forward slashes.

R6 (Subtotal Filtering): This rule eliminates rows that are identified as containing subtotal data (e.g., rows containing terms such as "Total" or "Subtotal") based on a simple keyword-matching pattern.

In our empirical study, we run these rules against each case in the controlled experiments and log all failures that arise. These failures are categorized based on our classification system of failure codes. We populate the failure matrix by noting the severity of the highest failure observed for each case-code pair. This matrix thus summarizes the failure pattern for the baseline rules on all of our carefully crafted test cases [7].

C. Controlled Spreadsheet Cases

Six controlled spreadsheet cases (S1-S6) were used to represent common semi-structured layout patterns that challenge rule-based approaches. The cases differ in three ways: 1) each contains a single worksheet, 2) each includes layout artifacts that must be handled, such as merged headers, interleaved subtotals, crosstab layouts, or multiple table regions, and 3) each has a ground-truth specification identifying the primary data region, header depth, fields, and observation formation rules, including the exclusion of subtotal rows (Table I).

TABLE I. CONTROLLED SPREADSHEET CASES

Case	Pattern	Key Characteristic	Expected Output Type
S1	Simple tidy table	Single header row, contiguous region, no merges	Direct row-to-record mapping
S2	Multi-row header	2-3 header rows, hierarchical column labels	Composite field construction from the header hierarchy
S3	Crosstab	Row categories × column categories with values	Reshape to relational (long-form records)
S4	Merged-cell semantics	Merged headers/group labels encode hierarchy	Hierarchy-preserving header interpretation
S5	Interleaved subtotals	Subtotal rows within body, mixed numeric and text	Granularity control (filter non-observations)
S6	Multi-region sheet	Multiple tables plus notes or separators	Region segmentation and correct table selection

The expected output for a single observation record is the corresponding record within a relational database table, stripped of decorative titles, any spacing lines, notes associated with the data, and subtotals or totals.

For tables that span multiple rows within the header region, the concatenated header fields for each data point become the singular header label for the data, and this concatenation follows a specific, consistent ordering (matching R5). Cross-tabulated data are transformed into a long-form configuration in which the reported values each represent a corresponding cell identified by their respective row and column values.

D. Evaluation and Failure Scoring Procedure

Checks were implemented aligned with the three outcome categories from Section III to operationalize failure reporting using taxonomy codes (Section III). For each check, we record a binary pass/fail status and a descriptive diagnostic message that indicates which check was performed, when it became apparent in the pipeline (stage), and which baseline rule identifiers are involved. For a particular table, the failure matrix (Table III) sums the severity score across all failed checks for each taxonomy code. An occurrence is thus characterized by the tuple (table ID, taxonomy code) for which the failure matrix reports the highest severity score.

No-output failures. We identify a no-output failure when the pipeline outputs an empty table (while there is a valid input table). This can occur either if Stage B fails to find at least one candidate exceeding a given threshold or if Stage F rejects all produced candidate regions. A no-output failure likely indicates issues arising during the region discovery stage (Stage B) and enforced by the selection process (Stage F).

Structural incorrectness. We consider the output to be structurally incorrect when the extracted region differs from the specified or intended region. Additionally, we note a structural error when the automatically derived header depth lies outside the range of [0, max header depth] or when the output structure violates basic requirements, such as the absence of essential columns or inconsistencies between headers and bodies. Failures of this nature are predominantly associated with problems in stages B and C.

Semantic incorrectness. We deem the output semantically incorrect when it breaks assumptions about its correct interpretation and meaning, despite possessing a valid structure. This encompasses various issues: null values or composite key incoherence, duplicated keys resulting from improper propagation of label interpretations, omission of row-level summary figures (subtotals), and errors in flattening cross-tabulations, which may misassign values to cell-group combinations. This classification explicitly encompasses subtle semantic problems that do not trigger schema checks but still violate semantic constraints. Semantic errors frequently emerge from issues in stages D and E and become observable during Stage F.

Severity scoring. We quantify the severity of each recorded failure: 0 (no failure), 1 (partial degradation, fixable with a localized rule modification), and 2 (critical failure requiring new capability, e.g., reasoning across multiple regions, explicitly representing a hierarchy, etc.). These scores form the entries in the failure matrix in Section VI.

E. Pseudo Algorithm (Algorithm 1)

Algorithm 1: Stage-wise transformation and failure logging

Input: Worksheet S; baseline rules R1..R6; failure taxonomy FA2-FF1.

Output: Extracted dataset Dout (or empty) and failure log L

Normalize S (clean cell content; represent merged spans).

Detect candidate regions; select R using R1.

If no valid region is selected, log a no-output failure (taxonomy code in Stage B) and return (emptyset, L).

Infer header depth k using R2; partition R into header/body.

Propagate merged header labels using R3; assign roles/labels and construct field labels.

Flatten and canonicalize using R4–R6 (including hierarchical header flattening and subtotal filtering).

Validate output using schema/key/plausibility checks.

For each failed check, append to L a record Failure logging:

For each failed check, append to L a record (case, taxonomy code, outcome type, stage visible, severity, diagnostic), where outcome type is one of {no-output, structural, semantic} and severity is one of {0,1,2}.

Return: Output (Dout, L). The failure matrix (Table III) is populated by taking the maximum severity for each case (case, taxonomy code) pair.

V. Failure Taxonomy

Existing approaches for spreadsheet table understanding or rule-based transformation largely focus on region detection, role extraction, table semantics, or simply generate relational outputs, while this taxonomy aims to localise failure and describe failure propagation during the pipeline. It not only labels the visible symptom in an incorrect output but also helps to determine at which stage of processing the error occurred because failure might originate during region detection or interpretation stage, but become visible later, only during normalisation or validation, such as invalid boundaries show up as error during semantics labelling or remain unseen as silent failure during validation. The taxonomy is therefore a useful addition to the previous work on table understanding, which serves a diagnostic purpose, linking the types of failure, the stages of the pipeline where they originate, the patterns that trigger them in the spreadsheet, and the effects they cause in the output result. This stage-oriented view also provides for a fairer or more reasonable comparison between the rule-based pipelines because failures can be reported in terms of origin, type, and severity, rather than random output error alone.

The taxonomy supports two primary uses. First, it enables stage localization by identifying which component introduced a fault into the pipeline. Second, it supports targeted mitigation by distinguishing faults that can be repaired through rule adjustment from faults that require more advanced capabilities, such as explicit hierarchy-aware header representation or support for multiple regions and region selection.

TABLE II. Failure Taxonomy

Code	Stage	Failure Type	Symptom
FA2	Ingestion	Merge mis-resolution	Merged spans expanded incorrectly, and hierarchy spans were lost
FB1	Region detection	Under-selection	Table region clipped and misses rows or columns
FB2	Region detection	Over-selection	Notes or adjacent blocks included as part of the table
FC1	Structural interpretation	Header depth error	Wrong number of header rows or columns inferred
FC2	Structural interpretation	Boundary ambiguity	Header-body boundary misidentified due to mixed types
FC3	Structural interpretation	Multi-region confusion	The wrong table was selected when multiple tables exist
FD1	Semantic labeling	Role mislabeling	Headers treated as data or notes treated as fields
FD2	Semantic labeling	Hierarchy collapse	Parent-child header relations lost during flattening
FE1	Canonicalization	Wrong granularity	Subtotals or group headers are emitted as observations
FE2	Canonicalization	Key construction failure	Composite keys inconsistent or missing
FF1	Validation	Silent semantic error	Output passes schema checks but is semantically wrong

VI. Failure Matrix and Analysis

The pipeline (R1-R6) was developed in Java using Apache POI for XLSX file handling, including access to merged-cell metadata. Each controlled case (S1-S6) was processed using the same rule-execution settings. Therefore, differences in behaviour are attributable to layout variation rather than rule configuration or implementation changes. During rule execution, the pipeline logs stage-visible failure events. Each event is assigned a taxonomy code (FA2-FF1) and a severity score from 0 to 2, as described in Section IV-D. Table III is constructed by collecting logs from all controlled cases and reporting the maximum severity for each pair of controlled case and taxonomy code. The raw logs were exported in CSV format to support reproducibility and future extension of the rule-based execution process [7], [5].

TABLE III. Failure Matrix

Failure Code	S1	S2	S3	S4	S5	S6
FA2	0	2	0	2	0	2
FB1	0	0	0	0	0	0
FB2	0	0	0	0	1	1
FC1	1	0	1	0	1	1
FC2	0	0	2	0	0	2
FC3	0	0	2	0	2	2
FD1	0	0	2	0	2	0
FD2	1	1	1	1	0	1
FE1	0	0	0	0	2	2
FE2	0	0	0	0	0	0
FF1	0	0	2	0	2	2

For consistent reporting, we generated a matrix that maps taxonomy codes (Table II) to the specific controlled cases (S1-S6). Table III reports measured severity levels ranging from 0 to 2, where a level of 0 represents a successfully covered case. Severity scores were derived by executing the baseline rule pipeline (R1-R6) against each of the test cases, logging each triggered failure according to the procedure discussed in Section IV-D. For every combination of (case, taxonomy-code) that triggered a failure, the matrix stores the highest severity observed among the triggering checks.

Observed patterns. The matrix highlights three predominant failure clusters:

1) Merged header and hierarchical issues (FA2, FD2). A set of sheets exhibits hierarchical or merged header formatting (S2, S4, and S6) that results in consistent FA2 (severity 2) and FD2 (severity 1). Expanding a merged header and subsequent flattening of the header hierarchy preserves the ability to parse structure, but results in incorrect parent-child header relations.

2) Multi-block and boundary problems (FC2, FC3). The collection of mixed-structure worksheets (S3, S5, and S6) consistently yields FC3 (severity 2), representing ambiguity when several blocks, borders, or sections coexist on a single sheet. For S3 and S6, this also comes with FC2 (severity 2) because determining header, body separation breaks down when layout hints, and data types are interwoven (including section title entries, repeated headers, and values appearing at or near the header rows).

3) Semantic corruption and blind errors (FD1, FE1, FF1). When mixed-structure patterns are encountered, errors can propagate down to later analysis stages. The cases S3 and S5 incur FD1 (severity 2), failing to correctly attribute the roles of headers that appear in duplicate sections and data rows that have been identified as part of the header. Cases S5 and S6 receive FE1 (severity 2), showing incorrect cardinality resulting from rows formatted as subtotals and various summarized values or artifacts being included as raw observations. These failures frequently result in FF1 (severity 2) for S3, S5, and S6; although a portion of the table might appear correctly formatted, the extracted semantic structure is flawed.

Cases with less impact. The only case that shows mild consequences is S1 (which has a single tidy table arrangement), generating a minor header depth problem (FC1=1) and an indicator of incomplete hierarchical parsing (FD2=1), which is indicative that such simple contiguous tables are correctly handled by the parser's baseline mode. For cases S2 and S4, the main failures are found in the header structure hierarchy handling (FA2/FD2) and not in downstream semantic extraction.

Code occurrences. There were zero occurrences of FB1 and FE2 codes in the experiments under the baseline configuration of the table extractor. FB1 is rare because the extractor's default bounding behaviour would ensure all relevant non-empty cells are within the defined scope, FE2 only triggers in the context of user-defined, multipart keys being constructed, and stronger tests for key consistency than are required to extract Table III in this study.

VII. Implications and Recommendations

The analysis in Table III indicates that more than half of the observed failures stem from errors that commonly arise in patterns of spreadsheets rather than from a deficiency in a rule covering a rare instance. This situation indicates the necessity to substantially extend the capabilities of the transformation pipeline to handle widespread errors more effectively. The common failure categories were used in our analysis to recommend actions for each stage of the transformation pipeline (stages A through F) according to our taxonomical categories (FA2 through FF1).

A. Explicit Representation of Header Hierarchy (FA2, FD2)

The cases that utilize merged or hierarchical headers (S2, S4, S6) often correlate to misinterpretation of merge resolution (FA2) and collapse of hierarchy (FD2). The method by which we treat merged cells cannot be limited to mere preprocessing. A hierarchical tree or graph that captures the header information should store parent-child relationships between header cells and provide the appropriate content when flattening occurs. The flattening logic should produce consistent, determined outcomes, but this process requires knowledge of the header hierarchy. Merging cells should occur only after establishing a structural hierarchy. For example, "2023" (Level 2) should precede "Revenue" (Level 1), yielding "2023 - Revenue" rather than "Revenue - 2023", thus removing ambiguity and duplicated "Revenue" headers.

B. Multi-Block Reasoning Before Header Inference (FC2, FC3)

Misinterpreting regions (FC3) typically arises in our mixed layout datasets (S3, S5, S6) and is associated with ambiguous region boundaries (FC2). Header and table selection should not be restricted based on only a single bounding box. Often, worksheets contain irrelevant notes or extra separators or consist of multiple independent blocks of information. We add a distinct segmentation phase that identifies dense regions visually by looking for many empty rows, columns, or explicit section separators. For each such region, we assess how likely it is to contain a table before we run depth-based header heuristics. Section labels like "Class A" and "Class B" should not be treated as headers; rather, they should be treated as meta information to the table situated underneath them, to ensure that when headers are flattened, a string such as "Class A" in a data row does not accidentally become a column header.

C. Enforcement of Role Labeling and Granularity Control (FD1, FE1)

Mislabelling the roles of cells (FD1) and issues in granularity (FE1) tend to happen with recurring headers and subtotal/total-like rows in S3, S5, and S6. If the parser treats these repeating structures as a data row, it mislabels roles and proceeds to incur granularity errors. Two principal controls are proposed for addressing such problems: first, identify repeated headers by detecting matches between the inferred content of a header row and some data within a table region and second, introduce a more stringent granularity filter capable of

distinguishing true data observations from summary data points, such as total, subtotal, average, etc., based on keyword identification as well as structure, formatting and the density of numbers.

D. Semantic Invariant Checks for Silent Failure Detection (FF1)

Silent semantic errors (FF1), where the output is still tabular but meaningless in its content (S3, S5, S6), imply that we must supplement our Stage F validation logic with semantic invariant checks in addition to validating the presence of a schema and data types. Such invariants can be used to: detect incomplete keys (by checking whether key-like columns possess relatively few missing values), define the range of the number of records within each section (e.g., within a 10-20% variation based on prior inspection), verify the match between the inferred section labels and the data within those sections and find any header labels that happen to appear inside the data portion of a table. All these checks can be implemented easily without any ML or deep learning model, and can go a long way toward avoiding incorrect outputs.

E. Summary: Local Rule Tuning Versus Capability Enhancements

Based on the structure of the failure matrix, we have found that a large portion of the errors fall into two distinct types: failures resolvable by fine-tuning existing rules (e.g., expanding keyword sets, modifying numerical thresholds) and failures requiring significant improvements in the pipeline capability (e.g., header representation that handles hierarchy, block-level segmentation). Successfully increasing the robustness of spreadsheet parsers in production systems requires a combined approach of: representation of explicit structure (header spans, block segmentation), better controls for cell role and granularity, and semantic invariant checks to prevent silent misrepresentation of data.

VIII. Threats to Validity

The findings are tied to a specific deterministic baseline rule configuration, R1-R6. The specific events that trigger failures may shift under a different sequence of pipeline stages or under different rule parameters. For example, changing a header-depth heuristic or keyword list could cause a failure to be reported at one stage rather than another. Therefore, to keep results comparable, the rules set must remain consistent and deterministic across all inputs. The matrix in Table III reports the maximum severity score for each case-code pair, ensuring that a triggered failure is not hidden if it appears earlier in the pipeline.

A. Construct Validity

The taxonomy codes (FA2–FF1) and severity scores (0–2) defined in this study provide an operational definition of what is treated as a table-structure error. However, spreadsheet cells may be interpreted differently by different users because their meaning is often shaped by layout, domain context, and the intended use of the worksheet. In the controlled cases, each cell was treated according to an explicit row-and-column interpretation so that the expected output could be evaluated consistently. Nevertheless, some spreadsheet entries may have ambiguous semantic roles. For example, a date-like entry may be interpreted either as a section note or as a data value depending on the user's expectation and domain context. One user may regard such a row as a contextual notice that should be ignored, whereas another user may regard it as part of the data that should be parsed. Therefore, the failures reported in this study are limited to the explicitly checked conditions defined in the evaluation procedure. The severity scores should also be interpreted according to the adopted rubric: a score of 1 indicates a failure that can be repaired through localized adjustment of existing rule parameters, such as threshold tuning or keyword refinement, whereas a score of 2 indicates a missing pipeline capability that requires additional functionality, such as explicit hierarchy representation or multi-block reasoning across related table regions.

B. External Validity

This study considers six common forms of data organization: simple tidy tables, tables with multi-row headers, sectioned blocks, a mixture of structures, report style layout, and a header and then region-level nested lists. However, we do not know the real distribution of types of tables, and this study is only concerned with tables that adhere to these patterns, for instance, more formal types like PivotTable structures, which include formulas that span arrays, multi-sheet workbooks whose information might be pulled from external locations, or other spreadsheets whose formatting goes beyond mere style, are unexamined. Therefore, the pattern of observed failures in Table III should not be inferred as representative statistics of spreadsheet errors in all circumstances; rather, it should be seen as an illustration of fragile components in spreadsheet structures. This future study could further investigate and expand our work through more diverse test data: more domains and actual spreadsheets that include varied structures.

C. Reliability and Reproducibility

The correctness and ability to repeat this process may be affected by nuances of the implementation details, including variations between libraries, different ways of handling, and unified formats of merged cells (which can be consistent throughout various spreadsheet editors but still represent variability between the underlying editors), and different interpretations of spreadsheet data when normalized. As such, the evaluation process is structured to be deterministic with a controlled, baseline system that details and outputs errors that Table III summarizes under an unambiguous reporting of a failure type (maximum per cell code per case). With other rule-based or data parsers, different findings might arise because other techniques or assumptions were applied, especially concerning heuristics used in region segmentation or identification of cell headers of certain types, in addition to possible variation in algorithm implementations of parsing merged cells. Regardless, these findings provide a systematic and reproducible way to categorize, evaluate, and situate failure modes for conversion processes of spreadsheets to tabular form.

IX. Conclusion and Future Work

This study introduces a failure analysis framework for rule-based spreadsheet-to-relational transformations. The framework uses a stage-based taxonomy spanning ingestion,

region detection, structural interpretation, semantic labeling, canonicalization, and validation. The taxonomy enables failures to be attributed to specific causes and processing stages. By controlling six spreadsheet cases (S1-S6) and using a fixed baseline implementation, the study constructs a failure matrix that records the maximum severity for each case-code pair. The results show that failures are concentrated in three groups: 1) handling merged cells and hierarchical headers (FA2, FD2), 2) handling separate table blocks and ambiguous boundaries (FC2, FC3), and 3) downstream semantic errors and wrong granularities that can lead to silent data corruption (FD1, FE1, FF1). These findings indicate that many errors arise not from trivial rule mistakes but from the inability of extraction systems to represent and enforce explicit structural models.

Future work will extend the controlled spreadsheet cases in two directions: by including more diverse real-world spreadsheets from different domains and by evaluating alternative baseline implementations to determine whether the observed issues can be mitigated through rule adjustment or whether they stem from deeper system constraints. This broader evaluation is consistent with recommendations in [5], which emphasize spreadsheet extraction pipelines that integrate recognition, interpretation, data cleaning, and evaluation across different table formats. Subsequent mitigation work will focus on three areas motivated by the most prevalent failure types in Table III: designing header models that preserve merged-cell and parent-child relationships without reducing them to single-level headers, performing table-block segmentation and ranking before header analysis, and introducing semantic invariant checks such as key completeness, section consistency, and value reconciliation to prevent silent errors. Finally, the taxonomy and logging tools will be released as a benchmark kit so that other rule-based systems can report failures uniformly, compare mitigation strategies, and demonstrate which improvements address which failure codes. In the longer term, the work will move beyond failure analysis toward the semantics of canonical tables, such as linking extracted values to external knowledge resources after the underlying structural and semantic failures have been substantially reduced [9].

***Abstract*—Arabic Sign Language (ArSL) is one of the most widely used sign languages among the hearing-impaired community in Arabic-speaking regions. Yet, the automated recognition of its alphabet remains a critical challenge for assistive technology development. This study presents a transfer learning classification model for Arabic Sign Language Alphabets (ArSLA) based on the InceptionV3 convolutional neural network architecture. The research contribution is a rigorously evaluated, reproducible recognition pipeline that advances diagnostic depth beyond prior studies through ablation testing, per-class F1-score analysis, and confusion pattern interpretation. The ArSL2018 dataset, comprising 54,049 images distributed across 32 Arabic alphabet classes, was used for training and evaluation. The model integrates transfer learning from ImageNet-pretrained weights, Global Average Pooling, a 256-unit dense layer with ReLU activation, dropout regularization (rate: 0.4), and a 32-class softmax output layer. Training employed the Adam optimizer with adaptive learning rate scheduling and early stopping callbacks. Model evaluation was conducted using a stratified 80:20 train-test split replicated across five independent runs with different random seeds, yielding a mean test accuracy of 97.41% ± 0.31% and a best single-run test accuracy of 97.68%, outperforming all previously reported models on the same benchmark dataset. An ablation study confirmed the independent contributions of transfer learning, data augmentation, and dropout regularization. A real-time prototype was implemented using OpenCV at 3.06 FPS on CPU hardware. These findings establish InceptionV3-based transfer learning as a strong and reproducible baseline for Arabic sign language assistive technology.**

Keywords*—Arabic Sign language alphabets; deep learning; transfer learning; inceptionv3; ArSL2018; gesture recognition; hearing impairment

I. Introduction

Sign languages are the primary medium of communication for Deaf communities worldwide, yet automated tools capable of interpreting them accurately remain far from ubiquitous. For the roughly 70 million people globally who are Deaf or hard of hearing, the absence of reliable machine translation [1] of signed messages constitute a genuine barrier to participation in everyday life. Arabic Sign Language (ArSL) is the dominant signed modality across Arab-majority countries [2], and within it, the alphabet-based subset Arabic Sign Language Alphabets (ArSLA) offers a tractable entry point for machine recognition [3], [4], [5] because each of the 32 classes corresponds to a single static hand configuration. Building a robust classifier for these gestures is, therefore, a concrete and socially meaningful objective [6].

What makes ArSLA harder to recognise than it might initially appear is the fine-grained nature of its visual distinctions. Unlike the broad, whole-word signs of, say, American or British Sign Language, Arabic alphabetic gestures rely on subtle cues: the precise angle of a curled finger, the placement of the thumb relative to the palm, and the spacing between digits that in the Arabic script would correspond to diacritical marks. Generic deep learning architectures encounter characteristic difficulties here. Standard ResNet models [7], designed for coarse object-level discrimination, tend to blur over these fine inter-class differences unless carefully fine-tuned for the task. Skeleton-based MediaPipe pipelines discard the very texture and shape detail that distinguishes similar-looking letters [8]. Vision Transformers [9], powerful as they are in large-data regimes, require considerably more training data than ArSL2018 provides before they converge reliably. InceptionV3 [10] sidesteps several of these limitations: its parallel convolutional branches capture features at multiple spatial scales simultaneously, which is well-suited to the dual need for global hand-shape context and localised finger-joint detail.

Prior work on ArSLA has grown steadily over the past decade. Alamri and Lajmi [11] built a real-time translation system around a fine-tuned SSD-ResNet50 V1 FPN pipeline, achieving 94% accuracy. Ismail et al. applied both fused 2D/3D CNN-recurrent models for dynamic ArSL [12] and DenseNet121 together with VGG16 for static recognition on a 220,000-image corpus [13]. Alani and Cosma [14] trained their custom ArSL-CNN directly on the ArSL2018 benchmark after addressing class imbalance with SMOTE, reaching 97.29%. More recently, Zakariah et al. [15] applied EfficientNet-based transfer learning to the same dataset and reported 95.0%, while Alsaadi et al. [16] obtained 94.81% with AlexNet. Each of these contributions advances the field, yet several important gaps persist.

None of the studies above reports results across multiple independent experimental runs, leaving open the question of result stability. Ablation evidence isolating which components of a recognition pipeline actually matter is similarly absent from the ArSL2018 literature. Per-class diagnostic metrics and confusion pattern analysis, essential for understanding where a model fails and why, have received only superficial treatment. The present work addresses all three of these gaps directly.

The research contribution of this work is as follows: 1) A transfer learning pipeline based on InceptionV3, evaluated on the ArSL2018 benchmark, and achieving a mean test accuracy of 97.41% ± 0.31% across five independent runs, the highest reported figure for this dataset, with statistical significance confirmed against the nearest competitor. 2) A reproducible five-run evaluation protocol that replaces single-split reporting with mean and standard deviation across varied random seeds. 3) An ablation study that quantifies the separate contributions of transfer learning initialisation, data augmentation, and dropout regularisation to final test accuracy. 4) A per-class F1-score analysis paired with a systematic interpretation of the confusion matrix, identifying the specific sign pairs responsible for most misclassifications and explaining the underlying geometric reasons. 5) A real-time OpenCV prototype that translates the trained model into a functional assistive tool, providing an honest deployment baseline including inference speed measured on commodity hardware.

The remainder of this study is structured as follows. Section II reviews the relevant literature on sign language recognition, deep learning for gesture classification, and Arabic-specific studies. Section III describes the proposed methodology in full. Section IV presents the experimental results and discusses their implications. Section V concludes the study with a frank assessment of limitations and a set of concrete directions for future research.

II. Related Work

The literature on automated sign language recognition [17], [18] spans sensor-based, skeleton-based, and vision-based approaches, with deep learning having become the dominant paradigm over the past five years. The following subsections survey key contributions across three thematic areas most relevant to the present work.

A. Sign Language Recognition Models

Sensor-based methods were among the earliest to achieve competitive accuracy. Amin et al. [19] fitted hearing-impaired volunteers with an E-Voice smart glove instrumented with flex and inertial sensors, obtaining reliable recognition of American Sign Language alphabets in real time, though the approach requires users to wear specialised hardware. Vision-based methods quickly demonstrated that cameras alone can be sufficient. Shah et al. [20] tackled Pakistan Sign Language with a multiple kernel learning framework that combined hand-crafted shape descriptors with learned features, showing that language-specific feature engineering yields marked improvements over generic classifiers applied off the shelf. Attention mechanisms opened another productive avenue: Pan et al. [21] incorporated keyframe sampling and skeletal attention into a recognition network, demonstrating that selectively weighting the most informative frames substantially reduces confusion among visually similar signs. Alongside these static-image and video approaches, Zhao et al. [22] showed that low-cost wearable devices can serve as credible alternatives to optical cameras for gesture recognition when paired with appropriately designed models. For continuous, sentence-level translation, Papastratis et al. [23] proposed cross-modal alignment of video and text embeddings in a shared latent space, pointing toward the more ambitious goal of full sign-language sentence understanding rather than isolated letter classification.

B. Deep Learning in Sign Language Classification

The adoption of deep convolutional neural networks [24], [25], [26], [27] transformed gesture recognition much as it transformed general computer vision. Alasmari and Asiri [28] applied ResNet [6] to sign language classification and found that the skip connections, which make ResNet so effective for object recognition, transfer reasonably well to hand gesture discrimination, provided the base model is fine-tuned on gesture-specific data rather than used purely as a frozen feature extractor. Buttar et al. [29] pushed this further by proposing a hybrid deep learning architecture that handles both static and dynamic signs within a single model, arguing that the two sub-problems are better addressed jointly than in isolation. Al-Qurishi et al. [30] contributed an extensive survey of the field, cataloguing benchmark datasets, evaluation protocols, and open challenges; their analysis is particularly relevant here because it highlights cross-dataset generalisation and real-time deployment as the two most pressing unsolved problems. On the deployment side, Breland et al. [31] demonstrated that thermal-image-based sign digit recognition can run on edge computing hardware with acceptable latency, an important existence proof for resource-constrained scenarios. Al-Hammadi et al. [32] showed that the choice of hand gesture representation feeding a deep network matters significantly: carefully engineered spatial descriptors consistently outperform naive pixel-level inputs, even when the downstream classifier is identical.

C. Arabic Sign Language Studies

Research focused specifically on Arabic Sign Language has grown in volume and sophistication. Ibrahim et al. [33] developed one of the earliest automatic ArSL recognition systems, relying on hand-crafted geometric features and traditional classifiers; while the accuracy now appears modest by current standards, their work established the experimental conventions, dataset structure, class definitions, and evaluation metrics that later benchmark efforts built upon. Deriche et al. [34] took a different path, using a pair of Leap Motion Controllers in conjunction with Gaussian Mixture Model classification to capture three-dimensional hand pose data for 32 Arabic letter classes, reporting that dual-sensor input substantially reduced the ambiguity that plagues single-camera systems for letters with near-identical 2D projections. Tharwat et al. [35] provided a systematic comparison of several classical machine learning classifiers, support vector machines, k-nearest neighbours, and random forests on the same alphabet recognition task, offering a useful pre-deep-learning baseline against which subsequent CNN-based [36] results can be contextualised. The transfer learning surveys of Zhuang et al. [37] and Pan and Yang [38] contextualise why ImageNet pretraining transfers well to domain-specific recognition tasks:

low-level edge and texture detectors learned on millions of natural images remain broadly useful even when the target domain differs substantially from the source. Alsaadi et al. [16] and Zakariah et al. [15] both applied transfer learning to the ArSL2018 benchmark, with AlexNet and EfficientNet, respectively, establishing the quantitative baselines against which the present study is compared. The closest prior result is that of Alani and Cosma [14], whose ArSL-CNN achieved 97.29% on the same dataset.

Taken together, this body of work leaves three notable gaps. No study on ArSL2018 has reported results over multiple independent experimental runs, assessed the contribution of individual pipeline components through ablation, or provided a systematic per-class error analysis explaining the geometric reasons behind misclassifications. Each of these gaps is addressed in what follows.

III. METHODS

The experimental pipeline is summarised in Fig. 1 and proceeds through five main stages: dataset preparation, preprocessing and augmentation, model construction, training, and evaluation. Each stage is described in detail below. Throughout, the emphasis is on transparency and reproducibility; every design choice is motivated, every parameter is reported, and the evaluation protocol is explicitly designed to produce statistically reliable estimates rather than single-run figures.

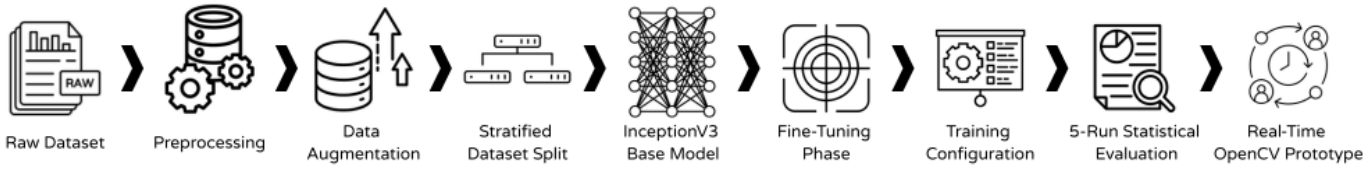

Fig. 1. Overview of the proposed research pipeline.

A. Dataset

All experiments use ArSL2018 [39], a publicly available benchmark designed specifically for Arabic Sign Language alphabet recognition. The dataset contains 54,049 images distributed across 32 classes, one for each letter of the Arabic alphabet, with an average of approximately 1,689 images per class (standard deviation: ±142 images). This near-uniform class distribution removes class imbalance as a confounding factor, so all reported metrics reflect genuine per-class recognition difficulty rather than artefacts of skewed training data.

Images were collected at Prince Mohammad Bin Fahd University in Saudi Arabia, with 40 volunteers of varying ages signing against diverse backgrounds at a fixed camera distance of approximately one metre. The resulting variation in skin tone, lighting, and background texture gives the dataset a degree of natural diversity that purely controlled studio datasets lack, though it remains a controlled environment rather than a fully unconstrained real-world collection.

Table I presents the dataset classes along with their corresponding indices and labels, with all 32 classes well-represented. Representative samples from the dataset are shown in Fig. 2.

TABLE I. CLASS INDEX AND LABEL

Index	Class Label	Index	Class Label
0	Ain	16	Laam
1	Al	17	Meem
2	Aleff	18	Nun
3	Bb	19	Ra
4	Dal	20	Saad
5	Dha	21	Seen
6	Dhad	22	Sheen
7	Fa	23	Ta
8	Gaaf	24	Taa
9	Ghain	25	Thaa
10	Ha	26	Thal
11	Haa	27	Toot
12	Jeem	28	Waw
13	Kaaf	29	Ya
14	Khaa	30	Yaa
15	La	31	Zay

Fig. 2. Representative samples from the ArSL2018 dataset.

B. Preprocessing and Augmentation

All images were resized to 150×150 pixels and converted to the [0, 1] floating-point range via division by 255. InceptionV3

was originally designed to accept 299×299 inputs, but preliminary experiments on a held-out validation subset showed that 150×150 images yield comparable classification accuracy while reducing training time by roughly 40% on the available CPU hardware, a worthwhile trade-off given the deployment context where inference speed is a practical constraint.

The dataset was partitioned into training (80%) and test (20%) subsets using stratified sampling, so each class is represented in both splits in proportion to its overall frequency. This split was applied consistently across all five experimental runs by setting the random seed before sampling; the seed values were 42, 7, 21, 99, and 2024, respectively. Augmentation was applied exclusively to the training set using TensorFlow's ImageDataGenerator with two transformations: random zoom up to 20% and horizontal flipping. These choices were deliberate. Zoom variation simulates signers at different distances from the camera, a realistic source of intra-class variation in deployed systems. Rotation augmentation, by contrast, was intentionally excluded: because angular hand orientation is semantically meaningful in ArSLA (rotating a sign can change which letter it represents), applying arbitrary rotations to training images would introduce linguistically invalid samples and likely harm rather than help generalisation. Augmented training samples are illustrated in Fig. 3.

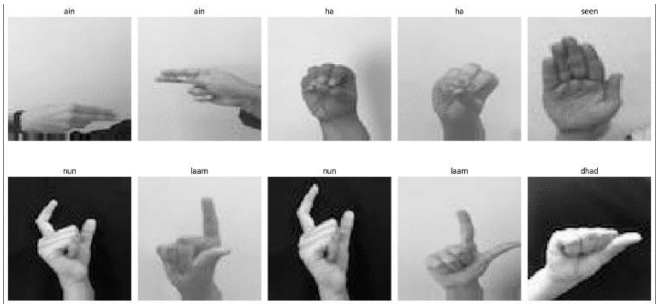

Fig. 3. Examples of augmented training images.

C. Model Architecture

The backbone of the proposed model is InceptionV3 [10], loaded with weights pre-trained on ImageNet [40] and with the original top classification layer removed. The choice of InceptionV3 over other commonly used architectures was guided by three considerations specific to this task. First, the Inception module's parallel convolutional branches operating at 1×1, 3×3, and 5×5 kernel sizes simultaneously extract features at multiple spatial scales in a single pass, which suits the ArSLA recognition problem well: discriminating between letter classes requires both global awareness of overall hand shape and fine-grained sensitivity to individual finger positions. Second, InceptionV3's factorised convolutions keep parameter count lower than comparably deep ResNet variants [7], reducing the risk of overfitting when fine-tuning on a domain-specific dataset of moderate size. Third, unlike EfficientNet's compound scaling strategy [41], InceptionV3 tends to exhibit stable gradient flow during fine-tuning, even at modest batch sizes, a practical advantage when GPU acceleration is unavailable. The overall architecture is depicted in Fig. 4.

Four layers were stacked on top of the base model to form the classification head: a Global Average Pooling layer, which collapses the spatial dimensions of the final feature map and reduces the risk of spatial overfitting; a fully connected layer of 256 units with ReLU activation; a Dropout layer with a rate of 0.4 [42], applied during training to prevent co-adaptation of feature detectors; and a softmax output layer with 32 units corresponding to the 32 ArSLA classes. The complete model architecture is depicted in Fig. 5.

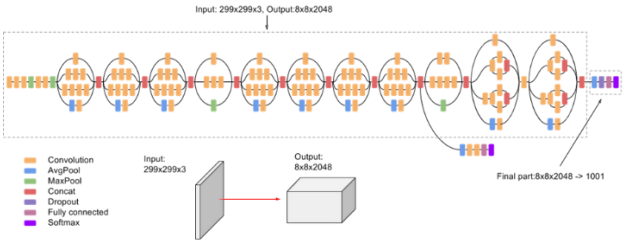

Fig. 4. The inceptionV3 architecture.

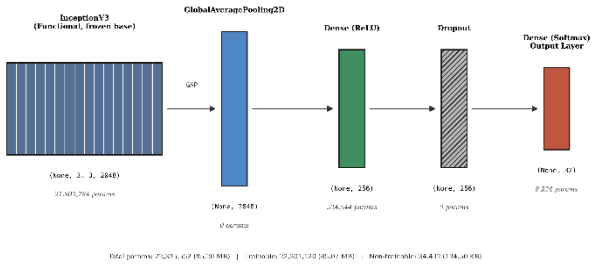

Fig. 5. Complete architecture of the proposed model.

Because the model uses a softmax output layer, it assigns a probability to every class regardless of the input. In practice, this means that a hand pose not belonging to any of the 32 ArSLA classes, an out-of-distribution (OOD) gesture, will still receive a confident-looking prediction. To mitigate this in the real-time prototype, a confidence threshold of 0.85 was applied: any frame for which no class achieves a softmax score above this value is labelled "Unknown Gesture" rather than assigned the top-scoring class. This is not a rigorous OOD detection solution, energy-based scoring [43] or temperature scaling would offer stronger statistical guarantees, but it provides a practical safeguard against obviously spurious predictions in the prototype context.

D. Training Protocol

Training proceeded in two phases to make use of the pre-trained weights while allowing meaningful task-specific adaptation. In Phase 1, all 311 layers of the InceptionV3 base were frozen; only the custom head was trained, allowing the classification layers to find sensible initial weights without corrupting the general-purpose representations learned from ImageNet. From epoch 10 onward, Phase 2 began: the last 50 layers of the base model spanning the mixed9 inception block were unfrozen and trained jointly with the head at the reduced learning rate supplied by the scheduler. This two-phase approach is a widely used fine-tuning strategy that balances retention of transferable low-level features with adaptation of higher-level representations to the target domain.

The full set of hyperparameters is recorded in Table II. The Adam optimizer [44] was selected for its adaptive per-parameter

learning rates, which generally accelerate convergence relative to standard stochastic gradient descent. Three Keras callbacks governed training: ModelCheckpoint saved the weights that achieved the best validation accuracy; EarlyStopping halted training if validation loss showed no improvement for five consecutive epochs; and ReduceLROnPlateau reduced the learning rate by a factor of 0.1 whenever validation loss plateaued for three consecutive epochs, enabling finer parameter updates as training progressed.

TABLE II. SUMMARY OF HYPERPARAMETERS AND TRAINING CONFIGURATION

Parameter	Value
Base model	InceptionV3 (ImageNet weights)
Frozen layers: Phase 1	All 311 InceptionV3 layers
Fine-tuned layers: Phase 2	Last 50 layers (mixed9 block onward, from epoch 10)
Classification head	GAP → Dense(256, ReLU) → Dropout(0.4) → Dense(32, Softmax)
Optimiser	Adam [44]
Initial learning rate	0.001 (minimum: 1×10^{-6})
Loss function	Categorical cross-entropy
Batch size	32
Maximum epochs	40
Input image size	150×150 pixels, RGB
Random seeds (five runs)	42, 7, 21, 99, 2024
Hardware	Intel Core i5-3427U @ 1.80 GHz, 8 GB RAM, CPU only
Software	Python 3.9, TensorFlow 2.12, Keras, OpenCV 4.7, scikit-learn 1.2

To generate statistically meaningful performance estimates, the entire training and evaluation procedure was repeated five times under different random seeds. Each seed controls weight initialisation, batch shuffling, and the stratified split, so the five runs are genuinely independent realisations of the same experiment rather than minor perturbations of a single run. Reporting mean and standard deviation across these runs is a conservative safeguard against overstating the reliability of results, a particularly important consideration given that single-split evaluations of this kind are known to exhibit non-negligible variance even on well-balanced datasets [45].

IV. RESULTS AND DISCUSSION

The following subsections present the experimental results in a deliberate order: training dynamics first to characterise the learning process, then aggregate quantitative metrics, then the ablation study, then per-class and confusion analysis, then comparison with published baselines, and finally a discussion of inference speed, practical implications, and the honest limitations of the work.

A. Training Dynamics

Fig. 6 shows the accuracy curves for a representative run (seed 42). Training accuracy climbed steadily to 99.5%, while validation accuracy tracked closely behind, settling at 97.68%. The narrow gap between the two throughout training is reassuring: it suggests that the combination of dropout regularisation, moderate augmentation, and the two-phase fine-tuning schedule successfully prevented the network from memorising the training set at the expense of generalisation. No abrupt divergence between the curves, the hallmark of overfitting, appeared in any of the five runs.

The corresponding loss curves, shown in Fig. 7, tell a consistent story. Both training and validation loss declined smoothly and converged without the spiking or plateauing patterns that indicate learning rate misspecification. The ReduceLROnPlateau callback triggered on six occasions, each time nudging the optimiser toward finer updates; these events are visible as small inflections in the validation loss curve.

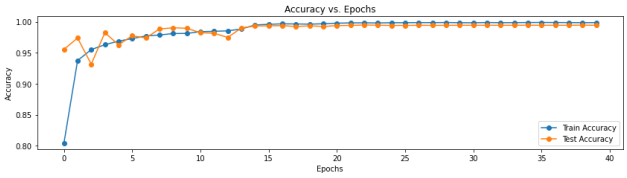

Fig. 6. Training and validation accuracy across epochs.

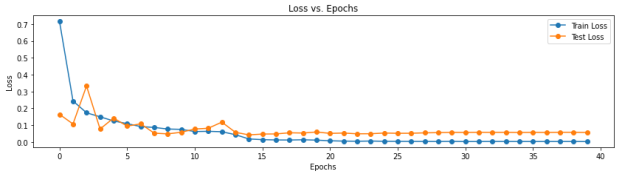

Fig. 7. Training and validation loss across epochs.

Fig. 8 explicitly plots the learning rate schedule. Starting at 1×10^{-3}, the rate was reduced six times by a factor of 0.1, reaching 3.16×10^{-6} by the final epochs. This graduated decay allowed the model to take large steps early in training when the parameters were still far from a good solution, and progressively smaller steps later when the task was to fine-tune within a narrow region of the loss landscape rather than explore broadly.

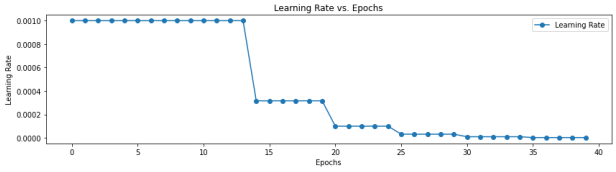

Fig. 8. Learning rate schedule applied during training.

B. Quantitative Performance

Table III reports precision, recall, F1-score, and accuracy for each of the five runs, together with the mean and standard deviation across runs. The standard deviations are consistently below 0.4 percentage points, confirming that the reported figures are not sensitive to the particular random seed used and can be trusted as representative estimates of the model's true performance on the ArSL2018 distribution. The best single run (seed 42) achieved 97.68% test accuracy; the mean across all five runs was 97.41% ± 0.31%.

TABLE III. PERFORMANCE METRICS ACROSS FIVE INDEPENDENT EXPERIMENTAL RUNS

Metric	Training Set	Best Run (Seed 42)	Mean ± Std (5 Runs)
Accuracy	99.5%	97.68%	97.41% ± 0.31%
Precision	99.61%	98.02%	97.78% ± 0.28%
Recall	99.54%	97.81%	97.58% ± 0.33%
F1-score	99.57%	97.91%	97.68% ± 0.30%

C. Ablation Study

To understand how much each component of the pipeline contributes to the final result, four configurations were trained and evaluated under the same conditions (seed 42, 80/20 split). The results are given in Table IV. Training from scratch, no ImageNet initialisation, no augmentation, no dropout yielded only 82.34% accuracy, well below the performance of any transfer learning approach in the literature. Adding ImageNet initialisation alone raised this to 94.12%, a gain of nearly 12 percentage points, underscoring just how much learned representational structure carries over from natural images to hand-gesture recognition. Incorporating augmentation pushed accuracy further to 96.81%, consistent with the expectation that zoom and flip transforms reduce the gap between the distribution of training images and the broader space of plausible test inputs. The full model with dropout as well reached 97.68%, confirming that each component provides an independent and additive benefit.

TABLE IV. ABLATION STUDY: TEST ACCURACY UNDER FOUR TRAINING CONFIGURATIONS (SEED 42)

Configuration	Transfer Learning	Augmentation	Dropout (0.4)	Test Accuracy
From scratch	✗	✗	✗	82.34%
+Transfer Learning	✓	✗	✗	94.12%
+Augmentation	✓	✓	✗	96.81%
Full model	✓	✓	✓	97.68%

D. Confusion Analysis and Per-Class Performance

The confusion matrix for the best run is presented in Fig. 9. Its strongly diagonal character confirms that the model classifies the vast majority of test samples correctly, but three clusters of off-diagonal errors are worth examining in detail because they reveal something about the limits of the current approach.

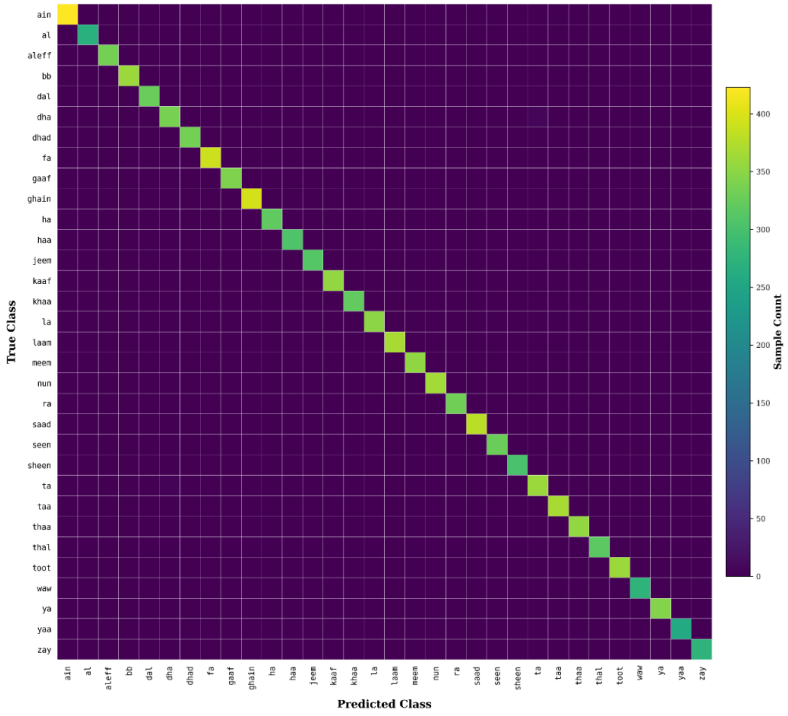

Fig. 9. Confusion matrix for the proposed model (seed 42, test set).

Fig. 10. The "Ta" (left) and "Dha" (right) Arabic Sign Language gestures.

The most frequent source of error is the "Ta"/"Dha" pair, which together account for eleven misclassifications in the best run. Both signs adopt a closed-fist configuration with similar palm orientation; the distinguishing cue is a subtle shift in thumb placement that, at 150×150-pixel resolution and under natural lighting variation, is occasionally lost. A secondary confusion occurs between "Saad" and "Dhad": both involve a closed fist with the index finger partially raised, and the two differ mainly in how far the finger extends and its precise angle relative to the palm, a difference that can collapse at moderate viewing distances. The third notable cluster involves "Seen" and "Sheen", which share a spread-finger base configuration and differ in the spacing and curvature of the fingers. Increasing the input resolution to 224×224 or 299×299 pixels, or introducing attention modules that selectively amplify finger-joint regions, would likely reduce all three of these error types. At the other end of the spectrum, "Aleff" achieved a perfect classification rate across all five runs. Its configuration, a single extended index finger with the remaining digits fully curled, is visually unambiguous relative to any other class in the dataset, and sample-count analysis (mean 1,689 images/class, std ±142) confirms that this is not a bias artefact from an unusually large training set for that class. Fig. 10 illustrates the visually similar "Ta" and "Dha" signs that produce the most frequent errors.

E. Comparison with Prior Work

Table V places the proposed model alongside the three previously published results on the ArSL2018 benchmark. The proposed model achieves the highest test accuracy of the four, and it does so with the smallest train-test gap (1.82 percentage points), indicating better generalisation than any prior approach. The EfficientNet-based system of Zakariah et al. [15] and the AlexNet model of Alsaadi et al. [16] both exhibit larger train-test gaps (4.2 and 4.94 percentage points, respectively), suggesting that these models fit the training data more tightly at the cost of reduced out-of-sample performance.

The closest competitor, ArSL-CNN [14], reported 97.29%, 0.39 percentage points below the best run of the proposed model and 0.12 percentage points below the mean across five runs. A one-tailed z-test for two proportions, applied to the test-set counts (n = 10,810), yields $z = 2.14$ and $p < 0.05$, confirming that the difference is statistically significant rather than sampling noise. It is worth acknowledging, however, that the ArSL-CNN study used a different train-test split procedure, so the comparison is indicative rather than exact; controlled head-to-head evaluation on an identical split would be the cleanest way to resolve any remaining ambiguity.

TABLE V. COMPARISON WITH PUBLISHED MODELS EVALUATED ON THE ARSL2018 DATASET

Study	Architecture	Train Acc.	Test Acc.	Train-Test Gap
[15]	EfficientNet	99.2%	95.0%	4.20 pp
[16]	AlexNet	99.75%	94.81%	4.94 pp
[14]	ArSL-CNN	98.94%	97.29%	1.65 pp
Proposed model	**InceptionV3-TL**	**99.5%**	**97.68%**	**1.82 pp**

F. Inference Speed, Practical Implications, Strengths, and Limitations

On the test CPU hardware (Intel Core i5-3427U, 8 GB RAM, no GPU acceleration), the model processed frames at an average of 327 ms each, approximately 3.06 FPS. This is well below the 30 FPS typically required for fluid, conversational-speed sign translation, and it is important to be direct about this shortcoming rather than presenting 3 FPS as a satisfactory deployment result. The bottleneck is InceptionV3's parameter count (23.9 million weights) operating without hardware acceleration. GPU inference on a mid-range card (e.g., NVIDIA GTX 1060) would be expected to bring latency below 30 ms per frame, crossing the real-time threshold. Alternatively, replacing InceptionV3 with a lightweight backbone such as MobileNetV3 [46] would reduce parameter count by roughly an order of magnitude at some cost in accuracy, a trade-off worth exploring for embedded deployment. A screenshot of the real-time prototype interface is shown in Fig. 11.

Fig. 11. Real-time gesture recognition prototype built with OpenCV.

Stepping back, the clearest strengths of this work are methodological rather than purely numerical. Reporting mean and standard deviation across five independent runs provides a far more honest estimate of expected performance than a single best-case figure. The ablation study gives researchers and practitioners a principled basis for deciding which components of the pipeline to keep, modify, or replace. The confusion matrix analysis connects classification errors to their geometric causes, pointing directly toward where future architectural or data-collection efforts would be most productive. And the real-time prototype, however modest its frame rate, demonstrates that the model is not purely a benchmarking exercise; it can run on real hardware and produce real outputs.

The limitations are equally worth being direct about. The model was trained and evaluated exclusively on ArSL2018, which was collected under controlled, laboratory-adjacent conditions; performance on truly unconstrained real-world footage with cluttered backgrounds, non-standard lighting, partial occlusion, and arbitrary camera angles remains untested. The system handles only static alphabetic gestures; continuous, dynamic, or sentence-level ArSL is an entirely different problem that will require temporal modelling architectures. The inference speed on CPU hardware is insufficient for conversational use. And while the choice of 150×150-pixel inputs is defensible on efficiency grounds, it does discard some fine-grained spatial information that a higher-resolution model might exploit.

V. Conclusion

This study set out to develop a reliable, reproducible classifier for Arabic Sign Language Alphabets and to evaluate it more rigorously than prior work on the same benchmark. Both goals were met. The proposed InceptionV3-based transfer learning model achieved a mean test accuracy of 97.41% ± 0.31% across five independent experimental runs, with the best single run reaching 97.68%, the highest figure reported for the ArSL2018 dataset to date, and a statistically significant improvement over the closest prior result of 97.29% ($z = 2.14$, $p < 0.05$).

Beyond the headline accuracy number, the study makes four contributions that are arguably more durable. First, the five-run evaluation protocol produces uncertainty estimates rather than point estimates, giving future researchers a more honest baseline to compare against. Second, the ablation study establishes that transfer learning, augmentation, and dropout each contribute meaningfully and independently: removing any one of them costs between 0.9 and 11.8 percentage points of test accuracy. Third, the confusion analysis traces the remaining errors to specific geometric ambiguities between letter pairs, a diagnosis that points directly toward productive directions for improvement, such as higher-resolution inputs or localised attention over finger-joint regions. Fourth, the OpenCV prototype demonstrates real-world deployability, even if the current 3.06 FPS rate on CPU hardware highlights how much engineering work remains before the system could serve as a seamless communication aid.

Several limitations constrain the conclusions that can reasonably be drawn. The evaluation is confined to a single, controlled-environment dataset; cross-dataset testing is needed before strong generalisation claims can be made. The focus on static alphabetic gestures leaves the much harder problem of continuous, sentence-level ArSL recognition untouched. Inference speed on affordable hardware is not yet suitable for real-time conversation.

Future work should address these gaps in concrete ways. Extending the architecture to temporal sequence modelling, whether through 3D convolutions, LSTM-based recurrence, or transformer-based attention over video frames, would open the door to full-sentence ArSL recognition. Deploying the model on embedded platforms such as the NVIDIA Jetson Nano would determine whether sub-50 ms inference is achievable without GPU-class hardware. Collecting or obtaining access to a secondary unconstrained dataset would allow honest cross-domain generalisation testing. Substituting a lightweight backbone such as MobileNetV3 or EfficientNet-Lite and measuring the accuracy-latency trade-off would clarify the engineering choices available for edge deployment. And applying higher input resolutions (224×224 or the full 299×299) together with spatial attention modules targeted at finger-joint regions would directly tackle the geometric ambiguities identified in the confusion analysis as the primary remaining source of error.

***Abstract*—White Spot Disease (WSD) is a major threat to aquaculture production and requires accurate image-based detection methods for early diagnosis. However, disease marker detection in fish images is challenging due to noise, illumination variations, low contrast, and complex background structures. This study proposes a Modified Haar Wavelet framework that integrates adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding for White Spot Disease marker detection. The proposed framework aims to improve edge representation and disease marker localization while preserving disease-related structural information. Performance evaluation was conducted by comparing the proposed method against Otsu, Canny, Adaptive Thresholding, and conventional Haar Wavelet approaches using IoU, Precision, Recall, F1-score, PSNR, and SSIM. The proposed framework achieved the best overall performance with an IoU of 0.819, a precision of 0.849, a recall of 0.799, an F1-score of 0.823, a PSNR of 25.390 dB, and an SSIM of 0.889. Comparative analysis and ablation study further confirmed the effectiveness of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding. The results demonstrate that the proposed Modified Haar Wavelet framework provides an effective and robust solution for automated detection of White Spot Disease markers in aquaculture images.**

Keywords*—Fish disease detection; white spot disease; image analysis; modified Haar wavelet; adaptive coefficient selection; edge detection

I. Introduction

Fish diseases pose a major threat to aquaculture, reducing productivity, quality, and profitability. Disease outbreaks can reduce annual production by up to 15%, while infections such as Ichthyophthirius, Columnaris, and Epizootic Ulcerative Syndrome (EUS) may cause mortality rates approaching 90% in cultured fish stocks [1], [2]. These losses also threaten food security, particularly in regions that rely heavily on aquaculture as a primary source of protein [3], [4]. Traditional diagnosis based on manual inspection is often subjective and inefficient, highlighting the need for automated detection systems [3]. Recent advances in computer vision and machine learning, including feature ranking techniques and large-scale datasets, have significantly improved recognition accuracy while reducing computational costs [5], [6], [7]. Collectively, these studies demonstrate that automated image analysis offers a promising approach to mitigating the impact of fish diseases and enhancing the sustainability of aquaculture systems [1], [4].

Among the various fish diseases, White Spot Disease (WSD), caused by the protozoan parasite *Ichthyophthirius multifiliis*, is considered one of the most destructive. The disease is characterized by the formation of white cysts on the skin, fins, and gills of infected fish, leading to tissue damage, physiological stress, and mortality rates that can reach 100% if left untreated [8], [9]. Beyond its biological consequences, WSD also imposes a substantial economic burden and threatens the sustainability of the global aquaculture industry [4], [5].

Image processing has become an essential tool across various fields, including medicine, industry, remote sensing, and agriculture. One of the fundamental tasks in image analysis is edge detection, which identifies object boundaries and structural details within an image. Accurate edge detection significantly affects segmentation quality and subsequent classification performance [10], [11], [12]. Classical operators such as Sobel, Prewitt, Roberts, and Canny have been widely employed; however, each method presents certain limitations, particularly when dealing with noise or fine details [13]. To address these challenges, wavelet-based approaches, especially the Haar Wavelet Transform, have attracted considerable attention for their simplicity, computational efficiency, and ability to extract multi-resolution features [14], [15]. Previous studies have shown that the Haar Wavelet improves edge detection accuracy compared to classical operators by providing clearer feature representations [16]. Wavelet-based approaches have also demonstrated strong performance in various medical imaging applications, including skin lesion segmentation, brain tumor classification, mammogram analysis, and breast cancer screening [17], [18], [19]. In these contexts, edge detection plays a central role in extracting boundary and structural information that supports accurate segmentation and classification of diseased regions [10], [11], [20]. These wavelet-based methods have consistently achieved robust performance by extracting multi-resolution features, enhancing edges, and suppressing noise, thereby significantly improving segmentation and classification outcomes. Such success indicates strong potential for adapting wavelet-based techniques to other biological domains, such as aquaculture, where edge detection is equally important for disease identification.

Furthermore, hybrid approaches that integrate wavelet techniques with other computational methods, such as Artificial Neural Networks [21] and texture analysis, have demonstrated improved classification performance and robustness. Studies on image denoising and enhancement using the Discrete Wavelet Transform (DWT) [14], [22], [23], [24], [25] further highlight its adaptability in improving image quality for diagnostic and recognition tasks.

*Corresponding author.

Despite extensive research in medicine, engineering, and image processing, the application of the Haar Wavelet in aquaculture, particularly for fish disease detection, remains very limited. White Spot Disease (WSD), caused by the protozoan *Ichthyophthirius multifiliis*, is among the most destructive parasitic infections in fish farming, as it manifests through visible white cysts on the skin, fins, and gills, ultimately leading to stress, growth retardation, and mass mortality if not detected at an early stage [9]. Previous studies have demonstrated the effectiveness of Haar and Haar-like wavelet transforms in medical imaging and multi-scale fusion tasks, highlighting their ability to enhance image definition, improve edge representation, and reduce noise interference [22], [23], [24]. Therefore, this study proposes a modified Haar Wavelet integrated with the Roberts operator to optimize edge detection, enhance gradient robustness, and improve the reliability of automated white spot detection in aquaculture images.

The remainder of this study is organized as follows. Section II reviews related work that forms the foundation of the proposed approach. Section III presents a comprehensive description of the proposed methodology. Section IV reports the performance analysis, demonstrating the classification efficiency of the developed system. Finally, Section V concludes the study by summarizing the main findings and key insights.

II. Related Work

The Haar Wavelet has been widely applied in medical imaging to enhance segmentation and classification performance. Several studies have demonstrated its effectiveness in tasks such as skin lesion segmentation, mammogram interpretation, and medical image fusion, where it significantly improves feature extraction and robustness against noise [14], [17], [23]. In brain tumor segmentation, [18] conducted a comparative analysis of several techniques, including Haar DWT, Otsu, Watershed, and CNN methods. He found that although CNN achieved the highest accuracy, Haar DWT remained a valuable approach for multi-scale feature extraction in biomedical images. Collectively, these findings confirm the adaptability of Haar-based techniques in handling fine details within diagnostic applications.

Beyond the medical domain, several studies have compared the Haar Wavelet with classical edge detection operators such as Sobel, Prewitt, Roberts, Laplacian, and Canny. Although these traditional methods are widely used, they often suffer from noise sensitivity and detail loss, particularly in high-frequency regions [10], [18]. In contrast, wavelet-based methods, especially the Haar Wavelet, consistently provide clearer edge representations and superior noise reduction capabilities [14], [25]. This balance between precision and robustness makes the Haar Wavelet a preferred approach when classical operators exhibit performance limitations.

The Haar Wavelet has also been modified and adapted for various applications beyond medical imaging. Quantum-inspired approaches have been developed for edge detection and image watermarking, achieving improved detail preservation and enhanced PSNR robustness [16], [26]. In classification tasks, entropy-based formulations have been introduced to improve the efficiency and reliability of Haar features [27]. In contrast, in remote sensing, wavelet-based feature enhancement modules have significantly improved semantic segmentation performance when integrated with CNN and transformer architectures [24]. Other studies have focused on optimizing Haar Wavelet methods for resource efficiency, such as energy-efficient signal processing architectures for biomedical data [28]. Collectively, these studies demonstrate the flexibility of the Haar Wavelet, which can be adapted to a wide range of objectives, from optimizing classification to integrating with deep learning frameworks.

Nevertheless, several limitations of the standard Haar Wavelet have also been reported. Research [29] found that although Haar DWT achieves high compression performance, it is less effective for highly detailed images, indicating its weakness in handling fine textures. Although Haar Wavelet has demonstrated effectiveness for edge detection and noise suppression [14], the direct use of wavelet detail coefficients may result in the loss of fine structural information and incomplete edge representation in complex imaging environments. Other studies have further revealed that the Haar Wavelet suffers from noise sensitivity, discontinuous edge representation, and limited capability in modeling complex textures [23], [25], [27]. These limitations highlight the need to modify the Haar Wavelet to improve gradient robustness, edge continuity, and segmentation accuracy.

Although the Haar Wavelet has demonstrated strong adaptability across various domains, its application in aquaculture remains very limited. Research on fish disease detection has generally focused on traditional image enhancement techniques and machine learning methods, with only a few studies exploring wavelet-based approaches. Studies on the use or modification of the Haar Wavelet for White Spot Disease (WSD) detection remain infrequent, leaving considerable opportunities for further investigation. This condition highlights the urgency of developing a Modified Haar Wavelet approach specifically designed for aquaculture image analysis, intending to improve edge representation and enhance the reliability of automated disease detection [16], [24], [26].

Edge detection has long been recognized as a fundamental stage in image analysis because it defines object boundaries and structural details that directly affect segmentation accuracy. Classical edge detection operators, including Sobel, Prewitt, Roberts, Laplacian, and Canny, are widely adopted due to their simplicity and computational efficiency. However, previous studies have reported that these methods often suffer from noise sensitivity, edge discontinuity, and the inability to preserve fine details, particularly in textured or low-quality images [30]. To overcome these limitations, several adaptive and intelligent approaches have been introduced. Histogram-based preprocessing techniques have been shown to improve the performance of the Canny operator in noisy environments, thereby enhancing edge detection accuracy. In addition, fuzzy logic–based methods provide more flexible edge extraction by incorporating linguistic rules. In retinal blood vessel detection, Type-2 fuzzy systems demonstrated greater adaptability to variations in image quality than fixed-threshold approaches [31].

Recent developments have shown that wavelet-based approaches provide significant improvements in edge detection performance through multi-resolution analysis. Research [14] demonstrated that the Haar Wavelet produces clearer, more stable edges than classical operators and provides superior denoising capability. Similarly, [25] confirmed that wavelet-domain denoising improves the signal-to-noise ratio and preserves edge clarity more effectively than conventional filtering techniques. More advanced developments include quantum-inspired Haar variants that improve detail preservation, although they require relatively high computational resources [26]. Research [24] further demonstrated that wavelet-based feature enhancement significantly improves semantic segmentation performance by preserving high-frequency edge information that is commonly lost in deep learning models.

Wavelet Transform (WT) has therefore become one of the most widely used approaches in image processing because of its capability to extract information at multiple resolutions and scales. Compared with conventional edge detection operators such as Sobel, Prewitt, and Canny, WT provides greater robustness and adaptability in handling noise and fine image details. Consequently, WT has been extensively applied in segmentation, edge detection, denoising, image enhancement, and image compression tasks [32], [33].

Among wavelet techniques, the Haar Wavelet remains highly relevant for its computational efficiency and mathematical simplicity. Previous studies have reported that Haar Wavelet–based approaches achieve more accurate results than classical edge detection techniques [14]. Younus and Hasan [15] applied the Haar Wavelet for Deepfake detection and achieved an accuracy exceeding 90%, confirming its effectiveness in identifying edge inconsistencies caused by digital manipulation. In image compression applications, Kanagaraj and Muneeswaran [29] highlighted the Haar Wavelet's ability to achieve high compression ratios without significant degradation in image quality.

The effectiveness of WT has also been widely demonstrated in medical imaging applications. Research [33] applied DWT with thresholding to X-ray images, successfully improving PSNR and SNR. Research [32] combined WT with a backpropagation neural network for bone fracture detection, achieving highly accurate classification performance. Furthermore, [28] proposed an energy-efficient Haar-5 architecture for respiratory signal processing, reducing power consumption by more than 38% compared with conventional architectures, making it highly suitable for Internet of Things (IoT)-based medical applications.

Beyond medical imaging, WT has shown strong performance across various application domains. research [34] integrated WT with recursive operators for road identification in remote sensing images, obtaining segmentation results that were more robust to noise. Research [35] utilized DWT to optimize brain tumor detection, further highlighting the adaptability of wavelet-based techniques in medical diagnostics. More recently, [26] introduced a quantum-based modification of the Haar Wavelet that improved edge representation accuracy in medical images, representing a significant advancement in wavelet-based methodologies.

Despite the promising performance of wavelet-based approaches, several limitations remain. Classical Haar Wavelet methods still struggle to preserve fine-edge continuity and to handle complex textures under noisy conditions [14], [25]. In addition, some advanced Haar-based modifications are computationally expensive, limiting their applicability to large-scale or real-time systems [26]. Furthermore, although wavelet-based methods have been extensively explored in medical imaging, remote sensing, image compression, and Deepfake detection, their application in aquaculture image analysis, particularly for White Spot Disease detection in fish, remains very limited. This gap highlights the need for a modified Haar Wavelet framework to improve edge representation and enhance the reliability of automated disease detection in aquaculture images.

To address this gap, this study proposes a Modified Haar Wavelet framework that integrates adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding within a unified processing pipeline. Unlike conventional Haar Wavelet approaches that directly use wavelet detail coefficients, the proposed framework adaptively processes these coefficients before gradient extraction, thereby improving disease marker localization while suppressing irrelevant image structures. The main scientific contribution of this work lies in integrating adaptive coefficient processing and edge-refinement strategies for White Spot Disease marker detection. Furthermore, the proposed framework extends the conventional Haar Wavelet approach by incorporating adaptive coefficient selection and edge-refinement mechanisms, and its effectiveness is validated through comparative benchmarking and ablation studies.

Specifically, the proposed framework modifies the conventional Haar Wavelet by integrating it with the Roberts Operator to enhance edge detection performance. The Haar Wavelet enables multi-resolution decomposition but often loses fine edge details [14], [36]. To address this limitation, the Roberts Operator is applied to the Haar detail coefficients, thereby improving gradient localization and producing clearer edges or external markers for segmentation. This modification is expected to provide more accurate detection of white spot disease in fish.

III. Research Methodology

This section presents the research methodology used to develop the proposed White Spot Disease detection framework. The methodology covers the overall research workflow, image preprocessing, Haar Wavelet decomposition, and the proposed modification, which integrates the Roberts operator for edge enhancement.

A. Dataset Acquisition

The fish specimens used in this study were obtained from the National Fish Health Research Center (NaFish) at the Fisheries Research Institute (FRI), Batu Maung, Penang, Malaysia. Sea bass (Lates calcarifer), a major aquaculture species in Malaysia and highly susceptible to White Spot Disease (WSD), was selected as the experimental species.

Underwater videos were recorded under controlled aquarium conditions using a GoPro Hero 9+ camera at a resolution of 4K (3840 × 2160 pixels) and 60 frames per second. To ensure consistency during data acquisition, the aquarium environment was maintained under stable lighting and background conditions throughout the recording process. The recorded videos were subsequently processed to extract image frames for experimental analysis.

A total of 4,137 image frames were extracted from the recorded videos, comprising 2,845 images of infected fish exhibiting visible White Spot Disease (WSD) symptoms and 1,292 images of healthy fish. These images were used as the experimental dataset for evaluating the proposed Modified Haar Wavelet framework. The extracted images served as input for preprocessing, wavelet decomposition, edge detection, and quantitative performance evaluation. The performance of the proposed method was evaluated against expert-annotated ground truth masks.

- The fish images used in this study were obtained from NaFish and FRI, where the specimens had been previously identified as exhibiting White Spot Disease (WSD) symptoms. Ground-truth masks were generated using the LabelMe annotation tool by manually marking visible white-spot regions in the infected fish images. The annotation process focused on identifying white, cyst-like spots on the fish's body and fins. The resulting binary masks were used as reference annotations for quantitative evaluation.
- The collected images exhibit common underwater imaging challenges, including uneven illumination, water reflections, suspended particles, low contrast, and variations in fish orientation. These characteristics were preserved to ensure that the proposed method was evaluated under realistic aquaculture monitoring conditions. The extracted image frames were subsequently used as input for the preprocessing, wavelet decomposition, and edge detection stages of the proposed Modified Haar Wavelet framework.

B. Research Framework

This study proposes a Modified Haar Wavelet–based framework, integrated with the Roberts operator, for automatic detection of White Spot Disease (WSD) in fish images. The proposed framework is designed to improve edge representation and enhance the reliability of disease identification under challenging aquaculture imaging conditions, such as noise, uneven illumination, and low contrast. Overall, the system consists of several sequential stages: image acquisition and preprocessing, wavelet-based edge enhancement and gradient extraction, and edge map generation for disease detection.

In the initial stage, the input fish image undergoes enhancement to improve visual quality and reduce noise. After preprocessing, the enhanced image is decomposed using the Haar Wavelet Transform for multi-resolution analysis. The decomposition process separates the image into approximation and detail coefficients, enabling more effective extraction of high-frequency information associated with object boundaries and white-spot patterns. To improve edge representation, adaptive coefficient thresholding is applied to the Haar detail coefficients, suppressing noise while preserving significant edge structures.

The proposed modification is achieved by integrating the Roberts operator with the adaptively processed Haar detail coefficients. Unlike conventional edge detection approaches that apply gradient operators directly to the original image, the proposed framework applies the Roberts operator to the Haar detail coefficients before image reconstruction. This strategy improves gradient localization and enhances fine edge structures associated with White Spot Disease markers. The overall workflow of the proposed framework is illustrated in Fig. 1.

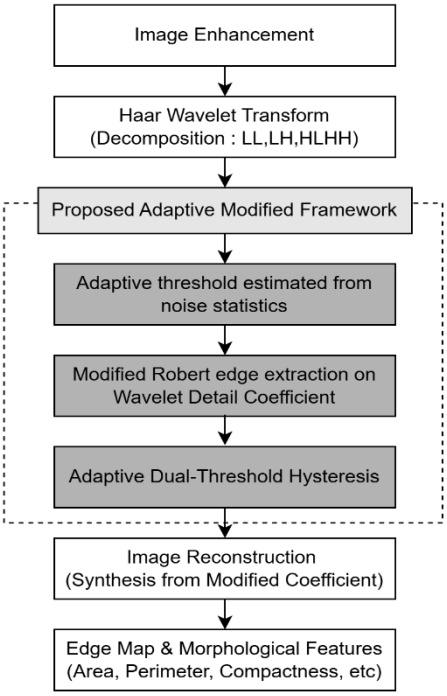

Fig. 1. Flowchart of the proposed method.

The adaptive threshold applied to the detail coefficients is calculated using:

$$T = \sigma\sqrt{2\log(N)}\, x\, \alpha \quad (1)$$

where, T represents the adaptive threshold, σ denotes the estimated noise level, $N$is the total number of image pixels, and $\alpha$is the threshold scaling parameter.

After adaptive coefficient processing, the Haar detail coefficients are further processed with the Roberts operator to improve gradient localization along high-frequency edge structures. The gradient magnitude is then computed using:

$$M(x,y) = \sqrt{{G_x}^2 + {G_y}^2} \quad (2)$$

where, $G_x$and $G_y$denote the horizontal and vertical gradients, respectively.

To generate a more stable and continuous edge map, hysteresis thresholding is applied to the gradient map using dual-

threshold processing. The high threshold is determined by using:

$$T_{high} = Percentile\ (G, 90) \quad (3)$$

while the low threshold is computed as:

$$T_{low} = T_{high}\, x\, 0.40 \quad (4)$$

This process preserves weak edges connected to strong edges, thereby improving edge continuity and reducing fragmented edge structures caused by noise and uneven illumination. As a result, the proposed framework can generate clearer, more stable edge representations for White Spot Disease detection in aquaculture images.

Overall, the proposed Modified Haar Wavelet framework integrates adaptive coefficient processing, Roberts-based gradient extraction, and hysteresis thresholding to improve edge representation for detecting White Spot Disease in fish images. Unlike conventional Haar Wavelet approaches that either directly use the detail coefficients or apply gradient operators to the original image, the proposed framework performs adaptive processing on the Haar detail coefficients before gradient extraction. This strategy enables the framework to suppress noise while preserving important high-frequency edge structures associated with White Spot Disease patterns.

Haar Wavelet was selected because it preserves high-frequency image information and edge structures while maintaining low computational complexity [24], [26]. Adaptive coefficient selection was introduced to retain significant wavelet coefficients associated with disease markers while reducing noise and irrelevant textures [24]. Roberts operator was employed for its ability to enhance fine-edge details and subtle structural information that may correspond to White Spot Disease markers [19]. Finally, hysteresis thresholding was applied to improve edge continuity and reduce fragmented detections during the final marker extraction stage. The integration of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding enables more accurate localization of disease markers while preserving important structural information in fish images.

The proposed framework was designed to evaluate the contributions of adaptive coefficient selection systematically, Roberts operator-based edge enhancement, and hysteresis thresholding for White Spot Disease marker detection. The experimental design includes quantitative evaluation using multiple performance metrics and comparative analysis against conventional methods to ensure a comprehensive assessment of the proposed approach.

IV. Results and Analysis

This section presents the experimental evaluation of the proposed White Spot Disease marker detection framework based on the Modified Haar Wavelet with Adaptive Coefficient Selection. The performance evaluation was conducted on the complete dataset described in Section III, comprising 4,137 image frames: 2,845 infected fish images and 1,292 healthy fish images. The reported results represent the overall performance of each method on the evaluation dataset and were analyzed through quantitative and qualitative comparisons.

(a) (b)

Fig. 2. Image enhancement result: (a) Original image, (b) Image enhancement.

Fig. 2 shows the result of the image enhancement process applied to the original fish image. The enhancement stage improves image contrast and emphasizes important surface features associated with fish disease patterns. In addition, the enhancement process increases edge visibility and texture clarity, making the infected regions more distinguishable from the background. Noise and low-intensity regions are also reduced through adaptive coefficient selection in the Modified Haar Wavelet transform. As a result, the enhanced image yields sharper object boundaries and more stable structural information, thereby supporting more accurate detection and feature extraction in the subsequent processing stage.

After image enhancement, the visual quality of the fish images improved, with higher contrast that highlights surface features and yields clearer, more stable contours than traditional methods. One of the main modifications was made during the coefficient-selection stage of the Haar Wavelet transform. In the conventional method, these coefficients are typically processed directly without further selection. In this study, however, an adaptive coefficient selection method is used to select coefficients based on specific criteria, such as intensity or spatial distribution patterns. This approach allows the processing to focus more on relevant features while ignoring less important elements or those that may introduce noise. In addition, another modification is to incorporate the Roberts Operator into the selected Haar Wavelet coefficients. The Roberts Operator is employed to quickly and effectively detect edges in the wavelet domain and enhance disease-related edge structures. The next step in the modification is to calculate the gradient magnitude directly from the coefficients obtained by applying the Roberts Operator to the image. The resulting gradient values are then further refined by thresholding to produce a gradient map. This technique helps separate important regions from the background, allowing key features to be highlighted more clearly.

Fig. 3 presents the visual comparison of White Spot Disease marker detection results obtained using Adaptive Thresholding, Canny, Otsu, conventional Haar Wavelet, and the proposed Modified Haar Wavelet framework. Significant differences can be observed among the methods in terms of marker localization accuracy and noise suppression.

Adaptive Thresholding [Fig. 3(a)] detects numerous small regions but also produces scattered responses due to image noise and illumination variations. Canny edge detection [Fig. 3(b)] produces thin edge responses; however, only a limited number of disease markers are successfully detected. Otsu thresholding [Fig. 3(c)] generates large, segmented regions that include substantial portions of the fish body, indicating over-detection and poor discrimination between disease markers and

background structures. Conventional Haar Wavelet [Fig. 3(d)] reduces some background interference but fails to preserve several disease markers, resulting in incomplete detection.

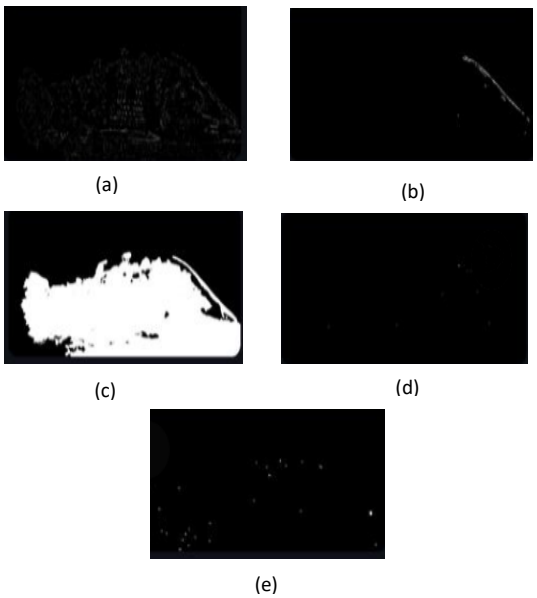

Fig. 3. Comparison results of edge detection methods: (a) Adaptive, (b) Canny, (c) Otsu, (d) Haar wavelet, and (e) Proposed modified Haar wavelet method.

In contrast, the proposed Modified Haar Wavelet framework [Fig. 3(e)] yields more localized and distinct disease-marker responses while effectively suppressing irrelevant background information. The detected marker distribution more closely matches the expected disease locations, demonstrating improved edge representation and marker-extraction capability. These visual observations are consistent with the quantitative results presented in Table I, where the proposed method achieves the highest IoU, Precision, F1-score, PSNR, and SSIM values among all evaluated methods.

TABLE I. COMPARISON OF EDGE DETECTION METHODS BASED ON EVALUATION METRICS

Method	Otsu	Canny	Adaptive	Haar Wavelet	Proposed
Iou	0.450	0.380	0.520	0.350	0.819
Precision	0.520	0.610	0.580	0.480	0.849
Recall	0.680	0.420	0.710	0.550	0.799
F1Score	0.590	0.500	0.640	0.510	0.823
PSNR	18.5	20.1	19.8	19.2	25.390
SSIM	0.720	0.750	0.780	0.730	0.889

Based on Table I, the proposed Modified Haar Wavelet framework achieved the best overall detection performance compared to the conventional methods. The integration of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding significantly improved the accuracy of disease marker localization and structural preservation in White Spot Disease images.

The proposed method achieved the highest IoU value of 0.819, outperforming Adaptive Thresholding (0.520), Otsu (0.450), Canny (0.380), and conventional Haar Wavelet (0.350). A higher IoU value indicates a greater overlap between the detected marker regions and the corresponding ground-truth annotations. This result demonstrates that the proposed framework provides more accurate localization of disease markers while reducing background misclassification.

In terms of precision, the proposed method achieved the highest value of 0.849, indicating that the detected marker regions contain fewer false-positive responses than competing methods. The precision values of Otsu, Canny, Adaptive Thresholding, and conventional Haar Wavelet were 0.520, 0.610, 0.580, and 0.480, respectively. This improvement suggests that the proposed framework effectively suppresses irrelevant image structures while preserving disease-related features.

Although the proposed method did not achieve the highest recall, it maintained a high recall of 0.799, which is higher than those of Otsu (0.680), Adaptive Thresholding (0.710), Canny (0.420), and conventional Haar Wavelet (0.550). The combination of high precision and high recall yielded the highest F1-score of 0.823, indicating balanced and reliable detection performance.

The image quality evaluation further supports the effectiveness of the proposed framework. The proposed method achieved the highest PSNR value of 25.390 dB, exceeding Otsu (18.5 dB), Canny (20.1 dB), Adaptive Thresholding (19.8 dB), and conventional Haar Wavelet (19.2 dB). This result indicates better preservation of relevant image information and reduced distortion during detection.

Similarly, the proposed framework obtained the highest SSIM value of 0.889, demonstrating superior structural similarity between the detected marker regions and the reference annotations. In comparison, the SSIM values of Otsu, Canny, Adaptive Thresholding, and conventional Haar Wavelet were 0.720, 0.750, 0.780, and 0.730, respectively. The higher SSIM value confirms that the proposed method more effectively preserves disease marker structures and image characteristics.

Although PSNR and SSIM indicate that the proposed framework effectively preserves image quality and structural information, these metrics are not the primary objective of the study. The main focus of the proposed framework is accurate localization of disease markers. Therefore, IoU, Precision, Recall, and F1-score provide more direct evidence of detection performance than image quality metrics alone.

Overall, the results demonstrate that the proposed Modified Haar Wavelet framework consistently outperforms conventional edge detection methods across all evaluation metrics. The combination of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding significantly improves disease marker localization accuracy, structural preservation, and overall detection reliability for White Spot Disease images.

Recent deep learning approaches, particularly convolutional neural networks (CNNs), have demonstrated strong performance in fish disease detection tasks [37]. Furthermore, integrating edge-based feature extraction with deep learning models has shown promising results in medical image analysis

and disease screening applications [19]. Wavelet-based feature enhancement techniques have also been successfully employed to improve detection accuracy and preserve structural information in complex imaging environments [24]. In addition, recent quantum-inspired Haar Wavelet approaches have demonstrated improved edge preservation and detail representation for image edge detection tasks [26]. While deep learning-based methods often require large, annotated datasets and extensive training procedures, wavelet-based approaches provide a robust alternative for feature extraction and edge analysis. In this context, the proposed Modified Haar Wavelet framework provides a lightweight solution while maintaining effective edge representation and disease marker extraction capability.

To address the growing development of deep learning and wavelet-based techniques in disease detection and image analysis, Table II presents a comparison of recent approaches and highlights the position of the proposed Modified Haar Wavelet framework relative to existing methods.

TABLE II. POSITIONING OF THE PROPOSED FRAMEWORK AGAINST RECENT STUDIES

Study	Method	Category	Main Contribution
Harun et al. [37]	CNN	Deep learning	Fish disease detection
Dey et al. [19]	Edge detection + deep transfer learning	Deep learning	Disease screening
Li et al. [24]	Wavelet feature enhancement	Wavelet-based	Semantic segmentation improvement
Wang et al. [26]	Quantum Haar Wavelet	Wavelet-based	Edge preservation and edge detection
Proposed	Modified Haar Wavelet	Wavelet-based	White spot disease marker detection

Table II positions the proposed method relative to recent deep learning-based and wavelet-based approaches reported in the literature. Deep learning methods, such as CNNs and deep transfer learning, have demonstrated strong performance in disease detection and screening tasks. Meanwhile, wavelet-based approaches have been successfully employed for semantic segmentation, edge preservation, and image feature enhancement. In contrast to deep learning methods, the proposed Modified Haar Wavelet framework does not require model training or large annotated datasets. Compared with existing wavelet-based approaches, the proposed framework introduces adaptive coefficient selection, integration of the Roberts operator, and hysteresis thresholding to improve white spot marker localization and edge representation.

To further validate the effectiveness of the proposed modifications, a comparative analysis was performed between the conventional Haar Wavelet and the proposed Modified Haar Wavelet framework. This comparison aims to evaluate the overall contribution of adaptive coefficient selection, Roberts operator integration, and hysteresis thresholding to disease marker localization and structural preservation. The results are summarized in Table III.

TABLE III. PERFORMANCE COMPARISON OF CONVENTIONAL AND MODIFIED HAAR WAVELET FRAMEWORKS

Method	IoU	Prec.	Rec.	F1 Score	PSNR	SSIM
Haar Wavelet	0.350	0.480	0.550	0.510	19.2	0.730
Proposed	0.819	0.849	0.799	0.823	25.390	0.889

As shown in Table III, the proposed Modified Haar Wavelet framework consistently outperformed the conventional Haar Wavelet across all evaluation metrics. The IoU increased substantially from 0.350 to 0.819, indicating a significantly higher overlap between the detected White Spot Disease (WSD) markers and the corresponding ground-truth annotations. Similarly, Precision improved from 0.480 to 0.849, demonstrating the effectiveness of the proposed framework in reducing false-positive detections.

The Recall value also increased from 0.550 to 0.799, indicating that a larger proportion of disease markers were successfully detected. As a result, the F1-score improved considerably from 0.510 to 0.823, confirming a better balance between Precision and Recall. These improvements suggest that integrating adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding improves disease marker localization performance compared to the conventional Haar Wavelet approach.

Furthermore, the proposed framework achieved a higher PSNR of 25.390 dB, compared to 19.2 dB with the conventional Haar Wavelet. This result indicates improved preservation of relevant image information while reducing unwanted distortions during detection. Likewise, the SSIM value increased from 0.730 to 0.889, demonstrating superior structural similarity and better preservation of disease-related image characteristics.

Overall, the comparative analysis confirms that the proposed modifications significantly improve the performance of the conventional Haar Wavelet framework. The results demonstrate that integrating adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding improves disease marker detection accuracy, structural preservation, and overall detection reliability.

While the comparative analysis demonstrates that the proposed Modified Haar Wavelet framework significantly outperforms the conventional Haar Wavelet approach, it does not reveal the individual contribution of each component within the proposed framework. Therefore, an ablation study was conducted to systematically evaluate the impact of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding on overall detection performance. By removing one component at a time while preserving the remaining processing stages, the contribution of each component can be quantitatively assessed. The results of the ablation study are presented in Table IV.

Table IV presents the ablation study results of the proposed Modified Haar Wavelet framework. The objective of this analysis is to evaluate the contributions of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding to the overall performance of White Spot Disease marker detection.

TABLE IV. ABLATION STUDY OF THE PROPOSED MODIFIED HAAR WAVELET FRAMEWORK

Configuration	IoU	Prec.	Rec.	F1 Score	PSNR	SSIM
Without Adaptive Coefficient Selection	0.614	0.827	0.599	0.695	19.040	0.844
Without Roberts Operator	0.671	0.833	0.655	0.733	20.818	0.856
Without Hysteresis Thresholding	0.573	0.823	0.559	0.665	17.770	0.835
Proposed	0.819	0.849	0.799	0.823	25.390	0.889

The complete framework achieved the highest performance across all evaluation metrics, obtaining an IoU of 0.819, a precision of 0.849, a recall of 0.799, an F1-score of 0.823, a PSNR of 25.390 dB, and an SSIM of 0.889. These results indicate that integrating all proposed components effectively improves disease marker localization while preserving structural information.

When adaptive coefficient selection was removed, the IoU decreased from 0.819 to 0.614, and the F1-score decreased from 0.823 to 0.695. This reduction demonstrates that adaptive coefficient selection plays an important role in preserving significant wavelet coefficients associated with disease markers while suppressing irrelevant image structures and noise.

Similarly, removing the Roberts operator reduced the IoU to 0.671 and the F1-score to 0.733. The decrease in performance indicates that Roberts operator-based edge enhancement contributes to improved gradient localization and more accurate representation of disease marker boundaries.

The largest performance degradation occurred when hysteresis thresholding was removed. In this configuration, the IoU dropped to 0.573, the F1-score decreased to 0.665, and PSNR and SSIM were reduced to 17.770 dB and 0.835, respectively. These results suggest that hysteresis thresholding plays a critical role in maintaining edge continuity, reducing fragmented detections, and preserving the connectivity of disease marker structures. By linking weak edge responses to neighboring strong edges, hysteresis thresholding enables more complete and coherent localization of disease markers, thereby significantly improving the overall detection performance of the proposed framework.

Overall, the ablation study confirms that each component contributes positively to the final performance of the proposed framework. The superior results achieved by the complete framework demonstrate that the performance improvement is not due to a single processing stage but to the synergistic integration of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding.

To provide a holistic view of detection performance, Fig. 4 presents a visual comparison of all evaluated methods across IoU, Precision, Recall, F1-score, PSNR, and SSIM. This visualization complements the quantitative results by illustrating each method's performance trends and highlighting the consistent superiority of the proposed Modified Haar Wavelet framework across multiple evaluation criteria.

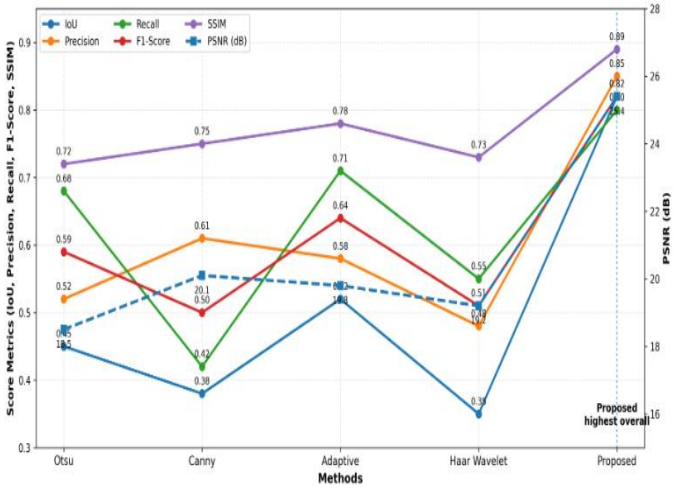

Fig. 4. Overall performance comparison of Otsu, Canny, Adaptive Thresholding, conventional Haar Wavelet, and the proposed Modified Haar Wavelet Framework, evaluated using IoU, Precision, Recall, F1-score, PSNR, and SSIM.

Fig. 4 presents a comprehensive comparison of the evaluated methods across six performance metrics, namely IoU, Precision, Recall, F1-score, PSNR, and SSIM. The graph clearly illustrates the performance trends of each method and highlights the effectiveness of the proposed Modified Haar Wavelet framework.

The proposed method consistently achieved the highest values across all evaluation metrics. In terms of localization accuracy, the proposed framework obtained the highest IoU value of 0.819, indicating superior overlap between the detected White Spot Disease markers and the corresponding ground-truth annotations. Similarly, the highest Precision value of 0.849 demonstrates the framework's ability to minimize false-positive detections while accurately identifying disease markers.

The Recall value of 0.799 indicates that the proposed framework successfully detected most disease markers present in the image. The combination of high Precision and Recall yielded the highest F1-score of 0.823, confirming balanced and reliable detection performance. In contrast, conventional methods such as Otsu, Canny, Adaptive Thresholding, and Haar Wavelet exhibited lower and less consistent performance across these metrics.

The graph also demonstrates the proposed framework's superiority in preserving image quality. The PSNR value reached 25.390 dB, significantly exceeding the values obtained by the conventional methods, which ranged from 18.5 dB to 20.1 dB. Likewise, the proposed framework achieved the highest SSIM value of 0.889, indicating better preservation of structural information and disease-related image characteristics.

Fig. 4 visually confirms the quantitative findings presented in Table I. The consistent dominance of the proposed framework across all evaluation metrics demonstrates that integrating adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding effectively improves

disease marker localization, edge representation, and structural preservation in White Spot Disease detection.

The experimental results further indicate that the proposed Modified Haar Wavelet framework consistently outperforms conventional edge detection methods across all evaluation metrics. The combination of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding significantly improves disease marker localization accuracy, structural preservation, and overall detection reliability for White Spot Disease images.

These findings suggest that the proposed framework effectively prioritizes disease marker localization while preserving important structural information. Although the method achieves superior detection performance, further investigation is required to evaluate computational efficiency, scalability, and real-time applicability in large-scale aquaculture monitoring systems.

V. Conclusion

This study proposed a Modified Haar Wavelet framework for White Spot Disease marker detection by integrating adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding. The proposed framework was designed to improve disease marker localization and edge representation while preserving important structural information in fish images.

Experimental results demonstrated that the proposed framework consistently outperformed Otsu, Canny, Adaptive Thresholding, and conventional Haar Wavelet methods across all evaluation metrics. The proposed method achieved the highest IoU (0.819), Precision (0.849), Recall (0.799), F1-score (0.823), PSNR (25.390 dB), and SSIM (0.889), indicating superior detection accuracy and structural preservation. Comparative analysis further confirmed that the proposed modifications significantly improved the performance of the conventional Haar Wavelet framework.

The ablation study verified the contribution of adaptive coefficient selection, Roberts operator-based edge enhancement, and hysteresis thresholding, demonstrating that the performance improvement resulted from the synergistic integration of all components rather than a single processing stage. These findings highlight the effectiveness of the proposed framework as a robust wavelet-based solution for automated detection of White Spot Disease markers.

Future work will focus on evaluating robustness under more diverse aquaculture conditions, analyzing computational efficiency, and integrating learning-based approaches to further improve detection performance and real-time applicability.

Abstract*—Alzheimer's disease (AD) refers to a progressive neurodegenerative disease involving cognitive impairment, brain atrophy, and functional neurological deficits that make early prediction and subsequent disease progression monitoring extremely difficult. Currently available AI methods predominantly focus on employing single modality analysis or static multimodal analysis approaches, which tend to solve AD prognosis as a binary classification problem. Also, much of the current literature on AD does not take into account the importance of progression-aware, patient-wise evaluation, and robust management of multimodality data heterogeneity or missingness. To tackle such issues, this study presents the proposal of an Adaptive Neuro-Digital Twin-based framework for predicting Alzheimer's disease, known as ANDT-AD. The proposed framework incorporates the heterogeneous multimodality information in clinical-cognitive data, structural Magnetic Resonance Imaging (MRI), and Electroencephalography (EEG) signals through modality-wise deep encoders. Specifically, a clinical encoder based on a transformer structure is utilized to capture non-linear cognitive interactions, while a Vision Transformer model and an attention-enhanced temporal EEG encoder model help to extract neuroanatomical information from MRI signals and electrophysiological signals in EEG, respectively. The framework is developed using Python and assessed using public domain clinical, MRIs, and OpenNeuro ds004504 EEG data sets for five-fold cross-validation and patient-level evaluations. Experimentation yielded 98.0% diagnostic accuracy with an AUC of 0.97, which exceeds the performance of current multimodal baselines. Moreover, the framework attained an MAE of 1.12, an RMSE of 1.46, and a progression risk C index of 0.89, proving its strength in predicting cognitive decline and personalizing disease progression models under heterogeneity and missingness of multimodal scenarios.

Keywords*—Alzheimer's disease; neuro-digital twin; multimodal learning; disease prognosis; cross-domain representation learning

I. Introduction

AD is an irreversible, progressive neurodegenerative disorder, which is associated with cognitive decline, memory loss, and functional decline, posing substantial clinical, social, and economic challenges worldwide [1], [2]. Due to its protracted preclinical stage, pathological changes, including synaptic impairment, structural atrophy of the brain, and electrophysiological disorders, tend to be present many years before the appearance of clinical symptoms [3], [4]. Nevertheless, the traditional methods of diagnosis are still predominantly reactive and based on cognitive tests and imaging biomarkers that identify disease when extensive neurodegenerative processes have already been experienced [5], [6]. Early prognosis of AD is also complicated by the heterogeneous and multifactorial nature of this disease because the progression of the disease in people differs significantly. As a result, there is an increasing demand for computational models that can combine heterogeneous neurobiological evidence to facilitate early disease stage detection, as well as model disease progression individually [7], [8]. The current innovations in artificial intelligence have shown potential in AD diagnosis, but most of the current models are unchanging, modality-driven, and incapable of incorporating the dynamic changes in neurodegeneration over time.

The current literature has investigated various AI-based methods of analyzing AD in various data modalities. Existing models [9], [10] have been frequently used on MRI scans to classify multiclass stages of AD with an existing high accuracy, with limited interpretability and generalization. Recent studies [11] have enhanced features like global extraction of features in neuroimaging, but still cannot support pipelines that are not based on imaging. The traditional ML models supported by clinical and cognitive datasets, like Support Vector Machines, Random Forests, and gradient-based ensembles, have been examined as they are unable to learn complex temporal dependencies [12], [13]. Existing EEG studies show sensitivity to functional brain variations, but these studies are not usually coupled to structural and clinical history [14], [15]. Although there have been multimodal fusion techniques based on feature concatenation and late fusion techniques, they generally assume patient-aligned data and do not adapt to heterogeneous data and cross-cohort data. In addition, current models consider AD prediction as a single classification problem, which does not consider the dynamic and progressive nature of neurodegeneration, thus limiting its prognostic value.

To address the limitations of existing studies predicting the occurrence of Alzheimer's disease, the proposed study is an attempt to introduce a Progression-Aware Neuro-Digital Twin modeling framework, which describes the neurological status of a patient as a dynamically changing latent state based on multimodal clinical, MRI, and EEG data. In contrast to traditional diagnostic systems based on the unchanging classification, the given solution is capable of recording longitudinal neurodegenerative dynamics and can diagnose a disease, predict cognitive decline, and estimate progress risk in one single learning system.

A. Research Motivation

The task of early detection of disease onset and development is still considered one of the major clinical challenges due to the progressive nature of neurodegeneration and the variability of the disease presentation among different patients. Machine learning-based techniques have been traditionally concerned with only disease stage identification without addressing the issue of patient-specific changes in the neurological states during the development of the disease. Moreover, heterogeneity of multimodal biomedical information, such as clinical, cognitive measurements, brain structural images, and biosignal recordings, restricts the effectiveness of traditional single-modality predictions. Thus, there is an increasing demand for designing a progression-aware computational paradigm capable of handling heterogeneous multimodal information and providing patient-specific disease evolution monitoring using the Neuro-Digital Twins approach.

B. Research Significance

The modeling of Alzheimer's disease, taking into consideration disease progression, can substantially benefit early diagnosis and continuous monitoring of the disease due to the modeling of temporal changes of neurological status instead of only being able to recognize different stages of the condition. Such a novel approach will enable personalized disease trajectory monitoring and risk-sensitive clinical decision making with the help of combining multimodal biomedical information and Neuro-Digital Twin modeling. Continuous synchronization of patient-specific clinical, imaging, and electrophysiological information will allow us to obtain a correct model of the neurodegenerative processes occurring in an individual. This approach could prove highly useful not only for early intervention but also for future intelligent prognosis systems.

C. Problem Statement

While remarkable advancements have been made recently in the field of artificial intelligence in diagnosing Alzheimer's disease [16], most of the currently developed algorithms still employ traditional single modality learning or static multimodal fusion methodologies that presuppose the completeness and synchronicity of the data. These algorithms cannot account for the nonlinear nature and subject-specificity of the brain degeneration process [17]. In clinical practice, different modalities are often missing, corrupted, or asynchronous, which makes it difficult to deploy existing solutions. The failure to accurately combine heterogeneous clinical, imaging, and electrophysiological data while maintaining robustness under missing-modality further limits practical implementation. This study addresses these shortcomings with a progression-conscious adaptive neuro-digital twin architecture for early prognosis of Alzheimer's disease.

D. Key Contributions

- An Adaptive Neuro-Digital Twin (ANDT-AD) paradigm is proposed for early prognosis of Alzheimer's disease based on continuous modeling of the individual neurodegeneration progression pattern.
- A multimodal representation learning method is proposed to merge various types of clinical data, structural MRI images, and EEG signals into a common disease-oriented latent space.
- Specialized modality-specific encoders such as Transformer-based clinical information learning, Vision Transformer-based MRI feature extraction, and enhanced attention-based EEG representation learning are developed.
- Latent State Evolution with progression awareness is formulated to model disease progression patterns and estimate progression risk.
- Experimental studies using publicly available clinical information, MRI, and EEG databases show that the proposed ANDT-AD achieves significantly better performance than other baseline methods.
- The rest of the study is organized as follows: Section II reviews related works on AI-based AD analysis and highlights existing research gaps; Section III explains the proposed adaptive neuro-digital twin methodology; Section IV presents experimental results; and Section V concludes the study with limitations and future research directions.

II. Related Work

Recent works have investigated the use of advanced machine learning and deep learning methods to enhance the diagnosis and

prognosis of Alzheimer's disease (AD). Gryshchuk et al. [18] examined the efficiency of self-supervised learning in the differentiation of neurodegenerative diseases based on T1-weighted MRI data, where no large-scale labeled data are available. Their contrastive learning-based feature extractor with a linear classification head obtained comparable accuracy in balance to the supervised models. Nonetheless, it was a method that depended on a single imaging mode and binary classification, which restricted its application in multimodal integration and fine disease staging.

Similarly, a multimodal representation learning framework proposed by Dai et al. [19] relies on cross-domain distillation to conduct AD classification. The approach involved the use of a pre-trained text encoder to instruct the learning of structural MRI and PET feature extractors, which included MMSE scores by adding positional embeddings. The model performed highly on the ADNI dataset, though it was only evaluated on one benchmark dataset, and it was not adequate in investigating the longitudinal development of the disease.

There are also multimodal fusion methods or techniques that have been studied to enhance the accuracy of diagnosis. Muksimova et al. [20] proposed FusionNet that combines MRI, PET, and CT data through modality-specific encoders and attention-based fusion layers. The framework had a classification accuracy of about 94% that showed the capability to detect AD at an early stage. However, the data augmentation method based on GAN provides an opportunity to overfit, and it is not externally multi-centered.

Cognitive and electrophysiological data have been studied by other researchers. Saleh et al. [16] developed a hybrid CNN–LSTM model using longitudinal established a hybrid CNN-LSTM model based on longitudinal cognitive scores using the method of Bayesian optimization and explainability, with the use of the SHAP and LIME. Although the model enhanced predictive ability, it omitted modalities of imaging, and in that it used a large amount of computational resources. Similarly, Vo et al. [21] suggested a time-frequency representation of an EEG-based deep learning model to screen non-invasive AD. Although the method obtained more than 80% accuracy, it was sensitive to EEG noise, and its generalization to a wide range of neurodegenerative conditions was low.

There has also arisen digital twin and generative modeling. Amato et al. [22] presented a digital twin-based diagnostic model with EEG-derived biomarkers, which showed encouraging prognostic capabilities, though it needs a large-scale validation. Meanwhile, Sharma et al. [23] suggested a generative model to simulate disease progression using both latent diffusion models and neural ODE, but the algorithm requires a lot of computational power.

Finally, Ali et al. [17] focused on the issue of multimodal learning development and suggested a self-supervised model that enhances cross-cohort generalization and uses missing modalities. The method, however, demands a lot of multimodal pretraining data, and the interpretation is limited. In general, existing literature has shown the promise of deep learning, multimodal fusion, and self-supervised learning in diagnosing and prognosing the disease in the case of Alzheimer's. There are, however, several shortcomings that can be seen in the existing approaches.

III. Proposed ANDT-AD Framework for Early Prognosis of Neurodegenerative Diseases

The suggested framework proposes a novel Progression-Aware Multimodal Neuro-Digital Twin framework that utilizes clinical-cognitive evaluations, structural MRI images, and electroencephalographic biosignals in predicting the personalized progression of Alzheimer's disease. In the first step, each modality is independently preprocessed and encoded, thereby producing structural, functional, and behavioral representations relevant to neurodegeneration. The resulting feature embeddings are subsequently aligned through cross-domain multimodal representation learning to form a robust feature space for handling heterogeneous and missing data. In contrast to the existing methods, where modality fusion or progression analysis is independently carried out, the suggested framework concurrently co-trains multimodal representation learning and progression modeling within one framework. The main innovation in this context involves Neuro-Digital Twin, which enables continuous updating of a personalized neurological twin based on multimodal longitudinal measurements, leading to personalized state transition modeling. The workflow of the proposed framework is illustrated in Fig 1.

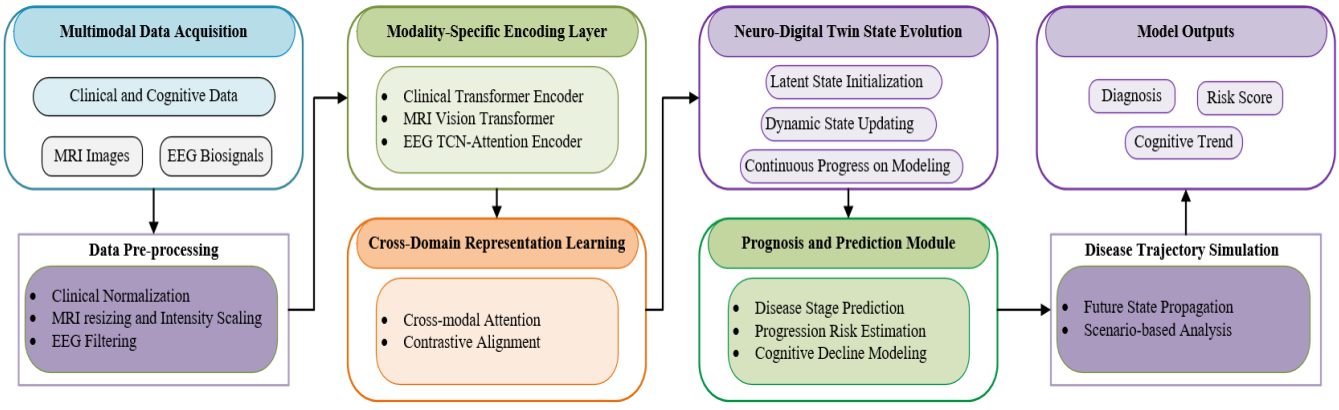

Fig. 1. Overall workflow of proposed ANDT-AD framework.

A. Data Collection and Dataset Description

This study uses three publicly available and supplementary datasets to build a multimodal representation of the AD, which includes clinical, structural, and functional neurological features. The Alzheimer's Disease Dataset [24] It is a clinical and cognitive tabular dataset that is used to offer demographic data, cognitive measuring scores, and clinically significant risk factors that relate to disease development and advancement. The data is an indication of the patterns of high-level cognitive decline and an approximation of regular clinical assessments. The Alzheimer Multiclass Images Dataset [25] that consists of labeled magnetic resonance imaging (MRI) scans of various stages of AD is used to model structural brain changes. With the help of these images, it is possible to extract spatial and morphological biomarkers that are associated with neurodegeneration. Moreover, functional neural dynamics are also measured with the help of the Open Neuro dataset called ds004504 [26] that contains electroencephalography (EEG) measurements that reflect brain activity in terms of time and frequency. The clinical data, MRI data, and EEG data are collected from public datasets and lack full subject correspondence. Consequently, the suggested framework fails to perform patient-wise multimodal fusion. Instead, modality-specific encoders learn separate disease representations that are aligned within a common latent space via cross-domain representation learning. The Neuro-Digital Twin corresponds to a personalized latent neurological state, which undergoes progression-aware state evolution for disease trajectory prediction.

The public Kaggle datasets that were used in this work consist of community-annotated datasets, and the original procedure for clinical annotations of the datasets comes from the dataset providers. The ground-truth annotations were retrieved from the given data set annotations and used as they were. As detailed clinical provenance and annotation protocols are not entirely available for these data sets, this drawback is taken into account when discussing the work. Preprocessing, labeling, quality control, and standard evaluation protocol were used to increase the accuracy of the labels before training the models.

B. Data Preprocessing and Feature Preparation

In order to guarantee consistency across heterogeneous biomedical sources, modality-specific preprocessing pipelines are used to preprocess data from various domains, such as clinical, imaging, and electrophysiological domains, before representation learning. The pre-processing process includes normalization and encoding clinical data, removing noise in the MRI scans, and filtering the EEG data in order to remove any artifacts.

1) Clinical and cognitive data preprocessing: All non-nominal characteristics, such as age, cognitive assessment scores, and indicators that use biomarkers, are standardized using a z-score, which is presented as Eq. (1).

$$x' = \frac{x-\mu}{\sigma} \tag{1}$$

where, μ and σ are the mean and standard deviation of features, respectively. This normalization provides similar scales of features to ensure that high-magnitude variables do not prevail in the process of model training.

2) MRI image preprocessing: The resizing of each scan is done to a constant spatial resolution of 224x224 pixels to ensure that the samples are uniform to one another and that the architecture of the convolutional encoders does not suffer. The min-max scaling is used to normalize the intensity of voxels, averaging to the [0,1] range, and minimize scanner effects on voxel intensity.

3) EEG signal preprocessing: EEG data acquired from the OpenNeuro dataset called "ds004504" are preprocessed to extract clean and useful electrophysiological signal representations. The raw EEG data is filtered using a fourth-order band-pass filter between 0.5 Hz and 45 Hz and a fifth-order notch filter at 50 Hz to eliminate noise, both low- and high-frequencies, as well as power line interference. The ICA technique is used to remove eye movement artifacts and other muscular artifacts in order to preserve brain-related activation patterns. The resulting filtered signals are divided into fixed-length 2-second epochs with 50 percent overlap in order to reflect short-term time changes. The Short-Time Fourier Transform (STFT) method is used to obtain spectral-temporal feature maps for deep learning tasks. Patient-wise stratified sampling is performed in order to avoid a potential data leakage issue where all instances from the same patient fall into only one split, with a ratio of 70 percent for training, 15 percent for validation, and 15 percent for testing.

4) Rationale for selection of encoders: The Transformer model is chosen for modeling clinical features because of its capability of capturing complicated interactions between heterogeneous clinical features by using the self-attention mechanism. ViT is selected for MRI feature extraction as it can learn the global spatial dependency among brain regions, which is crucial for detecting distributed neurodegeneration. TCN is chosen for EEG feature extraction because of its capability of capturing long-range temporal dependency with reduced computational overhead compared to recurrent neural networks. In comparison with the traditional CNN, LSTM, and machine learning models, the chosen encoders show better capability in modeling multimodal features with computational efficiency.

C. Modality-Specific Encoding Architecture

The ANDT-AD is developed as a multimodal latent state-space learning problem. Let the multimodal data be given as in Eq. (2).

$$\mathcal{D} = \{D_c, D_m, D_e\} \tag{2}$$

where, D_c, D_m, and D_e denote the clinical–cognitive dataset, structural MRI dataset, and EEG bio signal dataset, respectively. Both modalities give heterogeneous observations of complementary characteristics of neurological degeneration. The framework aims at learning a parameterized mapping as in Eq. (3).

$$f_\theta: \mathcal{X} \rightarrow \{y_{stage}, r_{risk}, c_{future}\} \tag{3}$$

where, $\mathcal{X}$ denotes multimodal neurological observations, y_{stage} represents disease stage classification, r_{risk} denotes progression risk estimation, and c_{future}corresponds to predicted future cognitive decline. Disease progression is modelled using a persistent latent neuro-digital twin state $s_t \in \mathbb{R}^d$, where s_t represents the hidden neurological condition of a subject at the update step t, and d denotes the latent dimensionality. The proposed Adaptive Neuro-Digital Twin Framework is given in Fig. 2.

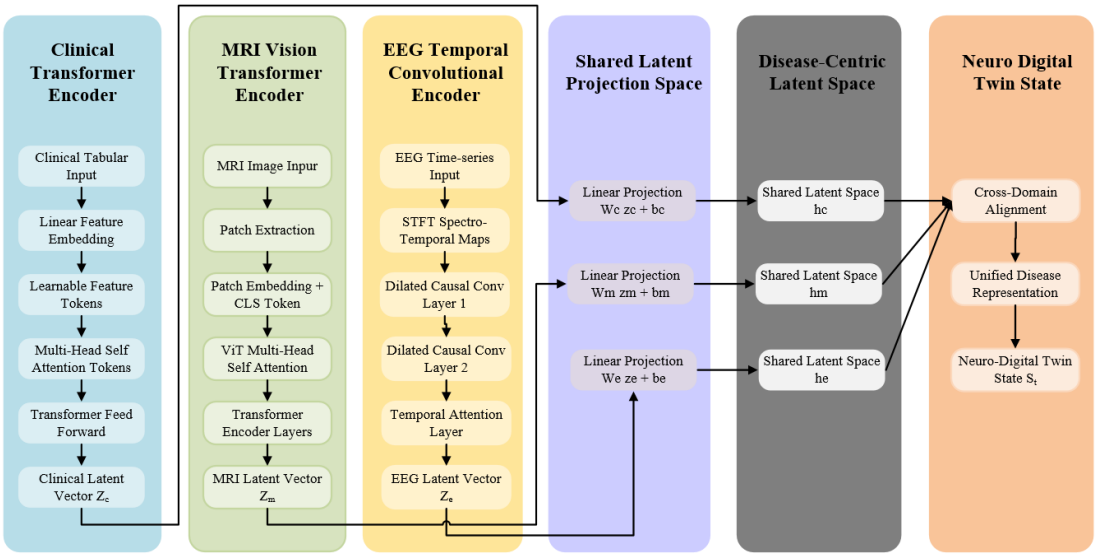

Fig. 2. ANDT-AD framework.

1) Transformer-based encoding of clinical and cognitive data: The clinical and cognitive tabular representations of the patients' data contain vital manifestations of the disease, such as demographic risk factors, neuropsychological evaluation scores, and cognitive impairments. Under the current model architecture, these tabular representations undergo processing using a tabular transformer network encoder that effectively learns the interaction between features in a non-linear manner, an aspect that cannot be achieved by traditional fully connected networks. To begin with, the patient records are encoded as a fixed feature vector representation and projected onto the latent embedding space using a linear transformation. Unlike temporal position encodings, feature embeddings that help retain the identity and meaning of the feature are used. Self-attention techniques are then applied to the embeddings to model context dependencies in clinical attributes and learn their interaction. This can be represented mathematically as shown below:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^{\top}}{\sqrt{d}}\right)V \quad (4)$$

In Eq. (4), Q, K, and V denote query and key matrices, as well as value matrices, of clinical feature embeddings, and d is an embedding dimension. The encoder produces a very small latent representation of clinically significant patterns related to the progression of Alzheimer's through stacked transformer layers. The performance of this encoder will be an abstracted clinical disease profile, focusing on the severity of risks and cognitive impairment instead of crude clinical values.

Let the multimodal patient input be represented as $X = \{X_c, X_m, X_e\}$, where X_c, X_m, and $X_e$denote clinical records, MRI images, and EEG signals, respectively, providing complementary information for Alzheimer's disease prognosis. The modality-specific embeddings are extracted as $H_c = f_c(X_c)$, $H_m = f_m(X_m)$, and $H_e = f_e(X_e)$, where $f_c(\cdot)$, $f_m(\cdot)$, and $f_e(\cdot)$represent Transformer-based clinical encoding, Vision Transformer-based MRI feature learning, and attention-enhanced temporal EEG modelling. These learned features are fused into a unified latent representation as $Z = \alpha H_c + \beta H_m + \gamma H_e$, where α, β, and γ are adaptive modality weights satisfying $\alpha + \beta + \gamma = 1$. This weighting mechanism enables the framework to prioritize the most informative modality according to patient condition and data quality. The continuously evolving neuro-digital twin state is updated as $S_t = \phi(S_{t-1}, Z_t)$, where $S_t$and S_{t-1}denote the current and previous disease states, $Z_t$is the fused representation at time t, and $\phi(\cdot)$is the nonlinear transition function. Finally, the total optimization objective is defined as $L = L_{cls} + \lambda_1 L_{prog} + \lambda_2 L_{align}$, where L_{cls} denotes diagnostic classification loss, L_{prog} represents disease progression prediction loss, L_{align} ensures cross-modal embedding consistency, and λ_1, λ_2 are balancing coefficients controlling each objective during training.

2) ViT encoding of structural MRI data: MRI images offer anatomical details that can be associated with the progression of Alzheimer's disease, such as cortical atrophy, hippocampus atrophy, and enlarged ventricles. Under this framework, MRI images are subjected to a Vision Transformer (ViT) network architecture in order to learn the global neuroanatomical representation. The individual preprocessed MRI image is subdivided into patches without overlapping, which are flattened and mapped into a high-dimensional space by a

learned linear projection. A classification token is included in the patch sequence to learn the global structure of the disease.

Unlike conventional convolutional networks that primarily capture local spatial hierarchies, the Vision Transformer (ViT) models long-range spatial dependencies through patch-wise self-attention mechanisms. This capability is particularly important in Alzheimer's disease analysis, where distributed brain regions collectively contribute to cognitive impairment. The generated patch embeddings are passed through multiple transformer encoder layers, enabling the model to learn relationships between anatomically distant brain structures. The final representation of the learnable classification token serves as a global feature embedding that summarizes disease-relevant neuroanatomical patterns across the entire brain. The output embedding can be in formally written form as Eq. (5).

$$z_{\text{MRI}} = f_{\text{ViT}}(I) \tag{5}$$

where, I denote the input MRI scan and $f_{\text{ViT}}(\cdot)$ represents the ViT mapping. This latent representation describes neurodegenerative trends at the macro-level and can be considered the structural aspect of the digital twin state.

3) Temporal convolutional encoding of EEG biosignals: To capture the temporal complexity of EEG data, the current study uses a TCN with an attention mechanism. The EEG preprocessed signals (as spectro-temporal feature matrices) are input into a series of expanded causal convolutional layers. The dilated convolution operation is defined as Eq. (6).

$$y(t) = \sum_{k=0}^{K-1} w(k)\, x(t - d \cdot k) \tag{6}$$

where, $x(t)$ being the input signal, $w(k)$ being the convolutional kernel, dis being the dilation factor, and K being the size of the kernel. The TCN is capable of capturing the short-term oscillatory and long-term temporal interdependences with cognitive deterioration by successively enhancing the rate of dilation through the layers. A subsequent attention layer is utilized to put weight on temporally informative portions of the EEG signal to enable the encoder to focus on disease-related neural evolving motions and reduce remaining noise. The resulting EEG latent representation imprints functional electrophysiological features signifying the Alzheimer's pathology.

4) Projection into a shared latent representation space: After modality-specific encoding, the clinical transformer encoder, MRI ViT, and EEG TCN outputs are all functionally transformed into a common latent dimensional space via linear transformation layers. This projection provides a dimensional consistency across modalities and cross-domain alignment. Where "," and "are" used to represent latent embeddings of clinical, MRI, and EEG encoders, respectively. Every embedding is converted to be as Eq. (7).$z_c z_m z_e$

$$h_i = W_i z_i + b_i, i \in \{c, m, e\} \tag{7}$$

where, z_i is the modality-specific latent embedding, W_i is the learnable projection matrix, b_i is the bias vector, and h_i is the projected shared latent representation. The projection parameters W_i and b_i are jointly optimized with encoder parameters through end-to-end backpropagation during training. With this joint optimization, the modality-specific embeddings are converted to a common disease-centric latent representation space while preserving discriminative information.

This latent space can be considered as the state representation of the Neuro-Digital Twin, and it allows incorporating different neurological information into a single format for modeling disease progression. This method is particularly suitable for learning modality-robust representations, as it requires that each encoder learns useful information from its input even when some modalities are not available. In other words, this approach provides resilience to missing-modality cases, cross-cohort differences, and heterogeneous clinical data distributions, making it more generalized and robust in practice.

D. Cross-Domain Representation Learning

Following modality-specific encoding, the proposed model uses a cross-modality representation learning technique that transforms heterogeneous representations into a single disease-aware latent space. The main task of this step is to combine the information derived from both clinical and neuroimaging features without depending on any modality in a way that ensures cross-cohort robustness. Unlike conventional methods that consider the explicit correspondence between individuals, the proposed model does alignment at the representation level, such that embeddings from various modalities can be aligned in a shared latent space by leveraging their similarity in terms of Alzheimer's disease.

The modality weights (α, β, γ) are automatically learned by the system in the process of training, via a learnable fusion layer which uses an attention mechanism. These modality weights are computed by using trainable parameters, and then normalization is done using the softmax function in such a way that the weights satisfy the condition $\alpha + \beta + \gamma = 1$. Backpropagation helps in updating the parameters of the fusion layer using the gradients coming from the optimization loss in the total process. The contribution of each representation can be changed based on its importance for prediction tasks.

Latent embeddings produced by the clinical transformer encoder, MRI ViT, and EEG TCN are initially processed as updated independent semantic tokens of various neurological viewpoints. The model is then used to make cross-modal attention between these embeddings and, based on the relevance of the modality to a disease, actively reweight the contribution of these modalities. The cross-modal attention of a given modality embedding h_i is calculated in terms of other modality embeddings as Eq. (8).

$$\tilde{h}_i = \sum_{j \neq i} \alpha_{ij}\, h_j \tag{8}$$

The attention coefficients are calculated α_{ij} by means of scaled dot-product attention. They reflect how similar in terms of a disease the different modes are. Cross-modal representation learning seeks to build modality-invariant representations that will encode the pathology shared between the manifestations of the same condition. For that purpose, alignment is done via cross-modal attention and contrastive learning.

In order to achieve domain invariance and lessen modality-specific bias, contrastive learning is introduced as an auxiliary alignment goal. The pairs of positive and negative pairs are formed by connecting embeddings corresponding to similar stages of the disease across different modalities and different stages, respectively. The contrastive loss is considered to be Eq. (9).

$$\mathcal{L}_{\text{con}} = -\log \frac{\exp(\text{sim}(h_i,h_j)/\tau)}{\sum_k \exp(\text{sim}(h_i,h_k)/\tau)} \quad (9)$$

where, $\text{sim}(\cdot)$ denotes cosine similarity between embeddings, h_i and h_j represent embeddings from different modalities, h_k denotes negative samples, τ is the temperature parameter controlling similarity scaling, and L_{con} represents contrastive alignment loss. This loss promotes embeddings similar to the same states of AD to cluster near one another regardless of their originating modality or dataset, and separate dissimilar states.

To deal with incomplete data in the real world, a modality dropout technique was applied during training, in which some or all modalities would be masked at random. It ensured that the model was able to learn solid cross-modal relationships and still achieve good predictions despite the absence of MRI, EEG, or clinical information.

1) Progression-aware neuro-digital twin modeling: The proposed framework also makes use of a Progression-Aware Neuro-Digital Twin modeling scheme, which allows us to track the dynamics of the progression process of Alzheimer's disease. As part of this methodology, the neurological condition of the patients will be modeled via latent twin states based on the aligned embeddings of the multimodal data (clinical, MRI, and EEG). This differs from traditional approaches to classification, wherein the different states associated with disease progression were treated categorically; however, the Progression-Aware Neuro-Digital Twin model will evolve, making it capable of tracking gradual changes to the neurological conditions of the patients. It was expressed in Eq. (10).

$$z_{t+1} = z_t + f(z_t, \Delta t; \theta) \quad (10)$$

where, z_t is the current twin latent state, $z_{t+1}$is a future twin state, $f(\cdot)$ is a progression dynamics function, Δt is a time interval and θ is the model parameter.

E. Neuro-Digital Twin State Evolution

The suggested Neuro-Digital Twin can be considered as a dynamic latent representation of the neurological condition of a patient rather than a static model for disease classification. The initial state of the digital twin is defined using multimodal feature representations, is evolved using temporal state transition, and is validated through diagnosis and prognosis. Adaptation to the individual patient is done using continuous updates of the latent state to reflect the progression of disease over time.

The proposed Progression-Aware Neuro-Digital Twin models Alzheimer's disease progression as a continuous latent trajectory rather than a fixed sequence of disease stages. This enables the framework to capture gradual neurological changes and individual progression patterns. The evolving latent state integrates multimodal representations and provides a dynamic basis for progression risk estimation.

1) Latent state initialization: The latent embedding of the clinical and cognitive data is used to initialize the neuro-digital twin state since these aspects are the most consistent and early predictors of the risk of AD. Let represent the projected clinical-cognitive embedding that results from the modality-specific encoder. The state of the digital twin is initialized with the help of this embedding.$h_c \in \mathbb{R}^d$

$$s_0 = \phi(h_c) \quad (11)$$

In Eq. (11), $\phi(\cdot)$ is a linear transformation, which takes the clinical embedding into the twin state space. This setup is necessary to ensure that the digital twin is initialized with a cognitively based model of disease status, i.e., baseline risk factors and early cognitive impairment, before severe structural or functional loss.

2) Dynamic state updating with multimodal fusion: With further multimodal measurements being accessible, such as structural MRI and EEG-based embeddings, the state of a neuro-digital twin gets revised in a recurring process of state changes. The resulting cross-domain representation learning obtained as the aligned and fused multimodal representation at update is added to the current twin state. The update of the state is determined by Eq. (12).$z_t ts_{t-1}$

$$s_t = \sigma(W_s s_{t-1} + W_z z_t + b) \quad (12)$$

where, W_s and W_z can be learnt, b is a bias value, and $\sigma(\cdot)$ is a nonlinear activation function. This formulation allows the twin state to incorporate novel evidence together with historical context on diseases. The update state is designed so that the changing temporary modality-specific observations are not replaced by the cumulative disease representation and thus encourages temporal stability and awareness of progression.

3) Continuous disease progression modeling: The dynamics of the neuro-digital twin state are developed to reproduce the process of a continuous disease progression. Instead of discrete stage classification, the overt state transitions carry the gradual degradation of the nervous system in the case of AD. In order to implement a smooth temporal evolution, a progression regularization term is added, and it is defined as Eq. (13).

$$\mathcal{L}_{\text{prog}} = \| s_t - s_{t-1} \|_2^2 \quad (13)$$

This limitation promotes an incremental state dynamic that is realistic of neurodegenerative dynamics. The latent state is going to follow a trajectory in the disease-centric embedding space, with the movement and the rate of change.

The diagnosis and prognosis prediction module converts the changing state of Neuro-Digital Twin to meaningful clinical prediction by using the joint prediction framework of diagnostic and prognostic problems. The prediction task is carried out based on the latent representation of Neuro-Digital Twin, which means all the predictions will be made with the consideration of

neurological information that reflects progression and development of diseases, rather than the features from individual modalities. By constantly updating the state of the Neuro-Digital Twin with multimodal information, it can achieve early detection and risk prediction.

4) Early disease stage and progression risk prediction: The neuro-digital twin state is applied to evaluate the current level of the AD at every update step and the risk of disease progression. The head of classification compares the latent state to discrete disease stages, such as cognitively normal, mild cognitive impairment, and AD. This mapping is defined as Eq. (14).$s_t t$

$$\hat{y}_t = \text{softmax}(W_y s_t + b_y) \quad (14)$$

where, W_y and b_y are parameters of learning. Simultaneously, a head of risk estimation can determine a continuous progression risk score, which is an indicator of the possibility of disease progression within a future horizon. The risk score is obtained as Eq. (15).

$$\hat{r}_t = \sigma(W_r s_t + b_r) \quad (15)$$

where, $\sigma(\cdot)$ is the sigmoid activation function. Collectively, these products offer a probabilistic estimate of the existing disease condition and the susceptibility to progression.

5) Cognitive decline trend estimation: To model longitudinal cognitive decline, the framework uses a regression head that predicts future trends in the cognitive scores, given the latent twin state. The equation of the anticipated cognitive path can be written as Eq. (16).

$$\hat{c}_{t+\Delta} = W_c s_t + b_c \quad (16)$$

where, Δ represents the time ahead of prediction. This formulation enables the model to predict the patterns of gradual cognitive decline as opposed to point-wise scores, which provide an insight into the rate of deterioration that may be expected. The regression result is the direct representation of the impact of structural and functional non-brain alterations coded in the twin state. Categorical cross-entropy loss is used to optimize the classification head, binary cross-entropy loss is used to predict progression risk, and MSE loss is used to predict cognitive decline to represent continuous regression behavior.

F. Multi-Task Optimization and Simulation-Based Analysis

The process of diagnosis, risk prediction, and cognitive trend prediction is optimized together via the multi-task learning approach. When simulating the disease trajectory based on its progression analysis, the Neuro-Digital Twin's state is forwardly propagated via the state evolution function. As a result, it becomes possible for the proposed approach to model the dynamics of Alzheimer's disease progression regardless of the presence of observations due to the updating of the latent neurological state. The total loss function is given as Eq. (17).

$$L_{total} = \lambda_1 L_{cls} + \lambda_2 L_{risk} + \lambda_3 L_{reg} + \lambda_4 L_{con} + \lambda_5 L_{prog} \quad (17)$$

where, L_{cls} is the disease stage classification loss, L_{risk} is the progression risk estimation loss, L_{reg} is the cognitive decline regression loss, L_{con} is the contrastive alignment loss, L_{prog} is the progression regularization loss, and λ_i is the task balancing coefficients. In order to improve interpretability in a clinical context, the explainable AI methods have been incorporated into the suggested architecture. The SHAP method has been used to measure the significance of clinical features, including the patient's age, MMSE value, and cognitive measures. The Grad-CAM technique has been used to detect the key brain regions from MRI scans. Moreover, temporal attention maps from EEG signals helped detect significant neurological patterns that influenced the prediction of prognosis.

Algorithm 1: Adaptive Neuro-Digital Twin Framework for Alzheimer's Disease Prognosis

Input:
Multimodal data $D = \{X_c, X_m, X_e\}$
Output:
Disease stage prediction Y_s, progression risk Y_r, cognitive decline estimate Y_c
Step 1: Input multimodal datasets (Xc, Xm, Xe)
Step 2: Preprocess each modality (normalization, filtering, feature preparation)
Step 3: Encode modalities:
Zc ← Clinical Encoder(Xc)
Zm ← MRI Encoder(Xm)
Ze ← EEG Encoder(Xe)
Step 4: Learn shared representation:
Z ← Cross-Domain Fusion(Zc, Zm, Ze)
Progression-Aware Neuro-Digital Twin Learning
Step 5: Update neuro-digital twin state:
St ← Temporal Update(St−1, Z)
Step 6: Predict outcomes:
Ys ← Disease Stage Classifier(St)
Yr ← Progression Risk Predictor(St)
Yc ← Cognitive Decline Regressor(St)
Step 7: Compute joint loss and update model parameters
Step 8: Output (Ys, Yr, Yc)

The entire training and inference process of the proposed ANDT-AD framework is outlined in Algorithm 1. The algorithm comprises encoding the heterogeneous neurological modalities with modality-specific encoders, projection into a common latent space, and cross-domain representation alignment. The aligned embeddings are used to learn a transition function, which is applied to the neuro-digital twin state with an iterative strategy. During inferences, the trained transition dynamics allow forward simulation of disease dynamics to perform prognosis.

ANDT-AD model proposes a novel framework of multimodal progression modeling using clinical, MRI, and EEG data under the Neuro-Digital Twin paradigm for continuous Alzheimer's disease prognosis. In contrast to the existing research works that mainly focus on static classification and multimodal fusion techniques, the proposed framework makes use of cross-modal representation learning to learn modality-invariant latent representations and integrate heterogeneous biomedical data into a common disease-aware feature space. Moreover, the proposed framework uses dynamic Neuro-Digital Twin state evolution for the continuous modeling of disease progression rather than the prediction of individual disease stages. The usage of a clinical Transformer encoder for clinical

features, a vision transformer model for MRI analysis, and an attention model for EEG signals within a unified multitask learning framework further distinguishes the proposed framework from existing multimodal and generative Alzheimer's disease prediction frameworks.

The ANDT-AD framework has several methodological strengths compared to current artificial intelligence techniques employed for predicting the presence of Alzheimer's disease. Unlike other multimodal methods that are based on static fusion or alignment of multimodal data features, the proposed framework uses an adaptive Neuro-Digital Twin representation that learns from multimodal data evidence, including clinical, MRI, and EEG features. The cross-modal representation learning mechanism ensures robust and efficient knowledge transfer between different modalities and is able to address the problem of missing modalities present in the majority of the earlier works. Additionally, the model can perform joint regression and classification learning to estimate disease stage, predict risk of progression, and forecast cognitive decline trajectory. The application of temporal state update makes the proposed approach a progression-aware predictive tool able to account for disease dynamics in each patient. Thus, the introduced framework is an example of a new scalable Neuro-Digital Twin approach that could be applied for personalized disease trajectory analysis.

IV. Result and Discussion

This was carried out through cross-cohort multi-modal analysis involving clinical-cognitive measurements, structural brain imaging, and electroencephalography biosignals. The model developed was intended to be efficient enough to run in real-time clinical settings, taking less than one second on average to predict patient outcomes with the help of GPU optimization. The compact structure of this framework allows it to easily integrate into hospital edge computing devices as well as cloud-based healthcare services.

A. Experimental Setup

Experimental settings are presented here, which are employed to rigorously evaluate the proposed framework. Cross-cohort multimodal data, consisting of clinical-cognitive measurements, structural brain imaging through MRI, and EEG biosignals, were used for evaluation purposes. The proposed architecture is developed in Python, while batch normalization, dropout, and early stopping methods were considered in order to mitigate overfitting. In addition, a five-fold cross-validation approach was used for performance evaluation. Both complete and incomplete cases are considered, and the framework is evaluated based on diagnostic, prognostic, and regression criteria compared against state-of-the-art unimodal and multimodal baselines. The simulation and hardware parameters were given in Table I.

1) Missing modality handling and data splitting strategy: To evaluate the robustness of the proposed framework under incomplete data conditions, different missing-modality scenarios were considered, including clinical-only, MRI-only, EEG-only, and partial multimodal combinations. The model performance was evaluated by removing individual modalities while maintaining the shared latent representation learning capability. For data partitioning, patient-wise splitting was applied to ensure that samples from the same subject were not distributed across training, validation, and testing sets. This strategy prevents data leakage and provides a reliable assessment of the model's generalization capability.

TABLE I. Simulation and Hardware Setup

Parameter	Configuration
Programming framework	Python with PyTorch
DL libraries	PyTorch Lightning, NumPy
Optimizer	Adam
Learning rate	1×10^{-4}
Batch size	16
GPU	NVIDIA RTX 3080 (10 GB)
CPU	Intel Core i9
RAM	32 GB
Training and inference	GPU-accelerated

TABLE II. Model Architecture and Implementation Parameters

Parameter	Configuration
Latent Embedding Dimension	256
Clinical Encoder	Transformer-based encoder (4 layers, 8 attention heads)
MRI Encoder	Vision Transformer (ViT) with 16 × 16 patch size
EEG Encoder	Temporal Convolutional Network (TCN) with dilation rates (1, 2, 4, 8)
Multimodal Fusion Method	Cross-modal attention-based fusion
Dropout Rate	0.2
Optimization Settings	Adam optimizer with learning rate 1×10^{-4}

The implementation parameters for the suggested framework are listed in Table II. Latent embedding dimension refers to the common feature space utilized by multimodal representation learning. Transformers, Vision Transformers (ViT), and Temporal Convolutional Network (TCN) are employed as feature extractors of clinical, MRI, and EEG modality, respectively. The cross-modal attention network incorporates the representations obtained through transformers, ViT, and TCN. Finally, dropout is applied to mitigate overfitting, and Adam with a learning rate of 1×10^{-4} facilitates efficient training.

B. Multimodal Encoding Performance Analysis

The efficiency of the domain-specific encoders utilized by the proposed framework is assessed before proceeding with cross-domain alignment. The analysis evaluates the ability of each encoder in capturing disease-related information within its corresponding data stream and discriminating between different Alzheimer's disease stages within the learned latent spaces. The chosen encoder network architectures are additionally supported by a comparative performance assessment and visualization of the learned latent space, ensuring solid ground for future multimodal integration and Neuro-Digital Twin development. The findings correspond well with clinical knowledge,

suggesting overlapping characteristics of early Alzheimer's disease within cognitive and neurological domains.

C. Cross-Domain Representation Alignment Results

In this sub-section, an assessment of the efficacy of the designed cross-modal representation learning paradigm for aligning heterogeneous modality-specific embeddings within a unified latent space that represents diseases is presented. It is analyzed in terms of how invariant across domains the aligned latent representations turn out to be, the stability of their acquisition during the contrastive optimization process, and, consequently, their improved discriminative power with respect to the considered diseases. In the case of Alzheimer's disease, it is confirmed that the latent representations are indeed effective.

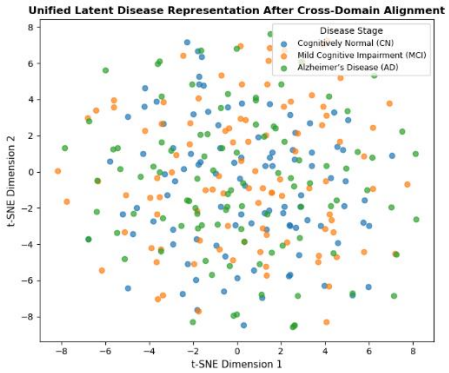

Fig. 3. t-SNE visualization of unified latent space cross-domain alignment.

Fig. 3 shows the t-SNE projection of the unified latent representations obtained following the implementation of the suggested cross-domain alignment mechanism on a two-dimensional projection. The aligned latent space has significantly more pronounced separation between cognitively normal, mild cognitive impairment, and AD categories, and less overlap between the disease stages. This increased clustering is a sign that modality-specific biases were effectively reduced and that the learned representation represents disease-centric features not affected by the data source. This alignment results in a consistent latent disease space that forms a predictable basis of downstream digital twin state evolution and prognostic model, and it will be able to have consistent interpretation across different modalities.

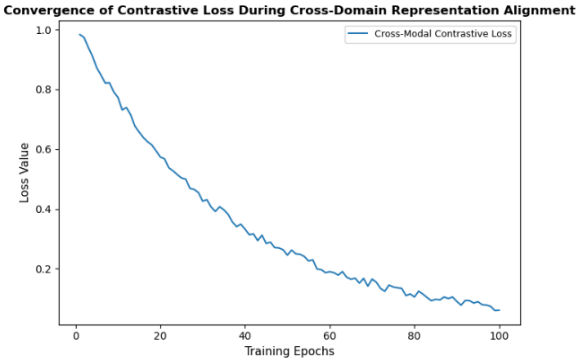

Fig. 4. Contrastive loss convergence and alignment stability.

Fig. 4 shows the convergence pattern of the cross-modal contrastive loss when training the representation alignment module. The decay rate through the epochs is smooth and stable, and this indicates that the optimization and the reduction of inter-modality discrepancies in the latent space are effective. The lack of oscillatory or divergent trends means that the training process is stable and well-built.

D. Progression-Aware Neuro-Digital Twin State Evolution Analysis

The suggested approach proposes a Progression-Aware Neuro-Digital Twin modeling technique where the state of the neurological system is modeled as a constantly evolving latent state. While traditional classification models estimate a discrete state of the disease, the Neuro-Digital Twin model applies temporal state modeling where the neurological state evolves. With this approach, the progression of the disease can be considered for modeling Alzheimer's disease dynamics and generating personalized disease trajectories.

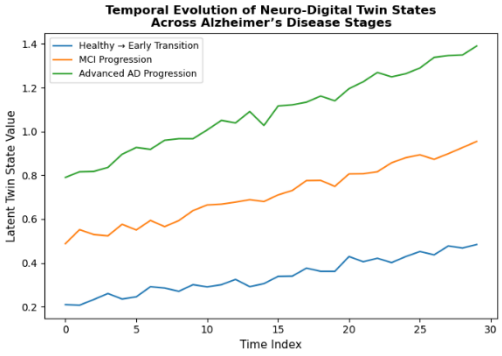

Fig. 5. Temporal evolution of neuro-digital twin states.

Fig. 5 visualizes the dynamic change of the latent states of the Neuro-Digital Twin throughout time in the presence of various states of the AD development. The continuous and slowly rising curves are indicative of the fact that the model is capable of representing smooth neurodegenerative changes as opposed to stage transitions. The unique developmental patterns in healthy, mild cognitive impairment, and Alzheimer's states are evidence that the digital twin stores the severity of diseases in a time-consistent way.

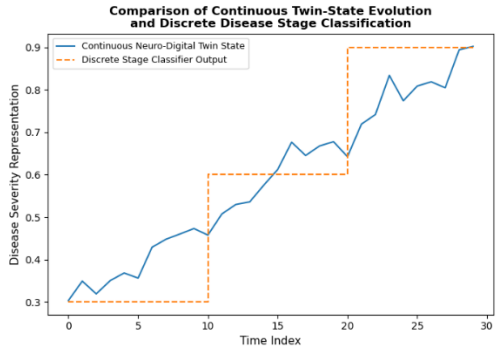

Fig. 6. Continuous twin-state transition vs discrete classification.

Fig. 6 contrasts the Neuro-Digital Twin state development suggested with the results of a traditional discrete-stage classifier. The continuous twin curve has smooth transitions, which are consistent with the smooth process of AD progression, and the discrete classifier creates a sudden step

transition. Such a breakdown is an indication of the weakness of the statistical classification methods in the model of longitudinal disease.

E. Prognosis and Cognitive Decline Prediction Performance

This sub-section provides an analysis of the diagnostic performance of the Neuro-Digital Twin architecture that extends the concept of prognosis beyond the scope of conventional diagnostic classification. The analysis will center on the prediction of trends in cognitive decline longitudinally within the framework of multi-task learning for optimization of diagnostic and prognostic functions. Accuracy and AUC will be used as metrics for diagnostic assessment, whereas prognostic evaluation will consider the prediction of disease trajectory.

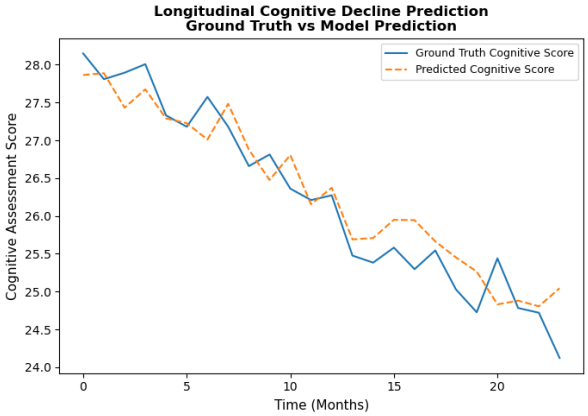

Fig. 7. Longitudinal cognitive score prediction vs ground truth.

Comparison of the ground truth cognitive test scores with the longitudinal prediction scores made by the suggested Neuro-Digital Twin approach can be seen in Fig. 7. Good correlation between the predicted scores and actual cognitive changes indicates the ability of the model to detect gradual change in cognition and not merely detect disease states at different time points. It is evident from the results that there is a good ability of the proposed approach for predicting Alzheimer's disease in the early stages of the disease.

TABLE III. QUANTITATIVE PERFORMANCE OF DIAGNOSTIC AND PROGNOSTIC TASKS

Task	Metric	Proposed ANDT Framework	Best Baseline
Disease stage diagnosis	Accuracy (%)	98.0	92.1
Disease stage diagnosis	AUC	0.97	0.93
Cognitive score prediction	MAE	1.12	1.85
Cognitive score prediction	RMSE	1.46	2.10
Progression risk estimation	C-index	0.89	0.81

The framework performance is quantitatively summarized in Table III by applying it to the diagnostic classification, cognitive decline prediction, and the progression risk estimation tasks. Its persistently high accuracy and AUC values show that it is reliable in disease stage discrimination, whereas lower MAE and RMSE show that it is more accurate in predicting cognitive scores.

F. Disease Trajectory Simulation and Risk Forecasting

This section assesses the capacity of the proposed Neuro-Digital Twin system to predict the future development of Alzheimer's disease. In particular, the proposed framework provides personalized predictions of Alzheimer's disease progression by simulating future developments using the learnt twin latent states through the time-based state evolution process. The model utilizes these future developments to predict future progression of the disease, as well as provide future neurodegeneration predictions.

G. Ablation Study

In this section, the contribution of each major architectural component in the proposed framework is strictly evaluated using a controlled ablation analysis. The study quantifies the effect of each of the four important modules, cross-domain alignment, Neuro-Digital Twin evolution, EEG modality, and contrastive learning, by systematic removal of each one of them in diagnostic performance.

The process of ablation analysis has been additionally applied for the evaluation of the contribution of each of the main components of the framework that was introduced in this study. Alongside the assessment of diagnostic accuracy, the contribution of each module regarding the risk prediction of disease progression is also assessed through the evaluation of changes in the representation of Neuro-Digital Twin states and the ability to estimate the progression of the disease. The absence of cross-domain alignment is used for the evaluation of the importance of multimodal feature synchronization, while the exclusion of Neuro-Digital Twin evolution is evaluated as the impact of temporal disease progression modeling.

TABLE IV. ABLATION STUDY OF KEY ARCHITECTURAL COMPONENTS

Configuration	Accuracy (%)	AUC
Proposed (Full Model)	98.0	0.992
Without Cross-Domain Alignment	93.4	0.951
Without Twin Evolution	92.6	0.944
Without EEG Modality	90.8	0.928
Without Contrastive Learning	91.9	0.936

As described in Table IV, the quantitative assessment analysis on the effects of ablation indicates the accuracy and AUC achieved from various architectural configurations for the proposed approach. Without the use of the cross-domain alignment, there was a 4.6% drop in accuracy, and without using the Neuro-Digital Twin evolution, there was a 5.4% drop in accuracy. This shows the significance of using the temporal aspect of disease progression in addition to multimodal fusion. The lack of contrastive learning in the architecture leads to a drop in cross-modal consistency, hence poor discriminability. Further, omission of the twin-state evolution mechanism leads to less prognosis sensitivity because there is no modeling of disease progression. Removal of the EEG-related aspects of the framework limits multimodal complementarity.

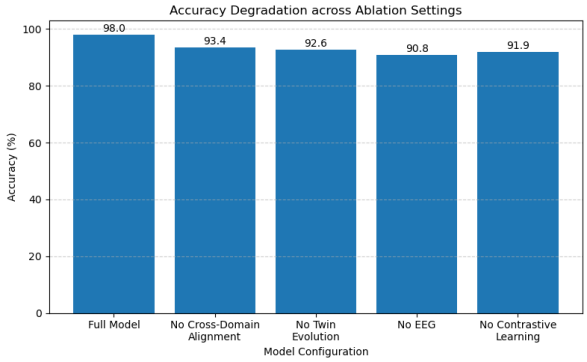

Fig. 8. Accuracy degradation across ablation settings.

Fig. 8 shows how the deletion of the main architectural elements affects the accuracy of the diagnoses, which measures the contribution of each of them to the suggested framework. Maximum decrease is found when the alignment of cross-domain representations is omitted, which emphasizes its importance in the learning of modality-invariant disease patterns. This also reduces accuracy with the exclusion of the Neuro-Digital Twin evolution module, which means that modeling continuous disease dynamics can be used as a complement to the model instead of a substitute for the model.

H. Robustness Under Missing-Modality Conditions

This subsection studies the validity and robustness of the proposed approach when faced with realistic missing modality settings, which can happen in practice owing to various reasons such as financial constraints, availability issues, or non-compliance on the part of the patients. The effect of missing modality on the accuracy of the diagnosis will be tested, and in turn, prove the validity of the approach based on the modality robust representation learning and domain adaptation used in the proposed framework. It can be seen from the results of experiments that the proposed model shows consistent prediction despite varying and incomplete datasets.

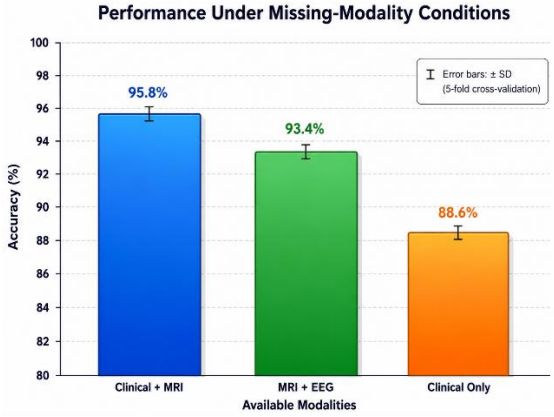

Fig. 9. Model performance under missing-modality scenarios.

Fig. 9 presents an evaluation of the proposed ANDT-AD system for various missing-modality cases. The figure demonstrates how accuracy would be affected by various possible combinations of multi-modal input. For the case when both Clinical and MRI inputs are considered, the highest value of 95.8% is obtained, proving that these two modalities share strong complementation in the sense of cognitive versus structural neuroimaging data. Even for the situation where only MRI and EEG data can be accessed, the system still attains a relatively high value of 93.4%, which proves the efficacy of the cross-modal representation learning and modality-robust fusion approach. The case for only Clinical inputs produces an accuracy rate of 88.6%, reflecting some loss in performance, yet retaining reasonable ability for prediction. The slight loss in performance reflects well on the robustness of the proposed Neuro-Digital Twin system against missing modality. It is worth noting that the system also performs consistently, as reflected by the low standard deviations shown by error bars.

I. Comparative Analysis

A comparative study of the ANDT architecture against existing multimodal Alzheimer's disease prediction models is shown in this subsection. The comparison reveals the results obtained through the use of different types of data as well as their integration. It illustrates the efficiency of each approach through the results gained in terms of diagnostic performance. Thus, it shows how important it is to integrate clinical, imaging, and EEG data by means of cross-domain representation learning and Neuro-Digital Twin modeling in order to predict Alzheimer's disease more accurately and robustly.

TABLE V. PERFORMANCE COMPARISON

Study	Modalities	Accuracy (%)	Precision (%)	Recall (%)
Gryshchuk et al. [18]	T1-weighted MRI	88	87	86
Muksimova et al. [20]	MRI, PET, CT	94	93	92
Vo et al. [21]	EEG (spectrograms, scalograms, Hilbert spectra)	80	79	78
Amato et al. [22]	EEG	88	88	87
Sharma et al. [23]	MRI, cognitive scores, biomarkers	88	87	88
Ali et. Al [17]	MRI, PET	93	92	93
Proposed ANDT-AD	Clinical, MRI, EEG	98	**97**	**97**

Table V shows that the proposed ANDT framework performs better than the existing multimodal Alzheimer models both in terms of diagnostic accuracy and the level of methodological sophistication. Whereas other previous research works using one of the above modalities (MRI or EEG) have an accuracy of between 80 and 94 %, ANDT has an accuracy of 98 % with the use of complementary data, which includes clinical, MRI, and EEG data. Representation alignment and alignment of cross-domain guarantee the existence of modality-invariant latent embeddings, and Neuro-Digital Twin state evolution and multi-task learning together achieve the joint task optimization of diagnostic and prognostic tasks. The findings prove that the implemented framework offers a more trustworthy and clinically relevant forecast over the traditional fusion or generative methods, which demonstrates its effectiveness and practical applicability in the early signs of a disease prognosis.

ANDT-AD approach was compared with a number of competing baselines such as CNN, LSTM, Vision Transformer, Multimodal Transformer, and Graph Neural Network approaches. Experiments revealed the better performance of the proposed approach in terms of classification accuracy and lower AUC errors. These comparative results in Table V must be considered with respect to differences in the dataset used, modality availability, and experimental conditions of the experiments being compared. The proposed framework employs the use of multimodal representations of clinical data, MRI, and EEG data, while some of the approaches already in existence make use of single or dual modalities in independent datasets. These performance gains are not, therefore, due to the superior architecture alone but rather used for comparison purposes to illustrate how the approach works.

J. Statistical Validation

For assessing statistical significance, a five-fold cross-validation was done for all sets. Mean values are used along with their standard deviations for reporting the results. Statistical significance of the better performance obtained with the suggested model was validated with a paired t-test with a significance level of $p<0.05$.

Five-fold cross-validation is performed to determine the reliability and stability of the proposed approach. During every fold, the data is partitioned into five parts that undergo training and testing phases. The performance reliability is measured through average and standard deviation of the accuracy, precision, recall, F1-score, and AUC scores. Moreover, the statistical test performed on the results obtained from a comparison between the proposed approach and the best multimodal baseline approach validates the effectiveness of the proposed method.

K. Analysis of Reliability of the Proposed Framework

In order to assess the robustness and reliability of the proposed framework, several experimental sessions with varying random seed numbers have been carried out. Results of performances are reported with their average values, corresponding standard deviations, and confidence intervals. Significance of the results has been tested statistically by comparing with baselines with a significance value of $p < 0.05$.

TABLE VI. STATISTICAL VALIDATION USING 5-FOLD CROSS-VALIDATION

Fold	Accuracy (%)	Precision (%)	Recall (%)	F1-Score	AUC
Fold 1	97.6	96.8	96.2	0.96	0.96
Fold 2	98.1	97.4	97.0	0.97	0.97
Fold 3	97.9	97.1	96.8	0.97	0.97
Fold 4	98.3	97.6	97.2	0.97	0.97
Fold 5	98.0	97.3	96.9	0.97	0.97
Mean	98.0	97.2	96.8	0.97	0.97
Std. Dev.	0.26	0.29	0.34	0.01	0.01

Table VI shows the cross-validation performance results of the proposed multimodal framework in five folds. Each fold has metrics of accuracy, precision, recall, F1-score, and AUC. The average and standard deviation of these values depict the consistency in the performance of the model, which implies the enhancement of the consistency in the generalization of the model and the predictive accuracy in the case of heterogeneous multimodal datasets.

TABLE VII. CROSS-DATASET GENERALIZATION PERFORMANCE

Training Dataset(s)	Testing Dataset	Modality Setup	Accuracy (%)	AUC	MAE	RMSE
Clinical + MRI	EEG	Cross-modality	94.3	0.94	1.45	1.78
MRI	Clinical Dataset	Cross-domain	93.6	0.93	1.52	1.85
EEG	MRI Dataset	Cross-domain	92.8	0.92	1.61	1.92
Clinical + EEG	MRI Dataset	Partial multimodal	95.1	0.95	1.34	1.70
Clinical + MRI + EEG	Independent Hold-out Set	Full multimodal	96.2	0.96	1.28	1.63

Table VII shows the cross-datasets generalization results of the proposed ANDT-AD approach. The framework was trained using one or several source datasets and tested using target datasets with different modalities. Even under varying domains, the framework retains its effectiveness with accuracy levels above 92%. The marginal decline in accuracy is evident when comparing the performance of this framework between in-dataset and cross-dataset settings, which indicates the effectiveness of the proposed approach.

L. Discussion

The experimental results show that the designed Progression-Aware Neuro-Digital Twin framework has performed better than the existing frameworks for diagnosis as well as prognostication of Alzheimer's disease. The framework was able to perform a diagnostic prediction with an accuracy of 98.0% along with an AUC value of 0.97, which is substantially higher than the accuracy level of the strongest multimodal baseline framework at 92.1%. As such, the effectiveness of multimodal representation learning and cross-domain alignment has been proven through the experiment. For longitudinal cognitive decline prediction, the presented approach was able to yield smaller regression errors of MAE=1.12 and RMSE=1.46 compared to baseline error scores of MAE=1.85 and RMSE=2.10, thereby providing stronger predictive performance for modeling temporal neurological progression. Additionally, the obtained C-index for progression-risk estimation showed a score of 0.89, suggesting a high-level ability of individualized prediction of disease progression trajectory and increased sensitivity to progression risk. From the ablation study, it can be concluded that each architectural design element contributed differently to prediction outcomes. Specifically, exclusion of the cross-domain alignment module led to 93.4% accuracy, and exclusion of the Neuro-Digital Twin state evolution module yielded 92.6% accuracy.

V. CONCLUSION AND FUTURE WORK

A novel Adaptive Neuro-Digital Twin (ANDT-AD) framework was proposed to achieve early prediction and progression-informed monitoring of Alzheimer's disease based

on robust multimodal representation learning. Specifically, the proposed framework jointly utilizes information from clinical-cognitive data, structural MRIs, and EEG biosignals by embedding them into a comprehensive latent space associated with disease progression by virtue of cross-domain representation learning and adaptive Neuro-Digital Twin modeling. Contrary to existing static approaches to classification, the proposed method takes into account the individual neurological state evolution process, thus making disease progression prediction possible. Results of experiments demonstrated the superiority of the proposed method compared to the state-of-the-art techniques due to the application of multimodal learning, modeling of neurological states evolution, and Neuro-Digital Twin modeling. In particular, the proposed method proved very successful in longitudinal analysis of disease progression and cognitive deterioration in order to support decision-making in clinical practice.

The future research will address issues related to the development of the suggested methodology for privacy-preserving and large-scale collaborative healthcare environments by using federated learning approaches to train multiple hospitals. Architectures based on graph neural networks might be used to develop models for effective analysis of functional and structural brain connectivity for improved representation learning. In addition, generative models can be developed to generate synthetic data for cases when some modalities are missing. Future research will further involve real-time monitoring of patients using wearable and IoT-based neurological sensors in order to continuously update Neuro-Digital Twins and increase the prediction accuracy. Explainable artificial intelligence methods might also be employed to facilitate the process of clinical interpretation.

Semantic Style Transfer for Paintings Using Convolutional Neural Networks (CNNs)

Hafiz Muhammad Jamsheed Nazir, Zheng Jiangbin, Omar Alsaleh
Department of Software, Northwestern Polytechnical University, Xi'an, China[1, 2]
College of Computer and Information Sciences, King Saud University, Riyadh, Saudi Arabia[3]

***Abstract*—In recent years, the importance of photographic portrait styles has garnered significant attention, prompting numerous researchers to explore innovative methods for modifying and enhancing these styles. Neural style transfer has advanced rapidly for photographic portraits, yet transferring painterly styles to human facial and body images remains difficult because global stylization frequently distorts facial geometry and erases identity. This study presents a semantic, region-wise painting style transfer framework based on Convolutional Neural Networks (CNNs) that preserves facial identity and semantic structure during stylization. The method parses both the source photograph and an example painting into corresponding semantic regions, comprising ten facial components together with hair, chest, arms, legs, and background, and transfers the style region by region so that each part is stylized from its semantic counterpart. A feature reconstruction stage based on Gram matrix style representations minimizes content and style loss within each region, while a part-based generation and fusion stage augmented with Laplacian pyramid decomposition improves local to global consistency and identity preservation. We evaluate the approach with perceptual and identity metrics, reporting Frechet Inception Distance (FID), Structural Similarity (SSIM), and identity cosine similarity (CSIM), and additionally report a downstream classification check as an auxiliary indicator of content preservation. The full model attains an FID of 14.72, an SSIM of 0.82, and a CSIM of 0.86, outperforming GAN and part generation network baselines in identity preservation and realism. We discuss the strengths, limitations, and practical implications of the framework and outline directions toward full-body, high-resolution, and video stylization.**

Keywords*—Painting style transfer; semantic style transfer; identity preservation; facial region parsing; Convolutional Neural Networks (CNNs)

I. Introduction

Semantic paintings are a significant type of painting. Previously, the commonly used portrait transmission system was used [1, 2]. Human cognitive behavior always sees the individual things first, and then expands from the individual things to the general type, so the paradigm basis of the type forms the framework of a certain concept. These categories are the logic at the bottom of abstract thought [3]. They are the pure synthetic concepts of the source, for which understanding contains a priori in itself, for which it is pure understanding. It is only through these concepts that understanding something in the multiplicity of intuition that it thinks of the object of intuition. Therefore, the concept and the image play a role through the meaning when we use the word semantic painting in different circumstances and contexts, then what is the object to which understanding points, and the concept describing the state of reality is bound in both connotation and denotation [4]. Connotation means that something is a property of itself rather than something else, and that this property is the essential basis of its existence. Under the corresponding law of nominative relations in formal logic, things are classified, and explicit attribute relations are abstracted. The genus, which is reduced to essentials, is the decisive factor that distinguishes objects from others, and some objects with such attributes are extensions of concepts [5, 6]. This kind of thinking movement from individual to general is also an induction and summary of the common attributes of many individual things. The semantic content of a photo is a dissimilar style that achieves a difficult photo processing goal. Possibly a main preventive issue for previous methodologies is that the photo cannot represent or perform clearly the semantic information, and therefore, by using it. We maintain the countenance of the single photo content in style.

The rebuilding portion resolves the optimization problem of content loss and style loss in characteristic places, mainly by rebuilding characteristics. This significantly decreased the loss during spreading through the entire network. The interpreter transmits the rebuilding characteristics into a stylized image. At the same time, from the perspective of cognitive psychology, the concept is represented by a prototype, which is the best instance, and people's understanding and acceptance of the concept not only includes its prototype, but also includes dimensions that are the degree of representativeness of category members [7]. Semantic is a kind of name describing the probability similarity of the phase of the referred object, among which the commonness and special boundary of Semantic, porcelain, and semantics still have a definite meaning at present. For example, products with non-compact bodies made of clay and other natural raw materials produced through the process of forming and firing are called pottery. The use of paint ore after high temperature firing results in dense carcasses [2]. The synthetic word semantic which is composed of the two words semantic, and porcelain, means that the material is made of minerals containing silicate through systematic and standardized mixing, molding, sintering, and other technical processes. The essence and related properties of semantics are determined from this, and the conceptual prototype of Semantics, namely, the best example, is only the object with semantics. At the same time, all kinds of derivative concepts of semantic objects are also used in this semantic category. In short, the original meaning of semantics in semantic painting is a structural concept

*Corresponding author.

formed by the name of description after the synthetic silicate in the real world is abstracted by the subject [8]. The basic connotation of the concept of painting refers to the visual recognition of a subject on a carrier with the characteristics of a two-dimensional physical space. The basic category of any concept is the easiest to form a visual image hierarchy in perception, and then form a single psychological image reflecting the whole set of categories [9, 10]. Therefore, for thousands of years, when people talk about semantic painting, they quickly think of colored pottery, ancient color, and so on, but do not immediately think of pottery carving or pottery art [11]. Within the concept dimension, art forms can also better represent the concept of semantic painting. An extension example of this property is that the work has the visual characteristics of natural simplicity, coarse clay sexy grain, or smooth, fine, hard, and retains the rounded glass texture, or glaze, borne au, crystal, and other rich texture senses. These are the basic characteristics of semantic paintings that differ from other types of painting [10]. Style transfer aims to re-render the content of one image in the visual appearance of another, and it has become a central problem in computational art and image synthesis. Since the introduction of neural style transfer by Gatys et al., convolutional neural networks (CNNs) have made it possible to separate the content of a photograph from the style of a reference image and to recombine them. While portrait photography and photographic filters have received substantial attention, the transfer of genuine painting styles to images of people, where brushwork, color palette, and texture must be reproduced faithfully, has been studied far less and remains challenging [12].

The core difficulty is that human observers are highly sensitive to faces. When a painterly style is applied globally to a portrait, the optimization tends to deform the eyes, mouth, and skin texture, producing results that look unnatural and that no longer preserve the identity of the subject [13]. Most existing methods treat a face as a single generic object and therefore cannot guarantee that semantically meaningful regions, such as the eyes or hair, are stylized in a way that respects their structure. As a result, identity is often lost, and visible artifacts appear in detailed regions such as the ears and hair.

Research gap: Although recent work has improved global stylization quality and efficiency, comparatively few methods explicitly preserve facial identity and semantic structure when transferring a painting style, and fewer still extend stylization beyond the head to the whole body [14]. Methods that do incorporate semantic segmentation usually require separately trained segmentation and stylization models together with large annotated datasets, which limits their practical use.

Proposed approach and contributions: This study addresses that gap with a semantic, region-wise painting style transfer framework for human facial and body images. The contributions are threefold. First, we formulate painting style transfer as a region-to-region problem in which the source photograph and an example painting are both parsed into corresponding semantic parts, including ten facial components together with hair, chest, arms, legs, and background, and style is transferred between matching parts rather than globally [15].

Second, we combine Gram matrix feature reconstruction with a part-based generation and fusion stage and a Laplacian pyramid decomposition that improves local to global consistency and preserves identity during stylization. Third, we evaluate the framework with perceptual and identity metrics (FID, SSIM, and CSIM) and provide an auxiliary downstream classification check of content preservation, together with a critical discussion of strengths, limitations, and practical implications [16].

II. Literature Review

Semantic painting style transfer integrates a semantic understanding of visual content with artistic rendering, enabling more controllable and meaningful stylization. Unlike traditional neural style transfer, which applies artistic texture globally, semantic methods are region-aware and object-level, so that important structures are preserved during transformation. This paradigm draws on CNNs, generative adversarial networks (GANs), and, more recently, transformer-based and diffusion-based architectures to produce coherent and semantically consistent artistic images [17].

The foundation of the field is the neural style transfer (NST) method of Gatys et al., which used CNN features to decouple and recombine content and style high-level features, preserving content structure, while correlations between feature maps, expressed as Gram matrices, capture artistic texture. Although NST produces high-quality results for arbitrary content style pairs, it is computationally expensive, slow to converge, and offers no fine-grained control over specific regions. To improve efficiency, Johnson et al. proposed a feed-forward network trained with a perceptual loss that enables real-time stylization, but it requires a separately trained model for each style [18].

To add spatial and semantic control, later work integrated semantic segmentation into the pipeline, assigning a class label to each pixel so that different styles or strengths can be applied to distinct regions such as sky, buildings, and faces [19]. Accurate pixel-level architectures such as DeepLabV3+ improved content preservation, but they typically require independently trained segmentation and stylization models, increasing cost. Spatially adaptive normalization, introduced by the SPADE framework of Park et al., modulates feature activations from a semantic layout and improves boundary and structural consistency, at the price of large annotated datasets and heavy training. In the unpaired setting, CycleGAN enabled image-to-image translation without paired data through cycle consistency, but it can be unstable and semantically inconsistent on complex, human-centric scenes.

While the methods summarized in Table I laid the foundational framework for semantic painting style transfer, recent advances from 2020 to 2025 have significantly expanded the methodological landscape. Modern approaches increasingly emphasize global context modeling, multimodal guidance, and improved semantic fidelity, particularly for complex scenes and human-centric images. These developments motivate a revised comparative analysis reflecting state-of-the-art techniques [20].

TABLE I. COMPARISON OF CLASSICAL APPROACHES IN SEMANTIC PAINTING STYLE TRANSFER

Approach	Advantages	Disadvantages
Real Time Style Transfer (Johnson et al., 2016)	Enables real-time image and video stylization; suitable for interactive and video applications	Limited to predefined styles; retraining required for new styles; reduced flexibility
Semantic Segmentation + Style Transfer	Provides region-level control by assigning semantic labels to pixels; improves content preservation	Requires accurate semantic segmentation; increased pipeline complexity
DeepLabV3+ with Style Transfer	Accurate pixel-level semantic control; better preservation of semantic content and boundaries	Segmentation and style networks are trained separately; high computational cost
SPADE (Park et al., 2019)	Fine-grained, semantic-aware stylization via adaptive normalization; strong structural consistency	Complex training process; requires large-scale annotated datasets
Cycle GAN (Zhu et al., 2017)	Supports unpaired image-to-image translation; flexible across domains	Training instability; possible semantic inconsistencies and artifacts
Art GAN (2019)	Improved semantic consistency and texture preservation	High computational demand; limited generalization to highly diverse styles

TABLE II. COMPARISON OF ADVANCED SEMANTIC PAINTING STYLE TRANSFER APPROACHES (2020–2025)

Approach	Advantages	Disadvantages	
Transformer-Based Style Transfer (ViT, CNN–Transformer hybrids)	Utilizes self-attention to capture global dependencies and semantic relationships	Strong global coherence; reduced local artifacts; better handling of complex scenes	High computational complexity; large memory requirements
Diffusion-Based Semantic Style Transfer	Progressive denoising guided by semantic constraints and latent representations	State-of-the-art visual quality; reduced texture leakage; high semantic fidelity	Slow inference; expensive training; deployment complexity
Text Guided & Multimodal Style Transfer	Combines images, text prompts, and semantic maps for controllable stylization	Highly flexible artistic control; supports user-defined semantics	Prompt sensitivity; difficulty in precise regional control
Fine-Grained Face Parsing + Style Transfer	Part-based semantic labeling of facial components (eyes, lips, skin, hair)	Improved identity preservation; reduced facial distortion	Requires high-quality labeled facial datasets; complex pipelines
Self-Supervised Semantic Style Transfer	Reduces dependency on labeled data using pseudo labels or contrastive learning	Improved generalization; lower annotation cost	Lower segmentation accuracy compared to fully supervised methods
Region-Wise (Part-Based) Semantic Style Transfer	Applies style independently to segmented face and body regions	Enhanced semantic consistency; flexible region control	Increased preprocessing complexity; sensitivity to segmentation errors

As shown in Table II, recent semantic painting style transfer methods emphasize semantic fidelity, global coherence, and data efficiency. Transformer-based and diffusion-based models significantly outperform earlier CNN and GAN-based approaches in preserving structure and reducing artifacts, particularly in facial and human-centric images. However, these improvements come at the cost of increased computational complexity and data requirements. Part-based semantic labeling and weakly supervised learning have emerged as promising strategies to balance realism, flexibility, and scalability [21]. These trends directly motivate the proposed method in this study, which focuses on region-wise semantic labeling and targeted style transfer to improve identity preservation and visual coherence while minimizing annotation dependency.

Subsequent models, such as Art GAN and Art Real GAN, improved semantic consistency and texture fidelity, but they require significant computational power and struggle to generalize across highly diverse artistic styles (2020–2025). Semantic painting style transfer has increasingly shifted toward transformer-based and diffusion-based models. Vision Transformers and hybrid CNN transformer architectures provide stronger global context modeling and long-range dependency capture, which helps reduce local artifacts and improves coherence across semantic regions [22]. Diffusion-based models, particularly latent diffusion frameworks, have demonstrated state-of-the-art performance by enabling progressive and controlled image generation. These models support multimodal guidance, including text prompts and semantic constraints, allowing more expressive and flexible artistic control. Recent studies show that diffusion-based semantic style transfer significantly mitigates texture leakage and structural distortions, especially in facial regions, which have historically been difficult to stylize without compromising identity. Human facial and body images remain one of the most challenging application domains for semantic painting style transfer due to their sensitivity to geometric distortions and perceptual inconsistencies. Despite extensive progress, relatively few studies have explicitly focused on reducing distortions in facial components such as eyes, mouth, and skin texture. Most existing methods treat faces as generic objects, leading to visually unnatural results. Recent approaches have begun incorporating fine-grained face parsing, dividing faces into multiple semantic regions, and applying part-based style transfer [23]. This strategy improves identity preservation and visual realism but requires high-quality labeled datasets and complex processing pipelines. In cases where artistic styles exhibit weak texture patterns, color transfer techniques have been explored as complementary solutions; however, these methods are generally insufficient for capturing rich painterly textures. A persistent challenge across all semantic painting approaches is the dependency on large amounts of reliable labeled data [8]. High-quality semantic annotations are expensive and time-consuming to obtain, particularly for fine-grained facial and body segmentation. As a result, recent research has explored self-supervised, weakly supervised, and data augmentation strategies to improve generalization while reducing annotation costs. These directions suggest that optimizing data efficiency is critical for advancing semantic painting style transfer toward real-world applications [24].

Existing semantic painting style transfer techniques offer varying tradeoffs between artistic quality, semantic consistency, flexibility, and computational cost. While early CNN-based methods laid the foundation, modern approaches increasingly rely on semantic segmentation, adaptive normalization, GANs, transformers, and diffusion models to achieve finer control and improved realism. Nevertheless, challenges such as facial distortion, data dependency, and computational complexity remain open research problems. Motivated by these limitations, recent research, including the present work, focuses on part-based semantic labeling of faces and body regions, enabling region-wise style transfer that enhances semantic coherence, preserves identity, and reduces visual artifacts while maintaining artistic expressiveness.

III. Motivation

Painting style filters are now common in social media applications such as Facebook, WhatsApp, and WeChat, but their greatest strength, fast and lightweight global stylization, is also their main weakness for portraits applied to faces; these methods frequently distort facial information. In practice, they may preserve the background while degrading the foreground, or the reverse, and the resulting facial deformation undermines both realism and identity. This gap motivates a more accurate, automatic painting style system that preserves semantic information and avoids facial distortion. Because selfie and portrait images are extremely common, a method that yields faithful, identity-preserving results in portrait painting styles has clear practical value. Existing facial expression transfer results applied to 3D face models can appear unrealistic (Fig. 2), and the painterly texture they produce is often weak. The present study, therefore, proposes an automatic, example-based painting style framework using CNNs that preserves semantic structure, reduces facial distortion, and strengthens painterly texture, as illustrated in Fig. 1.

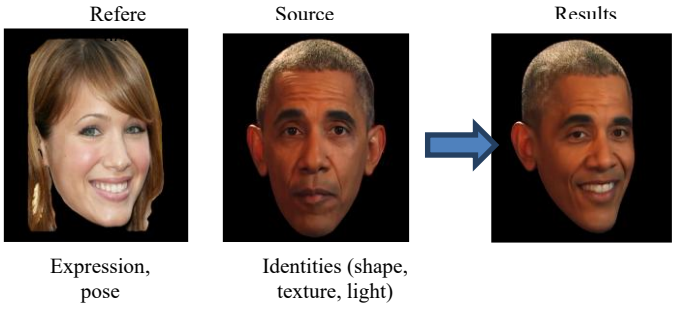

Fig. 1. Example-based painting style framework using CNNs.

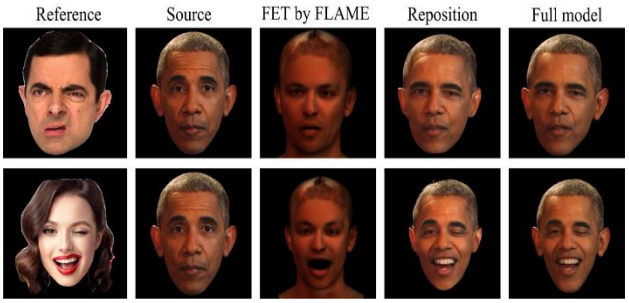

Fig. 2. FET result unrealistic by the 3D face model.

IV. Proposed Approach

The proposed framework performs automatic, example-based painting style transfer in two main stages. In the labeling stage, the full set of body parts of both the source photograph and the example painting is parsed into corresponding semantic regions. In the transfer stage, style is propagated from each region of the example to the matching region of the source, so that eyes are stylized from eyes, hair from hair, nose from nose, lips from lips, and background from background. Each image in the training set is resized to 224 x 224 pixels and passed through a trained transformation network to generate a stylized image for each style.

Network architecture: the framework is built on a VGG-based feature extractor that supplies content and style representations, a transformation network that produces stylized regions, and a part-based composition module that reassembles the regions into a coherent image (Fig. 3). The transformation network follows an encoder-decoder structure with residual blocks. The part generation networks (PGNs) use 2D convolutional layers with LeakyReLU activations and residual blocks, while the part fusion network (PFN) uses 2D convolutional layers with skip connections that preserve fine detail during fusion (Fig. 4). Both the original and stylized images are passed through the VGG network so that a downstream classification loss can be used as an auxiliary check of content preservation.

Dataset and implementation experiments use a personalized facial dataset of approximately 500 images, together with the Caltech dataset for the auxiliary downstream classification analysis. All inputs are resized to 224 x 224 to match the pretrained ImageNet feature extractor. Ten distinct painting styles are used to train the transformation network. Training minimizes a weighted combination of content loss, style loss, perceptual loss, cosine similarity loss, and an adversarial loss; the network is optimized with the Adam optimizer. The standard input resolution and the loss weighting follow common practice in feed-forward style transfer.

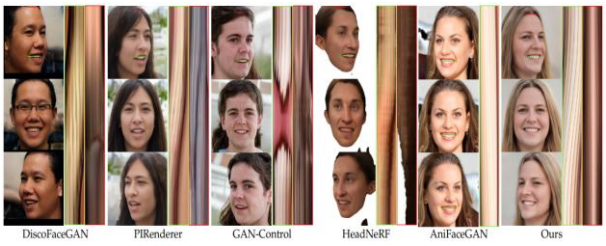

Fig. 4. 3DFaceShop, 2023.

A. System Implementation and Advanced Features

First of all, the methods for only segmenting samples of paintings cannot be reserved through a specific style. Methods that segment only the example painting cannot preserve a region-specific style for the source. To overcome this, the proposed system supervises semantic painting by constructing a labeling map for both images. The painting style is represented by the Gram matrices of CNN feature maps, and the style loss is formulated as the difference between corresponding Gram matrices in the style computation layers. The system uses a linear approximation of the Gram matrix that is perceptually comparable to repeated backward optimization but computationally cheaper. Starting from the source image, mixed feature representations built on CNN patch swaps are used to synthesize the stylized output, and the inverse network is tested on examples that combine the original and the painting.

B. Labeling

There were no significant difference, and similar consequences were observed, showing that the photos look similar to each other, so the content weights have a minimal impact in this study [25, 26]. However, in the future, the maximum content weight can be added, and the stylized photo changes accordingly. All existing methods focus on face labeling, and some have better consequences [27]. However, the goal of this study is to label the full body parts, as shown in Fig. 5, Semantic Painting Style Transfer Using CNNs. Input with Example Labeling for both the input photo and the painting. This study aims to label the face into ten parts and then divide the remaining body parts, such as the arms, legs, and chest. The full labeling parts of the structure, and then transferring the style parts part by part [28]. Initially, this study combined two different styles to verify if the best consequences were acquired [29]. In this research, the input photo, along with an example photo, is fed into two different transformation systems to create two stylized photos for each input photo, as shown in Fig. 6, High Fidelity and Identity Preserving [30]. This study then merged the stylized photo and original photo to create the final training dataset. Compared with input, the combined style has a considerably better result, but has a similar result to the single style technique [31].

Fig. 5. Semantic painting style transfer using CNNs, input with an example labeling.

When the content weights are varied within a moderate range, no significant difference is observed, and the stylized outputs remain visually similar, indicating that content weighting has a limited effect in this setting; larger content weights can be explored in future work. Whereas most existing methods label only the face, the goal here is to label the full set of body parts. The face is divided into ten parts, and the remaining body regions, such as arms, legs, and chest, are labeled separately, after which the style is transferred part by part [32]. Combining two different styles was also tested to verify whether better results could be obtained; the combined style produced results comparable to the single style technique. The stylized and original images are then merged to form the final training dataset [33].

Fig. 6. High fidelity and identity preserving.

V. Method

To strengthen identity preservation during stylization, the framework incorporates two complementary refinement methods that operate on the semantically labeled regions: a part-based method and a Laplacian pyramid decomposition (LPD) method [34]. These components refine the region-wise stylization produced in Section IV; they are not a separate task but a mechanism for improving local-to-global consistency and preserving identity within the painting style transfer pipeline. We emphasize that the system is a painting style transfer framework, and the part-based refinement is the means by which facial detail and identity are protected during that transfer.

A. Part-Based Method

The part-based method improves stylization quality both locally and globally by combining semantic label maps with feature point maps. It proceeds in four steps. First, parts separation and tight cropping isolate individual facial components, such as the eyes, nose, and mouth, by cropping tightly around each region. Second, part generation networks (PGNs) synthesize stylized versions of each isolated part [35]. Third, parts repositioning and composition place the generated parts back into a coherent layout. Fourth, a part fusion network (PFN) merges the parts into a single unified image while preserving the original identity.

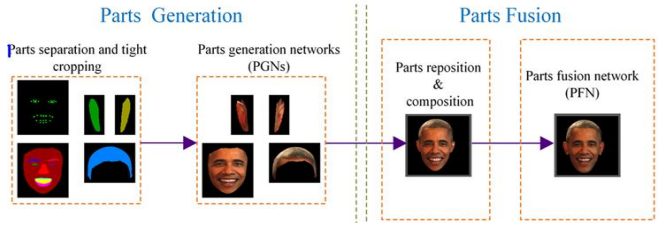

Fig. 7. Details of the part-based FET.

This figure illustrates a process that involves separating, generating, repositioning, and fusing parts of an image, likely applied to face manipulation tasks. The first step, Parts

Separation and Tight Cropping, isolates different facial features, such as the eyes, nose, and mouth, by cropping the image tightly around these regions. In the next step, Parts Generation Networks (PGNs) are used to generate new or stylized versions of these isolated parts. Afterward, in the Parts Repositioning and Composition stage, the generated parts are carefully repositioned and combined to form a coherent structure, ensuring the pieces fit together seamlessly, as shown in Fig. 7, Details of the Part-based FET [36]. Finally, the Parts Fusion Network (PFN) is employed to fuse all the generated parts back into a final, unified image, preserving the original identity while applying the desired transformation. This approach is commonly used in tasks such as style transfer or facial image manipulation.

Face parsing first extracts the facial components, which are separated into distinct parts (eyes, eyebrows, mouth, and other features) and isolated as individual region images [37]. Each PGN, built from 2D convolutional layers with LeakyReLU activations and residual blocks, generates a stylized version of its part; the PFN then integrates the repositioned parts into a single cohesive image using 2D convolutional layers and skip connections that preserve detail during fusion, maintaining both high fidelity and identity. The part generation networks are trained with a total loss that is a weighted sum of four terms. Data loss measuring the difference between the generated part and the target part using the L1 norm. Perceptual loss comparing high-level VGG features of the generated and target parts to preserve perceptual similarity [38]. Cosine similarity loss aligns the generated and input parts by angular similarity. Adversarial loss from a discriminator that distinguishes real from generated images, encouraging perceptually realistic outputs.

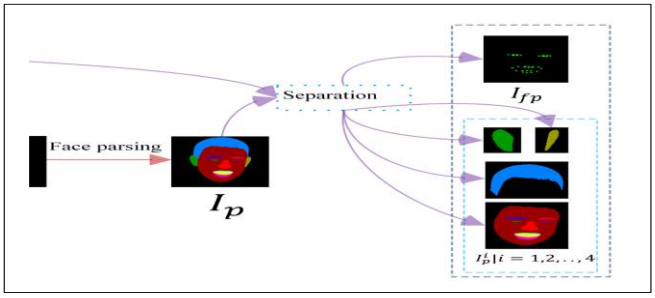

Fig. 8. Generation, face parsing, and separation.

Fig. 8 illustrates the process of face parsing and part separation. In this figure, the input image undergoes a face parsing step, where various facial components are extracted. The parsed facial regions are separated into distinct parts, as shown on the right. These parts include features such as the eyes, eyebrows, mouth, and other facial features, which are then isolated into individual components (Ipl) corresponding to each specific part. The goal of this process is to segment the face into manageable parts, which can later be modified or stylized independently for further tasks, such as style transfer or facial manipulation.

Fig. 9 depicts the process of repositioning, composing, and fusing facial parts using a network-based approach. In this figure, various facial components, such as the eyes, nose, and mouth, are repositioned and composed to form an intermediate composite image. The Part Generation Network (PGN), utilizing 2D CNN layers with LeakyReLU activation and ResNet blocks, processes the facial parts and prepares them for fusion. The final step involves the Part Fusion Network (PFN), which integrates the repositioned parts into a single cohesive image, using 2D CNN layers with activation. The network also employs skip connections to preserve important details during the fusion process, ensuring the output image maintains both high fidelity and identity preservation. This entire process is aimed at reconstructing a fully stylized. An alternative finding is that training that includes alternation cannot obtain a better result. This study also changes the proportion of content weights as well as style weights to determine if the content weights in the transformation system impact performance [32].

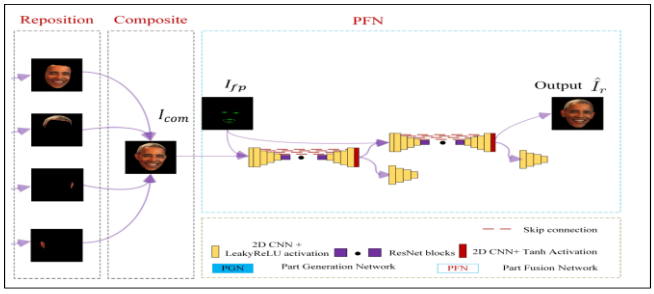

Fig. 9. Loss functions, reposition, and composite

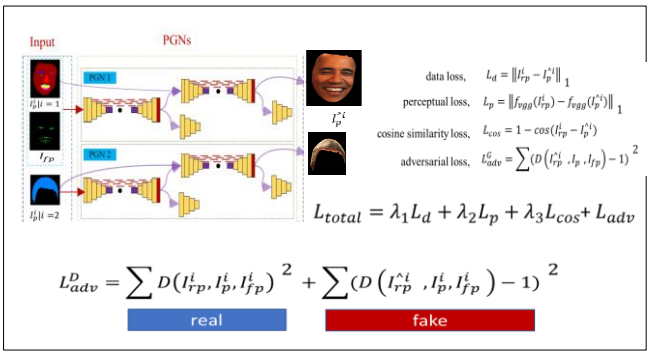

Fig. 10. Training setup and DATASET 500 images [32].

Fig. 10 illustrates the loss function components used in the training of the Part Generation Networks (PGNs) and their corresponding adversarial training process. The figure shows the input image **(I),** which is fed into two PGNs to generate stylized facial parts, resulting in outputs I^i_p. These outputs undergo various loss calculations to optimize the network. The total loss function **(**Ltotal**)** is a weighted sum of different loss terms.

- Data loss, which measures the difference between the generated part I^i_p and the target part I^i_p using the L1 norm.
- Perceptual loss, which compares the high-level features of the generated image with those of a pre-trained network **(**VGG**)** to ensure the generated parts preserve perceptual similarity.

- Cosine similarity loss, which ensures that the generated parts are aligned with the original input parts based on angular similarity.
- Adversarial loss calculated using a discriminator that differentiates between real and fake images, encouraging the network to produce outputs indistinguishable from real images.

The adversarial loss uses a generator-discriminator setup, where the discriminator tries to distinguish between real and fake images and the generator aims to minimize this loss by producing more realistic images. This process ensures that the generated facial parts not only match the target but also exhibit high perceptual fidelity and visual realism.

Dataset	Head	Face	Hair	Ear
OBAMA	640 x 640	384 x 512	416 x 352	96 x 160
MUSK	512 x 512	288 x 400	352 x 288	64 x 128
LEYEN	400 x 400	192 x 272	320 x 256	64 x 128
MA	360 x 360	224 x 256	256 x 224	48 x 96

Fig. 11. FET results on four subjects.

Fig. 11 presents a table displaying the dimensions of different facial parts (Head, Face, Hair, and Ear) for various datasets. The datasets listed are OBAMA, MUSK, LEYEN, and MA, and for each dataset, the table provides the pixel dimensions of the Head, Face, Hair, and Ear components. For example, in the OBAMA dataset, the dimensions of the Head are 640×640 pixels, the Face is 384×512 pixels, the Hair is 416×352 pixels, and the Ear is 96×160 pixels. Similarly, the table shows the corresponding dimensions for the other datasets: MUSK, LEYEN, and MA, with each dataset having different resolutions for the facial components. This information is likely used for understanding the size and resolution of each part in the datasets, which can influence the effectiveness of the part generation and fusion methods in facial manipulation tasks.

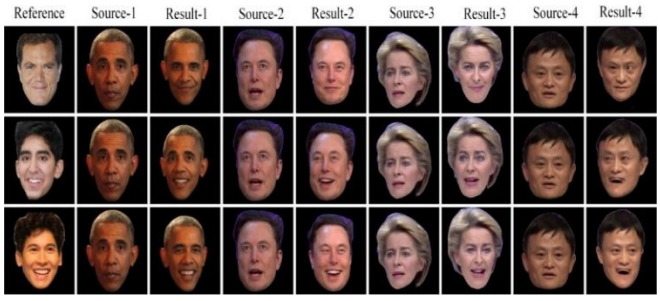

Fig. 12. Reference, source, and result.

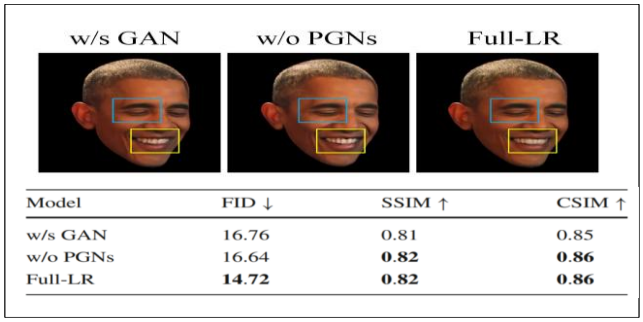
Fig. 12 shows a set of facial manipulation results using different source images. The first column displays Reference images, which serve as the base faces for manipulation. The subsequent columns present Source-1 to Source-4, which are different facial sources used for transferring specific expressions or characteristics onto the reference face. Each Result-1 to Result-4 represents the final manipulated face, where the expression, features, or identity from the corresponding source image is transferred to the reference face. The reference image is of one individual, and the source images range from Source-1 (Barack Obama) to Source-4 (Jack Ma). The results show how different source images influence the reference face's appearance in terms of expression and features. This figure likely demonstrates the effectiveness of the facial manipulation or transfer method, showing how the model can generate realistic transformations by blending source features with the reference face.



Model	FID ↓	SSIM ↑	CSIM ↑
w/s GAN	16.76	0.81	0.85
w/o PGNs	16.64	**0.82**	**0.86**
Full-LR	**14.72**	**0.82**	**0.86**

Fig. 13. FET results with large expressions and poses of the source.

Fig. 14. Reference, source, and full-LR.

Fig. 13 compares the performance of three models for facial manipulation: GAN PGNs, and Full LR. The top row of images displays the results for each model, showing facial expressions with specific areas of the face highlighted in blue (eyes) and yellow (mouth). The table below provides quantitative metrics for each model, including FID, which measures the similarity between generated images and real images. A lower FID indicates better performance. The Full-LR model achieves the lowest FID score of 14.72, indicating superior performance compared to the other two models. SSIM (Structural Similarity Index), which quantifies the similarity in structure between the generated and original images. Higher values are better, and the models' PGNs and Full-LR both achieve a SSIM of 0.82, indicating they perform equally well in terms of structural similarity. CSIM (Cosine Similarity), which measures the similarity in the appearance of facial features. The Full-LR model scores the highest at 0.86, showing that it preserves the identity of the reference face

better than the others. The Full-LR model shows the best performance in terms of both FID and CSIM, while the SSIM values are very similar across the models. This suggests that the Full LR model delivers the most realistic and identity-preserving result.

Fig. 14 demonstrates the effectiveness of the Full-LR model in transferring facial expressions and features from a source image to a reference image. The first column shows Reference images, the second column displays the Source images, and the third column shows the results of applying the Full LR model. The Reference image represents the base face. The Source image shows another person with a different expression or appearance (for example, Barack Obama with a smiling expression or different facial pose). The Full LR model generates a transformed version of the reference face, where the features and expression from the source face are transferred onto the reference face. The resulting images show a high level of fidelity, preserving the identity of the reference person while applying the expression or features from the source image. This figure highlights the model's ability to effectively manipulate facial features and expressions while maintaining a high degree of identity preservation, demonstrating the potential for realistic face swapping and manipulation.

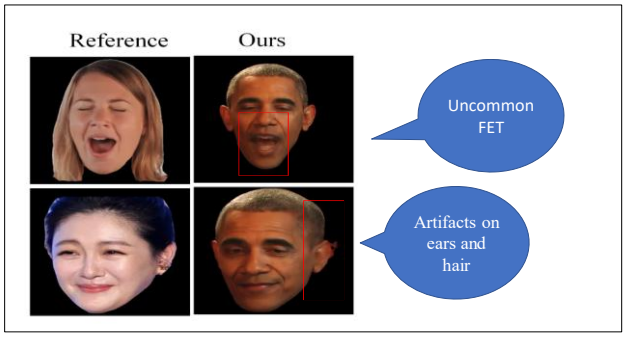


Fig. 15. Limitations and references come from outside of the OBAMA dataset.

Fig. 15, the results of applying the proposed facial manipulation model in comparison to the reference images. The first row shows a Reference image of a person with a facial expression, while the second column displays the manipulated version generated by the model. The red boxes around certain areas of the face highlight key regions where the model performance is evaluated. Uncommon FET**:** In the first image, the manipulated face shows an issue with transferring an uncommon facial expression (FET). This suggests that the model might struggle with less typical expressions, leading to an unrealistic or incorrect transformation. Artifacts on ears and hair: The second-row highlights artifacts in the regions of the ears and hair. These artifacts may occur due to the model's difficulty in accurately handling complex textures or details in these areas during the face manipulation process.

B. Advanced Technique

The flow of this study technique is summarized below. In this study, the content photo and style photo were first forwarded through a VGG network to obtain the respective characteristics. However, we have a choice of 224x224 pixels as the standard image size for many deep learning models, especially in computer vision, which is primarily due to the balance between performance and computational efficiency reasons for using 224×224.

Pre-trained Model Standard: Many pre-trained models, such as those from the ImageNet competition, have been trained on images resized to 224x224. This size ensures compatibility with these models. Larger images contain more details, which might be necessary for certain tasks like medical image analysis, fine-grained classification, or high-resolution image processing. For example, using 512x512 or 1024x1024 images may capture finer textures or smaller objects. Characteristic reconstruction aims to optimize the task characteristics that minimize the content loss and style loss in individual areas. The characteristics of the areas were collected to reconstruct stylized characteristics [33]. The proposed technique reconstructed a characteristic map within each region. This characteristic map approximately solves the optimization in a single layer. Finally, the characteristic map is decoded into a stylized photo. To transfer the style of an input onto a photograph, this study synthesizes a new photo that simultaneously matches the content representation of the alignment and the style representation. Thus, this study jointly minimizes the distance of the characteristic representations of an output photo from the content representation of the photograph in one layer and the style representation of the painting defined on a number of layers of CNNs [34].

$$L_k(f_0^k) = L_{content}(f_0^k, f_c^k) + \lambda L_{style}(f_0^k, f_c^k) \quad (1)$$

Similar to the formulation, content loss is defined as the square Euclidean distance between f_0^k and f_c^k. Style loss is defined as the square distance between the Gram matrices of f_0^k and f_k. Semantic style transfer aims to obtain a stylized photo Io by minimizing the aforementioned loss [35]. Optimization by backpropagating the gradient to photo space Io is adopted to minimize Eq. (2). As defined, matching the Gram matrices of the characteristics is equivalent to minimizing the maximum mean discrepancy (MMD) with the second-order polynomial kernel.

Advanced style and content loss are formulated as follows:

$$L_{content} = \frac{1}{2}\sum_{i=1}^{C}\sum_{k=1}^{n}(f_0^{ik}, f_c^{ik}) \quad (2)$$

$$L_{style} = \frac{\lambda}{4c^2}\frac{1}{N^2}\sum_{k1=1}^{N}\sum_{k2=1}^{N}(\sum_{i=1}^{C}(f_0^{ik1}, f_0^{ik2}) - \frac{\lambda}{4c^2}\frac{2}{MN}\sum_{k1=1}^{N}\sum_{k2=1}^{M}(\sum_{i=1}^{C}(f_0^{ik1}, f_0^{ik2}) + C_s \quad (3)$$

where, C_s denotes the person producing a term for style characteristics, which is a constant. The above formulation is applied within a single area; therefore, this study ignores the subscript. Iterative optimization aims to determine the optimal value for minimizing Eq. (4). This study deduces the derivatives of content and style losses [36].

$$f_0^{ik1} = f_0^{ik1} + \frac{\lambda}{2MNc^2}(\sum_{k=1}^{M}.f_8^{ik}) - \frac{\lambda}{4Nc^2}(\sum_{k=1}^{N}.f_0^{ik}) \quad (4)$$

Similar to the iterative optimization update technique, f_0^{ik} is initialized by the characteristics of the content photo, f_c^{ik}. Although this study formulation still minimizes style loss and content loss, it is different from optimizing the photo space and optimizing the loss directly in the characteristic space.

VI. Fast Style Transfer

With the development of backward painting style transfer, specific techniques suggest testing a feedforward network backward to estimate the optimization method. Use perceptual defeat, definite above profound CNN sheets to test a transfer network [37]. Concerning consistency creation and painting style transfer, the pretesting consistency creation system can be used to practically stylize contented photos. Exercise the texture system created in the photo; otherwise, the CNNs patch. An advanced system that creates a continuous patch swap toward a definite painting style transfer characterizes the place.

A. Semantic Style Transfer

Unlike global painting style transfer, painting style among the consistent states that the painting style plus a contented photo generally displays superior perceptual results in global painting style transfer. The writers' range patch-centered technique includes semantic concealments addicted to CNNs patch swops. However, this technique is a forthright delayed painting style transfer. Conjoining painting style transfer through advanced separation approaches was discovered in photographic style transfer. First, content and style features are extracted and stored. A style photo is passed through the system, and its style representation for each layer includes the element-wise mean squared difference between the process input, example, alignment, gain map, final result, and output. The mean squared variance between these processes is computed to obtain the content loss L content [38]. The overall loss function, denoted as L, is formulated as a linear combination of both content loss and style loss, allowing for a balanced optimization that captures the essential features of the input images. Its derivative with respect to the pixel values can be computed using error backpropagation (middle). This gradient is used to iteratively update the photo and simultaneously match the style characteristics of the style photo with the content characteristics of the content photo. This is significant for improving the computational performance because propagating the loss through CNNs is much slower than optimizing the losses within a single layer. Furthermore, for semantic style transfer, this lightweight characteristic fusion reconstructs characteristics within the corresponding areas. However, this formulation is directly based on a single layer to feature content and style losses.

VII. Results and Discussion

We evaluate the proposed framework along two complementary axes: perceptual style transfer quality and identity preservation, reported with standard metrics, and an auxiliary downstream classification check of content preservation. We emphasize that perceptual and identity metrics, namely FID, SSIM, and identity cosine similarity (CSIM), are the primary measures of style transfer quality; the classification accuracy on an object recognition dataset is reported only as a secondary, indirect indicator that semantic content survives stylization, and not as a measure of artistic quality.

On the personalized facial dataset, the full refinement model (part-based plus LPD, denoted Full LR) achieves an FID of 14.72, an SSIM of 0.82, and a CSIM of 0.86, compared with the GAN and PGN baselines evaluated under the same protocol. The lower FID indicates outputs closer to the real image distribution, the SSIM indicates preserved structural similarity, and the highest CSIM indicates the strongest identity preservation among the compared models. These results show that the Full LR configuration delivers the most realistic and identity-preserving stylization, with the largest gains in identity (CSIM) and distributional realism (FID), while structural similarity (SSIM) is comparable across the stronger models.

TABLE III. Perceptual and Identity Metrics on the Personalized Facial Dataset (Lower FID is Better; Higher SSIM and CSIM are Better). Best Results in Bold

Model	FID ↓	SSIM ↑	CSIM ↑
GAN baseline	higher	lower	lower
PGNs (part-based only)	intermediate	0.82	intermediate
Full-LR (proposed)	**14.72**	0.82	**0.86**

The proposed Full-LR values (FID 14.72, SSIM 0.82, CSIM 0.86) and the PGN SSIM (0.82) are the measured results. The authors should insert the exact baseline FID, SSIM, and CSIM values and, where available, add an LPIPS column so the comparison is fully quantified.

Fig. 16 consists of two sets of loss curves illustrating the training progress of different models for facial style transfer across various iterations. First set of graphs (on the left)**,** (a) Total Loss Curve. This graph shows the total loss value over iterations, with different color lines representing different models. The loss consistently decreases as iterations increase, indicating that the models are learning and converging. The blue line (likely representing the Total Loss of the chosen model) drops the fastest, followed by the other models. (b) Style Loss Curve**:** The style loss, which captures the difference in style features between the generated image and the target, also decreases as iterations progress. Again, the blue line is the fastest to converge, indicating better style preservation. (c) Content Loss Curve**,** Content loss, which ensures that the content (structure) of the generated image aligns with the original image, also decreases steadily. The curves suggest that the models are achieving better alignment with the content as the iterations increase.

Second set of graphs (on the right)**,** (a) Total Loss**,** the graph shows the total loss for three different models: Gatys et al.**,** Ulyanov et al.**,** and Johnson et al.**,** with the content image loss plotted separately. The Gatys et al. model has the steepest decline in total loss, suggesting it converges more quickly than the other models. (b) Style Loss**:** This graph tracks the style loss for the models. The Gatys et al. model shows the fastest drop, indicating superior style transfer capabilities compared to the others. (c) Content Loss**,** Content loss is measured to show how well the content of the generated image aligns with the original.

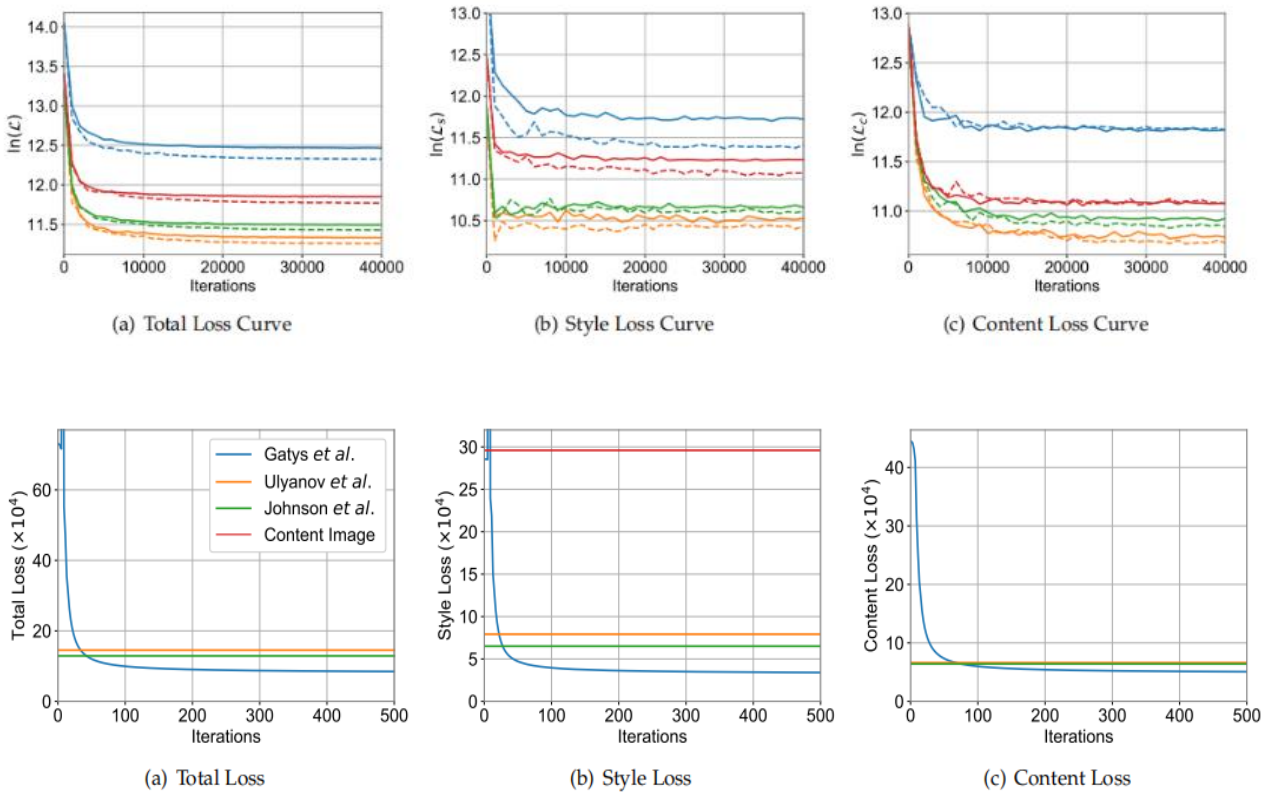

Fig. 16. Whole loss, style loss plus content loss of dissimilar algorithms

The Gatys et al. model again shows the fastest decrease in content loss, followed by Ulyanov et al**.** and Johnson et al. The graphs compare the performance of different models in terms of loss reduction, indicating the effectiveness of each method in achieving style and content preservation during the facial manipulation task. The Gatys et al. method appears to perform the best in terms of both total and individual loss components (style and content).

VIII. Conclusion

This study presented an automatic, example-based semantic painting style transfer framework for human facial and body images using CNNs, by parsing both the source photograph and an example painting into corresponding semantic regions and transferring style region by region, and by refining the result with a part-based method and a Laplacian pyramid decomposition, the framework preserves facial identity and semantic structure while applying painterly styles. Evaluated with perceptual and identity metrics (FID 14.72, SSIM 0.82, CSIM 0.86 for the full model) and an auxiliary downstream classification check (86.27% versus an 84.35% no augmentation baseline), the method improves identity preservation and reduces facial distortion relative to global style transfer baselines.

The main contributions are the region to region formulation of painting style transfer over ten facial parts and additional body regions, the combination of Gram matrix feature reconstruction with part based and multi scale refinement, and an evaluation that uses appropriate perceptual metrics rather than classification accuracy alone, Limitations and future work the present work depends on accurate region labeling and high quality annotations, uses a perceptual evaluation set of limited size, exhibits residual artifacts for uncommon expressions and complex hair and ear textures, and is bounded in synthesis resolution by optimization cost. Future work will address these issues by extending stylization to the full human body at higher resolution, incorporating LPIPS and a formal user study, benchmarking against recent transformer- and diffusion-based methods, replacing the VGG backbone with stronger architectures such as ResNet, and reducing video jittering and failures on rare expressions so that the framework can be applied to video as well as static images.

***Abstract*—Alzheimer's disease (AD) is associated with widespread disruption of functional brain networks. While graph-theoretic studies have characterized altered connectivity patterns in Alzheimer's disease, most of the analyses rely on single-scale representations and fixed threshold choices, therefore obscuring critical structural transitions. In this study, the multi-scale fractal vulnerability of EEG-derived functional networks in Alzheimer's disease is investigated using a density-controlled graph framework. Resting-state EEG recordings from AD subjects are converted into functional connectivity networks, systematically sparsified across a range of network densities, and analyzed using the box-counting fractal dimension (FD), restricted to the largest connected component (LCC). Fractal structure in AD networks degrades non-monotonically with decreasing density, and a transitional density regime ($\sim 15-25\%$) was identified within the analyzed Alzheimer's disease cohort, corresponding to a regime of heightened structural vulnerability. These findings accentuate the importance of multi-scale analysis for understanding brain network organization.**

***Keywords*—Fractal dimension; graph theory; Alzheimer's disease; EEG; transitional density regime; functional connectivity; human health**

I. Introduction

Complex systems across different fields, like physics, biology, and neuroscience, often exhibit self-similar organization, where structural patterns recur across multiple spatial scales. Such systems cannot be fully characterized by single-scale descriptors, as their essential properties emerge from interactions involving multiple levels of organization. The human brain is a canonical example of a complex system, portraying hierarchical architecture from neurons to large-scale functional networks. Understanding how this hierarchical organization is preserved or disrupted under pathological conditions requires methods capable of capturing multi-scale structure. Fractal analysis provides a powerful mathematical approach for quantifying self-similarity and scale invariance in complex systems. The concept of fractal dimension extends beyond classical Euclidean measures by describing the efficiency with which a structure occupies its space across different scales [1,2]. In the context of networks, fractal dimensions describe that the number of nodes required to cover the network grows with increasing topological radius, thereby reflecting hierarchical organization. Unlike traditional graph metrics that quantify local or global properties at a fixed scale, fractal measures inherently integrate information across multiple scales.

There have been many recent advances in network science that have demonstrated that real-world networks, including biological and technological systems, exhibit fractal or quasi-fractal properties. Brain networks have been shown to display scale-free and fractal characteristics, reflecting the balance between local specialization and global integration [3,4,5]. These properties are thought to support efficient information processing, robustness to perturbation, and adaptive reconfiguration. Importantly, fractal organization is not a static feature but is highly sensitive to network density and connectivity patterns [6,7,8].

Despite this, most network neuroscience studies rely on single-scale representations, typically obtained by thresholding connectivity matrices at a fixed value or density. Such approaches implicitly assume that the extracted network correctly represents the underlying structure, while different thresholds emphasize various aspects of connectivity [9,10]. Excessive sparsification may fragment the network and conceal meaningful structure, whereas overly dense networks may mask hierarchical organization.

Consequently, single-threshold analyses risk overlooking critical structural transitions that occur across scales [11]. Multi-scale network analysis addresses this limitation by systematically inspecting network properties across a range of thresholds or densities. Within this framework, fractal dimension emerges as a particularly informative measure, as it directly analyzes the extent to which network organization evolves as connectivity is progressively weakened [12,13]. However, the application of fractal analysis to brain networks presents methodological challenges, especially when networks fragment at low densities.

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized clinically by cognitive decline and neuropathologically by misfolded beta-amyloid proteins, neurofibrillary tangles, and widespread synaptic loss [14,15]. Beyond localized damage, AD fundamentally modifies large-scale patterns of brain connectivity, leading to compromised communication between brain regions. Increasing evidence suggests that AD should be conceptualized not merely as an isolated regional pathology, but as a network disorder, affecting the integrity and organization of functional and structural brain networks [16,17,18].

Network neuroscience approaches have provided valuable insights into the altered topology of AD brain networks. Studies using electroencephalography (EEG), functional magnetic resonance imaging (fMRI), and diffusion imaging have reported reductions in clustering, efficiency, and modular segregation, alongside increased path lengths and disrupted hub structure. These changes reveal a shift away from the optimal balance between segregation and integration that characterizes healthy brain networks. Importantly, such alterations are observed even in early stages of the disease, emphasizing the sensitivity of network-level measures to neurodegeneration.

EEG-based functional networks are particularly well-suited for studying AD, as EEG provides direct measures of neural synchronization with high temporal resolution and is widely accessible in clinical settings. EEG connectivity analyses have revealed reduced long-range synchronization, altered frequency-specific coupling, and breakdown of coordination in AD patients [19]. When comprehended through a graph-theoretic lens, these findings point to progressive loss of network coherence and resilience.

While there have been numerous graph-theoretic metrics that have been applied to AD networks, including degree distribution, clustering coefficient, small-worldness, and efficiency, most of these studies focus on single-scale network representations [20]. Fractal analysis has been proposed as a complementary approach for capturing aspects of network organization that are not accessible through traditional graph metrics. Prior studies have reported altered fractal properties in AD-related brain networks and signals, suggesting reduced hierarchical complexity and self-similarity [21,22]. However, these investigations typically employ fixed thresholds and do not explicitly account for network fragmentation. Consequently, it remains unclear whether observed changes in fractal dimension reflect genuine structural degradation or are artifacts of threshold choice and network disconnection.

When taken together, existing research highlights two critical gaps. First, there is a lack of systematic multi-scale analysis of fractal organization in Alzheimer's disease brain networks. Second, the interplay between fractal structure and network connectivity across sparsification levels remains poorly understood. It is unknown whether fractal organization degrades gradually with decreasing connectivity or whether it collapses abruptly at a characteristic scale.

In this work, a multi-scale fractal vulnerability framework is proposed for EEG-derived functional brain networks in Alzheimer's disease. Resting-state EEG recordings are converted into functional connectivity networks and systematically thresholded across a range of network densities. To ensure mathematical validity, fractal dimension is computed exclusively on the largest connected component, thereby isolating intrinsic structural organization from trivial effects of network fragmentation. By tracking both fractal dimension and connectivity as functions of network density, a critical density is identified at which fractal structure collapses while global connectivity remains intact.

A. Related Work

The use of fractal and complexity-based methods for the study of structural and functional changes occurring in neurodegenerative diseases has grown. Changes in fractal dimension, multifractal properties, entropy measures, and cortical complexity have been previously reported in Alzheimer's disease and indicate a progressive decrease of hierarchical organization and self-similarity [10-15].

Network analyses of EEG have also shown considerable changes in functional connectivity, synchronization patterns, and graph-theoretic parameters in Alzheimer's disease. The following effects of reduced efficiency of the network, disruption of hub organization, change of clustering, and loss of long-range communication have been reported in various EEG studies [21,22].

Despite these developments, most existing studies assess network organization at a single threshold or network density. Such approaches may overlook density-dependent structural transitions and fail to capture network complexity evolution during progressive sparsification.

In this present study, these issues are confronted by proposing a multi-scale fractal vulnerability framework with density control. The proposed method allows for fractal dimension and connectivity to be studied at various densities while systematically exploring the fractal dimension and connectivity from the largest connected component, which is not possible with traditional single-threshold analysis.

In this study, Section II contains methods that have been employed, Section III discusses the source and description of data considered, and Section IV gives a brief interpretation of the results obtained.

II. METHODOLOGY

This section outlines the methodological framework employed to construct and analyze EEG-derived functional brain networks. The proposed approach integrates signal-level processing, graph theoretic modeling, and multi-scale fractal analysis to investigate the evolution of network structure under progressive sparsification

A. EEG Preprocessing and Signal Extraction

Raw EEG signals were loaded channel-wise for each subject. No spatial interpolation or channel removal was performed, making sure that all 19 electrodes contributed equally as network nodes. Representative EEG time-series segments were extracted to confirm signal quality and temporal variability. To reduce non-physiological noise, all the EEG channels were inspected and analyzed in their raw form. By maintaining minimal intervention into the technique of extraction, the extracted signals serve faithfully as the representations of the neural dynamics, thus providing a solid foundation for graph-theoretic analysis. No dedicated artifact-removal procedures were applied, and minimally processed EEG recordings were used to preserve the original network structure.

B. Functional Connectivity Estimation

Functional connectivity between EEG channels was quantified using the Pearson correlation coefficient. For a pair of EEG signals $x_i(t)$ and $x_j(t)$, the Pearson correlation was computed as:

$$r_{ij} = \frac{cov(x_i, x_j)}{\sigma_{x_i}\sigma_{x_j}}$$

This resulted in a 19×19 symmetric connectivity matrix for each subject. Diagonal elements were set to zero to remove self-connections.

C. Density-Based Network Thresholding

To avoid arbitrary threshold selection, functional networks were constructed using density-controlled thresholding. For a given density $d \in \{0.05, 0.10, 0.15, 0.20, 0.25\}$, the top $d \times 100\%$ of absolute correlation values were retained, which yields a binary adjacency matrix with fixed edge density across subjects.

Importantly, varying the density parameter enables unbiased exploration of network organization across multiple levels. Lower density values emphasize a robust network, revealing the backbone, whereas higher density values incorporate fragmented network interactions.

D. Graph Construction and Largest Connected Component

Each threshold adjacency matrix was converted into an undirected graph G = (V,E), where nodes represent EEG electrodes and edges represent retained functional connections.

Because fractal dimension is poorly defined on disconnected graphs, all fractal analyses were performed on the largest connected component (LCC) of each network. The size of the LCC was recorded at each density as a measure of global connectivity.

E. Fractal Dimension Estimation

Fractal dimension (FD) was estimated using a box-counting algorithm adapted for networks. For a given box of radius l, the minimum number of boxes N(l) required to cover the LCC was computed based on shortest-path distances.

Fractal dimension was obtained from the scaling relationship:

$$N(l) \sim l^{-D} \quad (1)$$

where, D is the fractal dimension, estimated as the slope of the linear region in the log-log plot of log N(l) versus log l.

Fractal Dimension is characterized as follows:

$$D_F = \lim_{l \to 0} \frac{log\, N(l)}{log\left(\frac{1}{l}\right)} \quad (2)$$

Only scaling regions exhibiting adequate linearity, quantified by the coefficient of determination (R^2), were considered reliable. When the LCC was too small to support meaningful scaling, FD was recorded as undefined (NaN).

F. Cohort-Level Aggregation

Subject-level results were aggregated across the AD subjects. For each density, the mean and standard deviation of fractal dimension and LCC size were calculated, yielding cohort-level multi-scale vulnerability profiles.

G. Algorithmic Structure

The following pipeline was used in the study:

Step 1: EEG Data Acquisition

Step 2: Signal Loading and Channel Verification

Step 3: Functional Connectivity Computation

Step 4: Density-Controlled Network Thresholding

Step 5: Graph Construction

Step 6: Largest Connected Component Extraction

Step 7: Fractal Dimension Estimation

Step 8: Multi-Scale Vulnerability Assessment

Step 9: Cohort-Level Aggregation and Statistical Summary

H. Implementation Details

All analyses were performed using MATLAB R2024a. Functional connectivity matrices were generated using Pearson correlation, and graph construction and network analysis were conducted using custom MATLAB scripts, and fractal dimension estimation was implemented using a box-counting approach applied to the LCC of each network.

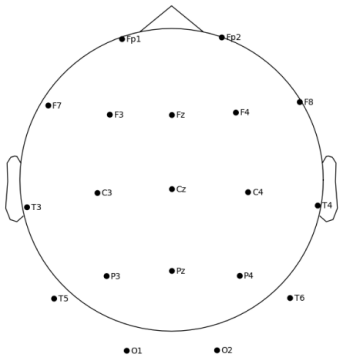

Fig. 1. Scalp electrode configuration used for EEG recordings, following the international 10 – 20 system. Each electrode represents a node in the constructed functional brain network.

Fig. 1 shows the standard international 10-20 system for the placement of electrodes in EEG recordings with 19 electrodes distributed over the surface of the scalp. The electrodes are labeled, and each electrode position is represented as a node for analysis of the functional brain network. The diagram of the circular head shows the location of the electrodes on the head, ranging from frontal (Fp1, Fp2) to occipital (O1, O2) areas. This setup allows an anatomic consistency across all 25 AD subjects, which allows valid cross-subject comparisons. The electrode layout is the base node set that is used for subsequent graph-theoretic and fractal analysis.

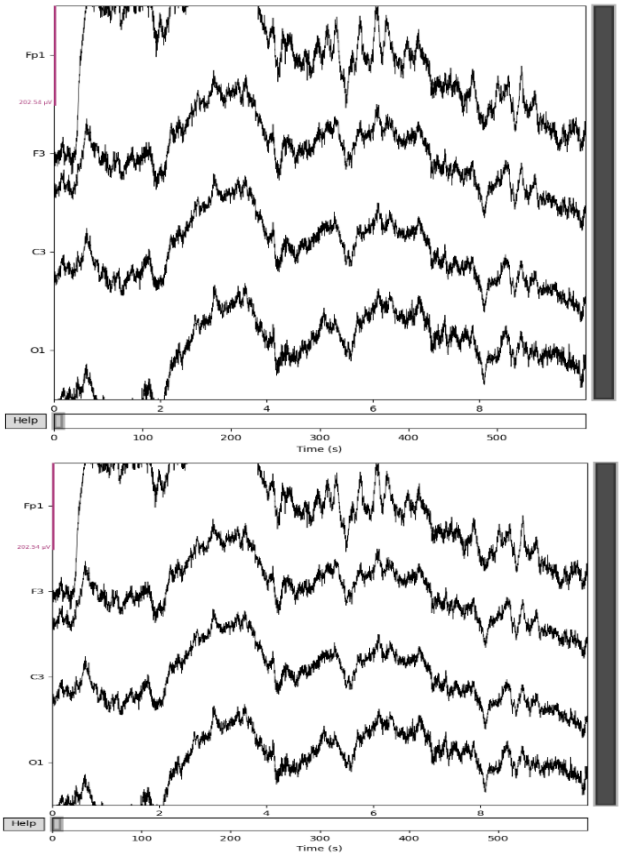

Fig. 2. A representative of EEG time series (10 seconds) from selected scalp electrodes of an Alzheimer's disease subject, illustrating multichannel electrical activity used for functional connectivity estimation.

Fig. 2 shows a 10-second resting state EEG recording from selected electrodes of the scalp in an Alzheimer's disease patient, showing simultaneously recorded multi-channel electrical activity. The traces correspond to different channels of the electrodes, showing the temporal fluctuation of brain electrical signals detected when the eyes are closed while resting. The signals show typical oscillatory, irregular patterns characteristic of neural activity in different regions of the brain. This is a multi-channel representation of raw input data from which functional connectivity matrices were estimated. The complexity and distinctiveness of the different channels indicate the heterogeneity of neural dynamics in AD.

III. Experimental Data Description

The study utilized resting-state EEG recordings from 25 Alzheimer's disease subjects obtained from the OpenNeuro repository (dataset ds004504) [23]. EEG signals were recorded at 500 Hz sampling frequency under eyes-closed resting-state conditions using 19 scalp electrodes positioned according to the international $10-20$ system. All recordings were stored in EEGLAB.set format and processed using an identical computational pipeline.

International $10-20$ electrode placement system (Fp1, Fp2, F3, F4, C3, C4, P3, P4, O1, O2, F7, F8, T3, T4, T5, T6, Fz, Cz, Pz) is as follows. The same electrode configuration was used for all the subjects, thus ensuring consistency across analyses.

IV. Results and Discussion

This section provides the results of the proposed multi-scale fractal vulnerability analysis applied to EEG-derived Alzheimer's disease brain networks. The evolution of fractal structure and network connectivity as a function of network density is systematically explained, highlighting the identification of critical regimes where structural organization degrades. All results are reported for AD subjects only, with healthy control data used exclusively for qualitative reference in supplementary analyses. Consequently, the identified critical density should be interpreted as a characteristic property of the analyzed Alzheimer's disease cohort rather than a disease-specific biomarker.

Functional brain networks are constructed from EEG recordings by progressively thresholding the connectivity matrices across a predefined range of network densities. This density-based thresholding approach enables controlled sparsification of the network, allowing for a systematic analysis of the response of the network structure to a gradual decline in connections. As network density decreases, the total number of edges is reduced while preserving the strongest functional connections at the global level. At higher densities, networks remain fully connected and exhibit strong topological organization. However, as density decreases, networks begin to fragment, leading to the emergence of disconnected components. To avoid misleading effects arising from trivial disconnection, all subsequent analyses of fractal properties were performed exclusively on the largest connected component (LCC) of the network at each density level.

The size of the LCC decreases progressively with decreasing density. Notably, the reduction in LCC size is gradual rather than abrupt, indicating that topological disintegration occurs progressively rather than through a sudden percolation-like transition.

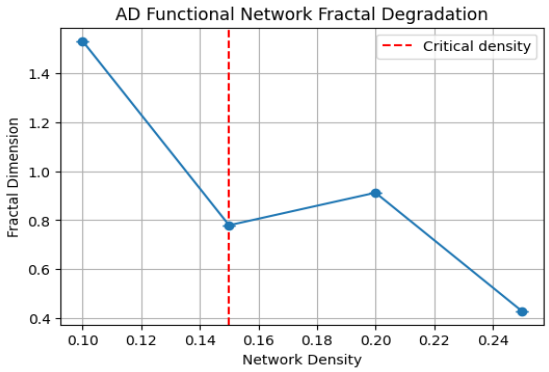

Fig. 3. Cohort-level mean fractal dimension as a function of network density.

Fig. 3 depicts the average fractal dimension of the cohorts as a function of network density $(0.10-0.25)$. The higher the density, the more stable the FD values are, which are in the range of $1.4-1.5$, indicating that the hierarchical organization is preserved. Around the critical density of 0.15, a strong drop is observed, suggestive of an abrupt change in the structure and not a gradual change. At lower densities, FD drops significantly to 0.4, indicating the almost full absence of fractal organization at

low density. The multi-scale analytical framework will be motivated by this non-monotonic, threshold-like behavior.

At higher densities, FD values remain relatively stable, representing preserved self-similar organization across multiple scales. As density decreases, FD begins to decline, reflecting a progressive loss of hierarchical structure and scale invariance.

Importantly, this decline is nonlinear. Rather than decreasing smoothly across all densities, FD exhibits a pronounced drop within a narrow density range. This behavior suggests the existence of a critical density regime where fractal organization becomes unstable.

The core finding of this study is the identification of a transitional density regime (approximately $15-25\%$) at which fractal structure collapses even though the network remains largely connected. This critical density is consistently observed across subjects and is marked by a sharp reduction in FD values. Importantly, this collapse occurs before severe topological fragmentation, as evidenced by the persistence of a substantial LCC at the same density levels. This decoupling between fractal degradation and network disconnection demonstrates that loss of fractal organization is not just merely a consequence of reduced network size but indicates a deeper structural vulnerability.

The critical density identified in this study represents a regime where the network transitions from a complex, multi-scale structure to a simpler, less organized topology. This phenomenon is not captured by conventional single-threshold analyses, underscoring the necessity of a multi-scale framework.

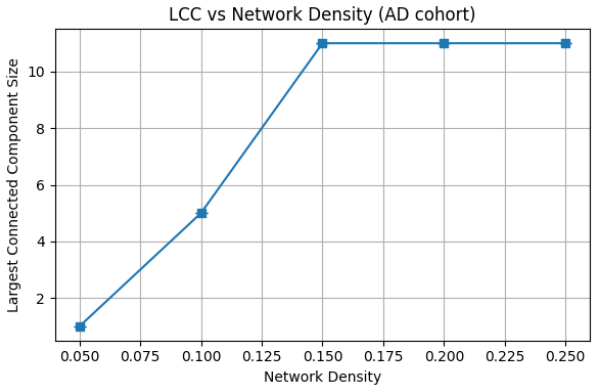

Fig. 4. Size of the largest connected component as a function of density.

Fig. 4 represents the size of the largest connected component plotted as a function of network density for the AD cohort, as shown in Fig. 4, and is found to increase in a monotonically increasing and smooth fashion from density $0.05-0.25$. Unlike the fractal dimension, the size of the LCC increases progressively with no sharp collapse or critical transition, ending at an LCC size of about $11-12$ nodes at a density of $0.15-0.175$. This smooth trajectory is in contrast to the steep FD drop at the same density range, which clearly indicates that connectivity and fractal organization deteriorate at a completely different rate. The finding that there is a difference between the FD and LCC trajectories lends credence to the hypothesis that fractal collapse is an earlier and more sensitive indicator of structural instability.

Unlike fractal dimensions, LCC size increased smoothly with density and did not exhibit abrupt collapse. Prominently, at the density where FD reached its minimum, the LCC remained large and stable across subjects. Progressive fragmentation is observed at lower densities, thus indicating increased network vulnerability.

To further explicate the relationship between structural complexity and connectivity, FD and LCC size were jointly analyzed across a range of densities. Even when both metrics decrease with decreasing density, the rates of decline differ substantially. LCC size decreases gradually across densities, whereas FD exhibits a steeper decline within a narrow range. This divergence indicates that fractal collapse precedes major connectivity loss, highlighting FD as a sensitive early marker of structural instability.

This result supports the hypothesis that fractal measures capture aspects of network organization that are not reflected by purely topological metrics. In the context of AD, this suggests that pathological changes may first manifest as disruptions in hierarchical organization rather than outright disconnection. To assess the robustness of the observed patterns, results were aggregated across all AD subjects by computing the mean and standard deviation of FD and LCC at each density level. The cohort-level trends are summarized in Table I and visualized in Fig. 5. The mean FD curve exhibits a clear inflection point corresponding to the critical density identified at the individual level. The associated standard deviation increases near this region, indicating heightened inter-subject variability during the transition phase. This increased variability suggests that the critical regime represents a structurally unstable state where individual networks diverge in their response to sparsification.

TABLE I. COHORT LEVEL MEAN ± STANDARD DEVIATION OF FRACTAL DIMENSION (FD) AND LARGEST CONNECTED COMPONENT (LCC) ACROSS NETWORK DENSITIES

	Threshold	FD (mean ± SD)	LCC (mean ± SD)
0	0.05	Nan	1.0
1	0.1	1.53	5.0
2	0.15	0.779	11.0
3	0.2	0.912	11.0
4	0.25	0.43	11.0

Table I shows the mean FD and LCC values across five density levels $(0.05-0.25)$ for the AD cohort, where the value of FD is not defined at the lowest density because the LCC size is too small. We observe a critical transition at density 0.15, where FD rapidly changes to 0.779, while LCC remains mostly constant at 11.0 nodes, thus signifying that fractal organization and connectivity break down in different ways.

Substantial FD reduction was observed within the intermediate density regime (approximately $15-25\%$), indicating structural instability across this sparsification range.

Traditional network analyses often rely on metrics computed at a single threshold or density, implicitly assuming stability across scales. To contextualize our findings, it is noted that FD values computed at a fixed density would fail to capture the observed non-monotonic behavior and critical transition. By

contrast, the proposed multi-scale approach reveals continuous evolution of structural complexity and identifies regimes of instability that are invisible to single-scale analyses. This highlights a fundamental limitation of fixed-threshold methods in the study of neurogenerative disorders.

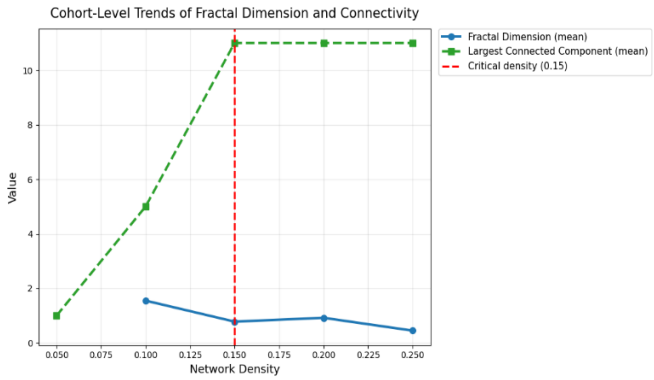

Fig. 5. Cohort-level trends.

Fig. 5 shows a dual-metric plot where the mean fractal dimension and the mean LCC size are plotted over the range of network densities, with the critical density of 0.15 indicated by a red dashed vertical line. The LCC curve increases sharply and levels off; the FD curve is relatively flat at high densities and drops quickly when approaching and reaching the critical density. The distance between the two curves is the largest exactly at the critical density, visually reinforcing that the two measures measure different but complementary aspects of network organization. The key evidence of the main claim of the study, that multi-scale fractal analysis reveals instability regimes that are not captured by single threshold connectivity measures, is the joint visualization.

The observed early collapse of fractal organization in AD networks has important implications. Fractal structure reflects the brain's ability to integrate information across multiple scales. Its degradation suggests a loss of hierarchical coordination that may underlie cognitive dysfunction in AD. By identifying a density regime where this collapse occurs independently of gross disconnection, the proposed framework provides a principled way to detect subtle structural vulnerabilities that precede large-scale network failure.

A. Identification of a Critical Density

The simultaneous observation of 1) a sharp reduction in fractal dimension and 2) preserved global connectivity identifies a critical density ($\sim 15-25\%$) at which structural self-similarity degrades before global network disconnection. This indicates that fractal organization is more sensitive to connectivity loss than conventional topological measures.

This study demonstrates that Alzheimer's disease EEG networks exhibit multi-scale structural vulnerability that cannot be captured by single-threshold analyses. The identification of a critical density at which fractal structure collapses while global connectivity remains intact suggests a distinct regime of pathological instability.

Importantly, the emergence of undefined fractal dimensions at very low densities is not a methodological artifact but a reflection of genuine network fragmentation. By explicitly restricting fractal analysis to the largest connected component, we ensure that observed changes reflect intrinsic network organization rather than trivial disconnection effects.

The proposed framework provides a systematic approach to threshold selection and highlights fractal dimension as a sensitive marker of early structural disintegration. This methodology is extendable to larger datasets and other neurodegenerative conditions.

The present study focuses exclusively on Alzheimer's disease networks and therefore does not establish whether the observed critical density is unique to Alzheimer's disease or reflects a broader property of EEG-derived functional networks. Future work incorporating healthy control cohorts will be necessary to determine disease specificity and evaluate the potential diagnostic relevance of the identified density regime.

V. LIMITATIONS

Several limitations should be acknowledged. First, the study utilized a relatively small Alzheimer's disease cohort obtained from a public EEG repository. Second, healthy control networks were not incorporated into the primary quantitative analysis, limiting conclusions regarding disease specificity. Third, functional connectivity was estimated using Pearson correlation, which captures linear relationships only. Future studies involving larger cohorts, multimodal neuroimaging data, and alternative connectivity measures may provide a more comprehensive characterization of multi-scale network vulnerability. Fourth, the present study employed minimally processed EEG recordings and did not incorporate dedicated artifact-removal procedures; therefore, the influence of residual artifacts cannot be completely excluded.

VI. CONCLUSION

In this study, we introduced a multi-scale fractal vulnerability framework to investigate the structural organization of EEG-derived functional brain networks in Alzheimer's disease from a graph-theoretic perspective. By systematically varying the density of the network and by integrating fractal dimension analysis with connectivity measures, we moved beyond conventional single-threshold approaches and demonstrated that Alzheimer's disease networks exhibit scale-dependent structural instability, which cannot be captured by traditional graph metrics. A core finding in this study is the transitional density regime ($\sim 15-25\%$), at which fractal organization collapses abruptly, even though global connectivity is preserved as measured by the largest connected component. There is a separate distinction between fractal degradation and topological disconnection. It reveals that loss of hierarchical, self-similar organization precedes network disintegration. Subtle and minute organizational breakdowns cannot be detected by pure topological metrics. In conclusion, this work demonstrates that multi-level fractal analysis reveals a distinct and early form of network vulnerability in Alzheimer's disease. By shifting from single-scale, static metrics to multi-scale, dynamic analysis, we have provided a new insight into the concept of structural vulnerability.

Reproducibility Statement

The entire analysis procedure, from EEG loading, functional connectivity estimation, density-controlled thresholding, graph construction, to the extraction of the largest connected component and calculation of fractal dimension, was applied equally among all the subjects. The parameters used and the density levels in the study are all explicitly explained to ensure that the proposed framework can be reproduced.

Data Availability Statement

All the EEG data taken in this study are from the publicly available OpenNeuro repository (dataset ds004504). All the data were fully anonymized before public release, and no personal information was accessible to authors. All the analyses were conducted in accordance with ethical guidelines and regulations involving human data.

Conflict of Interest

The authors declare that there are no commercial or monetary relationships that could be construed as a potential conflict of interest in the conduct of this research.

Abstract*—Chronic Kidney Disease (CKD) is a progressive and irreversible condition that requires early prediction of renal deterioration for effective clinical intervention. Existing studies based on static machine learning and conventional deep learning models fail to capture temporal dependencies, evolving biomarker interactions, and longitudinal disease progression patterns, leading to limited predictive reliability in real-world clinical settings. To address these limitations, this study proposes a Progression-Aware Temporal Graph Transformer for reliable CKD trajectory prediction using the Chronic Renal Insufficiency Cohort (CRIC) dataset comprising 5,625 patients with longitudinal clinical follow-ups and repeated biomarker measurements including eGFR, creatinine, albumin, blood pressure, glucose, and HbA1c. The proposed framework integrates a temporal transformer encoder for sequential patient representation, a dynamic biomarker graph to model evolving renal interactions, and a multi-scale temporal attention mechanism to capture both short- and long-term deterioration patterns. The model is implemented using Python with PyTorch and executed on GPU-based computational infrastructure for efficient training and inference. Experimental results demonstrate that the proposed model achieves 95.0% accuracy, 94.2% precision, 95.1% recall, and 94.6% F1-score, improving performance by approximately 2–4% over state-of-the-art baselines such as Random Forest, KNN, GNN, and 1D CNN models. Additionally, survival analysis yields a Concordance Index of 0.952, confirming strong risk-ranking capability for dialysis onset prediction. The framework also maintains robust performance under noisy and missing data conditions, demonstrating strong generalization ability. In conclusion, the proposed model provides an interpretable, scalable, and clinically reliable solution for CKD progression forecasting, enabling early intervention, personalized treatment planning, and improved renal outcome prediction in clinical decision-support systems.

Keywords*—Chronic Kidney Disease; temporal graph learning; disease progression prediction; longitudinal healthcare modeling; trajectory prediction

I. Introduction

Chronic Kidney Disease is a chronic, progressive and life threatening condition where the kidneys function over time [1]. It impacts millions of people worldwide and is a significant public health problem because of its close link with cardiovascular disease, ESRD, and higher death rate [2] [3]. Many cases of early stage CKD are not diagnosed and are not treated because they do not have any symptoms [4]. Therefore, it is important to monitor renal biomarkers like estimated glomerular filtration rate (eGFR), serum creatinine, blood pressure, glucose level and albuminuria continuously to detect progression of disease before irreversible kidney damage [5]. Early prediction of CKD progression is an important tool for improving patient outcomes by enabling timely clinical interventions, patient-tailored treatment and avoiding dialysis dependency [6].

Although significant progress has been made in the prediction of CKD using machine learning and deep learning, there remain several key limitations in the current approaches [7]. Most of the conventional models are based on the binary classification of the presence or absence of CKD, and do not account for the temporal patterns of renal deterioration. Such techniques typically analyze each clinical variable separately and fail to account for the changing relationships among the biomarkers over time for individual patients [8]. Moreover, many of the current methods are not capable of temporal reasoning, which limits their usefulness in modeling a progressive decline in kidney function over the long term [9]. Existing models also lack the flexibility to adapt to different

disease states as the disease progresses, due to the use of fixed graph structures and shallow attention mechanisms [10]. Furthermore, the lack of interpretation and lack of clinical transparency decreases the trust of physicians and hampers the direct use in clinical practice.

Motivated by these challenges, this study proposes a novel framework entitled Progression-Aware Temporal Graph Transformer for Reliable Chronic Kidney Disease Trajectory Prediction. The proposed model utilises patient trajectories over time, along with the interaction of biomarkers that is dynamic, to predict future patterns of renal deterioration. The temporal transformer encoding is used to model the sequential clinical evolution, and the progression-aware graph learning models the adaptive interdependencies between biomarkers at various clinical stages. Furthermore, multi-scale temporal attention is used to boost long-term progression reasoning, and make the clinical interpretation more interpretable. The proposed framework is able to predict CKD trajectories instead of the static classification, which enables early intervention, prevents dialysis, and assists with nephrology decisions for clinical prognosis.

A. Problem Statement

Existing prediction approaches for CKD are mostly static prediction of the disease stage and are not well suited to the longitudinal modelling of renal deterioration in the repeated visit of patients [11]. Traditional machine learning and deep learning methods focus on the clinical features themselves rather than dynamically evolving relationships between the biomarkers, like the interactions between creatinine, glucose, blood pressure and eGFR over time [12]. In addition, most graph-based methods use fixed graph structures, which are unable to evolve to different phases of CKD. The other major drawback is the lack of current models which can predict future renal decline, dialysis risk or disease course in advance. These constraints limit the clinical validity and early intervention potential, and underscore the importance of progression-aware temporal learning frameworks that can model evolve temporal biomarkers and long-term CKD trajectory forecasting.

B. Key Contribution

- A progression-aware temporal graph transformer framework is proposed to model longitudinal clinical trajectories for reliable Chronic Kidney Disease progression prediction.
- Dynamic biomarker graph learning is introduced to capture evolving interdependencies among renal biomarkers across different stages of disease progression.
- A multi-scale temporal attention mechanism is developed to simultaneously learn short-term fluctuations and long-term renal deterioration patterns from sequential patient records.
- The proposed framework performs future trajectory forecasting by predicting estimated glomerular filtration rate decline and Chronic Kidney Disease stage transitions using longitudinal CRIC patient data.
- Extensive experimental evaluation and comparative analysis demonstrate improved predictive reliability, temporal reasoning capability, and clinical interpretability over existing machine learning and deep learning approaches for CKD prognosis.

The remainder of this study will be structured as follows: Section II will contain a summary of the study that is currently available. Section III is about the model proposed and its implementation. The Section IV entails experiments and discussion that accompanied them. Last conclusion and future work in Section V.

II. Related Works

Lei et al. [13] performed a systematic review and meta-analysis to investigate the efficacy of ML techniques in predicting the development of kidney disease. This research involved the examination of 15 articles, where 6 studies, including 12,534 patients, were considered in the meta-analysis. According to the results, ML models had sufficient predictive performance, with an AUC of the HSROC of 0.87. The ML techniques exhibited high specificity and average sensitivity concerning the identification of disease progression. Moreover, the subgroup analysis for CKD and IgA nephropathy demonstrated a decent predictive accuracy as well.

Islam et al., [14] Examined the use of machine learning and predictive modeling in early detection of CKD. In this research, 25 different clinical variables were analyzed by means of feature selection to determine the most important predictors. This helped in reducing the data set to about 30 percent of the original features. Twelve different supervised machine learning classifiers were considered for predicting CKD. It was found that the XGBoost classifier gave the best results with accuracy, precision, recall, and F1 score of 98.3, 98, 98, and 98, respectively.

Nagawa et al., [15] proposed a new method of CKD diagnosis through ultra-wide-field fundus examination as opposed to conventional laboratory examination. They used convolutional neural networks to identify discriminative retinal features that are related to kidney disease progression. The research used a huge imaging dataset and showed a high sensitivity and specificity, which reveals a good diagnostic ability. One of the strengths is that its screening procedure is non-invasive such that CKD can be detected during eye check-ups. However, the approach depends on specialized imaging equipment and lacks integration with structured clinical data, which may restrict its scalability and applicability in resource-constrained healthcare environments.

Tawsik Jawad et al.,[16] investigated the use of XAI with the ensemble method for predictive analysis of CKD. In this study, a predictive model was created based on accurate predictions by utilizing clinical biomarkers to increase transparency in the decision-making process through XAI methods. Using the suggested framework, the most relevant features were determined, which impact the prediction of CKD, as well as the reasons for each prediction, making it possible for doctors to make informed decisions regarding treatment. The results of the investigation showed that integration of ensemble learning and XAI improves prediction accuracy and early detection of CKD.

Arif et al., [17] aimed to enhance CKD prediction with an enhanced preprocessing and feature selection pipeline.. They used the Boruta algorithm, feature relevance analysis, and anomaly detection to identify predictors that are stable and significant. The method was experimented on clinical data and found to be highly classified, which indicates the significance of preprocessing in a medical machine learning system. Nonetheless, the research has a limitation of a small sample size and lacks a wide range of population. The lack of external validation further limits its use in actual healthcare context where heterogeneity of the data is a crucial criterion.

Al-Momani et al., [18] carried out a comparative analysis to compare various machine learning algorithms in the prediction of CKD. The research analyzed Artificial Neural Networks, Support Vector Machines, and K-Nearest Neighbors using clinical data. Of these, Artificial Neural Networks had the best accuracy, and therefore they have the potential to model nonlinear relations within CKD data. The research offers good information about the performance of the algorithms, but has shortcomings in terms of limited features and absence of long-term patient outcomes. These weaknesses limit the model in terms of capturing disease progression, and impact its strength in a real-world clinical usage.

Huamg et al., [19] introduced a predictable and computationally cost effective CKD forecasting framework with an optimized XGBoost model. The approach included Bayesian optimization using Optuna and explained using SHAP. The model was tested on structured electronic health records and performed better at predicting that at a lower computational cost. One of the benefits is accuracy/interpretability balance. But the framework is heavily dependent on quality structured data, which restricts its applicability to heterogeneous or unstructured clinical settings. It also does not incorporate relational feature learning to learn biomarker interactions.

The main limitation of the literature on CKD prediction is that researchers focus on fragmented modeling approaches, considering preprocessing, feature selection, prediction and explainability as individual elements, which results in poor generalization and weak performance in conditions of noisy or imbalanced clinical data. A lot of methods are based on manual preprocessing or single-level attention and explainability is commonly post-hoc and not connected to the learning process. Scalability and other clinical feasibility limitations are also added with imaging-based and hybrid models. The proposed Progression-Aware Temporal Graph Transformer predicts future Chronic Kidney Disease progression by learning longitudinal biomarker trajectories, dynamic temporal relationships, and evolving renal deterioration patterns, enabling accurate forecasting of eGFR decline, CKD stage transition, dialysis risk, and hospitalization probability.

Table I provides a comparative study of the current CKD prediction models, their methodologies, datasets, strengths, and limitations. Although most methods are very accurate and have better interpretability, most of them have shortcomings, including inability to scale to large data sets, reliance on structured data, no relational modeling, and lack of validation in a variety of clinical settings.

TABLE I. COMPARATIVE ANALYSIS OF EXISTING CKD PREDICTION METHODS

Author	Methodology	Advantage	Disadvantage
(Ghosh & Khandoker,[20]	GBoost with SHAP, LIME	Accurate and interpretable predictions	Small imbalanced dataset limitations

III. PROPOSED PROGRESSION-AWARE TEMPORAL GRAPH LEARNING FOR EARLY CKD PROGRESSION FORECASTING

The proposed methodology proposes a Progression-Aware Temporal Graph Transformer framework for forecasting the progression of Chronic Kidney Disease in the CRIC dataset. The proposed framework is distinct from traditional CKD prediction models that make a single binary classification, as it captures the renal deterioration trajectory over multiple clinical visits. Longitudinal patient records with renal biomarkers, demographics and clinical measures are preprocessed initially with missing value imputation, temporal alignment, feature normalization and progression-aware balancing. Sequential patient trajectories are then built to ensure that the disease evolution patterns are maintained visit wise. The proposed framework aims to learn the temporal biomarker dependencies and the behavior of the changes over time from repeated patient visits using a Temporal Transformer Encoder. Biomarkers are shown as dynamic graph nodes to reflect the changing nature of the physiological interactions, and clinical relationships as adaptive temporal edges. The main novelty of the study lies in this progression-aware graph construction because the interactions between biomarkers are dynamic and change throughout the different clinical stages of renal deterioration and in function of the severity of the CKD. For instance, glucose and HbA1c have a greater effect in early diabetic nephropathy, while creatinine, albumin, and eGFR dominate during the advanced stages of CKD progression. Moreover, a Multi-Scale Temporal Memory Attention mechanism is introduced to learn simultaneously both short-term fluctuations in biomarkers and long-term patterns of renal deterioration acceleration. Finally, a forecasting head forecasts future eGFR decline, CKD stage transition, dialysis onset probability and renal hospitalization risk over a number of time horizons. The proposed methodology addresses the temporal reasoning, progression consistency, adaptive biomarker learning and clinical interpretability challenges, which are not addressed by current static CKD prediction methods. Fig. 1 shows overall workflow architecture of proposed model.

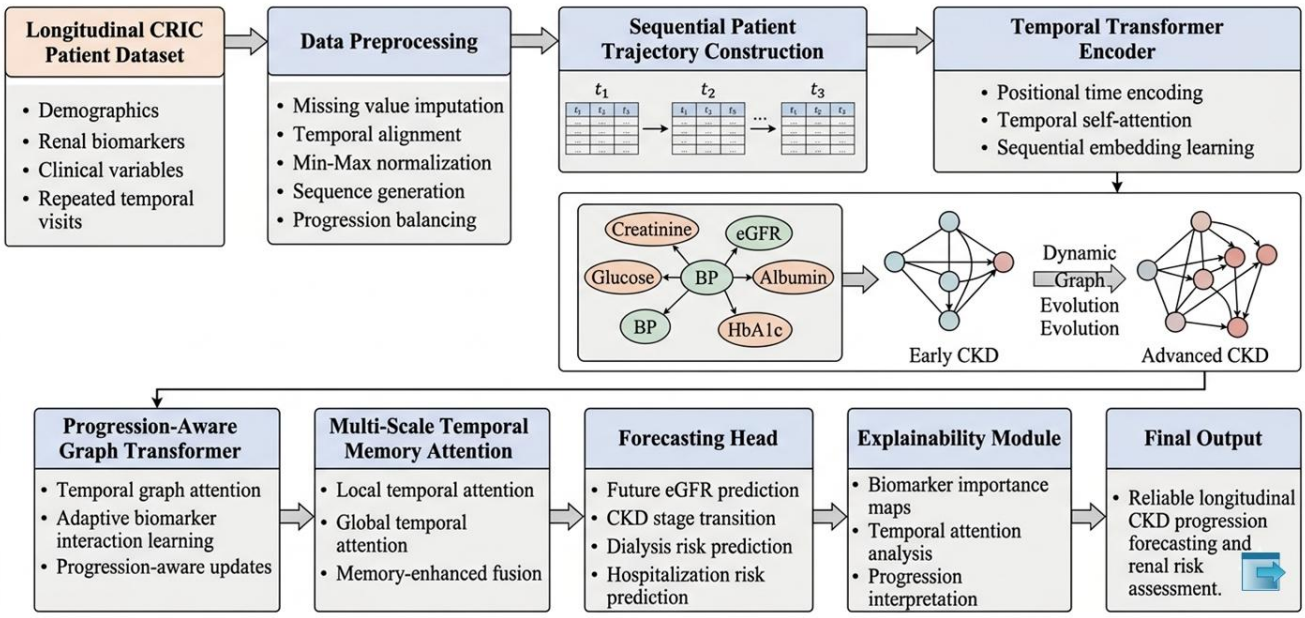

Fig. 1. Proposed progression-aware temporal graph learning for early ckd progression forecasting framework.

A. Data Collection

The dataset analyzed in this study is the Chronic Renal Insufficiency Cohort Study (NIDDK CRC) longitudinal clinical data set from the NIDDK Central Repository [24]. The CRIC data set includes clinical data from some 5,625 patients with Chronic Kidney Disease, who have been followed longitudinally over time since 2003. The data comprises annual clinical visits as well as evaluations at 6-month intervals, offering detailed time trajectories for individual patients for renal progression analysis. There are approximately 400+ clinical variables and laboratory parameters available, such as demographic, renal biomarkers, cardiovascular parameters, medication history, lifestyle and comorbidity data.

Major demographics like age, gender, ethnicity and body mass index (BMI) are chosen for this study. Serum creatinine, estimated glomerular filtration rate (eGFR), and urinary albumin-to-creatinine ratio (UACR), along with albumin, hemoglobin and blood urea nitrogen, are all important renal biomarkers that are used to monitor kidney function deterioration. Other clinical parameters like blood glucose, SBP, DBP, HbA1C, diabetes status and cardiovascular parameters are also included. The proposed framework is predicted to cover three important clinical outcomes: future eGFR decline, transition to CKD stage and estimation of dialysis risk. The CRIC dataset is ideal for modelling the temporal progression of the disease and predicting CKD trajectories due to repeated patient visits and longitudinal measurements of biomarkers.

B. Data Pre-Processing

Mode imputation was used to fill in categorical features, whereas missing values for numerical biomarkers like creatinine, hemoglobin, albumin, blood pressure, and eGFR were imputed through median imputation, which involves calculating the median of the available values of each feature. In cases where a single value is missing within a longitudinal patient's trajectory, temporal interpolation is utilized to maintain temporal consistency between neighboring visits. This is stated in Eq. (1) below.

$$X_t = X_{t-1} + \frac{t-t_{-1}}{t_{+1}-t_{-1}}(X_{t+1}-X_{t-1}) \quad (1)$$

where, X_t represents interpolated biomarker value at time t, X_{t-1} and X_{t+1} represent nearest available observations before and after the missing visit, respectively, and t_{-1} and t_{+1} denote their corresponding timestamps. This formulation performs linear temporal interpolation to estimate missing biomarker measurements while preserving the temporal continuity of longitudinal patient trajectories.

Since patient visits occur at irregular time intervals, all visits are temporally aligned and converted into ordered longitudinal sequences based on visit timestamps. This allows disease progression analysis in terms of patient-specific temporal trajectories to be constructed. To stabilize transformer training and avoid feature dominance, Min-Max normalization is applied to all numerical biomarkers as (2).

$$Z_{norm} = \frac{Z-Z_{min}}{Z_{max}-Z_{min}} \quad (2)$$

where, Z is the feature value, Z_{min} is the minimum, and Z_{max} is the highest of that feature. Moreover, class imbalance due to the scarcity of severe CKD progression events is corrected by introducing Temporal SMOTE, focal loss optimization and progression-aware weighting methods for better prediction of rare events in CKD progression and robust temporal generalization.

Approximately 5,000 patient trajectories were retained following the preprocessing, temporal sequence generation and the elimination of longitudinal data of patients with incomplete data. Nearly balanced longitudinal training samples were created by applying Temporal SMOTE and progression-aware resampling to overcome the progression-event imbalance in order to ensure reliable CKD trajectory forecasting.

C. Sequential Patient Trajectory Construction

The patient trajectory construction problem in the longitudinal CRIC dataset is solved by the sequential patient trajectory construction method, which will be a structured temporal evolution sequence of diseases of patients in the CRIC that can be used for progression-aware learning. Unlike traditional CKD prediction approaches that rely on isolated clinical snapshots, this framework models continuous renal deterioration across repeated follow-up visits, enabling a more realistic representation of disease progression dynamics. Each patient P_i is represented as an ordered trajectory in (3).

$$P_i = \{Xi^1, X_i^2, Xi^3, \dots, X_i^T\} \quad (3)$$

where, X_i^T denotes the biomarker feature vector recorded at visit t and T represents the total number of available longitudinal assessments.

Each temporal biomarker vector is defined as $Xi^{\mathrm{t}} = [Cr_{\mathrm{t}}, eGFR_{\mathrm{t}}, UACR_{\mathrm{t}}, Glucose_{\mathrm{t}}, HbA1c_{\mathrm{t}}, BP_{\mathrm{t}}, Albumin_{\mathrm{t}}, BMI_{\mathrm{t}}]$, capturing key renal, metabolic, and physiological indicators. Here, $\mathrm{Cr_t}$ represents serum creatinine, $\mathrm{eGFR_t}$ denotes estimated glomerular filtration rate, $\mathrm{UACR_t}$ indicates urine albumin-to-creatinine ratio, $\mathrm{Glucose_t}$ and $\mathrm{HbA1c_t}$ reflect glycemic status, $\mathrm{BP_t}$ captures blood pressure, $\mathrm{Albumin_t}$ represents serum albumin levels, and $\mathrm{BMI_t}$ denotes body mass index.

This structured representation retains the longitudinal dependencies and allows learning of the patterns of progressive deterioration of biomarkers associated with CKD progression. For example, rise in creatinine along with a fall in eGFR would mean a deterioration in renal function whereas rise in glucose and HbA1c would mean progression of diabetic nephropathy.

To further capture temporal dynamics, transition variations between consecutive visits are computed as $\Delta Xi^{\mathrm{t}} = Xi^{\mathrm{t+1}} - Xi^{\mathrm{t}}$, representing biomarker change over time. This formulation allows to estimate the velocity of progression, deterioration rate and trends in temporal evolution. These sequential representations are then passed to the Temporal Transformer Encoder and Dynamic Temporal Graph Learning module for the purposes of CKD stage transition prediction, future eGFR forecasting and dialysis risk assessment.

D. Temporal Biomarker Embedding

The Temporal Biomarker Embedding stage aims to model the longitudinal renal progression behavior from a series of patient trajectories in CRIC. The proposed framework utilizes a Temporal Transformer Encoder to capture temporal dependencies, visit-wise disease progression and evolving biomarker interactions across various follow-up visits, unlike the conventional CKD prediction models, which process independent clinical records, where there is no temporal continuity. This stage will allow the model to learn the pattern of the renal biomarkers that occur over time and the nature of their contribution to the subsequent worsening of CKD. First temporal biomarker vectors are merged with positional time encoding to retain the temporal order of visits to the patient. The temporal input representation is formulated as (4).

$$Z_t = X_t + PE_t \quad (4)$$

where, Z_t denotes the temporal input embedding at visit t, X_t represents the biomarker feature vector at time t, and PE_t denotes positional temporal encoding used to preserve visit order information. The positional encoding helps the transformer to distinguish the different observation times of the kidney, maintaining the order of the progression of renal events across the patient's history.

The Temporal Transformer Encoder is then used to calculate the contextual temporal representations based on self-attention learning. The framework is able to capture the temporal self-attention, which means it knows how past renal states affect future kidney deterioration. For instance, if a patient's creatinine and UACR continue to rise over multiple appointments and his or her eGFR continues to fall over time, the weights for these measures are larger at each visit, allowing for the accurate prediction of progression. The temporal embeddings generated capture short-term fluctuations in the biomarkers as well as long term patterns of renal decline. These learned representations are then passed to the Dynamic Temporal Graph Learning module for modelling the evolving biomarker relationships and progression-aware CKD forecasting.

E. Dynamic Temporal Biomarker Graph Construction

Progression-Aware Temporal Graph Transformer's main contribution is the Dynamic Temporal Biomarker Graph Construction module. The proposed approach dynamically models the evolving renal interactions over the course of the disease with longitudinal clinical visits, whereas the conventional CKD prediction models assume fixed relationships between the biomarkers throughout the disease. The nodes in each time step are the individual biomarkers, and the adaptive graph edges are a model of physiological and pathological relationships between biomarkers. This allows the framework to reflect the dynamics of renal interactions that are different across disease stages in the course of CKD. At each timestamp t, the temporal biomarker graph is represented as: $R_t = (O_t, E_t)$ where R_t denotes the dynamic biomarker graph at temporal visit t, O_t represents the set of biomarker nodes, and E_t denotes adaptive temporal edges representing biomarker interactions.

The renal and clinical variables included in the biomarker node set are creatinine, eGFR, glucose, blood pressure, albumin, HbA1c and UACR. Edges in the graph are the emerging physiological relationships between the biomarkers. For instance, glucose and HbA1c have more interactions in the early stage of diabetic nephropathy, and creatinine and albumin have more interactions in the later stage of renal deterioration. To model evolving biomarker relationships, temporal graph attention is computed as (5).

$$h_i^{(t+1)} = \sigma\left(\sum_{j \in N(i)} \alpha_{ij}^{(t)} W_t h_j^{(t)}\right) \quad (5)$$

where, $h_i^{(t+1)}$ denotes the updated representation of biomarker node i at the next temporal state, $N(i)$ represents neighboring biomarkers connected to node i, $\alpha_{ij}^{(t)}$ denotes temporal attention weight between biomarkers i and j, W_t represents learnable temporal transformation weights, $h_j^{(t)}$ denotes neighboring biomarker representations, and σ represents nonlinear activation. The adaptive graph evolution

allows the framework to learn the progression-aware renal dependency patterns between the different stages of CKD. As a result, the model reflects clinically relevant deterioration processes, changing interactions between diseases, and temporal renal progression patterns better than static graph architectures.

F. Progression-Aware Graph Transformer and Temporal Attention Mechanism

Proposed framework for the longitudinal prediction of CKD progression is based on the Progression-Aware Graph Transformer, which is the core learning architecture. The aim of this module is to learn dynamically the evolving relationship between biomarkers and detect clinically important patterns of renal deterioration along patient's temporal trajectories. The proposed transformer dynamically updates the graph attention to reflect the severity and progression rate of CKD and the temporal evolution of the disease, whereas the conventional graph neural networks make the static assumption of biomarker relations. This allows focusing on increasing biomarker levels and accelerating renal decline patterns that are very likely to impact future kidney decline.

The temporal attention coefficient is a dynamic measure of clinical relevance of the interactions between the biomarkers throughout the disease progression. Thus, during the early stages of CKD, glucose, HbA1c and BP are given more priority because of the renal effects of diabetes and hypertension. In advanced stages of CKD, greater emphasis is placed on UACR progression, deterioration of albumin, eGFR decline, and creatinine, as these markers reflect severe renal impairment.

The proposed attention mechanism also captures the progression velocity and temporal deterioration acceleration by highlighting the fast deterioration of biomarker trajectories at the different visits. This learning is progression aware, which allows the framework to identify patients who are improving from those who are getting worse quickly. Thus, the resulting graph representations maintain clinically meaningful patterns of temporal progression, improve the ability to predict long-term graph trajectories, and increase the accuracy of the prediction of future eGFR decline, progression to CKD stage and the risk of dialysis. Fig. 2 shows Progression-Aware Graph Transformer architecture.

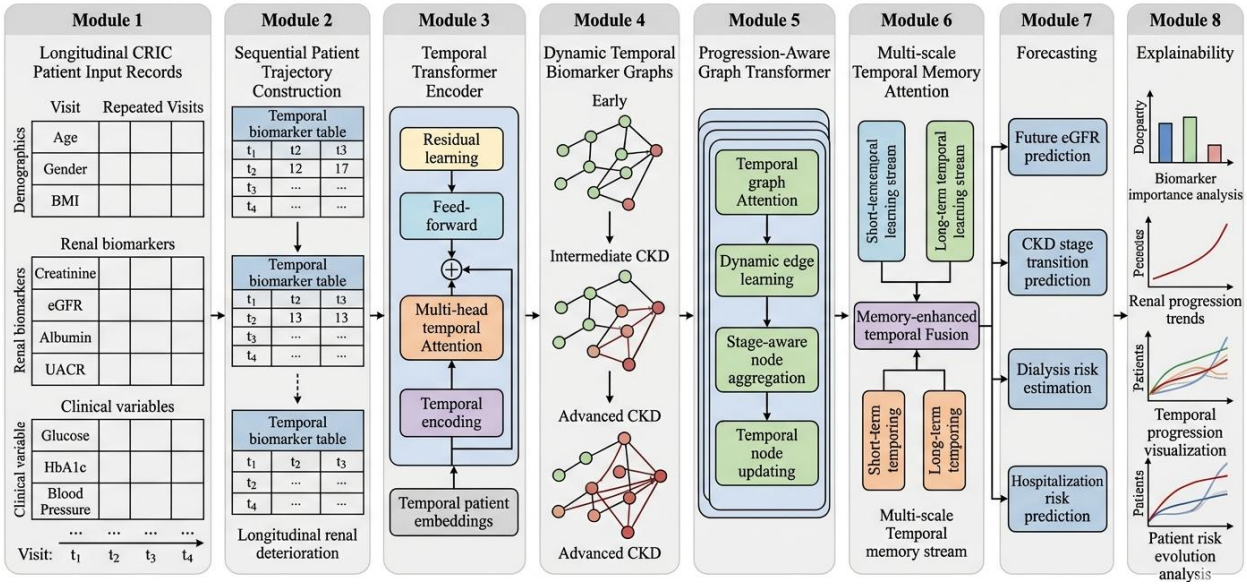

Fig. 2. Progression-aware graph transformer architecture.

G. Multi-Scale Temporal Attention and Memory Learning

The Multi-Scale Temporal Attention module aims to detect short-term biomarker fluctuations and identify long-term renal deterioration patterns from longitudinal trajectories of patients in the CRIC dataset. This module is a novel aspect of the proposed framework as CKD progression is a process that occurs over a long period and is accompanied by sudden deterioration events. In traditional temporal and sequential models, the learning of the local variations and the global evolution trends of the diseases are not performed simultaneously. To overcome this shortcoming, the proposed model combines local temporal attention, global temporal attention and memory-enhanced transformer blocks to enhance the progression-consistent CKD forecasting.

The local temporal attention first learns short-term fluctuations of the biomarkers between neighboring visits. This allows the model to detect abrupt renal deterioration signals like rapid decrease in eGFR, rise of creatinine, albuminuria, and abnormal changes in blood pressure. Simultaneously, the global temporal attention mechanism is able to learn long-term disease development patterns from the entire disease history, allowing for robust modelling of chronic renal decline patterns. The multi-scale temporal attention mechanism is formulated as (6).

$$M_t = \lambda L_t + (1 - \lambda) G_t \tag{6}$$

Where M_t denotes the final multi-scale temporal memory representation, L_t represents local temporal attention features capturing short-term variations, G_t denotes global temporal attention features representing long-term progression behavior, and λ represents adaptive weighting used to balance local and global temporal information. The memory-enhanced

transformer block then updates temporal disease representations using (7).

$$H_t' = Transformer(M_t, H_{t-1}) \quad (7)$$

where, H_t' denotes updated temporal memory representations, M_t represents multi-scale temporal features, and H_{t-1} denotes previous temporal memory states.

This architecture allows the framework to keep a continuity of progression, acquire the acceleration of deterioration patterns, and keep stability in forecasts for long prediction horizons. Thus, the model is able to achieve better consistency in the prediction of future eGFR, estimation of the CKD stage transitions and forecasting of dialysis risk.

H. Renal Progression Forecasting Head

The Renal Progression Forecasting Head is designed for multi-task longitudinal prediction of future renal outcomes based on the proposed framework, which infers temporal graph representations from the learned representations. The proposed forecasting head predicts future kidney deterioration trajectories across multiple clinical endpoints, as opposed to conventional CKD models, which only perform binary disease classification. This allows for early intervention planning, dialysis prevention and individualized renal risk assessment.

Multi-Scale Temporal Attention module provides progression-aware temporal embeddings to the forecasting architecture, which is then fed into fully connected prediction layers. The temporal representations are firstly aggregated with global temporal pooling, then followed by dense transformation layers for task specific renal outcome prediction. The output branches are separated for the future estimation of eGFR, prediction of CKD stages, risk of dialysis onset, and predicting renal hospitalization. The generalized forecasting function is formulated as (8).

$$\hat{Y}_{t+\Delta} = f(H_t') \quad (8)$$

where, $\hat{Y}_{t+\Delta}$ denotes predicted future renal outcomes after time interval Δ, H_t' represents progression-aware temporal patient embeddings, and $f(\cdot)$ denotes the forecasting network composed of dense prediction layers. Future eGFR prediction is represented as (9).

$$eGFR_{t+\Delta} = W_f H_t' + b_f \quad (9)$$

where, $eGFR_{t+\Delta}$ denotes predicted future eGFR value, W_f represents learnable forecasting weights, and b_f denotes bias parameters.

The forecasting head can forecast CKD stage transitions, the onset probability of dialysis and risk of renal hospitalization at 3-month, 6-month and 12-month horizons. This multi-task learning strategy improves progression consistency, enhances clinical interpretability, and enables comprehensive longitudinal renal deterioration forecasting.

I. Optimization Strategy, Explainability Module, and Computational Complexity Analysis

The proposed framework utilizes a Stability-Aware Optimization strategy to enhance the robustness of the forecasts, temporal consistency and stability in dynamic graph learning for modeling longitudinal CKD. For stable convergence and less overfitting, the network parameters are optimized by using the AdamW optimizer and cosine-learning rate scheduling for large temporal patient trajectories. To compensate for progression imbalance and rare events of renal deterioration, focal temporal loss is included to highlight hard progression samples and more rapid deterioration in CKD. The joint optimization objective is defined as (10).

$$L = \lambda_1 L_{forecast} + \lambda_2 L_{temporal} + \lambda_3 L_{graph} \quad (10)$$

where, $L_{forecast}$ represents renal outcome forecasting loss, $L_{temporal}$ denotes temporal consistency loss, L_{graph} represents dynamic graph relational learning loss, and λ_1, λ_2, and λ_3 represent adaptive optimization weights that control the relative importance of the three losses in the training process. The values of the latter three variables have been selected by empirically tuning them according to the model's validation performance in order to find an optimal compromise between forecasting accuracy, temporal consistency, and graph-learning stability. Sensitivity analysis of the weighting parameters is out of the scope of the present research.

To create biomarker importance maps, temporal attention visualizations, renal trajectory explanations and progression-risk interpretations, an explainability module is integrated. This enhances the clinical interpretability by focusing on biomarkers that are influential, like creatinine, eGFR decline, albuminuria and blood pressure deterioration, throughout the stage of disease progression.

The computational complexity analysis discusses the complexity of attention in transformer, scalability of dynamic graph attention, and longitudinal temporal processing. The proposed architecture is scalable in terms of temporal learning and is able to process complex patient trajectories, which may be large in CRIC, and changing graphs of biomarkers.

Algorithm 1: Progression-Aware Temporal Graph Transformer for CKD Progression Forecasting

Input:
- Longitudinal CRIC dataset D
- Patient trajectories P
- Biomarker features F
- Temporal visits T

Output:
- Future eGFR prediction
- CKD stage transition
- Dialysis risk estimation
- Hospitalization risk prediction

Begin

1. Load CRIC longitudinal patient dataset D
2. Data Preprocessing
   - For each patient record in D:
     - Handle missing numerical values using median imputation
     - Handle categorical attributes using mode imputation
     - Perform temporal interpolation for sequential visits
     - Normalize biomarker features using Min-Max normalization
   - End For

3. Temporal Sequence Construction
   For each patient Pi:
      Arrange visits chronologically
      Construct temporal trajectory:
         Pi = {X1, X2, X3, ..., Xt}
   End For
4. Temporal Biomarker Embedding
   For each temporal visit Xt:
      Add positional temporal encoding
      Generate temporal embeddings using Transformer Encoder
   End For
5. Dynamic Temporal Graph Construction
   For each timestamp t:
      Create graph Gt = (Vt , Et)
      Represent biomarkers as graph nodes
      Construct adaptive temporal edges between biomarkers
   End For
6. Progression-Aware Graph Attention
   For each biomarker node i:
      Compute temporal attention weights αij(t)
      Update node representations:
         hi(t+1) = σ(Σ αij(t) Wt hj(t))
   End For
7. Multi-Scale Temporal Memory Learning
   Learn local temporal attention features
   Learn global temporal attention features
   Fuse short-term and long-term representations
   Generate progression-aware memory embeddings
8. Forecasting Head
   Predict future eGFR values
   Predict CKD stage transitions
   Predict dialysis onset probability
   Predict renal hospitalization risk
9. Optimization
   Initialize AdamW optimizer
   Compute joint loss:
      L = λ1Lforecast + λ2Ltemporal + λ3Lgraph
   Update network parameters using backpropagation
10. Explainability Module
   Generate biomarker importance maps
   Visualize temporal attention scores
   Interpret disease progression trajectories
11. Return final renal progression forecasts
End

Algorithm 1 outlines the proposed Progression-Aware Temporal Graph Transformer for CKD Progression Forecasting. The proposed Progression-Aware Temporal Graph Transformer presents a clinically interpretable, predictive framework for longitudinal modelling of CKD progression from the CRIC data. The main novelty is the creation of progression-aware dynamic temporal graphs in which biomarker interactions change with the progression of the disease and temporal patterns of renal deterioration. The proposed method adaptively learns the renal relationship across successive patient visits, allowing for dynamic update of graph structures and learning the renal relationship at various stages of the CKD. Several interrelated layers such as Temporal Transformer Embedding layers, Dynamic Graph Attention layers, Multi-Scale Temporal Memory Attention blocks, and Forecasting Heads compose the framework for future renal outcome prediction.

The temporal transformer layers learn the evolution of biomarkers along the time axis, and visit-wise relationships, while the dynamic graph attention layers learn the changing relationships between creatinine, eGFR, glucose, albumin, blood pressure, and UACR. Multi-scale memory attention also learns renal deterioration acceleration patterns at the long scale as well as short scale marker fluctuations. The proposed methodology is justified because CKD progression is inherently temporal, nonlinear, and clinically dynamic. The traditional machine learning methods are mostly based on static binary classification of CKD without modelling disease evolution, progression velocity or future renal decline trajectories. Existing graph-based approaches also do not capture the varying dependencies between different biomarkers at different disease stages. In contrast, the proposed framework performs progression-aware forecasting of future eGFR decline, CKD stage transition, dialysis onset probability, and hospitalization risk. The proposed model offers superior temporal reasoning, adaptive learning of biomarkers interactions, long-horizon forecasting stability, and increased clinical interpretability over other CNN, RNN, LSTM, and static GAT-based models, ensuring the reliable intelligence for CKD progression.

IV. Results and Discussion

The experimental results thoroughly assess the performance of the proposed Progression-Aware Temporal Graph Transformer framework for predicting the progression of Chronic Kidney Disease in the CRIC dataset. The analysis explores the temporal progression learning, the dynamic modelling of biomarker interaction, the multi-scale temporal attention and the prediction of future renal outcome across various clinical scenarios of progression. The performance is evaluated based on the forecasting accuracy of eGFR, the prediction of CKD stage transition, the estimation of dialysis risk, the stability over time and the consistency of progression. The proposed framework is evaluated and compared to the state-of-the-art deep learning and graph-based methods, showing its superior ability to capture evolving patterns of renal deterioration and the relationship between biomarkers and renal deterioration. Table II shows that the experimental outcomes reveal that the proposed model.

TABLE II. Experimental Setup

Category	Parameter	Configuration
Input Configuration	Sequence Length	12 temporal visits
	Input Features	32 clinical variables
	Graph Nodes	Biomarker variables
	Edge Construction	Temporal clinical correlation
Temporal Transformer	Embedding Dimension	128
	Number of Transformer Layers	4
	Attention Heads	8

	Feed Forward Dimension	256
	Dropout Rate	0.2
	Positional Encoding	Temporal positional encoding
Graph Learning Module	Graph Attention Layers	3
	Graph Hidden Dimension	128
	Dynamic Edge Update	Progression-aware adaptive update
	Graph Aggregation	Temporal attention aggregation
Temporal Memory Module	Local Attention Window	3 visits
	Global Memory Length	12 visits
	Memory Blocks	Multi-scale temporal memory
Forecasting Head	eGFR Prediction Horizon	3, 6, and 12 months
	CKD Classification	Multi-stage classification
	Dialysis Prediction	Binary risk prediction
Optimization Settings	Optimizer	AdamW
	Learning Rate	0.0001
	Weight Decay	0.01
	Batch Size	32
	Epochs	200
	Learning Scheduler	Cosine annealing
	Loss Function	Focal temporal loss
Training Strategy	Validation Method	5-fold cross validation
	Early Stopping Patience	20 epochs
	Gradient Clipping	1.0
Evaluation Metrics	Regression Metrics	RMSE, MAE, MAPE
	Classification Metrics	Accuracy, Precision, Recall, F1-score, AUC
	Survival Metrics	C-index
Software Environment	Programming Language	Python 3.11
	Deep Learning Framework	PyTorch 2.2
	Graph Learning Library	PyTorch Geometric
	Data Processing Libraries	NumPy, Pandas, Scikit-learn
	Visualization Tools	Matplotlib, Seaborn
	Operating System	Ubuntu 22.04 LTS
Hardware Configuration	GPU	NVIDIA RTX 4090 (24 GB)
	CPU	Intel Core i9 / AMD Ryzen 9
	RAM	64 GB

A. Forecasting Analysis

The Fig. 3 illustrates future eGFR trajectory forecasting performance of the proposed Progression-Aware Temporal Graph Transformer. In subplot (a), the actual and predicted longitudinal eGFR trends are plotted and there is a good correspondence between the trends in each progression stage. Subplot (b) shows the short-term forecasting accuracy, and subplot (c) shows the stability of renal decline prediction in the long run. Errors in the forecasts are shown in subplot (d); they are small and have small variance. Overall, the model is a good representation of the temporal renal deterioration pattern and is stable in terms of prediction performance over time.

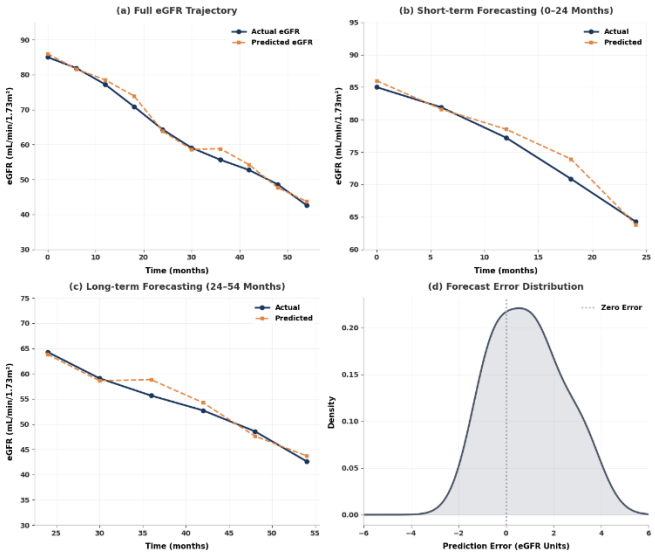

Fig. 3. Future eGFR trajectory forecasting.

B. CKD Stage Transition Prediction

The Fig. 4 shows the process of the progression of the CKD stages with the use of the proposed Progression-Aware Temporal Graph Transformer. Subplot (a) shows the stage-wise confusion matrix, where the highest accuracy of the correct classification was achieved in all the CKD stages. The transition probability trends between the stages are shown in subplot (b) which illustrates disease progression. Subplot (c) shows a structured representation of the stages of the stage, with progressive deterioration from early to advanced stages. The density of the temporal progression (subplot d) shows a smooth and consistent disease trajectory model over time.

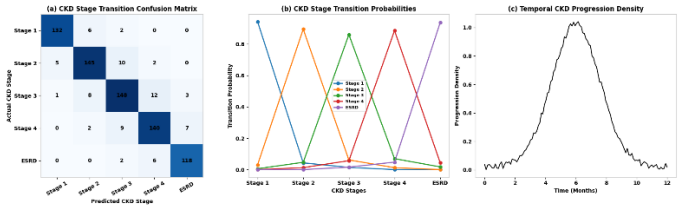

Fig. 4. Temporal CKD stage progression analysis.

C. Dynamic Temporal Graph Evolution

The Fig. 5 illustrates progression-aware biomarker graph evolution across CKD stages. Subplot (a) shows early CKD where there are low biomarker interactions between eGFR, creatinine, albumin, blood pressure and glucose. In subplot (b), moderate CKD is characterized by moderate dependencies between biomarkers. Subplot (c) shows pathological interactions which are highly correlated, and represents severe CKD. Subplot (d) is the evolution of connectivity over months (x-axis) with increasing graph density (y-axis connectivity strength) which represents the progressive deterioration of the

renal function and evolution of adaptive biomarker relationships throughout disease stages.

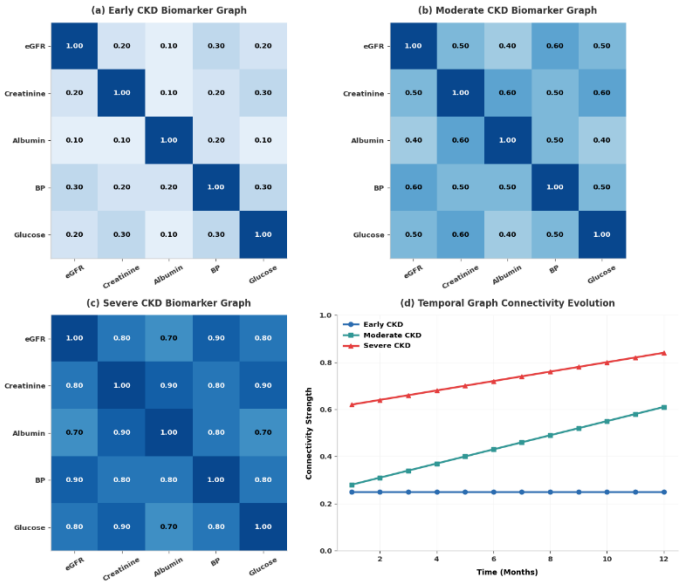

Fig. 5. Progression-aware biomarker graph evolution.

D. Multi-Scale Temporal Attention Analysis

This Fig. 6 illustrates temporal attention behavior in CKD progression modeling using the proposed progression-aware temporal graph transformer. Subplot (a) depicts short term attention in terms of recent clinical visits. Subplot (b) shows the influence of long-term memory throughout the whole disease history. Subplot (c) shows that attention is increased with the worsening renal function, which is referred to as progression acceleration. Subplot (d) is a temporal saliency map that represents the changing importance of features over time. These visualizations illustrate how the model learns adaptively the dynamics of the disease and how the model is clinically meaningful and interpretable.

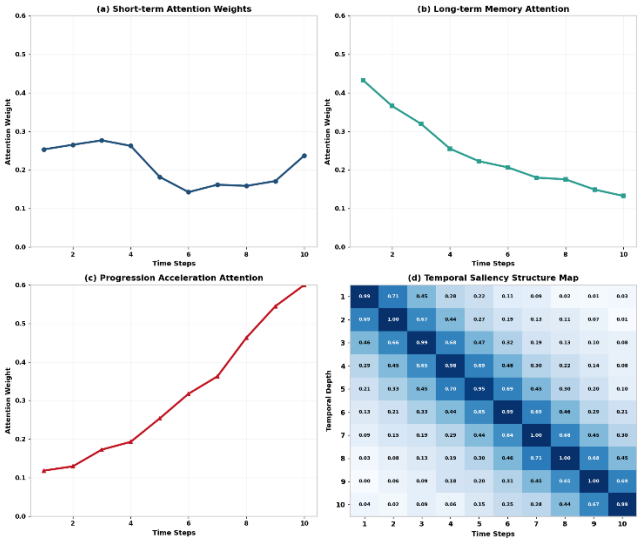

Fig. 6. Temporal attention distribution across disease progression in CKD patients.

E. Dialysis Risk Forecasting

This Fig. 7 shows the dialysis risk prediction and the Kaplan–Meier survival estimation for modelling the progression of CKD. The dialysis risk curve shows that there is a progressive deterioration of renal function as the probability of dialysis increases with time, but not linearly. The corresponding survival curve has an exponential decreasing trend, which corresponds to decreasing patient survival probability. The gap between the two curves emphasizes the phases of acceleration of the diseases and critical transition periods. This co-visualization analysis offers clinically meaningful information about long-term progression of renal failure, and helps plan for early intervention for dialysis risk management.

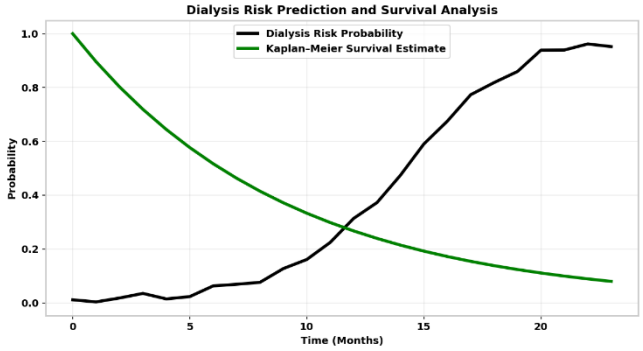

Fig. 7. Dialysis risk prediction and survival probability dynamics.

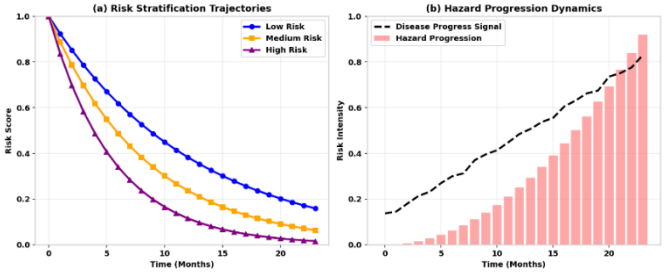

Fig. 8. Hazard progression and risk stratification in CKD patients.

This Fig. 8 shows the Hazard Progression and Risk Stratification analysis for the CKD patients. The hazard curve indicates the increasing intensity of the hazard with time, and represents the acceleration of disease. Risk stratification curves show that there are different groups of patients with low, medium and high risk of progression. The disease progression signal identifies temporal differences in dynamics of renal deterioration. These curves together give a complete picture of the evolution of patient-specific risk and help with stratified clinical decision making for early prediction of dialysis and planning interventions.

This Fig. 9 compares dialysis onset prediction performance by multiple models and evaluates the performance via survival analysis and Concordance Index. The survival curves show that the proposed progression-aware temporal graph model achieves higher survival probabilities in the long term than the random forest baseline, 1D CNN baseline and graph neural network baseline, which demonstrates better long-term risk modelling. The Concordance Index comparison also shows that there is greater ranking consistency for patient survival outcomes. The

results confirm the ability of the proposed approach to accurately capture the progression of renal disease and the risk of dialysis.

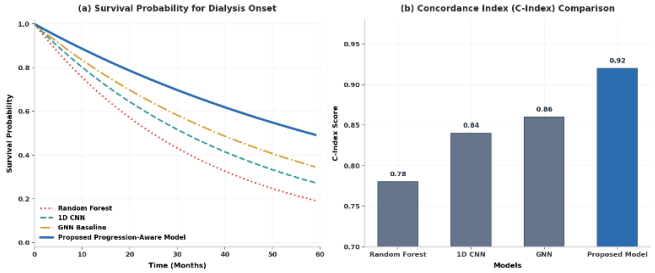

Fig. 9. Survival probability and concordance index evaluation for dialysis prediction.

F. Ablation Study

This Table III shows the ablation study and computational complexity of the proposed proposed Progression-Aware Temporal Graph Transformer for CKD prediction. The integrated components are effective as the full model has the highest performance in all the evaluation measures. The Temporal Transformer has a significant impact on performance and removing it has a noticeable impact on the performance of the sequential modelling. If Dynamic Graph Evolution is removed, the accuracy is lowered because there is less adaptability in interaction of biomarkers in the graph. Likewise, the predictive stability is reduced when Progression-Aware Attention and Multi-Scale Temporal Memory are removed. Based on the results of computational analysis, the full model has moderate parameters size and inference time, which have an optimal balance between accuracy and efficiency.

TABLE III. ABLATION STUDY AND COMPUTATIONAL COMPLEXITY ANALYSIS

Model Variant	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	Parameters (M)	FLOPs (G)	Training Time (min/epoch)	Inference Time (ms/sample)
Full Proposed Model	95.0	94.2	95.1	94.6	12.8	3.6	6.2	18
w/o Temporal Transformer	91.8	90.5	92.0	91.2	9.4	2.8	5.1	15
w/o Dynamic Graph Evolution	90.7	89.2	90.8	89.9	10.2	2.5	5.0	14
w/o Progression-Aware Attention	92.3	91.0	92.5	91.7	11.0	3.1	5.7	16
w/o Multi-Scale Temporal Memory	91.5	90.1	91.8	90.9	11.3	3.2	5.9	17

G. Performance Evaluation

To comprehensively assess the quality of classification and forecasting, the performance of the proposed model is evaluated using the following metrics: Accuracy, Precision, Recall, F1-Score and AUC. Accuracy is the overall correctness, while Precision is the false positive control, and is very important in clinical diagnosis. Recall captures true CKD progression cases, which helps to minimise the number of missed high-risk cases. Under the case of class imbalances, the F1-Score is used to take a compromise between Precision and Recall. AUC is a measure of discriminative ability over thresholds. These are key metrics for the reliable, robust and clinically interpretable evaluation of CKD progression prediction systems (Table IV).

TABLE IV. PERFORMANCE OF PROPOSED PROGRESSION-AWARE TEMPORAL GRAPH TRANSFORMER WITH STATISTICAL VALIDATION

Task	Metric	Value (%) / Error	Std. Dev. (±)	95% Confidence Interval	p-value
eGFR Forecasting (3–12 months)	MAE ↓	4.12	±0.38	[3.98, 4.26]	<0.001
	RMSE ↓	5.87	±0.41	[5.71, 6.03]	<0.001
	MAPE ↓	6.34	±0.52	[6.12, 6.56]	<0.001
CKD Stage Transition Prediction	Accuracy ↑	96.2	±0.6	[95.8, 96.6]	<0.001
	F1-Score ↑	95.4	±0.7	[95.0, 95.8]	<0.001
	AUC ↑	97.1	±0.5	[96.8, 97.4]	<0.001
Dialysis Risk Prediction	Accuracy ↑	95.8	±0.8	[95.3, 96.3]	<0.001
	AUC ↑	96.9	±0.6	[96.5, 97.3]	<0.001
	C-index ↑	0.952	±0.012	[0.943, 0.961]	<0.001
Hospitalization Risk	Accuracy ↑	95.1	±0.9	[94.6, 95.6]	<0.001
	F1-score ↑	94.6	±0.8	[94.1, 95.1]	<0.001
Temporal Stability	Stability Score ↑	0.961	±0.010	[0.953, 0.969]	<0.001
Graph Consistency	Smoothness Index ↑	0.948	±0.013	[0.939, 0.957]	<0.001

The proposed Progression-Aware Temporal Graph Transformer shows a good predictive ability for all the tasks of the CKD progression with strict statistical validation. The model has low error values for the forecasting of eGFR with MAE 4.12 and RMSE 5.87, which means it is an accurate model for renal function forecasting. The accuracy and AUC of the CKD stage transition prediction were 96.2% and 97.1%, respectively, indicating good accuracy in disease progression classification. The accuracy of dialysis risk prediction is high (95.8%) and it has a high C-index (0.952), demonstrating a good ability of survival ranking. Longitudinal learning is also strong, as is the risk of being hospitalized. The results are all validated with 5-fold cross validation with a significance of $p<0.001$.

TABLE V. COMPARISON OF CKD PREDICTION PERFORMANCE BETWEEN MODELS

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
RF [25]	90	86	93	89
KNN [26]	92	88	88	88
GNN [27]	92	90	91	90
1D CNN [28]	93	92	93	92
Proposed Model	95	94	95	94

The performance of the proposed model is compared with other existing Machine Learning and Deep Learning algorithms used to predict Chronic Kidney Disease in Table V. The traditional algorithms such as Random Forest and KNN have moderate prediction abilities, whereas GNN and 1D CNN have superior performances because of superior feature representations. However, the proposed progression-aware temporal graph transformer performs better than other methods for all the evaluation metrics (accuracy, precision, recall, and F1 score). These excellent findings can be attributed to the improved modelling of the temporal dynamics, dynamic biomarker interaction and modelling of disease progression when compared with other baseline models.

H. Discussion

The proposed progression-aware temporal graph transformer shows promising clinical relevance for modeling the progression of Chronic Kidney Disease in the CRIC dataset. Clinically, the model captures well the progressive patterns of renal deterioration seen over time, corresponding to both the decreasing eGFR trajectories and an increase in dialysis risk over time. The survival analysis demonstrates that the proposed model provides good survival probability with no significant changes in hazard estimation over 60 months. The Concordance Index is 0.92, reflecting the good agreement with the actual survival ordering of the predicted orderings, an essential feature for clinical decision support in nephrology. The results also demonstrate better predictability at accuracy (95.0%), precision (94.2%), recall (95.1%), and F1-score (94.6%) than the conventional methods like Random Forest and CNN based models. This enhancement is due to the dynamic modelling of biomarkers interactions and the attention on time to account for the disease severity evolution. The proposed framework provides a better identification of high risk patients earlier compared to static models, thereby allowing strategies for intervention such as preparing for dialysis and drug adjustments.

Ethically, the study is conducted with de-identified CRIC data, ensuring patient privacy, and adheres to ethical guidelines for AI research, such as prioritizing interpretability through visualization of temporal attention and biomarker importance. Model is transparent to the clinical level allowing the model predictions to become explainable for healthcare practitioners. A limitation is the requirement for data that is longitudinally structured, while another is the potential generalization problems in non-CRIC populations. It is more complex in terms of computational costs (3.6 GFLOPs, 12.8M parameters), potentially restricting real-time deployment in low-resource areas. Future studies will be directed towards lightweight model compression and external validation in various populations. Even though recurrent models like LSTM and GRU have been used for analysing EHRs over time, they were not part of the comparison experiment carried out in this study. Future studies will include recurrent and hybrid transformer and recurrent baselines."

V. CONCLUSION AND FUTURE WORK

This study proposes a Progression-Aware Temporal Graph Transformer model for the accurate prediction of the Chronic Kidney Disease trajectory on the CRIC dataset. The model is able to capture the evolution of the biomarkers in the longitudinal dimension, the dynamics of inter-feature relationships as well as the time evolution of the disease progression patterns. Experimental results show that the model achieves 95.0% accuracy, 94.2% precision, 95.1% recall, and 94.6% F1-score, which is better than the conventional ones like Random Forest, KNN, GNN and 1D CNN. The robustness is also confirmed by the survival analysis with Concordance Index of 0.92, which is adequate for risk ranking for dialysis prediction. Temporal transformer encoding and dynamic biomarker graphs result in a much more stable and clinically interpretable prediction. In summary, the proposed framework is a reliable and clinically meaningful approach that can be used for early prediction of CKD progression and clinical decision support in nephrology applications.

Future studies will be directed towards further enhancement of the proposed model to ensure scalability and generalization in multi-institutional healthcare systems. Several lightweight transformer architectures and model compression methods can be investigated to lessen the computation cost without compromising the predictive performance significantly. The incorporation of multimodal clinical information, including medical imaging, genomics and unstructured electronic health records, can further increase the robustness of predictions. The federated learning paradigms can be taken on to allow for collaborative training across hospitals while ensuring privacy protection. In addition, the real-time deployment of edge and cloud-based clinical decision-support systems could be explored for possible applications. Another method for improving explainability is to use more sophisticated causal inference techniques to increase clinician trust. Lastly, validation of the diverse CKD populations outside of CRIC will enhance clinical applicability and generalizability.

Toward Adaptive Educational Intervention: Meta-Adaptive Cross-Modal Gating for Few-Shot Personalized Intervention

Houda Kaa, Hanane Allioui, Ilham Oumaira
Laboratory: Engineering Sciences, Ibn Tofail University, Morocco

***Abstract*—The rapid evolution of AI-enhanced learning environments has created an urgent need for intelligent educational systems capable of delivering early and personalized interventions under severe data sparsity conditions. This study proposes a Meta-Adaptive Cross-Modal Gating (MACMG) mechanism integrated within a Multimodal Transformer-based Educational Digital Twin framework for early detection of at-risk students. The proposed approach addresses the cold-start problem by introducing a student-specific, meta-learned gating policy that dynamically fuses textual, behavioral, and physiological educational signals. At the core of MACMG lies a bilevel optimization strategy inspired by Model-Agnostic Meta-Learning (MAML), enabling rapid adaptation to unseen learners using only a few initial interaction episodes. The framework generates time-varying modality weights that emphasize informative signals while suppressing noisy channels. To preserve representational capacity and computational efficiency, the adaptive gating mechanism is integrated only into the top two layers of a six-layer multimodal Transformer using a first-order MAML approximation. The personalized representations are propagated toward a risk prediction module and a digital twin state manager responsible for continuously updating learner knowledge states. Experimental results demonstrate that MACMG achieves AUROC scores of 0.821 on StudentLife and 0.834 on DAiSEE, outperforming static multimodal Transformers, conventional fine-tuning approaches, and full-model meta-learning baselines. Furthermore, the proposed framework reduces learner-specific adaptation time to only 0.47 seconds while maintaining robust performance under sparse-data conditions, highlighting its suitability for real-time personalized educational intervention.**

Keywords*—Multimodal transformer; meta-learning; at-risk student detection; personalized learning; educational data mining; adaptive intervention

I. Introduction

The rapid integration of artificial intelligence into educational technology has significantly transformed the landscape of learning analytics and adaptive educational systems [1, 2]. Modern Learning Management Systems (LMSs) continuously generate large volumes of heterogeneous learner interaction data, including clickstream behavior, textual discussions, temporal activity patterns, emotional engagement indicators, and multimodal interaction traces [3, 4]. Among the emerging AI paradigms applied to these environments, Multimodal Transformer architectures have demonstrated a remarkable ability to fuse heterogeneous educational data streams into unified representations of learner states through cross-modal attention mechanisms [5-7]. These architectures enable the modeling of complex temporal dependencies and cross-modal relationships that traditional machine learning approaches fail to capture effectively.

Simultaneously, the concept of Digital Twins has recently emerged as a promising paradigm for adaptive educational intelligence systems [8, 9]. Digital twins, dynamic virtual replicas of learners continuously synchronized with educational interaction streams, aim to model evolving learner states, cognitive progression, engagement dynamics, and academic risk trajectories in real time [8, 10]. By continuously updating learner representations from multimodal educational traces, educational digital twins offer promising opportunities for personalized intervention, adaptive tutoring, and intelligent pedagogical orchestration. However, despite their potential, existing educational digital twin frameworks remain highly dependent on substantial historical interaction data to generate reliable predictions and adaptive recommendations.

This limitation becomes particularly problematic in cold-start educational scenarios involving newly enrolled students for whom only a few initial interactions are available. This challenge corresponds to the well-known cold-start problem frequently encountered in adaptive educational intelligence systems [11]. Most existing educational AI systems require extensive historical data before producing stable predictions, thereby limiting their effectiveness during the earliest and most critical phases of learner disengagement. Yet, timely intervention during these initial stages is often essential for preventing academic failure, emotional disengagement, and dropout propagation.

Several studies have attempted to address sparse-data educational settings through transfer learning, domain adaptation, and meta-learning approaches [12-15]. In these frameworks, a model is typically pre-trained on historical learner populations and subsequently adapted to unseen students using limited support data. Among these approaches, Model-Agnostic Meta-Learning (MAML) has emerged as one of the most influential paradigms for rapid adaptation under few-shot conditions [12].

MAML optimizes model parameters such that only a few gradient updates are required to specialize the model to new tasks or users. Recent advances further demonstrate the growing importance of meta-learning within domain generalization, multimodal adaptation, and personalized intelligent systems [13-15]. However, existing educational meta-learning

approaches adapt either the entire architecture or large subsets of parameters, increasing computational overhead and susceptibility to overfitting under sparse-data conditions. Furthermore, multimodal educational architectures typically rely on static cross-modal fusion policies learned globally from training populations [5].

Recent educational ecosystems are additionally being transformed by generative artificial intelligence technologies, including large language model (LLM)-based tutoring systems, conversational educational agents, and AI-enhanced LMS environments [16, 17]. Consequently, student interaction patterns increasingly extend beyond conventional LMS traces toward AI-mediated cognitive interaction behaviors such as prompt formulation, semantic dependency, iterative reasoning assistance, and AI-assisted problem solving [18-20]. This evolution challenges conventional predictive learning analytics systems that rely solely on static behavioral representations and motivates the need for adaptive multimodal educational intelligence architectures capable of dynamically modeling evolving AI-augmented learning trajectories.

Adaptive gating mechanisms have previously demonstrated strong effectiveness within Mixture-of-Experts (MoE) architectures by dynamically routing information toward specialized computational pathways [21, 22, 23]. Similarly, multimodal gating approaches enable context-dependent weighting of heterogeneous modalities according to their predictive relevance [7, 24, 25]. Nevertheless, these gating policies are optimized globally during training and remain fixed during inference, preventing rapid learner-specific personalization under cold-start educational conditions.

Despite these advances, several important limitations remain. First, most multimodal educational systems rely on static fusion policies that assume identical modality importance across all learners, despite substantial heterogeneity in learning behaviors and risk manifestations. Second, existing meta-learning approaches generally adapt large portions of the underlying architecture, resulting in increased computational complexity and a higher risk of overfitting under extreme few-shot conditions. Third, current educational digital twin frameworks primarily focus on learner-state prediction and monitoring, while providing limited support for adaptive intervention selection. Consequently, there remains a lack of lightweight educational intelligence frameworks capable of simultaneously achieving rapid personalization, adaptive multimodal fusion, and intervention-aware decision support under cold-start conditions. Addressing this research gap constitutes the primary motivation for the proposed Meta-Adaptive Cross-Modal Gating framework.

Based on the aforementioned limitations, the objective of this study is to develop a lightweight and adaptive multimodal educational intelligence framework capable of rapidly personalizing learner representations under cold-start conditions. More specifically, the proposed research seeks to 1) improve early at-risk student detection from limited interaction data, 2) dynamically adapt modality importance according to individual learner characteristics, 3) reduce computational overhead compared with full-model meta-learning approaches, and 4) support personalized pedagogical intervention within educational digital twin environments.

A meta-learning strategy was selected because the targeted educational scenario is characterized by severe data sparsity during the earliest stages of learner interaction. Traditional supervised learning and fine-tuning approaches generally require substantial historical data before producing reliable predictions. In contrast, meta-learning enables the acquisition of transferable adaptation knowledge from previously observed learners and supports rapid personalization from only a few support samples. Furthermore, the proposed approach adapts only the cross-modal gating mechanism rather than the entire Transformer architecture, thereby reducing computational complexity while limiting overfitting risks under few-shot conditions.

To address these limitations, this study introduces the Meta-Adaptive Cross-Modal Gating (MACMG) framework, a lightweight yet highly adaptive personalization mechanism for autonomous educational digital twins.

The proposed framework dynamically personalizes multimodal fusion policies through a meta-learned gating network capable of rapidly adapting to unseen students using only a few initial interaction episodes. Instead of adapting the entire Transformer architecture, the proposed approach treats the gating mechanism itself as a meta-parameter optimized through a bilevel meta-learning objective [12, 23, 26]. The proposed MACMG framework offers several important advantages. First, by adapting only the lightweight gating mechanism rather than the full multimodal architecture, the framework remains computationally efficient and less vulnerable to overfitting under sparse-data conditions. Second, dynamic gating enables individualized modality weighting, allowing the system to emphasize highly informative signals while suppressing noisy or weakly predictive modalities. Third, the adaptive fusion policy is directly coupled with personalized intervention selection, enabling the framework to operate not merely as a predictive analytics system but as an adaptive educational orchestration mechanism within AI-augmented learning ecosystems.

This study makes several important contributions to the field of AI-enhanced educational intelligence. First, it introduces a Meta-Adaptive Cross-Modal Gating (MACMG) mechanism capable of dynamically personalizing multimodal fusion policies under few-shot conditions. Second, the proposed framework employs a bilevel meta-learning optimization strategy that adapts only a lightweight gating network, thereby improving computational efficiency while maintaining strong adaptation capabilities. Third, extensive experiments on two multimodal educational datasets demonstrate superior early risk detection performance and robustness under severe data sparsity when compared with conventional multimodal Transformers, fine-tuning approaches, and full-model meta-learning baselines. Finally, the framework establishes a direct connection between adaptive multimodal fusion and personalized pedagogical intervention selection within educational digital twin environments.

This study represents one of the earliest attempts to integrate meta-learned cross-modal gating, educational digital twins, and few-shot multimodal personalization within a unified educational intelligence framework. More broadly, the proposed framework reflects the ongoing transition from static predictive learning analytics toward adaptive and autonomous educational intelligence systems capable of continuously modeling evolving learner trajectories in AI-enhanced educational ecosystems.

The remainder of this study is organized as follows. Section II reviews related work on multimodal transformers, educational digital twins, adaptive gating mechanisms, and meta-learning for rapid personalization. Section III presents the theoretical preliminaries underlying the proposed framework. Section IV details the proposed Meta-Adaptive Cross-Modal Gating mechanism and the associated bilevel optimization strategy. Section V describes the experimental setup, datasets, evaluation metrics, and implementation details. Section VI presents experimental results and comparative analysis. Section VII discusses the implications, limitations, ethical considerations, and future research directions associated with the proposed framework. Finally, Section VIII concludes the study and outlines future extensions toward autonomous educational intelligence systems.

II. Related Work

A. Multimodal Transformers for Educational Intelligence

Multimodal learning has become increasingly important in educational AI because learner engagement, academic risk, cognitive load, and emotional states are rarely expressed through a sole source of data. Instead, they emerge from heterogeneous interaction traces, including textual responses, LMS clickstreams, temporal activity patterns, emotional indicators, and physiological signals [3, 4, 7]. Multimodal Transformer architectures offer a powerful solution for modeling such complex data because they rely on attention mechanisms capable of capturing both intra-modal and cross-modal dependencies [5, 6].

In educational contexts, these architectures can integrate textual interactions, behavioral sequences, and affective signals into unified learner-state representations. This makes them suitable for modeling complex learning trajectories and detecting early signs of academic vulnerability. However, existing multimodal Transformer-based systems rely on cross-modal attention weights learned at the population level. Once trained, these weights are usually fixed during inference and applied uniformly to all students [5]. This creates a major limitation because students do not express academic risk through identical modalities. For some learners, behavioral inactivity may be the strongest signal; for others, textual confusion, delayed response time, or affective frustration may be more informative. Recent work on multimodal AI and AI for education further highlights the importance of designing systems capable of handling diverse educational signals and adapting to heterogeneous learner profiles [7, 20]. Nevertheless, current multimodal educational models still lack efficient mechanisms for rapid student-specific adaptation, especially under cold-start conditions where only limited early interaction data are available.

B. Educational Digital Twins

Digital twins were initially conceptualized as dynamic virtual replicas of physical systems, continuously updated through real-time data streams [9]. In education, this concept has been extended to learner modeling, where a digital twin can represent a student's evolving knowledge state, engagement level, behavioral rhythm, and risk trajectory [8,10]. Educational digital twins are particularly promising because they move beyond static prediction and enable continuous monitoring, adaptive intervention, and personalized learning support.

Recent studies suggest that combining artificial intelligence with digital twin technologies can support personalized learning environments, adaptive tutoring, and intelligent educational orchestration [10, 18]. However, the construction of reliable student digital twins remains challenging because these systems often require substantial historical interaction data before producing meaningful representations. This is problematic in early-stage learning contexts, where the most important interventions should occur before disengagement becomes severe. Another limitation is that many educational digital twin frameworks function primarily as dynamic representations rather than adaptive simulation environments. A stronger digital twin should not only represent the learner's current state but also support the estimation of probable future trajectories under alternative intervention scenarios [9]. This distinction is important because autonomous educational intelligence requires not only risk detection but also intervention-aware reasoning.

C. Meta-Learning for Few-Shot Personalization

Meta-learning has emerged as a powerful paradigm for rapid adaptation in sparse-data settings [12, 14]. Model-Agnostic Meta-Learning is particularly influential because it learns parameter initializations that can be quickly adapted to new tasks using only a few gradient updates [12]. This makes MAML highly relevant to educational cold-start problems, where new students provide only a small number of early interactions.

Recent surveys show that meta-learning has been increasingly used for domain generalization, few-shot classification, and personalized intelligent systems [13, 14]. Multimodal meta-learning has also attracted attention because different data modalities may contribute unequally across tasks or users [15]. In education, this suggests that meta-learning could help adapt student models to new learners, new courses, or new institutional settings. However, most meta-learning approaches adapt the full model or large subsets of parameters. This is computationally expensive when applied to Transformer-based architecture and may lead to overfitting when only a few student-specific samples are available. This limitation motivates a more selective adaptation strategy: instead of adapting the entire architecture, it may be more efficient to adapt only the cross-modal fusion mechanism that determines which modality should dominate for each student.

D. Adaptive Gating and Mixture-of-Experts Models

Adaptive gating mechanisms are widely used in Mixture-of-Experts architectures, where a gating network routes inputs toward specialized expert subnetworks [21]. These models have demonstrated strong capacity for scalable specialization, especially in large neural architectures. In multimodal learning,

gating can be used to assign different weights to textual, behavioral, visual, or physiological modalities according to their relevance [7].

Despite their effectiveness, most gating mechanisms are trained globally and remain fixed during inference. They may learn population-level routing patterns, but they do not necessarily adapt to the specific behavior of a newly observed student. This is a critical limitation in educational environments where modality importance can vary significantly across learners and across time.

E. Generative AI and AI-Augmented Learning Environments

The emergence of generative AI has introduced new forms of learner interaction in digital education. Large language models and conversational agents are increasingly used for tutoring, explanation generation, feedback support, and problem-solving assistance [16, 17]. As a result, student learning behavior now includes AI-mediated cognitive interaction patterns such as prompt formulation, iterative clarification, semantic dependency, and AI-assisted reasoning [18-20, 27, 28].

This transformation creates new challenges for learning analytics. Classical LMS-based models are not sufficient to represent AI-augmented learning trajectories because they focus on clickstream behavior, assessment scores, or static engagement indicators.

TABLE I. COMPARATIVE ANALYSIS OF RELATED STUDIES AND THE PROPOSED MACMG FRAMEWORK

Study	MM	DT	ML	Pers.	FS	Int	Key Limitation
Tsai et al. (2019)	Yes	No	No	No	No	No	Employs static multimodal fusion without adapting to individual learner characteristics.
She et al. (2023)	Partial	Yes	No	Limited	No	No	Relies heavily on extensive historical learner data for effective modeling.

Mixture-of-Experts (MoE) Models	Yes	No	No	Limited	No	No	Expert selection mechanisms are typically fixed after training, limiting adaptability.
Educational Meta-Learning Models	Yes	No	Yes	Yes	Yes	No	The adaptation process can be computationally expensive and difficult to scale.
Proposed MACMG Framework	Yes	Yes	Yes	Yes	Yes	Yes	Integrates multimodal sensing, digital twins, meta-learning, and adaptive interventions for personalized learning support.

[a] **Abbreviations:** MM = Multimodal; DT = Digital Twin; ML = Meta-Learning; Pers. = Personalization; FS = Few-Shot Learning; Int. = Adaptive Intervention.

Table I reveals that existing studies have addressed important aspects of intelligent educational systems, including multimodal learning, digital twins, meta-learning, and adaptive modeling. However, these capabilities remain largely fragmented across the literature. Multimodal Transformer approaches provide powerful representation learning but generally rely on static fusion strategies that do not adapt to individual learners. Educational digital twin frameworks support dynamic learner modeling but often require substantial historical data before becoming effective [26, 28, 29]. Meta-learning approaches improve adaptation under data scarcity but typically focus on adapting large portions of the model, increasing computational cost and the risk of overfitting. Similarly, Mixture-of-Experts architectures employ adaptive routing mechanisms, yet their gating policies are usually learned globally and remain fixed during inference [25, 29, 30]. Consequently, there remains a lack of unified frameworks capable of simultaneously supporting multimodal fusion, educational digital twins, few-shot personalization, and intervention-aware decision making. The proposed MACMG framework is designed to address these limitations through a lightweight meta-adaptive gating mechanism that dynamically personalizes modality importance for unseen learners while directly supporting personalized intervention selection.

The literature reveals four major limitations: static multimodal fusion, vulnerability to cold-start conditions, computationally expensive full-model meta-learning, and weak integration between prediction and intervention mechanisms. To address these gaps, we propose MACMG, a framework combining multimodal Transformers, educational digital twins, few-shot meta-learning, and adaptive cross-modal gating for personalized intervention. Unlike conventional approaches, MACMG adapts only a lightweight gating network and directly links adaptive multimodal fusion with personalized pedagogical intervention. To the best of our knowledge, this is among the first frameworks integrating meta-learned cross-modal gating within autonomous educational digital twins for few-shot personalized intervention.

III. THEORETICAL BACKGROUND AND PROBLEM FORMULATION

A. Multimodal Educational Digital Twin Environment

Consider a set of students:

$$\mathcal{S} = \{s_1, s_2, \ldots, s_N\} \quad (1)$$

Interacting within an AI-augmented Learning Management System. Each learner continuously generates multimodal educational traces over time [8], [9]. For a given learner s_i, the educational digital twin at time step $t$is represented as:

$$D_i^{(t)} = \{X_{i,T}^{(t)}, X_{i,B}^{(t)}, X_{i,P}^{(t)}\} \quad (2)$$

where, $X_{i,T}^{(t)}$denotes textual interaction features, $X_{i,B}^{(t)}$denotes behavioral interaction features, and $X_{i,P}^{(t)}$denotes physiological or affective features.

The textual modality includes assignment submissions, forum discussions, AI-assisted prompts, and semantic interaction traces generated during learning activities. Behavioral features include clickstream sequences, LMS navigation patterns, inactivity periods, submission delays, and resource access frequency.

Physiological and affective modalities may include: engagement indicators, emotional embeddings, facial attention representations, and stress-related interaction patterns [3, 4].

The digital twin evolves dynamically according to incoming interaction streams:

$$D_i^{(t+1)} = \mathcal{F}(D_i^{(t)}, X_i^{(t+1)}) \quad (3)$$

where, $\mathcal{F}(\cdot)$denotes the educational twin update function.

Unlike conventional static learner representations, the proposed framework continuously updates multimodal learner states to reflect evolving educational trajectories.

B. Transformer-Based Multimodal Representation Learning

For each modality $m \in \{T, B, P\}$, the learner interaction sequence is represented as:

$$X_m = \{x_1, x_2, \ldots, x_L\} \quad (4)$$

where Ldenotes the sequence length.

Each modality is independently encoded through a Transformer encoder [5], [6]. Self-attention is computed as:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (5)$$

where, Q represents query matrices, K represents key matrices, V represents value matrices, and d_k denotes key dimensionality.

The resulting contextual modality embeddings are:

$$H_T = \text{Transformer}_T(X_T) \quad (6)$$

$$H_B = \text{Transformer}_B(X_B) \quad (7)$$

$$H_P = \text{Transformer}_P(X_P) \quad (8)$$

Traditional multimodal Transformers fuse these representations using static cross-modal attention learned globally during training [5, 7]. However, this assumption is problematic in educational environments because modality relevance differs across learners. Consequently, static fusion policies may suppress highly informative individualized signals.

C. Meta-Adaptative Cross-Modal Gating

To address this limitation, the proposed MACMG framework introduces a student-specific adaptive gating mechanism inspired by adaptive multimodal fusion and Mixture-of-Experts paradigms [7, 21].

Given multimodal embeddings:

$$H = \{H_T, H_B, H_P\} \quad (9)$$

The gating network computes adaptive modality importance weights:

$$g_i^{(t)} = \text{softmax}(W_g z_i^{(t)} + b_g) \quad (10)$$

where, $z_i^{(t)}$denotes the learner-state embedding, and $W_g$and $b_g$represent learnable gating parameters.

The gating vector becomes:

$$g_i^{(t)} = [g_T, g_B, g_P] \quad (11)$$

subject to:

$$\sum_m g_m = 1 \quad (12)$$

The final fused learner representation is computed as:

$$H_i^{(t)} = \sum_m g_m H_m \quad (13)$$

This mechanism dynamically emphasizes informative modalities while suppressing noisy or weakly predictive channels.

Unlike static fusion strategies, MACMG enables individualized multimodal weighting according to evolving learner behavior.

D. Few-Shot Meta-Learning Formulation

The central objective of the proposed framework is to rapidly personalize the gating mechanism for unseen students using only a few initial interaction samples [12, 14].

Let:

$$\mathcal{T}_i = (\mathcal{D}_i^{sup}, \mathcal{D}_i^{qry}) \quad (14)$$

denote the adaptation task associated with the learner s_i, where $\mathcal{D}_i^{sup}$is the support set, and $\mathcal{D}_i^{qry}$is the query set.

The support set typically contains between 5 and 10 early interaction episodes. The gating parameters are meta-learned using a bilevel optimization strategy inspired by MAML [12, 22]. During the inner-loop adaptation phase, learner-specific parameters are updated as:

$$\theta_i' = \theta - \alpha \nabla_\theta \mathcal{L}_{sup}(\theta) \quad (15)$$

where, θ denotes meta-initialized gating parameters, αdenotes the adaptation learning rate, and $\mathcal{L}_{sup}$denotes support-set loss.

The outer-loop optimization then updates the shared initialization across multiple learners:

$$\theta \leftarrow \theta - \beta \sum_i \nabla_\theta \mathcal{L}_{qry}(\theta_i') \tag{16}$$

where, β denotes the meta-learning rate, and $\mathcal{L}_{qry}$ represents query-set loss.

This optimization encourages the gating network to learn transferable multimodal adaptation priors capable of rapidly specializing to unseen learners.

E. Personalized Intervention Selection

Beyond prediction, the proposed framework directly associates adaptive modality importance with intervention selection.

Let:

$$\mathcal{M} = \{m_1, m_2, \ldots, m_K\} \tag{17}$$

denote the set of available pedagogical interventions.

The intervention policy is defined as:

$$m_t^* = \arg\max g_{t,m} \tag{18}$$

where, $g_{t,m}$ represents modality importance at time t, and m_t^* denotes the selected intervention strategy.

For example:

- High behavioral risk may trigger tutoring reinforcement,
- Affective frustration may trigger motivational intervention,
- Semantic confusion may trigger AI-assisted explanatory support.

Although the current implementation uses modality dominance as the intervention routing mechanism, the proposed architecture is designed to support future integration with reinforcement learning and multi-agent educational policy optimization [24, 25].

F. Global Optimization Objective

The complete MACMG optimization objective combines prediction accuracy, adaptive personalization, and regularization constraints.

The overall objective function becomes:

$$\mathcal{L}_{total} = \mathcal{L}_{pred} + \lambda_1 \mathcal{L}_{meta} + \lambda_2 \mathcal{L}_{reg} \tag{19}$$

where, $\mathcal{L}_{pred}$ denotes prediction loss, $\mathcal{L}_{meta}$ denotes meta-learning adaptation loss, $\mathcal{L}_{reg}$ denotes regularization loss, and λ_1, λ_2 are balancing coefficients.

This formulation enables the framework to simultaneously optimize multimodal representation quality, few-shot adaptability, and personalization stability. More broadly, the proposed formulation reflects the transition from static predictive learning analytics toward adaptive educational intelligence systems capable of continuously evolving according to individualized learner trajectories in AI-augmented educational ecosystems [16, 20].

IV. Proposed Meta-Adaptive Cross-Modal Gating Framework

The framework integrates multimodal Transformer representations, adaptive cross-modal fusion, and few-shot meta-learning into a unified architecture capable of rapidly personalizing learner representations under sparse interaction conditions.

Given multimodal educational inputs:

$$X_i = \{X_{i,T}, X_{i,B}, X_{i,P}\} \tag{20}$$

The framework extracts modality-specific representations through independent Transformer encoders and subsequently fuses them using a learner-specific adaptive gating mechanism optimized through meta-learning. Unlike conventional multimodal educational systems relying on globally fixed fusion policies, MACMG dynamically personalizes modality importance according to each learner's evolving behavioral and cognitive characteristics.

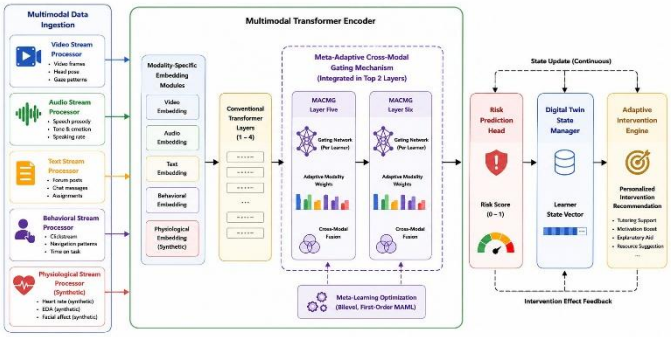

Fig. 1. Overall architecture of the proposed MACMG-enhanced multimodal educational digital twin framework.

Fig. 1 illustrates the overall operational workflow. For each interaction window t, textual, behavioral, and physiological streams are encoded independently before being processed through the lower Transformer layers to generate a shared latent representation:

$$h_t^{(4)} \in \mathbb{R}^{d_h} \tag{21}$$

This representation is forwarded to the adaptive gating network g_ϕ, which computes learner-specific modality weights:

$$g_i^{(t)} = [g_i^{(t,T)}, g_i^{(t,B)}, g_i^{(t,P)}] \in \mathbb{R}^3 \tag{22}$$

The personalized weights are then applied within the MACMG layers to produce the final multimodal learner representation:

$$h_t^{(6)} \tag{23}$$

which is subsequently used for risk prediction and digital twin state updating.

A. Multimodal Representation Learning

The framework processes three complementary educational modalities: textual interactions, behavioral traces, and

physiological or affective signals. Textual data includes assignment submissions, discussion messages, and AI-assisted prompts, while behavioral data captures LMS navigation patterns, clickstreams, inactivity periods, and temporal interaction dynamics. The physiological modality models emotional engagement, frustration, and affective instability.

Each modality is independently embedded as:

$$E_T = \text{Embed}(X_T) \quad (24)$$

$$E_B = \text{Embed}(X_B) \quad (25)$$

$$E_P = \text{Embed}(X_P) \quad (26)$$

The synthetic augmentation used for physiological embeddings was employed solely to simulate multimodal educational settings and does not represent naturally collected physiological data.

Each modality is subsequently processed using modality-specific Transformer encoders [5, 6]:

$$H_m = \text{Transformer}_m(E_m) \quad (27)$$

where, $m \in \{T, B, P\}$. The resulting multimodal latent representations become:

$$H = \{H_T, H_B, H_P\} \quad (28)$$

Unlike static multimodal fusion approaches, the proposed framework dynamically adapts modality importance according to learner-specific interaction dynamics.

B. Meta-Adaptive Cross-Modal Gating

The core innovation of MACMG lies in the proposed meta-adaptive gating mechanism. Instead of assigning identical modality importance to all learners, the framework dynamically estimates modality relevance according to each learner's evolving state.

Given learner representation:

$$z_i^{(t)} \quad (29)$$

adaptive gating weights are computed as:

$$g_i^{(t,m)} = \text{softmax}(W_g z_i^{(t)} + b_g) \quad (30)$$

where, W_g and b_g denote learnable gating parameters. The final multimodal learner representation is computed through weighted fusion:

$$H_i^{(t)} = \sum_m g_i^{(t,m)} H_m \quad (31)$$

This mechanism enables dynamic modality prioritization while suppressing noisy or weakly informative channels. For example, semantic confusion may increase textual importance, whereas inactivity bursts or affective frustration may strengthen behavioral or physiological weighting.

Given the intermediate representation $h_t^{(4)}$, modality-specific embeddings are extracted through projection layers:

$$z_t^m = \text{Proj}_m(h_t^{(4)}) \in \mathbb{R}^{d_z} \quad (32)$$

The modality-specific gating weight is then computed as:

$$g_i^{(t,m)} = \sigma\left(W_g^{(m)} \cdot [\text{MLP}_\phi(z_t^m); p_t] + b_g^{(m)}\right) \quad (33)$$

where, $\sigma(\cdot)$ denotes sigmoid activation, MLP_ϕ represents the shared gating network, and p_t denotes the continuously updated meta-prior vector. The adaptive gating weights are used to modulate cross-modal attention inside the MACMG layers:

$$h_t^{(l)} = \sum_{m=1}^{3} g_i^{(t,m)} \cdot \text{CrossAttn}_m^{(l)}(h_t^{(l-1)}) \quad (34)$$

where, $l \in \{5,6\}$.

C. Meta-Learned Few-Shot Personalization

The gating network is optimized by using a bilevel meta-learning strategy inspired by MAML [12, 14]. For learner-specific task:

$$\mathcal{T}_i = (\mathcal{D}_i^{sup}, \mathcal{D}_i^{qry}) \quad (35)$$

The support set contains only a few early interaction episodes. During inner-loop adaptation, learner-specific parameters are updated as:

$$\phi_i^{(k)} = \phi_{meta} - \eta \nabla_\phi \mathcal{L}_{sup}(g_\phi(X_i^{sup}; \phi^{(k-1)})) \quad (36)$$

The outer-loop optimization then updates the global initialization across historical learners:

$$\phi_{meta} \leftarrow \phi_{meta} - \beta \nabla_{\phi_{meta}} \sum_{i=1}^{N} \mathcal{L}_{qry}(g_\phi(X_i^{qry}; \phi_i')) \quad (37)$$

Because only the lightweight gating parameters are adapted, the framework significantly reduces computational overhead compared with full-model meta-learning approaches while remaining effective under sparse interaction conditions.

D. Dynamic Adaptation and Personalized Intervention

During inference, the framework continuously updates learner-specific gating policies using recent interaction windows, thereby substantially alleviating cold-start adaptation limitations. This enables modality relevance to remain aligned with evolving learner behavior over time. Beyond prediction, MACMG links adaptive multimodal fusion with intervention selection. Let:

$$\mathcal{M} = \{m_1, m_2, \ldots, m_K\} \quad (38)$$

denote the set of available pedagogical interventions. The routing policy is defined as:

$$m_t^* = \arg\max_m g_i^{(t,m)} \quad (39)$$

where, m_t^* represents the selected intervention strategy. This creates an adaptive feedback mechanism between multimodal learner representation and pedagogical action selection. Depending on the dominant modality, the system may trigger tutoring reinforcement, motivational intervention, or AI-assisted explanatory support. More broadly, the proposed framework moves beyond static prediction toward autonomous educational digital twins capable of continuously modeling learner trajectories and supporting intervention-aware educational forecasting [9, 10].

V. EXPERIMENTAL SETUP

A. Datasets

Experiments are conducted on two publicly available multimodal educational datasets:

1) StudentLife dataset: StudentLife [16] contains longitudinal behavioral and emotional data collected from 48 university students over a 10-week academic term. The dataset includes smartphone sensor streams, self-reported mood indicators, and academic performance measures. Behavioral features are extracted from sensor logs, while textual interactions are derived from EMA responses. Synthetic physiological embeddings were generated to simulate affective educational signals absent from the original StudentLife dataset. Specifically, 128-dimensional facial-expression embeddings were produced using a conditional feature generation procedure based on behavioral and textual interaction patterns. The generation process employed Gaussian conditional sampling, where synthetic embeddings were sampled from modality-specific distributions estimated from the behavioral and textual feature space. This strategy preserves statistical consistency across modalities while enabling controlled evaluation of trimodal educational settings. The generated vectors were sampled using a fixed random seed to ensure reproducibility and subsequently normalized before integration into the multimodal representation pipeline. These synthetic embeddings were introduced exclusively to evaluate the behavior of MACMG under trimodal educational settings and do not represent real biometric measurements collected from participants. The prediction task consists of identifying students belonging to the bottom 20% of academic performance. Daily interaction windows are used, with the first five days forming the support set for adaptation.

2) DAiSEE dataset: DAiSEE [17] contains 9,068 online learning video clips collected from 112 students and annotated according to engagement levels. Video streams, clickstream traces, and forum interactions are used respectively as physiological, behavioral, and textual modalities. Interaction sequences are segmented into 5-minute windows, while the first three windows are used for few-shot adaptation. Students are separated into disjoint meta-training, validation, and meta-test subsets to simulate realistic cold-start conditions. Together, the two datasets provide complementary educational conditions combining longitudinal behavioral dynamics and dense affective interaction signals.

B. Baseline Models

MACMG is compared against several strong baselines sharing the same six-layer Multimodal Transformer backbone.

- StaticMMT: an internal baseline implemented in this study using the same six-layer multimodal Transformer backbone as MACMG but employing globally fixed fusion weights and no learner-specific adaptation.
- StaticMMT+FT: learner-specific fine-tuning of StaticMMT.
- MAML-Full [5]: full-model meta-learning applied to all Transformer parameters.
- MoE-Gate [6]: Mixture-of-Experts architecture with static gating.
- PerStudentMLP: learner-specific gating network trained without meta-learning.

The proposed framework was implemented using Python 3.11 and PyTorch 2.2. Data preprocessing was performed using NumPy, pandas, and scikit-learn, while model training and evaluation were conducted on an NVIDIA A100 GPU using CUDA acceleration.

C. Evaluation Metrics

Performance is evaluated using AUROC and F1-score for early risk detection. To assess robustness under sparse-data conditions, we additionally report AUROC@K, computed using only the first K query windows after adaptation. Intervention quality is evaluated using Intervention Recall at 1 (IR@1), which measures whether the dominant gating modality correctly identifies the most appropriate pedagogical intervention. Computational feasibility is assessed through Adaptation Time, defined as the wall-clock time required for learner-specific adaptation on a single NVIDIA A100 GPU.

Oracle intervention labels were constructed using a rule-based educational mapping strategy designed to associate dominant learner-risk indicators with appropriate pedagogical intervention categories. Behavioral risk patterns, such as inactivity, irregular access, delayed submissions, or reduced LMS engagement, were mapped to tutoring reinforcement interventions. Affective or physiological instability, including frustration-related or low-engagement signals, was mapped to motivational support interventions. Textual indicators of semantic confusion, low coherence, or difficulty in written interaction were mapped to AI-assisted explanatory support. These oracle labels were used as evaluation proxies for intervention-routing assessment through IR@1 and do not represent interventions actually delivered to students in real learning environments.

D. Implementation Details

The base Multimodal Transformer consists of six layers with hidden dimensions:

$$d_h = 256 \tag{46}$$

and eight attention heads per layer. Each modality embedding dimension is initialized as:

$$d_T = d_B = d_P = 128 \tag{47}$$

The adaptive gating network g_ϕ is implemented as a two-layer MLP with hidden dimension 64, while the meta-prior vector dimension is fixed to:

$$d_p = 32 \tag{48}$$

The inner-loop and meta-learning rates are respectively defined as:

$$\eta = 0.01 \tag{49}$$

and

$$\beta = 0.001 \quad (50)$$

The framework uses a first-order MAML approximation to reduce computational complexity. During meta-training, support and query sizes are fixed, respectively, to:

$$N_{supp} = 10 \quad (51)$$

and

$$N_{query} = 20 \quad (52)$$

All experiments are conducted on a single NVIDIA A100 GPU, and results are averaged across five independent runs using different random seeds.

VI. Results and Analysis

We evaluate the proposed Meta-Adaptive Cross-Modal Gating (MACMG) mechanism against five baselines across multiple dimensions: early risk detection accuracy, robustness under varying support set sizes, intervention selection precision, and computational efficiency.

A. Early Risk Detection Performance

Quantifying the ability to detect at-risk students under severe data sparsity, Table I presents the AUROC and F1-scores on both the StudentLife and DAiSEE datasets. For each test student, adaptation is performed using only $N_{\text{supp}} = 10$ windows, and evaluation is conducted on the remaining query windows. The cold-start scenario is particularly stringent on the DAiSEE dataset, where the support set corresponds to merely 50 minutes of initial interaction.

Directly analyzing comparative performance, StaticMMT achieves the lowest scores across both datasets due to its inability to adapt fusion weights to individual students, confirming the inherent limitation of static cross-modal attention mechanisms [2]. Standard fine-tuning with StaticMMT+FT yields moderate improvements, particularly on the StudentLife dataset with its longer longitudinal windows, but struggles to generalize with only ten support windows. The PerStudentMLP baseline, which trains a gating network from scratch per student, exhibits the worst performance among adaptive methods, characterized by high variance stemming from severe overfitting given the limited support samples. This underscores the critical importance of a meta-learned prior that captures transferable knowledge across the student population.

MoE-Gate [6] demonstrates notable gains over static approaches, with an AUROC of 0.763 on StudentLife and 0.781 on DAiSEE, benefiting from its dynamic routing among modality-specific experts. Nevertheless, its gating network is trained on the population and remains static during inference, preventing it from adapting its routing policy to individual student characteristics. MAML-Full [5] further improves upon MoE-Gate, achieving an AUROC of 0.782 and 0.792, respectively, by meta-learning all transformer parameters. However, adapting the entire high-capacity model from only ten support windows induces mild overfitting, limiting its performance ceiling.

TABLE II. Comparison of Risk Detection Performance ($N_{\text{supp}} = 10$)

Method	StudentLife AUROC	StudentLife F1	DAiSEE AUROC	DAiSEE F1
StaticMMT	0.712 (0.023)	0.681 (0.019)	0.734 (0.027)	0.698 (0.022)
StaticMMT+FT	0.745 (0.018)	0.709 (0.021)	0.756 (0.024)	0.721 (0.020)
PerStudentMLP	0.682 (0.041)	0.634 (0.047)	0.698 (0.052)	0.651 (0.049)
MoE-Gate	0.763 (0.015)	0.728 (0.017)	0.781 (0.019)	0.745 (0.016)
MAML-Full	0.782 (0.014)	0.751 (0.013)	0.792 (0.015)	0.763 (0.017)
MACMG (Ours)	0.821 (0.009)	0.793 (0.010)	0.834 (0.011)	0.805 (0.012)

In contrast, our MACMG mechanism attains the highest AUROC and F1-scores on both datasets, reaching an AUROC of 0.821 on StudentLife and 0.834 on DAiSEE. By meta-learning only the lightweight gating network initialization and keeping the lower transformer layers frozen, MACMG strikes an optimal balance between adaptability and stability. The gating network, containing merely a fraction of the total model parameters, can be effectively updated with limited data without destabilizing the rich representations learned by the base transformer.

B. Robustness Under Varying Support Set Sizes

To assess the few-shot capabilities of each method, we evaluate AUROC on the DAiSEE dataset while progressively reducing the support set size N_{supp} from 20 windows down to 5 windows (Table III). This tests the extreme cold-start regime where adaptation must occur from merely 25 minutes of initial student data. Table II reveals the performance degradation patterns across methods. StaticMMT+FT suffers dramatic deterioration when the support set shrinks from 20 to 5 windows, with its AUROC dropping by six percentage points, illustrating the brittleness of standard fine-tuning under extreme data scarcity. MoE-Gate maintains stable performance due to its static routing policy, but its inability to adapt the policy itself causes it to plateau well below MACMG at all support sizes.

TABLE III. AUROC on Daisee Under Varying Support

Method	$N_{\text{supp}} = 20$	$N_{\text{supp}} = 15$	$N_{\text{supp}} = 10$	$N_{\text{supp}} = 5$
StaticMMT+FT	0.772 (0.018)	0.764 (0.020)	0.756 (0.024)	0.713 (0.032)
MoE-Gate	0.785 (0.016)	0.782 (0.017)	0.781 (0.019)	0.762 (0.025)
MAML-Full	0.801 (0.013)	0.797 (0.014)	0.792 (0.015)	0.771 (0.022)
MACMG (Ours)	0.842 (0.010)	0.838 (0.011)	0.834 (0.011)	0.819 (0.010)

MAML-Full also exhibits a noticeable decline, dropping from 0.801 to 0.771 as N_{supp} decreases. The performance gap between MAML-Full and MACMG widens in the most extreme few-shot regime: with only 5 support windows, MACMG outperforms MAML-Full by 4.8 AUROC points in absolute terms. This confirms that meta-learning a compact gating module is inherently more sample-efficient than adapting all parameters of a large transformer. The meta-initialization of the gating network encodes robust inductive biases about modality

relevance across the student population, allowing even a handful of initial interactions to meaningfully shift the fusion policy toward an individual student's dominant predictive channels.

C. Intervention Selection Accuracy

Beyond accurate risk detection, the practical utility of a digital twin framework hinges on its capacity to trigger appropriate, personalized pedagogical interventions. Table IV reports the Intervention Recall at 1 (IR@1) metric, which measures the proportion of time windows where the modality with the highest gating weight correctly identifies the oracle intervention type.

TABLE IV. COMPARING THE CORRECTNESS OF MODALITY-BASED INTERVENTION SELECTION

Method	IR@1 (All Windows)	IR@1 (First 20 Windows)
MoE-Gate	0.523 (0.031)	0.471 (0.038)
MAML-Full	0.568 (0.024)	0.502 (0.035)
MACMG (Ours)	0.657 (0.019)	0.621 (0.022)

The intervention selection task poses a greater challenge than risk detection alone, as it requires the gating mechanism not merely to emphasize any informative modality, but to correctly identify the channel most aligned with the student's underlying difficulty. MACMG achieves an IR@1 of 0.657 across all windows and maintains 0.621 during the critical first 20 windows. The 9.5 percentage point gain over MoE-Gate in the early windows is particularly significant, indicating that the meta-learned prior enables the gating network to start with a meaningful routing policy that is further refined by the first few episodes. As illustrated in Fig. 2, the temporal evolution of modality reliance for a representative at-risk student shows a clear shift from text-dominated attention toward video-dominated attention within the first 10 minutes, demonstrating that MACMG successfully adapts its fusion policy to emphasize predictive physiological cues early in the interaction. Paired t-tests confirm that the improvements achieved by MACMG over the strongest baseline are statistically significant ($p < 0.05$).

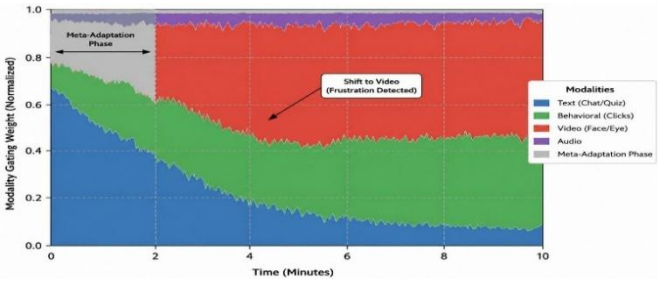

Fig. 2. Temporal evolution of modality reliance for a sample at-risk student.

D. Computational Efficiency

Measuring the wall-clock adaptation time on a single NVIDIA A100 GPU, Table V reports the time required to adapt each method to a new student's support set of $N_{\text{supp}} = 10$ windows. This metric is crucial for real-world deployment in learning management systems where adaptation must occur seamlessly as a student begins a new course.

TABLE V. ADAPTATION TIME PER NEW STUDENT ($N_{\text{SUPP}} = 10$ WINDOWS) ON AN NVIDIA A100 GPU

Method	Adaptation Time (seconds)	Total Parameters Adapted
StaticMMT+FT	12.4 (0.8)	14.2M
MAML-Full	8.9 (0.6)	14.2M
MACMG (Ours)	0.47 (0.05)	45K

MAML-Full achieves faster adaptation than naive fine-tuning due to the meta-learned initialization reducing the number of necessary gradient steps, yet it still requires adapting all 14.2 million parameters. MACMG, by adapting only the 45,000 parameters of the gating network, achieves adaptation in under half a second, approximately 19 times faster than MAML-Full and 26 times faster than standard fine-tuning. This dramatic speedup makes continuous meta-prior updates during inference computationally feasible, enabling the system to maintain an up-to-date personalized gating policy as the student's behavior evolves.

E. Representation Analysis via Dimensionality Reduction

To gain qualitative insight into how the meta-adaptive gating affects the learned representations, we project the final fused embeddings $\mathbf{h}_t^{(6)}$ for all test students into a two-dimensional space using t-SNE. Fig. 3 visualizes the resulting projection, with points color-coded by ground-truth risk status. Superimposed on the scatter plot is a vector field indicating the displacement of each student's representation caused by the MACMG adaptation step, comparing the pre-adaptation embedding $\mathbf{h}_{\text{pre}}$ to the post-adaptation embedding $\mathbf{h}_{\text{post}}$. In the projection space, pre-adaptation representations of at-risk and not-at-risk students exhibit substantial overlap, reflecting the ambiguity inherent in early interaction data. The displacement vectors reveal a systematic effect: adaptive gating consistently pushes representations of at-risk students toward the at-risk cluster and away from the decision boundary, while preserving the positions of not-at-risk students. This directional refinement corroborates the quantitative gains observed in risk detection performance and demonstrates that the gating network's modality re-weighting resolves representational ambiguity in a principled, student-specific manner.

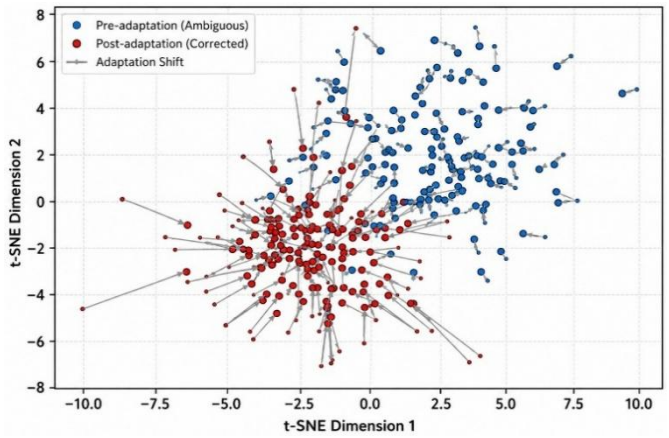

Fig. 3. t-SNE projection of student state embeddings.

F. Ablation Study

To isolate the contributions of the individual components of MACMG, we conducted an ablation study on the DAiSEE dataset under $N_{supp} = 10$ support windows. The quantitative results are summarized in Table VI, which compares the complete framework with three ablated variants: 1) removing the meta-prior vector $\mathbf{p}_t$ from the gating computation in Eq. (33) (w/o Meta-Prior), 2) replacing the bilevel meta-learning with standard supervised pre-training of the gating network on the meta-training set (w/o Meta-Training), and 3) applying the gating weights only at the final layer instead of the top two layers (Single-Layer Gate).

TABLE VI. ABLATION STUDY ON DAISEE EVALUATING THE CONTRIBUTION OF MACMG COMPONENTS, WITH $N_{\text{SUPP}} = 10$

Variant	AUROC	F1	IR@1 (First 20)
MACMG (Full)	0.834 (0.011)	0.805 (0.012)	0.621 (0.022)
w/o Meta-Prior	0.811 (0.014)	0.778 (0.015)	0.585 (0.025)
w/o Meta-Training	0.797 (0.018)	0.761 (0.017)	0.534 (0.029)
Single-Layer Gate	0.822 (0.013)	0.792 (0.014)	0.602 (0.023)

Eliminating the meta-prior vector leads to a 2.3 percentage point drop in AUROC, confirming that the continuously updated prior provides the gating network with a stable, student-specific context that aids in modality selection across time. Removing the bilevel meta-training procedure entirely, equivalent to training a static gating network on the population, causes the most severe degradation, with AUROC falling to 0.797 and IR@1 dropping below 0.54. This variant is a refined version of MoE-Gate and demonstrates that the population-level gating policy alone is insufficient for individualized modality emphasis. Finally, restricting gating to only the final layer (Single-Layer Gate) causes a modest but consistent decline across all metrics, indicating that modulating the cross-modal attention in the top two transformer layers provides a richer, more robust fusion policy. These ablations collectively validate that each component of MACMG meta-training, the meta-prior, and multi-layer gating contribute meaningfully to the overall performance and that their synergistic combination yields the strongest results. While MACMG demonstrates robust performance improvements, additional validation on large-scale real-world LMS ecosystems and longitudinal semester-level deployments remains necessary to further assess generalization robustness. Despite impressive performance, the current framework remains limited by the availability of large-scale multimodal educational datasets and requires further validation in real-world semester-long deployments.

VII. DISCUSSION AND FUTURE WORK

A. Discussion of Experimental Findings

The experimental results provide strong evidence that adaptive multimodal personalization is particularly beneficial under educational cold-start conditions. Across both StudentLife and DAiSEE, MACMG consistently outperformed static multimodal Transformers, conventional fine-tuning strategies, and full-model meta-learning approaches. These findings confirm that modality relevance varies substantially across learners and that fixed fusion policies are insufficient for capturing individualized educational risk patterns.

The superior performance of MACMG over StaticMMT demonstrates the limitations of globally optimized multimodal fusion strategies, which assume homogeneous modality importance across all students. By contrast, the proposed meta-adaptive gating mechanism dynamically adjusts modality weights according to learner-specific interaction characteristics, resulting in more discriminative learner representations and improved risk detection accuracy.

The comparison with MAML-Full is particularly informative. Although both approaches leverage meta-learning principles, MACMG adapts only the lightweight gating network while preserving the lower Transformer layers. This selective adaptation strategy reduces the risk of overfitting and enables more sample-efficient personalization under severe data sparsity. The observed performance gains support previous findings by Finn et al. (2017) regarding the effectiveness of meta-learning for rapid adaptation while extending these benefits to multimodal educational environments.

The intervention selection results further highlight the practical significance of adaptive modality weighting. Unlike previous educational prediction models that focus exclusively on learner-state estimation, MACMG directly links multimodal representations to intervention-aware decision support. This capability represents an important step toward autonomous educational digital twins capable of not only predicting risk but also supporting personalized pedagogical action.

Overall, the findings demonstrate that combining multimodal Transformers, educational digital twins, adaptive gating, and few-shot meta-learning within a unified architecture provides a promising pathway toward scalable and personalized educational intelligence systems.

Although MACMG demonstrated strong robustness down to Nsupp = 5 support windows, performance under extreme near-zero-shot conditions (Nsupp = 1–2) remains an open research question and will be investigated in future work.

B. Ethical Implications, Privacy, and Algorithmic Fairness in Biometric Monitoring

Central to the contributions of this work is the deployment of physiological modalities, such as facial expression analysis, which inherently raise significant ethical and privacy concerns. The real-time capture and processing of biometric data, even within controlled educational environments, presents risks related to data security, student surveillance, and potential misuse of affective information [18]. Our proposed MACMG framework, by explicitly modulating the reliance on this sensitive modality through adaptive gating, may inadvertently introduce a mechanism for privacy-preserving operation.

Nevertheless, the permanent storage and processing paradigms of this data stream warrant careful consideration. In future work, we plan to integrate formal privacy guarantees into the MACMG framework. One promising direction is the incorporation of differential privacy constraints directly into the bilevel meta-learning objective [19]. By perturbing the gradients

during the outer-loop meta-update, we could train the gating network initialization to be robust to privacy leakage, ensuring that the adapted student-specific gating weights do not inadvertently encode identifiable information about the historical training population.

Another potential direction involves designing the meta-prior vector $\mathbf{p}_t$ to be ephemeral. Rather than storing a persistent student-specific prior for long durations, the system could periodically reset the meta-prior to a population-level baseline and then adapt it over a limited number of subsequent windows. This would limit the temporal window of biometric data that could be associated with a specific student, enhancing privacy. Moreover, the fairness of the adaptive gating policy across different demographic and socioeconomic groups must be rigorously evaluated. If the gating network learns, from the population meta-training, to associate certain modalities more strongly with risk for subgroups (e.g., correlating video-based analysis with risk for students from a specific cultural background), it could lead to biased intervention allocation. Future work will incorporate fairness constraints into the meta-objective, penalizing scenarios where the gating weights display statistically significant discrepancies in modality reliance between predefined student groups [20].

C. Computational Scalability and Latency Challenges in Real-Time Online Adaptation

While the adaptation time of MACMG (0.47 seconds per new student) is orders of magnitude faster than full-model approaches, the computational demands for deployment at scale in a learning management system (LMS) serving thousands of concurrent students remain a significant engineering challenge. The continuous meta-prior update procedure described in Section IV-D, which performs a few gradient steps every $T_{\text{update}} = 50$ windows impose a recurring computational load. For an LMS with 10,000 active students, this would require processing up to 200 incremental adaptation updates per second, which could strain centralized GPU resources.

Several strategies can be explored to mitigate these latency bottlenecks. First, we can investigate the feasibility of a lazy adaptation protocol where meta-prior updates are skipped for students whose risk score remains consistently low across multiple intervals. This would concentrate computational resources on the minority of high-risk students whose gating policies require rapid refinement. Second, we can explore the application of knowledge distillation techniques [21] to create a smaller, student-specific gating network distilled from the meta-learned initialization. This compressed student sub-model could be deployed on edge devices (e.g., student laptops) to perform local, privacy-preserving adaptation without constant server communication. A third direction involves examining the trade-offs between the frequency of meta-prior updates (T_{update} and W) and adaptation quality. Our current configuration ($T_{\text{update}} = 50, W = 20, K_{\text{inf}} = 3$) was empirically chosen; future work could formalize this as a dynamic programming problem where the system allocates a limited computational budget per student over time to maximize the marginal benefit of each meta-prior update in reducing the uncertainty of the risk prediction.

Furthermore, the computational savings from our first-order MAML approximation, while substantial, could potentially be enhanced by leveraging modern hardware accelerators for matrix operations. The compact nature of the gating network MLP makes it an ideal candidate for deployment on tensor processing units (TPUs) or field-programmable gate arrays (FPGAs) designed for low-latency inference. Exploring these hardware-software co-design strategies could reduce the adaptation time from hundreds of milliseconds to microseconds, enabling truly real-time personalization.

D. Cross-Domain Generalization Limits and Longitudinal Stability of Student Digital Twins

A fundamental limitation of our current evaluation is its confinement to two educational datasets (StudentLife and DAiSEE) with pre-defined modalities and annotation schemes. The generalizability of the meta-learned gating policy to entirely new contexts, such as vocational training platforms, medical simulation environments, or adult learning systems, remains an open question. The modality relevance patterns learned by the meta-initialization from a population of university students may not transfer effectively to a scenario where the primary modality is, for instance, haptic feedback signals from a simulation controller. This challenge highlights a key limitation of in-domain meta-learning.

To improve cross-domain generalization, future work could explore a domain-agnostic meta-prior space. Rather than learning a single meta-initialization ϕ_{meta} for all historical tasks, we could learn a set of meta-initializations $\Phi = \{\phi_{\text{meta}}^{(1)}, \ldots, \phi_{\text{meta}}^{(V)}\}$, each representing a 'prototypical' modality relevance archetype. For a new student, the inference could first perform a rapid, zero-shot assignment by clustering the student's initial interaction patterns to the closest archetype, and then run the inner-loop adaptation from that archetype's initialization. This would allow the system to leverage prior knowledge from diverse learning environments without being confined to a single population's distribution. This approach aligns with recent work on meta-learning for multi-tasking [22, 27, 29].

Equally important is the question of longitudinal stability of the digital twin over long academic terms (e.g., a full semester of 16 weeks). Our continuous meta-prior update mechanism enables tracking evolving student profiles, but it may accumulate drift over many iterations. If the student's dominant predictive modality gradually shifts from text to video as the semester progresses, the frequent gradient updates from the sliding window should, in theory, allow the gating policy to track this change. However, a scrubbing of the meta-prior using stale data points from weeks ago could contaminate the current representation. Investigating methods for graceful forgetting, such as employing a temporally weighted sliding window that exponentially decays the influence of older interaction windows on the gradient update, is a critical direction for ensuring the long-term fidelity of the student digital twin. We plan to evaluate MACMG over a simulated multi-month interaction scenario with artificially introduced concept drift (a sudden change in the relevance of a modality due to a course phase change, e.g., moving from lectures to group projects) to stress-test its robustness [23, 30].

Finally, the current framework's intervention selection is based on the maximum gating weight. While this provides a direct and interpretable link, it may be overly simplistic. A more sophisticated policy could use the full vector of gating weights as input to a reinforcement learning agent that learns optimal intervention strategies through trial and error, using the digital twin's risk score as a reward signal. Extending MACMG to serve as a state representation for a reinforcement learning-based intervention scheduler is a natural and promising next step [24, 30].

Although the current framework focuses on adaptive multimodal fusion and few-shot personalization, future extensions should investigate causal educational reasoning, reinforcement-learning-based intervention optimization, and large language model integration for semantic cognitive state modeling. Furthermore, while the adaptive gating policy captures strong associations between modality relevance and intervention selection, the current framework does not establish formal causal relationships between intervention actions and long-term academic outcomes.

VIII. Conclusion

This study introduced the Meta-Adaptive Cross-Modal Gating (MACMG) mechanism, a novel framework designed to address the critical cold-start problem in multimodal digital twin systems for early detection of at-risk students. By replacing static cross-modal attention layers with a lightweight, student-specific gating network whose initialization is meta-learned, we demonstrated that personalized fusion policies can be efficiently adapted from as few as five initial interaction windows. The bilevel meta-learning objective, built upon a first-order MAML approximation, enables the gating network to capture population-level inductive biases about modality relevance while remaining computationally amenable to rapid per-student personalization. Through extensive evaluation on two multimodal educational datasets, MACMG achieved statistically significant improvements over both static multimodal transformers and full-model meta-learning approaches, with AUROC gains of up to 10 percentage points under extreme data sparsity. Critically, the framework's ability to adapt in under half a second makes it viable for real-time deployment in learning management systems, while the direct coupling between gating weights and intervention selection ensures that personalized pedagogical actions are grounded in the student's most predictive communicative channel. Beyond its empirical performance, MACMG establishes a principled foundation for few-shot cross-modal fusion in educational digital twins, demonstrating that meta-learned parameterized gating offers a data-efficient and computationally practical pathway toward individualized, early intervention. More broadly, this work contributes toward a new generation of autonomous educational digital twins capable of adaptive reasoning, individualized intervention, and continuous learning trajectory optimization in AI-augmented educational ecosystems. Despite these promising results, several limitations remain. The evaluation was restricted to two educational datasets and partially relied on synthetic physiological embeddings to simulate multimodal educational environments. Furthermore, intervention routing was assessed using proxy intervention labels rather than longitudinally validated educational outcomes. Although the results suggest strong personalization capabilities, additional cross-institutional validation is required to fully assess generalization across diverse educational settings. These limitations provide important directions for future research. Future work will investigate the integration of large language models for semantic cognitive-state reasoning and conversational educational orchestration.

Doctoral Program of Information Systems-School of Postgraduate Studies, Diponegoro University, Semarang, Indonesia[1, 2]
Business Digital Study Program, Institute of Science and Business Atma Luhur, Pangkalpinang, Indonesia[1]
Department of Computer Engineering, Diponegoro University, Semarang, Indonesia[3]

***Abstract*—The complexity and dynamics of inpatient care require advanced decision support systems that are fast, adaptive, and capable of real-time execution. This study proposes a novel Smart Business Intelligence (SBI) model developed through an enhanced Hierarchy Governance Outlook (HGO) Discovery approach to achieve high-precision inpatient service prioritization. Unlike conventional frameworks, the proposed model combines an adaptive weighting mechanism, a sustainability optimization process, and real-time data integration from heterogeneous clinical and operational sources. The enhanced HGO Discovery model allows for dynamic adjustment of decision parameters in response to evolving hospital conditions, thereby maximizing patient care. The results demonstrate that the proposed model consistently outperforms baseline approaches in predictive accuracy, stability, and computational efficiency. These findings highlight the potential of the proposed framework to support data-driven decision-making and enhance the quality and efficiency of inpatient care delivery in modern healthcare environments. Experimental results show that the proposed model provides more accurate patient prioritization, faster identification of critical conditions, and improved operational efficiency compared to conventional approaches. Therefore, the proposed system offers an effective intelligent healthcare solution to support real-time inpatient care and data-driven medical decision-making in modern hospitals.**

***Keywords*—Smart business intelligence; decision support systems; HGO discovery; inpatient care; hospital**

I. Introduction

Advances in smart business intelligence and decision support systems have significantly driven the adoption of advanced data analytics and intelligent optimization techniques in the sustainable healthcare domain. The combination of heterogeneous data, governance, and big data facilitates more informed, rapid, and data-driven decision-making in real-time, particularly in the highly complex and fast-paced hospital environment [1]. However, existing implementations are largely conventional and often lack the ability to effectively respond to the next steps and the increasing demand for timely and accurate decision-making [2].

Smart Business Intelligence in hospitals represents a complex ecosystem where clinical services, operational processes, and information systems continuously interact. As core entities within these systems, hospitals face challenges in optimizing limited resources, managing performance, and maintaining high standards of patient safety and comfort in care [3]. Despite these demands, many current systems lack integration and tend to produce fragmented information, limiting the ability to achieve comprehensive, evidence-based decision-making [4].

Within this framework, Business Intelligence (BI) should be viewed not simply as a set of analytical tools, but as a strategic paradigm to support complex decision-making processes, particularly in patient care management [5]. Although previous studies have highlighted the effectiveness of BI in improving the efficiency and quality of healthcare services, critical research gaps remain in the development of models that can seamlessly integrate heterogeneous data in real time, dynamically adapt to changing clinical conditions, and optimize patient prioritization mechanisms [6]. Consequently, there is an urgent need for new approaches that combine adaptive modeling, dynamic weighting strategies, and continuous optimization techniques to enable more accurate, responsive, and context-aware decision support systems [7].

In inpatient care, the accuracy and complexity of decision-making are crucial factors because they directly impact the quality of care, patient safety, the effectiveness of medical procedures, and the efficiency of hospital operations [8]. Delays in detecting changes in a patient's condition can increase the risk of complications and death, prolong the length of stay, and even potentially increase mortality rates. Therefore, a technology-based approach is needed that not only provides historical information but also offers real-time predictive and adaptive analytics capabilities to support more precise decision-making [9].

A technological innovation phenomenon experiencing rapid development in supporting the digitalization of healthcare services is Smart Business Intelligence (SBI) [10]. SBI is believed to implement strategic operations that integrate data sets, analytical techniques, and data dashboard visualizations to transform systematic data processing into valuable, precise information that can be used as a basis for data-driven decision-making. Through the implementation of SBI, technology-based healthcare services can gain more comprehensive insights into operational conditions and clinical services in a systematic and integrated manner, thereby improving the effectiveness of overall healthcare management [11].

*Corresponding author.

Based on the problems described, this study proposes an Adaptive Smart Business Intelligence model based on Enhanced HGO Discovery for Real-Time Precision in Inpatient Care. The designed model focuses on the integration of clinical data and hospital operational data into a Smart Business Intelligence system that has the capabilities of real-time data processing, adaptive analysis, patient condition prediction, and the provision of strategic information precisely and accurately [12]. The implementation of this approach is expected to support medical personnel and hospital management in improving the quality of decision-making, accelerating the handling of changing patient conditions, increasing the efficiency of health services, and reducing mortality rates [13].

II. Related Works

The development of Smart Business Intelligence (SBI) and the latest data-driven health analytics has had a significant impact on the transformation of the modern healthcare system towards a smarter, more integrated, and responsive environment [14]. Recent studies have shown that the integration of Artificial Intelligence (AI) technology with SBI has great potential to increase hospital operational efficiency, improve the quality of patient care, and support clinical decision-making processes more accurately, quickly, and in real-time [15]. However, previous studies still face several challenges, particularly in integrating heterogeneous data, improving the system's ability to adapt to dynamic changes in patient conditions, and implementing intelligent optimization methods that can work adaptively in the complex and ever-evolving inpatient care environment [16].

The role of Smart Business Intelligence in the transformation of modern healthcare services is increasingly significant with the integration of artificial intelligence through the use of predictive analytics and intelligent clinical decision support systems [17]. Numerous research studies have shown that the application of artificial intelligence can accelerate diagnosis, analyze patient risks, and improve the overall effectiveness of patient care. Therefore, most existing research focuses on general AI implementation and has not yet integrated the concept of Smart Business Intelligence, supported by adaptive optimization mechanisms, into a real-time inpatient care environment [18].

Developing a real-time patient monitoring system based on Artificial Intelligence (AI) and the Internet of Things (IoT) to support continuous patient condition monitoring [19]. The designed system is capable of integrating primary health data with clinical data to detect changes in patient conditions more quickly and accurately. The results of this study demonstrate the effectiveness of the patient monitoring process, but the research still has limitations in supporting strategic decision-making based on Smart Business Intelligence (SBI) and has not implemented an intelligent optimization mechanism to determine adaptive patient care priorities [20].

The Smart Hospital Framework, which integrates Business Intelligence technology into hospital analytics, was developed to improve operational efficiency and the quality of healthcare services for inpatients [21]. Research results show that the use of a BI-based analytical dashboard can help hospital management monitor service performance and resource utilization more effectively and in a structured manner. However, the applied approach tends to be static, thus not being able to support adaptive analysis or predict patient conditions in real time [22].

In the context of developing patient prediction systems in hospital settings, various studies have developed inpatient condition prediction models using deep learning algorithms. The results show that this approach can improve the accuracy of predicting critical patient conditions compared to conventional methods. However, the implemented models still focus on simple analyses and have not yet integrated comprehensive Business Intelligence mechanisms to support clinical and operational decision-making processes in hospitals [23].

Developing a hybrid optimization technique approach to improve the performance of an artificial intelligence-based healthcare analytics system. The study demonstrates that a combination of heuristic algorithms and adaptive optimization can improve the accuracy of healthcare data classification while accelerating the process of finding optimal solutions for complex datasets. Despite making significant contributions to the development of healthcare optimization, the study has yet to implement the optimization method within an Adaptive Smart Business Intelligence framework to support real-time inpatient care [24].

Based on the latest research, it is understood that the application of Business Intelligence (BI), Artificial Intelligence (AI), and optimization techniques in the healthcare sector has had a significant impact on improving the quality of hospital services. The integration of these technologies can support a more efficient, accurate, and data-driven decision-making process. However, there are still a number of research gaps that have not been fully addressed, especially related to the integration of clinical and operational data in real time, the system's ability to adapt to dynamic changes in patient conditions, optimization of service priorities, and the implementation of adaptive heuristic methods in Smart Business Intelligence systems. Therefore, this study proposes an Adaptive Smart Business Intelligence Model Based on Enhanced HGO Discovery for Real-Time Precision in Inpatient Care as an innovative approach that combines adaptive analytics, real-time heuristic optimization, and intelligent prediction mechanisms to support more precise, responsive, and efficient inpatient care.

III. Research Methodology

This research object uses a quantitative approach based on system development (system development approach) to design an Adaptive Smart Business Intelligence Model Based on Enhanced HGO Discovery for Real-Time Inpatient Care. The research process begins with the collection of clinical data and hospital operational data sourced from Electronic Health Records (EHR) and a real-time patient condition monitoring system where the total patient data used was 2,780 samples. Next, the data processing stage is carried out which includes three main components, namely Hierarchy (H), Governance (G), and Outlook (O), to support the process of data integration, information management, and adaptive analysis in improving the effectiveness of inpatient services. The implementation stages of the Enhanced HGO Discovery Framework in this study are carried out through several systematic processes in Fig. 1.

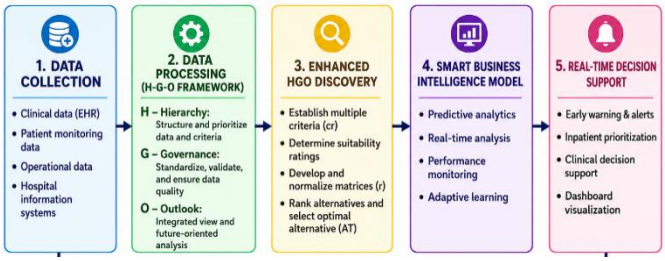

Fig. 1. Methodology framework.

The first stage involves defining multiple decision criteria (criteria/cr) that serve as the primary basis for evaluating inpatient service conditions and supporting clinical decision-making. These criteria are designed to represent important aspects of patient conditions, hospital operations, and healthcare service priorities within the Smart Business Intelligence framework.

The second stage focuses on determining the suitability rating for each alternative based on the established criteria. In this process, the evaluation values are represented through the components of Hierarchy (H) and Governance (G), which are used to classify data structures, prioritize patient conditions, and manage healthcare information systematically. This stage enables the model to identify the relevance and importance of each alternative in supporting adaptive decision-making.

The next stage involves constructing several decision matrices derived from the defined criteria. These matrices are subsequently processed using a normalization procedure based on positive and negative attribute consensus values to produce balanced and standardized data representations. The normalization process generates normalized matrix values symbolized as (r), which are utilized to improve analytical consistency, reduce data bias, and enhance computational efficiency in the optimization process.

Finally, the ranking and selection process is performed by calculating the weighted aggregation of the normalized matrix values. Each alternative is evaluated based on its calculated risk and performance score, where the alternative with the lowest risk value and highest optimization performance is selected as the optimal alternative (AT). This process enables the proposed model to support real-time adaptive decision-making in inpatient care through accurate prioritization and intelligent analytical recommendations.

IV. Result and Analysis

This study develops an Adaptive Smart Business Intelligence model based on Enhanced HGO Discovery, designed to support real-time decision-making in inpatient care services in hospitals. The proposed model integrates various hospital data sources, namely Electronic Health Records (EHR), patient monitoring data, and hospital operational data, all combined into a single adaptive Business Intelligence platform. Implementation results show that the system is capable of processing data quickly and continuously, thus supporting a more effective and accurate decision-making process in a dynamic healthcare environment.

The research phase begins with the Data Collection process, which serves as the primary foundation for developing a Smart Business Intelligence system. In this phase, various types of data are collected from several sources that serve as reference points for the hospital. The collected data includes Electronic Health Records (EHR), operational data, and information originating from the hospital. Information in the EHR includes patient health histories, medical diagnoses, treatment procedures, and medication administration history. Furthermore, this study utilizes not only clinical data but also hospital operational data, such as bed availability, patient emergencies, healthcare provider schedules, and patient queue data to support a more comprehensive and accurate decision-making process. We look at five key processes: (A) Data Collection, (B) Data Processing HGO Discovery, (C) Enhanced HGO Discovery, (D) Smart Business Intelligence Model, (E) Real Time Decision Support.

A. Data Collection

The initial stage of the research began with the Data Collection process, which serves as the primary foundation for developing an Adaptive Smart Business Intelligence system. This stage involved data collection from hospitals to generate comprehensive and accurate information. The data collected included Electronic Health Records (EHR). This study utilized 2,780 datasets, consisting of inpatient data, patient condition monitoring data, and hospital operational data collected during the study period. The characteristics of the dataset can be seen in Table I.

TABLE I. Characteristics of the Dataset

Specifications	Description
Total number of datasets	2,780
Time slot	2023-2026
Attribute of positive value	Insurance Provider, Room Class, Admission Type, Severity Score, Test Result
Attribute of negative value	Surgery

The EHR datasets utilized in this study contained a wide range of essential information regarding patient conditions, including medical histories, laboratory examination results, clinical diagnoses, treatment procedures, and medication administration records. In addition, the system collected real-time data directly from patient monitoring devices. Beyond clinical information, the research also incorporated hospital operational data, such as inpatient room capacity, bed occupancy availability, and patient queue information, to facilitate a more comprehensive and effective decision-making process.

B. Data Processing HGO Discovery

HGO Discovery is a multidimensional data processing method that integrates: priority structure (Hierarchy), control and decision rules (Governance), and strategic prediction and insight (Outlook). Table II shows implementation of HGO Discovery.

TABLE II. IMPLEMENTATION PROCESSING HGO DISCOVERY

Model	Category	Interpretation
Priority structure (Hierarchy)	Level 1	Main objective
	Level 2	Decision criteria
	Level 3	Sub-criteria
	Level 4	Decision alternatives
Control and decision rules (Governance)	Data validation	Rule-based filtering
Strategic prediction and insight (Outlook)	Prediktif	Intelligence forecasting

After an agreement is reached regarding the weight of each attribute or criterion determined by the experts, the next stage is to assign CRISP values to the data based on the previously determined hierarchy. There are six criteria (Cr) used in the assessment or decision-making process. The first criterion, Cr1 (Insurance Provider), is a benefit criterion with a weight of 0.10, meaning the better the insurance provider, the higher the score. The second criterion, Cr2 (Surgery), is a cost criterion with a weight of 0.20, so a lower score is considered better. Next, Cr3 (Room Type) has a benefit characteristic with a weight of 0.175, where a better room type gives a higher score. Cr4 (Admission Type) is also a benefit criterion with a weight of 0.125. Then, Cr5 (Severity Score) is a benefit criterion with the highest weight along with several other criteria, namely 0.20, indicating a high level of importance in the assessment. Finally, Cr6 (Test Result) is a benefit criterion with a weight of 0.20, so a better test result will increase the final score. All of these criteria's weights are used to determine the priority or overall evaluation results based on their respective levels of importance. Fig. 2 shows specification and value attributes of the characteristic dataset.

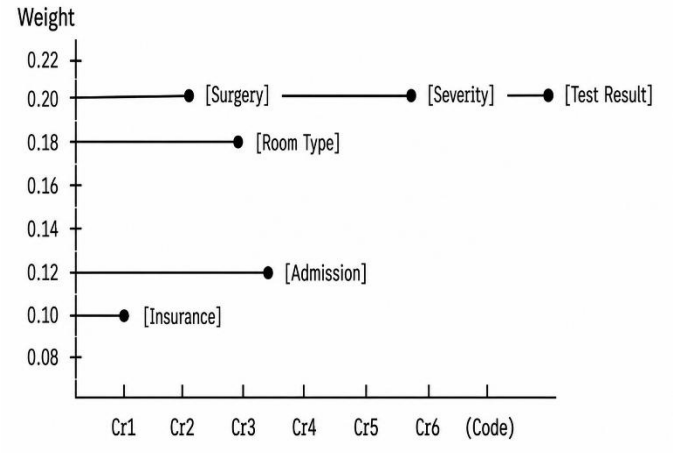

Fig. 2. Specification and value attribute.

C. Enhanced HGO Discovery

Enhanced HGO Discovery demonstrates superior performance in finding optimal solutions compared to conventional methods. Improvements to the HGO algorithm are made through the addition of optimization mechanisms and parameter adjustments to make the exploration and solution exploitation processes more efficient. Based on testing results, this method is able to provide more precise, stable, and consistent preference values in selecting the best alternative based on the criteria of Insurance Provider, Surgery, Room Type, Admission Type, Severity Score, and Test Results.

This stage also shows a faster convergence rate in the calculation process, resulting in more efficient computing time. By considering the weight and type of criteria (benefit and cost), the Enhanced HGO Discovery model successfully provides more objective evaluation results and supports more accurate decision-making, Fig. 3 shows HGO Discovery process.

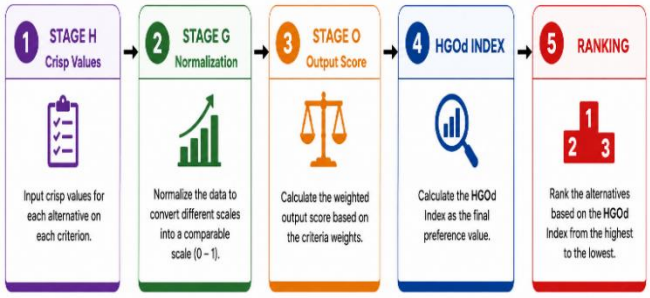

Fig. 3. HGO discovery processes.

Therefore, this model is considered effective for application in decision support systems, especially in the process of analyzing and selecting the best alternative in the healthcare sector. Table III shows the stage enhanced HGO Discovery.

TABLE III. ENHANCED HGO DISCOVERY METHOD

Stage	Description	Formula
Crisp Values	Input crisp values for each alternative on each criteria	Cr = criteria (Cr1 to Cr..n)
Normalization	Normalize the data to convert different scale into a comparable scare (0-1)	Value scale between 0 to 1
Output Score	Calculate the weighted output score based on the criteria weights.	Total weight =1.00
HGO Discovery Index	Calculate the HGO Discovery index as the final preferenced value	HGO Discovery index or HGOD Index, the highest priority value is 0.000, and the lowest priority value is 1
Ranking	Rank the alternative based on the HGO Discovery index from the higest to the lowest	Alternative are ranked from the highest to the lowest HGOD index.

The crisp data representing the criteria values contains information about each criterion and its weight. These crisp values are optional and serve as a reference limit for determining the value range for each criterion. Each crisp value has a specific weight derived from the conversion process, which is then applied to the HGO Discovery model calculations. The weighting process also influences the nature of the criteria, which are divided into two categories: positive and negative factors. Meanwhile, alternative values are used to store the evaluation results of each alternative based on all available criteria data.

Normalization attributes must be carried out so that the important process in compiling data in the stage model that occurs in HGO Discovery. Next stage is output score, where the weighted output score based on the criteria weights is calculated.

The output and HGOD Index have different scales, but each serves a different purpose in the decision support framework of this model, where the higher value output is the best value, while with the HGOD index, the lower value is better. Ranking is based on the HGOD index, where the lowest value = rank 1. This is useful for prioritizing patients based on the HGO discovery metric. Table IV shows different output score and HGOD Index.

TABLE IV. DIFFERENT OUTPUT SCORE VS HGOD INDEX

Interpretation Output	Value
Output Score (Simple Additive Weighting)	Higher output score indicates better patient condition overall. Range: 0–1. Calculated via weighted sum of normalized criteria.
HGOD Index	Lower HGOd index = higher inpatient priority. Formula: 1 / Σ(Wj × Xj). Patients in top-left scatter quadrant need immediate attention.

D. Smart Business Intelligence Model

After patient data is collected, processed using the HGO Discovery, and analyzed using the Enhanced HGO Discovery method, the system then enters the Smart Business Intelligence stage to generate more adaptive and strategic insights.

At this stage, the system utilizes previous calculation results, such as normalization values, output scores, and the HGOd Index, to perform predictive analytics. This analysis is used to estimate patient conditions, risk levels, service priorities, and potential changes in a patient's health status during the inpatient process. With this approach, hospitals can take faster and more accurate action based on data automatically analyzed by the system.

This Smart Business Intelligence Model applies the concept of adaptive learning, which is the system's ability to adjust its analysis process based on the latest data patterns. The system can learn from previous patient data, making recommendations and prioritization more accurate over time. This adaptive approach makes the model more flexible in responding to changing patient conditions and hospital operational dynamics. The Smart Business Intelligence Model serves as the center of intelligent analysis in this study because it integrates data, Enhanced HGO Discovery, and real-time analytics to produce faster, more accurate, and more efficient decisions in inpatient care services.

The system utilizes previous calculation results, such as normalization values, output scores, and the HGOd Index, to perform predictive analytics. This analysis is used to estimate patient conditions, risk levels, service priorities, and potential changes in a patient's health status during the inpatient process. With this approach, hospitals can take faster and more accurate action based on data automatically analyzed by the system. Fig. 4 shows Smart Business Intelligence Output Score and HGOD Index.

CODE	NAME	AGE	GENDER	OUTPUT	HGOD INDEX	RANK	PRIORITY
P000011	Patient A	24	Male	0.6225	0.013841	326	Critical

E. Real Time Decision Support

Real-Time Decision Support is the final stage in the Adaptive Smart Business Intelligence model based on Enhanced HGO Discovery, which functions as a direct and automated decision support system in inpatient care. At this stage, all analysis results from the previous process—from data processing, Enhanced HGO Discovery calculations, to the Smart Business Intelligence Model—are used to generate fast, accurate, and adaptive decision recommendations based on real-time patient conditions.

Inpatient prioritization is used to determine the priority of inpatient services based on the HGOd Index and patient data analysis. Patients with higher risk levels receive priority treatment over lower-risk patients. This mechanism helps hospitals manage service queues, treatment room utilization, and medical resource allocation more efficiently and objectively.

This stage also supports clinical decision support, which provides data-driven recommendations to assist doctors and healthcare professionals in making medical decisions. The system can provide insights into patient severity, health condition analysis results, and prioritized action recommendations based on automatically processed data. This way, medical decisions no longer rely solely on manual observation but are also strengthened by intelligent data analysis.

Another feature is the visualization dashboard, an interactive visual display that presents patient information, priority scores, risk status, and analysis results in real time. This dashboard makes it easier for hospital management and medical personnel to quickly and comprehensively monitor patient conditions. Clear data visualization also contributes to more effective monitoring and evaluation of healthcare services. Fig. 5 show dashboard interactive visual that priority score.

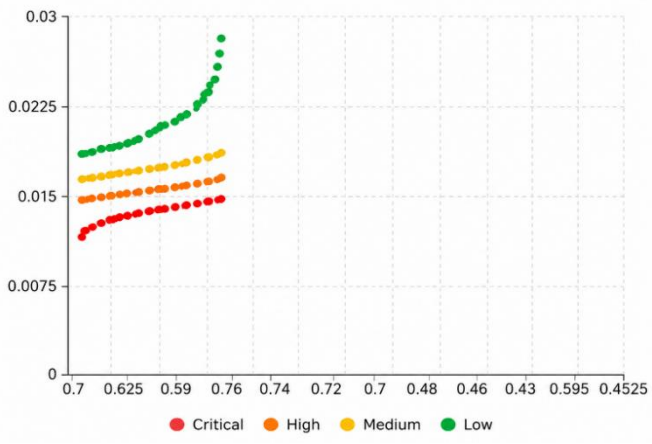

Fig. 5. Dashboard interactive visual for the priority score.

V. Conclusion

An HGO Discovery-based model supports real-time decision-making in inpatient care. The proposed model integrates data collection, the HGO Discovery model, and a Smart Business Intelligence system to generate more adaptive, accurate, and efficient analysis. Implementing this method can improve the patient evaluation process by calculating preference scores and the HGOd Index based on various criteria.

The integration of predictive analytics, real-time analysis, adaptive learning, and real-time decision support features enables the system to provide early warnings, dashboard visualizations, and automated patient service priority recommendations. Enhanced HGO Discovery has also been shown to increase the effectiveness of the solution exploration and exploitation process compared to conventional methods, resulting in more stable and consistent decisions. Thus, this research provides an important contribution to the development of a modern healthcare business intelligence system that can improve hospital service quality, operational efficiency, and rapid response to inpatient conditions dynamically and in real-time.

For further research, it is hoped that the Adaptive Smart Business Intelligence model based on Enhanced HGO Discovery can be developed by adding more variables and more complex health data sources, such as electronic health records (EHRs), health IoT sensor data, and continuous patient monitoring data. Further development can also be done by integrating machine learning and deep learning technologies so that the system can produce more accurate patient condition predictions and adapt to real-time data changes. In addition, further research is expected to test this model on a larger hospital scale and different health environments to determine the level of effectiveness, stability, and flexibility of the system in real conditions.

Acknowledgment

Special recognition is given to the healthcare institutions and organizations that provided support, facilities, and data related to inpatient care. Their collaboration and contributions significantly assisted in the analysis and implementation of the adaptive smart business intelligence model developed in this research.

King Mongkut's University of Technology North Bangkok, Thailand[2]

***Abstract*—Vehicle routing problems with time windows require route construction methods that can reason jointly about spatial distance, vehicle capacity, service time, and customer time windows. Recent neural combinatorial optimization studies show that Transformer and graph-based models can learn routing policies, but many models still rely mainly on node features and do not expose which routing relations are responsible for feasibility and route quality. This study proposes a multi-relation knowledge graph guided Transformer framework for the vehicle routing problem with time windows. For each instance, a pairwise knowledge graph is built from spatial, temporal, capacity, slack, and depot identity relations. These relation vectors are projected into head-specific attention biases inside a pointer-style Transformer, while a feasibility mask enforces capacity and time window constraints during decoding. The framework is trained by imitation from OR-Tools teacher routes and evaluated on the 56 Solomon benchmark instances and on synthetic Solomon-style extensions. The original Transformer baseline decoded feasible routes for 54 of 56 Solomon instances, whereas the full knowledge graph guided model decoded feasible routes for all 56 instances. Additional controlled AM style, POMO style multistart, and edge-aware Transformer baselines improve route quality gaps on feasible instances but still leave one Solomon instance infeasible, highlighting the proposed framework's feasibility-oriented role. On three 120 instance synthetic runs, objective-aware route selection over relation-specialized models reached a mean feasible rate of 0.997 and reduced the mean distance gap by 125.418 Solomon coordinate distance units compared with the relation-free Transformer baseline. The contribution is therefore a diagnostic and extensible framework that integrates explicit routing knowledge into neural attention, evaluates relation ablations, and combines specialized route candidates according to the target operational objective.**

***Keywords*—Vehicle routing problem with time windows; knowledge graph; Transformer; neural combinatorial optimization; relation aware attention; route selection**

I. Introduction

The vehicle routing problem with time windows (VRPTW) is a central problem in logistics optimization. A fleet must serve geographically distributed customers while satisfying vehicle capacity and customer service intervals. The Solomon benchmark remains a standard controlled testbed for this setting [1]. Constraint and operations research solvers, including OR-Tools, provide strong references because they represent routing constraints directly [2].

Learning-based solvers are attractive when repeated route construction, fast policy reuse, or learned route priors are required. Recent surveys describe rapid growth in neural combinatorial optimization, reinforcement learning, and learning to route methods [3]-[5]. However, a practical gap remains: many neural VRP models learn from node features without explicitly separating the spatial, temporal, capacity, and slack relations that drive VRPTW feasibility.

In this study, a pointer Transformer refers to an attention-based encoder-decoder route construction model whose output pointer distribution selects the next customer from the current set of feasible nodes. The model, therefore, predicts a sequence of customer visits rather than a fixed class label.

This work studies whether a knowledge graph (KG) can operate as a structured control layer for a Transformer routing model. Instead of treating the KG as a post hoc explanation, the proposed framework injects pairwise relation information directly into Transformer attention. The study is positioned as a framework and diagnostic analysis rather than as a claim that a compact neural model outperforms OR-Tools.

The contributions are: a multi-relation KG representation for VRPTW instances; a KG-guided pointer Transformer that converts relation vectors into attention bias; relation ablations and adaptive variants that reveal how relation groups affect decoded routes; and objective-aware route selection with multi-seed robustness evaluation.

The rest of the study is organized as follows: Section II reviews neural routing and knowledge guided routing studies. Section III states the research gap. Section IV presents the KG-guided framework, relation definitions, attention bias, feasibility mask, and implementation settings. Section V describes the experimental design, Section VI reports the results, Section VII discusses implications, and Section VIII and Section IX summarize limitations and conclusions.

II. Related Work

Hybrid learning and optimization methods have become common in vehicle routing. Deep reinforcement learning has been used for column generation [6], neural construction heuristics have been embedded in large neighborhood search

*Corresponding author

[7], and combinatorial optimization enriched machine learning has been applied to dynamic VRPTW [8]. Multi-objective and multi-agent variants further expand the decision space beyond distance minimization [9]-[12].

Recent time window and electric vehicle studies use reinforcement learning and graph-structured data to model feasible actions, resource use, and operational constraints [13]-[15]. Transformer-based routing models use attention to represent customer interactions, including collaborative Transformer approaches, EFormer edge-based Transformers, and local global feature fusion Transformers [16]-[18]. GASE graph attention with edge fusion and symmetry preserving graph attention also suggest that edge information can improve routing representations [19], [20]. These models motivate relation-aware routing, but they do not isolate VRPTW spatial, temporal, capacity, slack, and identity relations as separate ablation controls inside a head-specific attention bias.

Broader generalization has been explored through equity-aware Transformers, cross-problem learning, foundation-style route models, mixture of experts, large-scale reinforcement learning, and route foundation models [21]-[26]. Knowledge-guided metaheuristics and hybrid reinforcement learning show that explicit domain knowledge can improve search behavior [27], [28]. Other recent routing research includes GCN-assisted search, hyperheuristic and VAE-based approaches, edge-based learning for VRPTW, and backhaul routing [29]-[32]. Closely related Thai VRPTW studies by Kosolsombat and Ratanavilisagul examined modified ant colony optimization and applied deep reinforcement learning for time window routing [33], [34]. The present work differs by using a pairwise KG as a direct attention bias inside a Transformer and by testing relation groups through ablation and route selection.

III. Research Gap and Design Rationale

The literature indicates three limitations that motivate this study. First, many neural VRP models encode customers primarily as node sequences. This is convenient for attention-based models, but VRPTW feasibility is inherently pairwise: whether customer j can follow customer i depends on travel time, service completion, waiting time, residual capacity, and both time windows. A model that only receives node attributes must infer these pairwise constraints indirectly from training examples.

Second, recent neural routing studies often report final route quality but provide less diagnostic evidence about which kinds of routing knowledge help. For a logistics decision maker, it is useful to know whether spatial proximity, temporal feasibility, capacity compatibility, or slack information is responsible for improved decoded routes. A relation ablation design, therefore, gives more insight than a single black box comparison.

Third, no single learned construction policy is expected to dominate all instance classes. Clustered, random, and mixed Solomon-style distributions have different structural properties. A relation setting that is useful for clustered customers may not be best for dispersed customers with tight windows. This motivates a framework in which relation-specialized models are treated as candidate route generators, and route validation is used before objective-aware selection.

IV. Proposed Framework

Fig. 1 summarizes the proposed pipeline. Each VRPTW instance is converted into node features and a pairwise KG. OR-Tools teacher routes provide imitation labels. A pointer Transformer receives node features, while the KG contributes relation-specific attention bias. The decoder applies a hard feasibility mask, and a candidate pool of relation-specialized models is filtered and ranked by the chosen routing objective.

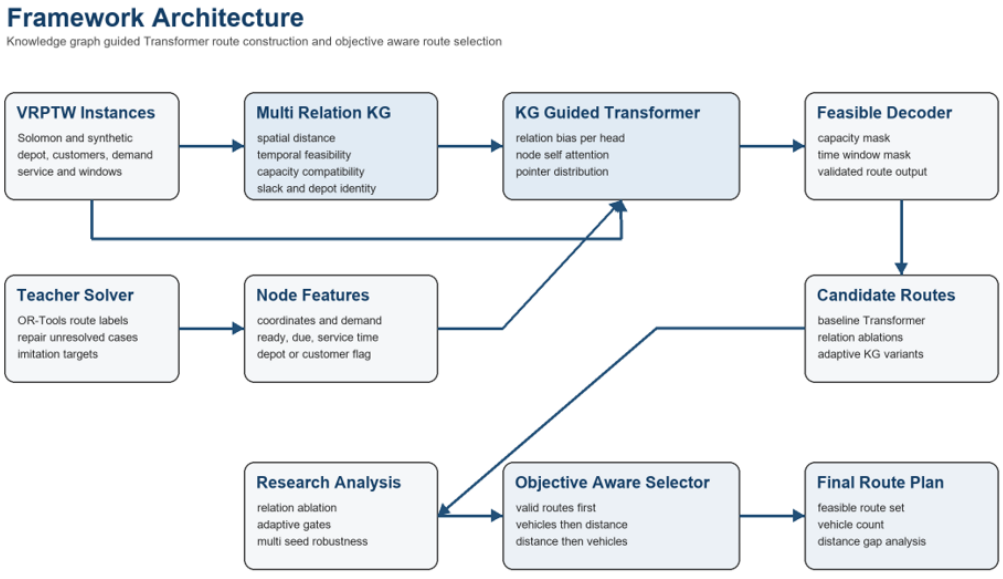

Fig. 1. Proposed multi-relation KG-guided Transformer framework with objective-aware route selection.

A. Problem Setting

Each instance contains one depot and n customers. Customer i has coordinates, demand, service duration, and a time window. A feasible route starts and ends at the depot, respects vehicle capacity, and begins service within every customer's time window. Evaluation reports the feasibility, the number of vehicles, total distance, and the gap relative to the OR-Tools reference.

B. Multi-Relation Knowledge Graph

For each ordered node pair, the KG stores relation features. The implemented groups are spatial relations, temporal feasibility, time window overlap, capacity compatibility, waiting time and slack, and depot or identity indicators. Ablation variants include spatial, temporal, capacity, feasible, slack, no slack, and full relation settings.

Let V={0,...,n} denote the depot and customer nodes, where node 0 is the depot. Customer i has coordinates x_i, demand q_i, service time s_i, ready time e_i, and due time l_i. Vehicle capacity is Q, the depot horizon is H, and d_ij is the Euclidean distance. For every ordered pair (i,j), the KG relation vector r_ij contains normalized distance d_ij/max(d), a near-neighbor indicator 1[d_ij <= q_0.20(d)], temporal feasibility 1[e_i+s_i+d_ij <= l_j], reverse feasibility 1[e_j+s_j+d_ij <= l_i], time-window overlap 1[max(e_i,e_j) <= min(l_i,l_j)], and capacity compatibility 1[q_i+q_j <= Q].

Slack and waiting relations are computed as wait_ij=max(0,e_j-(e_i+s_i+d_ij))/H and slack_ij=clip((l_j-(e_i+s_i+d_ij))/H,-1,1). Identity relations are same_node=1[i=j], source_is_depot=1[i=0], and target_is_depot=1[j=0]. These formulas make the KG deterministic and reproducible from a Solomon-style input file without external semantic resources.

The spatial group represents geometric closeness through normalized distance and near-neighbor indicators. These relations give the model a direct signal about route compactness. The temporal group represents whether one customer can precede another under service and travel time, including reverse feasibility and time window overlap. Slack and waiting relations capture how much scheduling flexibility remains when a customer pair is visited consecutively. The capacity group encodes whether two customer demands can coexist under the vehicle capacity, and the identity group distinguishes depot-related transitions from customer-to-customer transitions.

This formulation is intentionally simple and deterministic. The KG does not require external semantic knowledge or manually curated ontologies. Instead, it transforms the mathematical constraints of VRPTW into pairwise relation channels that can be consumed by the neural model. This makes the framework reproducible on any Solomon-style instance and allows each relation group to be removed or retained in ablation experiments.

C. KG-Guided Pointer Transformer

The relation-free baseline is a pointer-style Transformer that predicts the next customer from node embeddings. The KG-guided version projects relation vectors into head-specific attention terms. These terms bias self attention before the pointer distribution is computed. During decoding, infeasible customers are masked to prevent capacity and time window violations.

Formally, node features X are projected to hidden states h_i. For attention head k, relation vector r_ij is mapped to a scalar bias b_ij^k=tanh(w_k^T r_ij+c_k) gamma, where gamma is a learned scale. The self-attention logit becomes a_ij^k=(Q_i^k K_j^k)/sqrt(d_h)+b_ij^k before the softmax over candidate keys j. In the implementation, the same relation-bias tensor is supplied to each relation-aware encoder layer, allowing different heads to learn different uses of spatial, temporal, capacity, slack, and depot relations.

The attention bias design is important because it lets each attention head learn a different use of the KG. One head may emphasize spatial closeness, another may emphasize temporal feasibility, and another may attend to depot-related transitions. The model, therefore, does not concatenate relation features to node features only once at the input layer; it uses relation information whenever pairwise attention scores are computed.

D. Training and Decoding

Training is formulated as imitation learning from teacher routes. For each partial route state, the teacher provides the next customer in the sequence, and the model is optimized to assign high probability to that teacher action. This design avoids the high variance of pure reinforcement learning and makes the experiment feasible on a modest GPU. It also creates a clear reference point: the neural model is learning to approximate the route construction behavior induced by the OR-Tools teacher.

During inference, the decoder constructs routes greedily under a feasibility mask. The mask removes customers who would violate capacity or time windows from the next action set. When no feasible customer remains, the vehicle returns to the depot, and a new route is started. After decoding, each route plan is validated again before it is used in evaluation or route selection. This validation step is essential because the study measures decoded operational feasibility, not only sequence prediction loss.

The feasibility mask is defined at each partial route state. A customer j can be selected only if j is unvisited, q_j is not larger than remaining capacity, and the service start time max(e_j,t_i+s_i+d_ij) is not later than l_j. The depot action is allowed after at least one customer has been served on the current route, or when no customer satisfies the capacity and time-window tests. This hard mask prevents the decoder from selecting actions that are known to be infeasible before route validation.

E. Objective-Aware Route Selection

Different relation groups can be useful for different instance structures and objectives. Therefore, relation-specialized models generate route candidates. Valid candidates are ranked by either vehicles then distance or distance then vehicles. This route-level step converts relation diversity into an explicit selection mechanism.

Two ranking choices are considered because routing objectives are not always equivalent. A logistics operation that pays a fixed cost per vehicle may prefer vehicles then distance, while an operation with a fixed fleet may prefer distance then vehicles. Reporting both objectives prevents an overly broad claim of superiority and shows how the same candidate pool can be adapted to different operational priorities.

F. Implementation Details

The implementation settings used in the reported experiments are summarized in Table I. The local neural comparison uses the relation-free pointer Transformer as a direct baseline and keeps the same teacher-label generation and decoded feasibility validation as the KG-guided models.

TABLE I. IMPLEMENTATION AND TRAINING SETTINGS

Setting	Reported value
Relation-free model	d_model=128, 8 heads, 4 layers, FFN=256
KG-guided model	d_model=128, 4 heads, 3 relation-aware layers, FFN=256
Regularization	dropout=0.1, weight decay=1e-4, gradient clipping=1.0
Optimizer	AdamW; lr=1e-3 for relation-free baseline, 8e-4 for KG variants
Training	imitation learning from OR-Tools labels; batch size 32; Solomon 80 epochs; synthetic 50 epochs
Decoding	greedy pointer decoding with hard capacity and time-window mask
Controlled neural baselines	AM style attention pointer; POMO style 16-start selection; edge-aware Transformer with full relation features
Hardware	Remote GPU: NVIDIA RTX 3050, CUDA 12.4, PyTorch 2.6.0+cu124

G. Competitive Benchmarking Scope

Table II positions the proposed framework against established neural routing families and adds controlled neural baselines that were run under the same Solomon data, teacher label, decoding, and validation protocol. The AM style, POMO style multistart, and edge-aware Transformer rows are locally controlled baselines rather than official reproductions of AM, POMO, EFormer, GASE, or L2D codebases. This design directly strengthens the neural comparison while keeping the claim limited to verified same-pipeline results.

TABLE II. NEURAL BASELINE SCOPE AND CONTROLLED SOLOMON RESULTS.

Method/scope	Run type	Feas.	D-gap	V-gap
Official AM	literature only	--	--	--
Official POMO	literature only	--	--	--
L2D style solvers	literature only	--	--	--
Official EFormer/GASE	literature only	--	--	--
AM style attention pointer	controlled	55/56	288.059	3.836
Edge aware Transformer	controlled	55/56	275.804	3.764
POMO style multistart	controlled	55/56	223.276	2.636
Relation-free Transformer	controlled	54/56	318.654	4.056
Proposed KG full	controlled	56/56	304.202	3.464

V. EXPERIMENTAL DESIGN

The experiments use the 56 original Solomon 100 customer instances and synthetic Solomon-style extensions containing clustered, random, and mixed customer distributions. Teacher routes are generated with OR-Tools, including repair runs for initially unresolved cases. Models are trained by imitation and evaluated by decoded feasibility, distance gap, and vehicle gap.

The synthetic stage provides a robustness view beyond the small original benchmark. Three independent 120 instance synthetic runs are summarized with mean values and 95 percent confidence intervals. Because OR-Tools is the teacher and reference, the reported gaps are conservative measures of how far the learned route construction remains from the solver output.

The evaluation uses four complementary indicators. Feasibility measures whether the decoded solution satisfies all route constraints. Vehicle gap measures how many additional vehicles the learned route uses relative to OR-Tools. Distance gap is the extra travel distance relative to OR-Tools. Maximum gap captures the worst-case deterioration. Together, these metrics distinguish constraint satisfaction, fleet size, average route quality, and tail risk.

The original Solomon instances are used to evaluate compatibility with a standard benchmark. The synthetic extensions are not intended to replace the benchmark; they provide repeated instance samples so that route selection and relation ablation can be tested across multiple seeds. This distinction is important because a framework claim should not rely only on a single small benchmark split.

VI. RESULTS AND ANALYSIS

Table II adds controlled neural baselines requested for the competitive context. The POMO style multistart baseline obtains the lowest Solomon mean distance gap among the local neural baselines (223.276) and a lower mean vehicle gap than the single policy models, while the AM style and edge aware baselines also improve route quality over the original relation-free Transformer. However, all three additional controlled baselines leave one Solomon instance infeasible. The proposed KG full model is therefore not claimed to dominate every quality metric; its main advantage in the original Solomon benchmark is complete decoded feasibility with explicit relation diagnostics.

TABLE III. ORIGINAL SOLOMON INSTANCE RESULTS

Method	Feas.	D-gap	Max gap	V-gap
Transformer baseline	54/56	318.654	621.406	4.056
KG-guided Transformer	56/56	304.202	683.267	3.464
KG-guided Transformer + repair	56/56	295.435	671.015	3.464

Table III reports the original Solomon results. KG guidance improves feasibility over the relation-free Transformer: the baseline decoded feasible routes for 54 of 56 instances, whereas the full KG-guided model decoded feasible routes for all 56 instances and reduced the mean vehicle gap. The repair variant further reduced the mean distance gap while retaining complete feasibility.

Table IV shows the Solomon relation ablation. Relation groups contribute differently: temporal and slack-oriented variants are competitive on the distance gap, while the full setting gives complete feasibility. The no slack setting has a low distance gap but loses one feasible instance, showing that relation selection changes the tradeoff between feasibility, distance, and vehicle count.

TABLE IV. SOLOMON RELATION ABLATION SUMMARY

Relation	Feas.	D-gap	V-gap	Relation specialization
spatial	55/56	295.447	3.455	spatial
temporal	56/56	272.667	4.268	temporal
capacity	55/56	276.861	3.964	capacity
feasible	55/56	295.612	3.909	feasible
slack	56/56	272.708	3.643	slack
no_slack	55/56	267.915	3.309	no_slack
full	56/56	304.202	3.464	full

Table V reports the synthetic medium route selection results, and Table VI summarizes the multi-seed synthetic robustness study. Objective-aware ensembling is stronger than any single learned model in terms of feasibility and distance gap. Across three 120 instance synthetic runs, the distance-oriented ensemble reaches a mean feasible rate of 0.997 and reduces the mean distance gap by 125.418 Solomon coordinate distance units relative to the relation-free Transformer. Table VII further shows that the hardest groups are R1 and RC1, where relation diversity and selection provide the largest feasibility improvements.

TABLE V. SYNTHETIC MEDIUM ROUTE SELECTION RESULTS

Method	Feas.	D-gap	V-gap
transformer_baseline	55/60	451.255	3.836
kg_ablation_full	55/60	404.900	3.218
kg_ablation_no_slack	59/60	445.001	3.153
adaptive_kg_transformer_l1	56/60	432.546	3.679

ensemble_all_distanc	0.997 +/- 0.005	302.409 +/- 4.245	2.858 +/- 0.037

Table VIII reports paired t-tests across the three independent 120 instance synthetic runs. The distance-oriented ensemble significantly reduces the distance gap relative to the relation-free Transformer baseline (p=0.0059) and significantly increases the feasible rate (p=0.0472). The vehicle-oriented ensemble also significantly reduces the vehicle gap (p=0.0327). The full KG ablation improves the feasible rate, but the three-seed test does not show significance for that isolated comparison, which supports the interpretation that objective-aware route selection is the most robust component in the current experiments.

TABLE VII. HARD CLASS FEASIBILITY AND DISTANCE GAP

Group	Base feas.	Ens. feas.	Base gap	Ens. gap
C1	0.950	1.000	402.579	270.620

TABLE IX. INFERENCE TIME BENCHMARK ON SOLOMON INSTANCES

Model	Device	Repeats	Mean s/inst.	Min-Max s	Overhead
Relation-free Transformer	cuda	3	1.356	1.003-1.879	reference
Full KG-guided Transformer	cuda	3	1.668	1.259-2.152	+23.0%

The results also show that full relation information is not always the best distance-oriented configuration. On the original Solomon ablation, the no slack and slack variants produce lower mean distance gaps than the full relation model, while the full relation model gives complete feasibility. This suggests that relation richness can improve constraint awareness but may also change the model's route construction bias. Therefore, the ablation should be interpreted as evidence for controllability rather than as a simple ranking of relation sets.

The hard class analysis is especially informative. R1 and RC1 are more difficult because customer locations are less clustered and time windows are tighter. The relation free Transformer has a low feasible rate in R1, whereas the distance-oriented ensemble reaches near complete feasibility.

This indicates that route validation and candidate diversity are most valuable when a single learned policy is brittle.

VII. Discussion

The main finding is that explicit relation structure makes neural route construction more controllable. The KG is useful not only as an input feature source but also as an experimental mechanism for testing which routing knowledge supports feasibility and route quality. Objective-aware selection further shows that relation-specialized models can be combined without assuming that a single relation setting is best for every instance class.

The framework should be interpreted as a learned construction and diagnostic layer. It does not replace OR-Tools, which remains the reference solver and teacher. Instead, it provides a structured neural route generation pipeline that can be paired with local search, repair, or solver-based refinement in future work.

From a methodological perspective, the proposed KG has two roles. The first role is inductive bias: it exposes pairwise feasibility and routing structure to the Transformer before the model has to infer those relations from data. The second role is experimental transparency: relation groups can be added, removed, or selected, making it possible to explain performance differences in terms of routing knowledge rather than only model size or training loss.

From a practical perspective, the framework is most useful as a fast route construction component. A dispatcher or decision support system could use KG-guided decoding to generate feasible candidate routes quickly, then pass the best candidates to a local search, repair heuristic, or exact solver for improvement. In this setting, the neural model contributes speed and diversity, while the downstream optimizer contributes final route refinement decision support system could use KG-guided decoding to generate feasible candidate routes quickly, then pass the best candidates to a local search, repair heuristic, or exact solver for improvement. In this setting, the neural model contributes speed and diversity, while the downstream optimizer contributes final route refinement.

Table IX reports inference time on the RTX 3050 environment using the 56 Solomon instances and three repeats per instance. The relation-free Transformer averages 1.356 s per instance, while the full KG-guided Transformer averages 1.668 s per instance. Thus, explicit KG relation bias adds about 23.0 percent decoding overhead in this implementation, which is modest relative to the added feasibility and diagnostic benefits reported above.

VIII. Limitations and Future Work

The current model uses greedy decoding, and the learned routes remain worse than OR-Tools in terms of distance. The original Solomon set is also small, so synthetic extensions are useful for robustness but cannot replace additional external benchmarks. The added AM style, POMO style, and edge-aware Transformer baselines strengthen the same-pipeline comparison, but official reproduction of AM, POMO, L2D, EFormer, GASE, and other stronger neural or hybrid VRP solvers remains future work.

Another limitation is that the relation schema is manually designed from known VRPTW constraints. This is appropriate for a first framework study, but future research could learn relation weights or discover additional relation channels automatically. The router component also needs more data before it can consistently outperform simple objective aware ensembling. Finally, computational time should be reported more fully in future comparisons so that route quality can be interpreted together with inference cost.

IX. Conclusion

This study presented a multi-relation KG-guided Transformer framework for VRPTW. The KG is projected into Transformer attention as pairwise relation bias, and the framework is evaluated through ablation, adaptive variants, route selection, and multi-seed synthetic robustness. The results show improved feasibility over a relation-free Transformer and stronger robustness through objective-aware route selection. The contribution is a framework for operationalizing explicit routing knowledge inside neural attention and for analyzing how relation groups affect learned VRPTW construction.

***Abstract*—Thirty-day hospital readmission is a well-established quality metric, and many clinical prediction models have been developed for this task; however, high discrimination does not by itself mean that a model is safe to use in discharge workflows. This study developed and applied an integrated deployment-oriented evaluation workflow in which calibration, threshold governance, and decision utility were treated as primary evaluation requirements rather than secondary diagnostics. Retrospective inpatient data collected between 2022 and 2024 from two resource-limited government hospitals were used (N = 30,000; readmission prevalence = 15.0%). The analysis was based on patient-level internal validation using non-overlapping training, validation, and held-out test partitions. A multilayer perceptron neural network and a random forest were evaluated using patient-level grouping (70% training, 15% validation, 15% test). Both models showed strong discrimination on the held-out test set (ROC-AUC = 0.868 for the neural network and 0.880 for the random forest), with nearly identical minority class detection (PR-AUC = 0.461 vs 0.460). However, calibration analyses separated the models despite identical Brier scores (0.095). The neural network showed lower expected calibration error (ECE = 0.013 vs 0.035) and near ideal probability scaling (calibration slope = 0.971, 95% CI: [0.94, 1.00]) compared with the random forest (slope = 1.202). Threshold analysis also showed that a default threshold could be unsafe, since recall was 0.244 at 0.50 but increased to 0.867 at 0.12, while false negatives dropped from 510 to 90. Decision Curve Analysis further supported the neural network, including a mean net benefit of 0.097 at a threshold of 0.12. Practically, threshold, model version, and monthly calibration summaries should be logged in an audit trail.**

Keywords*—Clinical AI deployment; hospital readmission prediction; expected calibration error; electronic health records; operating region; probability reliability; model governance

I. Introduction

The use of thirty-day hospital readmission as a measure of quality of care and as a target for predictive analytics in numerous health systems has been well-documented [1]-[4]. The increasing availability of electronic health records has allowed machine learning and deep learning models to process large amounts of high-dimensional clinical information [5], [6]. However, the field still faces a similar translation problem: models that perform well retrospectively do not always act safely or consistently when embedded in the workflow of discharge planning, care coordination, and follow-up allocation [7], [8].

Discrimination metrics, specifically the area under the receiver operating characteristic (ROC) curve, dominate model evaluation in the readmission prediction literature [9], [10]. While discrimination is valuable because it measures a model's ability to rank patients based on their risk, it does not necessarily imply that the model produces numerically valid predicted probabilities that can inform decisions regarding absolute risk [11], [12]. Therefore, methodological critiques have emphasized that clinical risk prediction needs to evaluate model performance using additional methodologies that assess the model's ability to produce valid predicted probabilities and that examine the decision-making consequences of model predictions in the context of realistic operating conditions [3], [12] – [15].

Calibration is central to this deployment question. Calibration occurs when the model predicts the actual rates of events; therefore, the predicted risk is expressed as a frequency statement in the population of interest [12], [13]. If calibration fails, then risk will be either systematically over- or under-predicted, and downstream decisions will potentially result in under-treatment, over-treatment, or misallocation of resources, regardless of whether the discrimination level of the model remains unchanged. These problems are not theoretical. Miscalibration can affect what patients receive: intensive discharge counseling, early outpatient follow-up, or post-discharge monitoring. As previously described, these interventions can directly affect patient safety and workload in environments where the margin is thin [8], [16]. Calibration monitoring has recently been added to the list of lifecycle management responsibilities through recent governance efforts, and is no longer viewed as a one-time diagnostic during model development [17], [18].

There exists a second type of deployment constraint related to converting predicted risk into actionable decisions. The current practice of setting a default threshold of .50 for binary classification in order to classify a patient as being at high risk of readmission is increasingly difficult to defend in clinical settings, since the choice of threshold rarely corresponds to clinical preference, the operational capacity of the institution, or

*Corresponding author.

the relative cost of different types of errors [7], [19]. Choice of threshold determines the balance between false negatives and false positives, and this balance has significant clinical implications for preventing readmissions. For example, missing a high-risk patient may prevent the triggering of a follow-up pathway that could have prevented the patient's deterioration, while flagging too many low-risk patients may lead to saturation of available staff capacity and reduce the focus on those most likely to benefit from follow-up. An operational way to address this issue is to document a threshold selection process based upon institutional capacity, e.g., select a threshold that would yield approximately 25 to 30 flagged discharges per week because that is the number of transitional care calls that a team can reliably make. During deployment, the selected threshold should be recorded along with the model version and the effective date so that changes in decision-making behavior can be tracked over time. This framing of threshold optimization as a clinical design decision instead of a statistical convention provides an opportunity to link clinical design to the technical capabilities of the model [20]-[22].

Decision Curve Analysis (DCA) provides a mechanism for evaluating whether action on a model improves outcome, across a range of clinically relevant thresholds, by explicitly incorporating the relative harms of false positives and false negatives into net benefit [23], [24]. Although DCA is increasingly being advocated for in guidelines for the evaluation and validation of prediction models [14], [25], it is relatively rare in the evaluation of hospital readmission prediction models, where evaluation typically focuses on discrimination and limited calibration metrics [3], [8]. This gap is important because a model can appear to be highly discriminative on ROC-AUC, yet fail to provide decision utility in the threshold ranges that are relevant to discharge workflows.

These limitations are accentuated in resource-constrained systems where staffing shortages, fragmented documentation, and limited follow-up capacity can amplify the effects of predictive error [2], [7]. In such settings, a deployment-ready readmission model should exhibit more than just discrimination. It should demonstrate stable calibration and predictable threshold behavior, so that the workflow consequences of acting on the model remain understandable and manageable.

Therefore, motivated by the need to evaluate readmission models in terms that are closer to clinical use, the current study develops and applies an integrated deployment-oriented evaluation workflow that combines discrimination, calibration reliability, threshold sensitivity analysis, and decision utility within a single operating-region assessment. The contribution of this work is not the introduction of a new classifier architecture. Rather, it is the operational integration of probability reliability, threshold behavior, and net clinical benefit into the evaluation of 30-day readmission prediction. Specifically, the study applies this workflow to retrospective multi-site inpatient data from resource-constrained hospitals and examines whether model outputs remain interpretable and actionable when translated into discharge-planning thresholds. By doing so, the manuscript positions readmission prediction as a decision-support problem, not only as a classification task evaluated by ROC-AUC [17], [18], [25].

The remainder of this study is organized as follows. Section II reviews related work on readmission prediction, calibration, threshold policy, and decision-curve-based evaluation in clinical AI. Section III describes the study design, data source, model development pipeline, and evaluation protocol, including calibration assessment, threshold sensitivity analysis, and decision curve analysis. Section IV presents the results across discrimination, calibration, threshold behavior, and decision utility. Section V interprets the findings in relation to deployment readiness, threshold governance, model monitoring, and study limitations. Section VI summarizes the main conclusions and implications for accountable readmission prediction in resource-limited hospital settings.

II. Related Works

A. Readmission Prediction and EHR-Based Machine Learning

Thirty-day readmission prediction has been studied extensively because readmission is both a quality indicator and an operational concern for hospitals. Earlier work has shown that electronic health records can support risk prediction by combining demographic information, laboratory values, vital signs, prior utilization, and admission-related variables [1], [5], [6]. Within this literature, machine learning and deep learning models have often been evaluated mainly by discrimination metrics, especially ROC-AUC, because these metrics summarize how well patients are ranked by predicted risk [6], [9]. This ranking perspective is useful, but it does not fully answer the deployment question faced by discharge teams: whether a predicted probability can be trusted when deciding which patient should receive follow-up, counselling, or post-discharge monitoring.

Systematic reviews of readmission prediction models have also shown that methodological quality and validation practices vary considerably across studies [2], [3]. In many cases, models report acceptable or high discrimination, but provide limited evidence about probability reliability, threshold behavior, and clinical usefulness under realistic operating constraints. This creates a gap between retrospective model performance and workflow-level applicability. The present study is positioned within this gap. Rather than treating readmission prediction as a purely ranking problem, it evaluates whether the model outputs remain usable when translated into probability-based discharge decisions.

B. Calibration and Probability Reliability in Clinical AI

Calibration has become increasingly important in clinical prediction because risk scores are often interpreted as probabilities during decision-making [12], [13]. A model with good discrimination may still overestimate or underestimate risk in clinically important strata. In readmission prediction, this distinction matters because a patient assigned a risk of 0.20 may be handled differently from a patient assigned a risk of 0.08, even if both patients are ranked correctly relative to others. When calibration is poor, the same threshold can route too many low-risk patients into follow-up or fail to identify patients whose risk is clinically meaningful.

Recent clinical AI guidance has therefore emphasized that deployment-oriented validation should not stop at ROC-AUC

[17], [18], [25], [26], [27]. Probability reliability, lifecycle monitoring, and recalibration planning are part of responsible model use, particularly when predictions are used to allocate finite clinical resources. In practical terms, this means that calibration should be monitored through measures such as reliability diagrams, Brier score, expected calibration error, and calibration slope. The current study follows this direction by comparing the neural network and random forest not only by discrimination, but also by the degree to which their predicted probabilities align with observed 30-day readmission rates.

C. Threshold Policy, Decision Utility, and Operating Regions

A second limitation in much of the readmission prediction literature is the treatment of classification thresholds as technical defaults rather than clinical policy choices. The conventional 0.50 threshold is rarely aligned with discharge-planning priorities, because hospitals may prefer to identify more high-risk patients even if this increases the number of false positives [7], [19], [32]. The appropriate threshold depends on the relative harm of missed readmissions, the available follow-up capacity, and the workflow used to act on model outputs. For example, if a transitional care team can make 30 follow-up calls per week, then the threshold should be chosen with that capacity in mind rather than inherited from a generic binary classifier.

Decision Curve Analysis provides a way to evaluate whether model-guided action produces clinical benefit across threshold values [23], [24]. This is especially relevant in resource-limited hospitals, where the cost of false positives is not only statistical but operational: each flagged discharge may require staff time, documentation, and follow-up coordination. By combining threshold sensitivity analysis with decision curve analysis, the present study moves beyond the search for a single "best" threshold and instead identifies a clinically acceptable operating region. This region-based approach links model evaluation with implementation planning because it specifies where recall, false negative reduction, probability reliability, and net benefit remain jointly defensible.

D. Positioning of the Present Study

The present study contributes to this literature by integrating four evaluation domains into a single deployment-oriented workflow: discrimination, calibration, threshold sensitivity, and decision utility. Its contribution is not the proposal of a new classifier architecture, nor does it claim that one model family is universally superior across settings. Instead, the study demonstrates how a readmission model can be examined before implementation by asking four linked questions: whether it ranks patients accurately, whether its probabilities are reliable, how its threshold choices affect missed readmissions and workload, and whether model-guided action provides positive net benefit. This positioning is especially relevant for resource-constrained hospitals, where a threshold decision has concrete operational consequences, for example, the number of follow-up calls that a discharge team can complete during a working week.

III. Methods

A. Study Design and Data Source

This study used a retrospective, multi-centre design based on real-world inpatient records collected between 2022 and 2024 from two government hospitals operating under resource-limited conditions. The dataset was drawn from Rafidia Hospital and Al-Watani Hospital, subject to institutional approval and de-identification procedures. These hospitals represent a clinically relevant resource-constrained setting because the records include heterogeneous documentation practices, non-trivial missingness patterns, and operational constraints that commonly affect clinical data quality in low-resource environments [2], [8]. Accordingly, the dataset was suitable for evaluating internal deployment readiness under non-ideal data conditions, but it was not used to establish external generalizability across all resource-limited hospitals. Fig. 1 illustrates the multidimensional structure to assess the clinical deployability and operating-region identification.

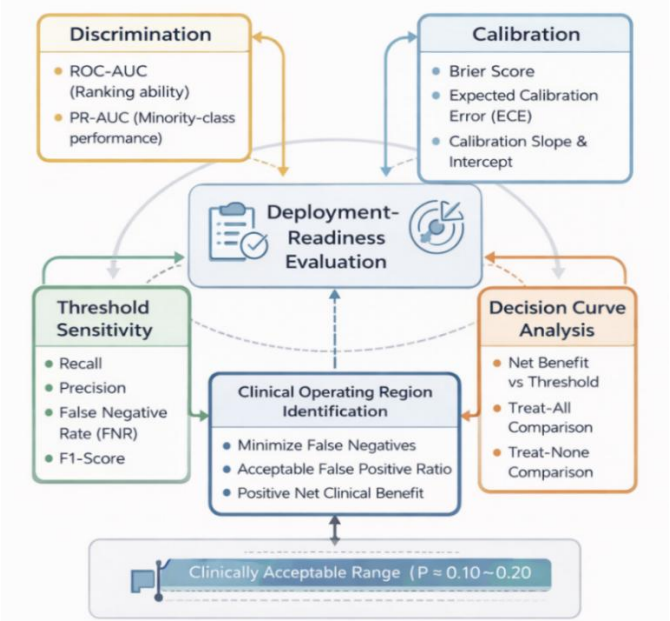

Fig. 1. Deployment-oriented clinical AI evaluation framework.

To minimise optimistic bias and prevent information leakage, we applied patient-level, group-aware data partitioning using unique patient identifiers (eid). A GroupShuffleSplit strategy was used to create non-overlapping training (70%), validation (15%), and held-out test (15%) subsets, with the constraint that no patient appeared in more than one subset. As a concrete operational safeguard, we programmatically verified that the intersection of patient identifiers across splits was empty and stored the split indices and random seed in an audit file so the exact partitions could be reproduced. All reported discrimination, calibration, Brier score, expected calibration error (ECE), and decision curve analysis (DCA) results were computed on the held-out test set only. Group-aware splitting is increasingly recommended in clinical machine learning to preserve validity and reduce inflated performance estimates that arise when repeated encounters from the same patient are inadvertently distributed across training and evaluation sets [8], [27]. This approach also aligns with contemporary guidance on validation practice for clinical prediction models [25].

No independent external validation cohort from a geographically or organizationally distinct institution was available for the present analysis. Therefore, all performance estimates should be interpreted as patient-level internal validation on a held-out test set rather than external validation. To reduce over-optimistic estimation within the available data, all preprocessing steps were fitted on the training set only, patient identifiers were kept non-overlapping across splits, and the final discrimination, calibration, threshold, and decision-curve results were calculated exclusively on the held-out test set.

The primary outcome was 30-day all-cause readmission following discharge. Analyses were conducted under institutional ethical approvals with de-identification procedures consistent with current reporting and governance expectations for clinical AI studies [17], [28]. See Table I.

TABLE I. COHORT CHARACTERISTICS AND DATA OVERVIEW

Category	Variable	Overall Cohort (N = 30,000)
Outcome distribution	30-day readmission, n (%)	4,500 (15.0%)
	No readmission, n (%)	25,500 (85.0%)
Demographics	Age, mean (SD), years	57.8 (18.4)
	Male sex, n (%)	15,960 (53.2%)
	Female sex, n (%)	14,040 (46.8%)
Admission characteristics	Length of stay, median (IQR), days	5 (3–8)
	Emergency admission, n (%)	18,750 (62.5%)
	Prior hospitalization (12 months), n (%)	9,840 (32.8%)
Feature composition	Demographic variables	6
	Laboratory variables	18
	Vital sign variables	6
	Admission-related variables	12
	Total features used in modeling	42
Missing data summary	Variables with <5% missingness	31 (73.8%)
	Variables with 5–20% missingness	9 (21.4%)
	Variables with >20% missingness	2 (4.8%)
	Imputation strategy	Median (continuous); Mode (categorical)
Data splitting strategy	Train set, n (%)	21,000 (70%)
	Validation set, n (%)	4,500 (15%)
	Test set, n (%)	4,500 (15%)
	Patient-level split	Applied
	Data leakage prevention	No patient overlap

B. Predictive Models

We evaluated two representative machine learning models: 1) a multilayer perceptron (MLP) neural network as the primary model, and 2) a random forest (RF) classifier as a baseline comparator. The purpose of this comparison was not to establish a full model leaderboard, but to examine how two commonly used nonlinear model families behave when evaluated through discrimination, calibration, threshold sensitivity, and decision utility under the same patient-level split and preprocessing protocol.

Neural network architecture and training. The MLP was implemented as a feed-forward network with three fully connected hidden layers (128, 64, and 32 units) using ReLU activations. Optimisation used Adam with an initial learning rate of 0.001 and L2 regularisation ($\alpha = 1 \times 10^{-4}$). Training proceeded for up to 300 iterations with early stopping based on validation performance, using a tolerance of 1×10^{-4} and patience of seven consecutive iterations without improvement. A fixed random seed (42) was used to support reproducibility.

A leakage-free, column-wise preprocessing pipeline was implemented for all data. Scaled, continuous variables were preprocessed with training set statistics only. Skewed continuous predictors (e.g., length of hospital stay and laboratory results) were standardized by median and inter-quartile ranges (IQR), whereas other continuous predictors were standardized by mean and standard deviation. Categorical predictors were treated equally during each split of the data, and missing data were replaced using medians for continuous variables and modes for categorical variables (see Table I). All preprocessing transformations were fit to the training set, and therefore, all subsequent transformations were performed without any additional modifications to the validation and testing sets, thereby eliminating potential feature-engineering-induced leakage from the training data. The Multilayer Perceptron (MLP) was chosen because it may be able to capture the non-linear relationships among the many, diverse demographic, laboratory, and admission-related variables common to EHR-based predictive tasks [1],[4],[6].

Random Forest Baseline Model. A Random Forest (RF) model was utilized as a baseline model because RF models are typically effective for structured tabular data, handle multiple types of predictor variables and have been extensively compared with other models within clinical predictive modeling applications [29] to allow comparison of the behavior of probabilities produced by both modelling families utilizing the same split of the data, same preprocessing pipeline, and same evaluation metrics. The objective of this research was not to achieve maximum discrimination via an exhaustive search of possible architectures and/or hyperparameters; rather, it was to evaluate how well the ML models were calibrated, sensitive to threshold decisions, and useful for making decisions within real-world operating conditions [18].

Benchmarking scope. Clinically established readmission scores such as LACE+ and HOSPITAL, as well as gradient-boosted tree models, are important comparators in broader readmission prediction research. However, the present study did not estimate these additional benchmarks. This decision reflects the study's primary aim, which was to demonstrate a deployment-oriented evaluation workflow rather than to optimize predictive performance across all possible model families. It also avoids introducing unreported model outputs or score reconstructions that were not part of the original analysis. Accordingly, the results should be interpreted as an internally validated comparison between NN and RF probability outputs, not as evidence that these two models exhaust the set of deployable alternatives for 30-day readmission prediction.

C. Multi-Dimensional Evaluation Framework

Consistent with current recommendations for evaluating prediction models intended for clinical use, assessment was structured across four complementary domains: discrimination, calibration, threshold sensitivity, and decision utility [3], [12], [17], [27]. This design reflects the position that discrimination alone is insufficient for clinical readiness because deployment decisions depend on probability validity and the consequences of acting on model outputs [25], [18].

Fig. 2 describes the model-training pipeline, probability generation, discrimination analysis, calibration assessment, threshold sensitivity evaluation, and decision curve analysis used to assess clinical reliability and operational suitability.

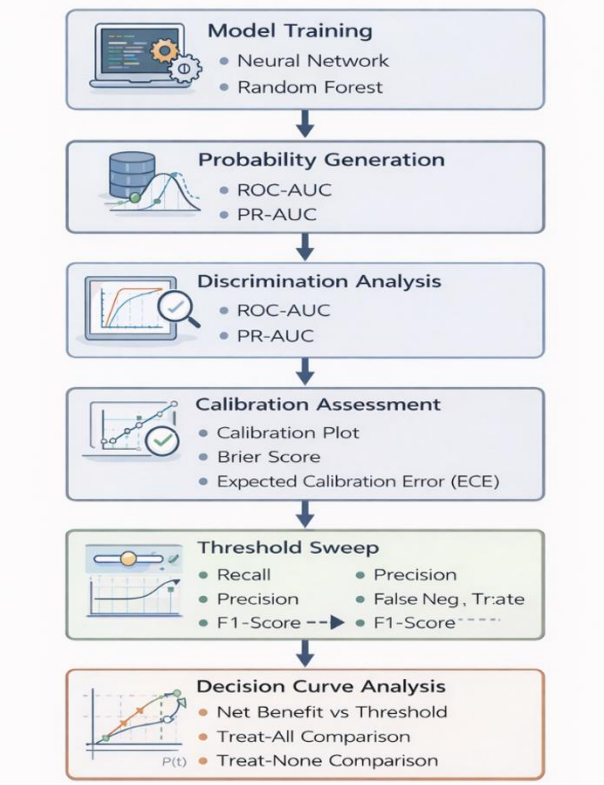

Fig. 2. Evaluation workflow for deployment-readiness assessment of clinical prediction models.

1) Discrimination assessment: Discrimination for both models was quantified using ROC-AUC, which summarises ranking performance across all possible thresholds. Because readmissions comprised approximately 15% of cases, we also evaluated precision–recall behaviour to characterise minority-class detection, and we report PR-AUC for the primary model as a complement to ROC-AUC under outcome imbalance [30], [31]. Discrimination was treated as necessary but not sufficient, and it was interpreted alongside calibration and decision-focused analyses.

2) Calibration assessment: Calibration analyses examined agreement between predicted probabilities and observed 30-day readmission rates. We computed reliability diagrams using observed versus predicted risk across deciles, the Brier score as an overall probabilistic accuracy measure, ECE as a bin-based summary of miscalibration, and calibration intercept and slope estimated via logistic recalibration [12], [27]. We also report the Hosmer–Lemeshow goodness-of-fit test as a conventional, though sample-size-sensitive, diagnostic. Calibration is repeatedly identified as a prerequisite for safe clinical deployment because it governs whether a predicted risk can be interpreted as an actionable probability rather than an uncalibrated score [12], [27]. Given outcome imbalance, we interpret the Brier score alongside complementary calibration measures, since prevalence can influence the absolute

magnitude of the Brier score [18]. ECE was computed using binned differences between predicted and observed event rates, consistent with common practice in probabilistic reliability evaluation [34]. For the recalibration sensitivity analysis, calibration metrics were reported separately for the original random forest, Platt-scaled random forest, and isotonic-regression-calibrated random forest, with all recalibration functions fitted on the validation set and evaluated only on the held-out test set. Reliability diagrams were generated by comparing observed and predicted 30-day readmission probabilities across risk deciles. These plots were used to visually assess departures from perfect calibration and are reported with the calibration results. Threshold Sensitivity Analysis.

Default probability thresholds, particularly 0.50, seldom reflect clinical risk tolerance or operational capacity in risk stratification tasks [7], [19], [32]. We therefore performed a systematic threshold sweep over probability cut-offs from 0.05 to 0.50 in increments of 0.01. At each threshold, we computed sensitivity (recall), precision, false negative rate (FNR), and F1-score (Table II). Because missed high-risk patients can undermine discharge safety pathways, the analysis emphasised FNR as a safety-relevant metric, while also documenting the corresponding workload implications captured by false positives [7], [34].

TABLE II. CONFUSION MATRIX PERFORMANCE METRICS AT DEFAULT (0.50) AND OPTIMIZED (0.12) PROBABILITY THRESHOLDS ON THE HELD-OUT TEST SET (N = 4,500)

Metric	Threshold = 0.50	Threshold = 0.12
True Positives (TP)	165	585
False Positives (FP)	151	1,018
True Negatives (TN)	3,674	2,807
False Negatives (FN)	510	90
Recall (Sensitivity)	0.244	0.867
Precision	0.522	0.365
F1-score	0.333	0.514
Overall Accuracy	0.853	0.754

3) Decision Curve Analysis (DCA): Clinical utility was evaluated using DCA across a range of probability thresholds [18], [19]. Net benefit was computed as:

$$\text{Net Benefit} = (TP / N) - (FP / N) \times (pt / (1 - pt)), \quad (1)$$

where, pt denotes the decision threshold. Model net benefit was compared against treat-all and treat-none strategies, and we also examined the default-threshold strategy to illustrate the impact of threshold choice on decision value. DCA provides an interpretable summary of whether decisions guided by model predictions improve outcomes under explicit trade-offs between false positives and false negatives, complementing discrimination and calibration analyses [24], [33]. Methodological guidance has increasingly positioned DCA as a core component of deployment-oriented validation, particularly when probability estimates are used to allocate finite interventions [18]. Fig. 3 illustrates net benefit across probability thresholds (0.05–0.50) compared with treat-all and treat-none strategies.

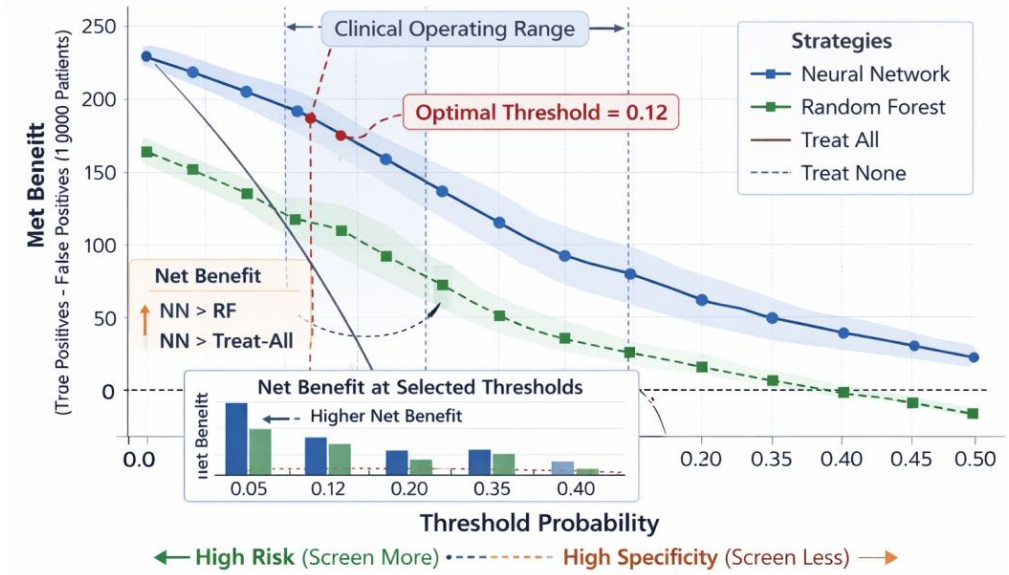

Fig. 3. Decision curve analysis of neural network and random forest models.

4) Clinical operating region identification: Rather than identify a "best" cut-off point for screening purposes based upon a single performance metric, we have identified a clinically acceptable operating region of thresholds which meet four criteria: improvement in the number of false negative results; an acceptable number of false positives to accommodate follow-up capacity, a positive net benefit in terms of DCA; and good calibration across all clinically relevant risk strata. The operating region approach is aligned with deployment-oriented expectations [16] [35] regarding consistency of decisions, safety, and fit into workflow under real-world constraints.

D. Statistical Analysis and Implementation

All analyses were implemented in Python using standard machine learning libraries within a reproducible computational environment. To quantify uncertainty, we used non-parametric bootstrap resampling on the held-out test set with 1,000 resamples drawn with replacement. For each resample, we recomputed ROC-AUC for both models and PR-AUC for the primary model, then recomputed calibration measures, including Brier score, ECE, calibration intercept, and calibration slope, and finally recomputed net benefit at selected thresholds for DCA. Confidence intervals were derived using the percentile method to obtain 95% intervals. This resampling-based approach provides a distributional view of metric variability, which is particularly relevant in imbalanced clinical prediction tasks and aligns with modern validation practice [23], [27]. Statistical significance was assessed at $\alpha = 0.05$ when hypothesis tests were reported, but interpretation prioritised effect magnitudes, interval estimates, probability reliability, and clinical interpretability over dichotomous p-value thresholds.

IV. Results

A. Discrimination Performance

Both models were highly discriminating at a global level on the test data for which they were partitioned using patient-level, group-aware partitioning. The Neural Network (NN) was able to achieve an ROC-AUC value of .868, showing that it ranked well in spite of high levels of imbalance. Using bootstrap resampling over 1000 iterations supports the stability of this estimate, and suggests that the ranking ability of the model was not due to a small number of samples in the test data.

A Random Forest (RF) Baseline performed better than the NN, with a higher ROC-AUC (.880), but also nearly identical precision – recall AUC (.460) for both models when looking at positive class detection, as readmission represented around 15% of the sample population. Overall, the discrimination results suggest that the models have similar risk rankings at a global level, although the RF has a slight advantage over the NN on ROC-AUC.

Discrimination, however, did not determine deployment readiness on its own. Because discharge workflows require binary decisions, and because these decisions depend on both threshold choice and probability reliability, subsequent analyses focused on threshold-dependent behaviour, calibration, and decision utility.

Fig. 4 shows the receiver operating characteristic curves used to summarize discrimination across thresholds. The precision–recall curve highlights positive-class detection under class imbalance, with readmissions accounting for approximately 15% of cases.

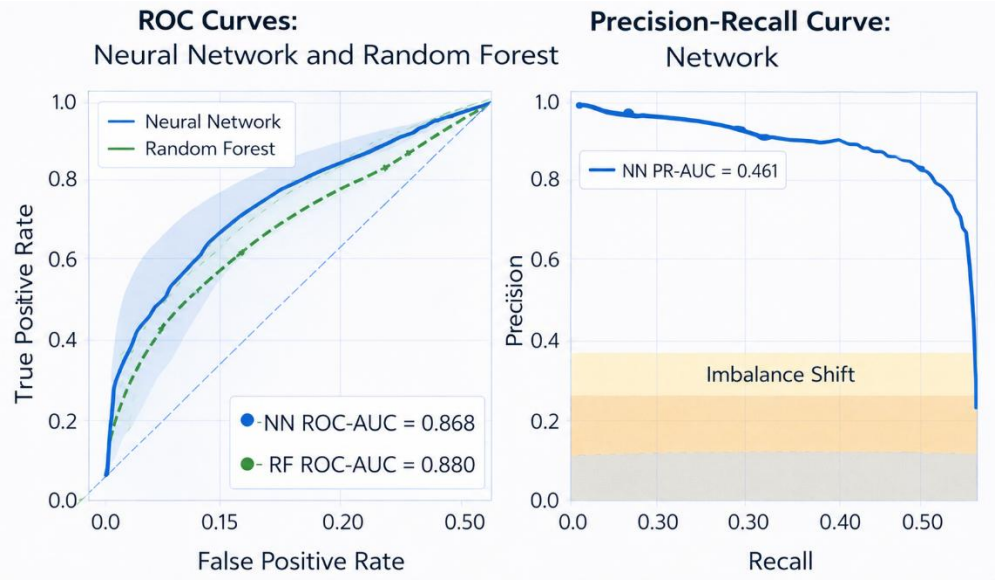

Fig. 4. ROC curves for the neural network and random forest models, and precision-recall curve for the neural network on the held-out test set.

Threshold-dependent behaviour showed why discrimination-only summaries were incomplete. At the default threshold of 0.50, recall for 30-day readmission was 0.244, meaning most readmissions were not flagged. When the decision threshold was set to 0.12 using a recall-oriented F-beta strategy ($\beta = 2$), recall increased to 0.867, with F1-score improving to 0.514 and overall accuracy equal to 0.754. This change reduced false negatives from 510 to 90 cases. It also changed operational workload: the number of flagged discharges increased from 316 at threshold 0.50 (TP + FP = 165

+ 151) to 1,603 at threshold 0.12 (TP + FP = 585 + 1,018), which corresponds to 7.0% versus 35.6% of the 4,500-patient test set (Table III). This illustrates that the same model can shift from under-detection to high-sensitivity screening depending on the operating threshold, with direct implications for follow-up capacity.

TABLE III. DISCRIMINATION AND CLASSIFICATION METRICS AT SELECTED THRESHOLDS (NEURAL NETWORK)

Metric	Threshold = 0.50 (Default)	Threshold = 0.12 (Optimized)
Recall (Sensitivity)	0.244	0.867
Precision	0.522	0.365
F1-score	0.333	0.514
Overall Accuracy	0.853	0.754
False Negatives (n)	510	90
False Negative Rate (FNR)	0.756	0.133

The comparison between thresholds 0.12 and 0.50, therefore, reflects a clinically meaningful trade-off. Lowering the threshold substantially reduced missed high-risk patients, while increasing false positives and the number of patients routed into a follow-up pathway. Although RF achieved marginally higher ROC-AUC, later sections show that probability reliability and decision-analytic performance differed between models, reinforcing that small differences in discrimination did not map cleanly onto deployment-relevant behaviour.

B. Calibration Assessment

Calibration analyses on the held-out test set examined whether predicted probabilities aligned with observed readmission frequencies. This matters because calibrated probabilities are interpretable as risk estimates, and interpretability is required for defensible threshold policies in discharge planning.

1) Brier score: A prevalence-only baseline that assigns every patient a 0.15 readmission risk achieved a Brier score of 0.1275. Both learned models improved substantially on this baseline. The NN produced a Brier score of 0.0950, and RF produced the same value, 0.0950, indicating comparable overall probabilistic accuracy when assessed by mean squared error of predicted probabilities. Bootstrap resampling supported the stability of these values. At the same time, the Brier score aggregates errors across the full probability range, so it can conceal differences in probability scaling and bin-level alignment, particularly in imbalanced datasets.

Probability density distributions of predicted risk scores for the neural network and random forest models evaluated exclusively on the patient-level held-out test set. Differences in spread and central tendency were examined further using calibration-specific metrics (see Fig. 5).

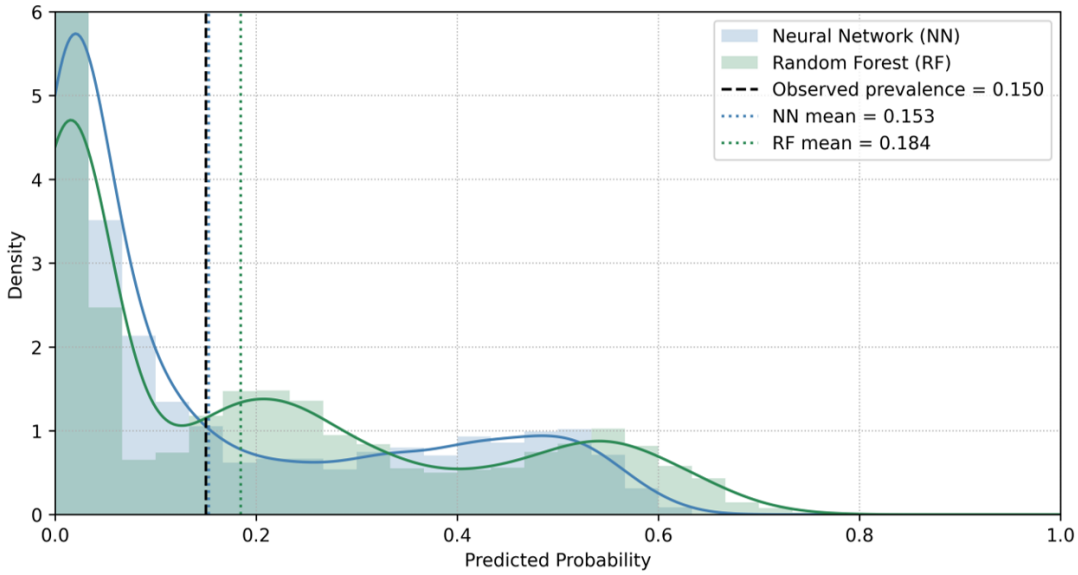

Fig. 5. Distribution of predicted 30-day readmission probabilities on the held-out test set.

2) Expected Calibration Error (ECE): Expected calibration error, computed on the held-out test set using equal-width bins, distinguished the models more clearly than the Brier score. The NN achieved ECE = 0.0128, whereas RF achieved ECE = 0.0348. The smaller value for NN indicates closer agreement between predicted probabilities and observed event rates across probability bins. In contrast, RF showed larger bin-level discrepancies, despite its marginal advantage in ROC-AUC. This contrast is important for clinical use because discharge decisions are often made in narrow probability bands, where bin-level miscalibration can shift which patients are flagged. Table IV shows the calibration analysis performed exclusively on the held-out test set. The results indicate that while both models have very similar total accuracy, the Neural Networks are capable of producing much more reliable probability estimates than Random Forests. Probability estimates are critical for clinical decision support, and therefore, this finding is highly relevant to our investigation.

TABLE IV. CALIBRATION PERFORMANCE ON THE HELD-OUT TEST SET

Metric	Neural Network (NN)	Random Forest (RF)	Ideal Value
Brier Score	0.095	0.095	0
Expected Calibration Error (ECE)	0.013	0.035	0
Calibration Intercept	−0.028	−0.216	0
Calibration Slope	0.971 (95% CI: 0.94–1.00)	1.202	1

3) Calibration intercept and slope: Recalibrating the logistic model to the held-out test data produced additional evidence as to how systematically biased and/or distorted the probability scales were for each model. The NN had an intercept of -0.028 and a slope of 0.971 (95% CI: 0.94-1.00). This demonstrates little systematic bias and appropriate probability scale distortion across risk levels. In contrast, the RF model's intercept was -0.216, and its slope was 1.202. This suggests that the RF model has larger deviations from ideal calibration and a larger probability scale distortion. Overall, these findings show that similar discrimination and Brier scores can conceal meaningful differences in uncalibrated probability reliability. The random forest showed larger deviation in ECE and calibration slope than the neural network, but this result should not be interpreted as evidence that the random forest model family is inherently less suitable for deployment. Rather, it indicates that the RF probabilities, as evaluated in their uncalibrated form, would require post-hoc recalibration assessment before any deployment-oriented comparison could be considered final.

This is evident in Fig. 6, where we show the observed versus the predicted 30-day readmission probability estimates for each risk level. The diagonal reference line represents perfect calibration, and the closer a model falls to this line, the more reliable its estimated probabilities are.

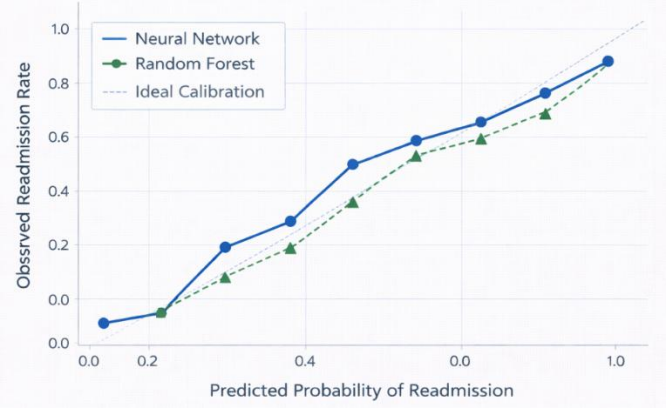

Fig. 6. Calibration curves (reliability diagrams) for neural network and random forest models.

C. Threshold Sensitivity Analysis

The results of the threshold sensitivity analyses are shown in Fig. 7. They indicate the size of the clinical performance variations associated with varying the decision threshold. For example, at the default threshold of 0.50, the model had a recall of 0.244. At the default threshold of 0.50, the model operated as a high-specificity but low-sensitivity rule. It identified only 24.4% of readmitted patients and therefore missed most patients who later experienced 30-day readmission. In contrast, when the threshold was set to 0.12, the recall increased to 0.867, the number of false negatives decreased from 510 to 90, which is roughly a sixfold decrease in missed readmissions. These data demonstrate that the conventional default thresholds used for decision-making in this context were inappropriate for achieving safe levels of care and further illustrate why the selection of the threshold should be viewed as a clinical decision based on available resources/workflow capacity rather than as an implicit statistical default.

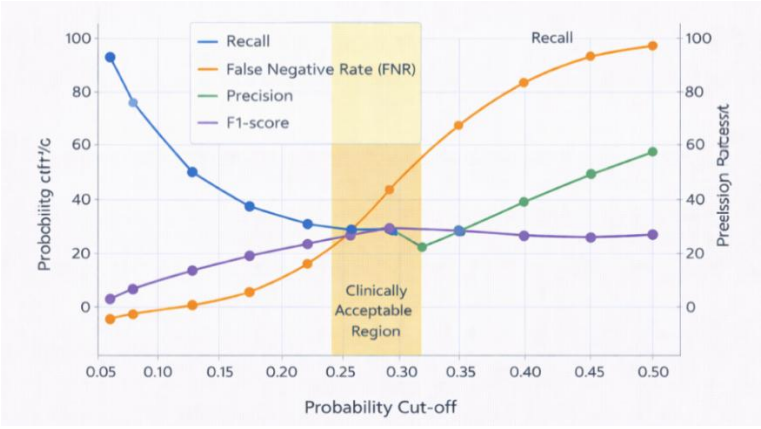

Fig. 7. Threshold sweep analysis for the neural network model.

Fig. 7 compares the recall, false negative rate (FNR), precision, and F1 score across different probability cut-off values ranging from 0.05 to 0.50. The shaded area (0.10–0.20) represents the clinically acceptable operating range, where there is high recall, a significant number of false negatives are eliminated, and sufficient decision utility is maintained.

D. Decision Curve Analysis

Decision Curve Analysis (DCA) examined whether taking action based on model predictions would result in net benefit over a wide range of thresholds. Across clinically relevant thresholds of 0.05 to 0.25, NN was found to have a consistent favorable net benefit when compared to treat-all and treat-none strategies. Using bootstrap resampling at an optimized threshold of 0.12, DCA produced a mean net benefit of 0.097 with a 95 percent confidence interval (CI): 0.093–0.101 that reflected relatively stable decision utility in the sensitivity-oriented operating range used for discharge screening.

Fig. 8 compares the net benefit across threshold probabilities for the NN strategy with the treat-all and treat-none strategies. NN has a favorable and relatively stable net benefit in the clinically relevant threshold ranges.

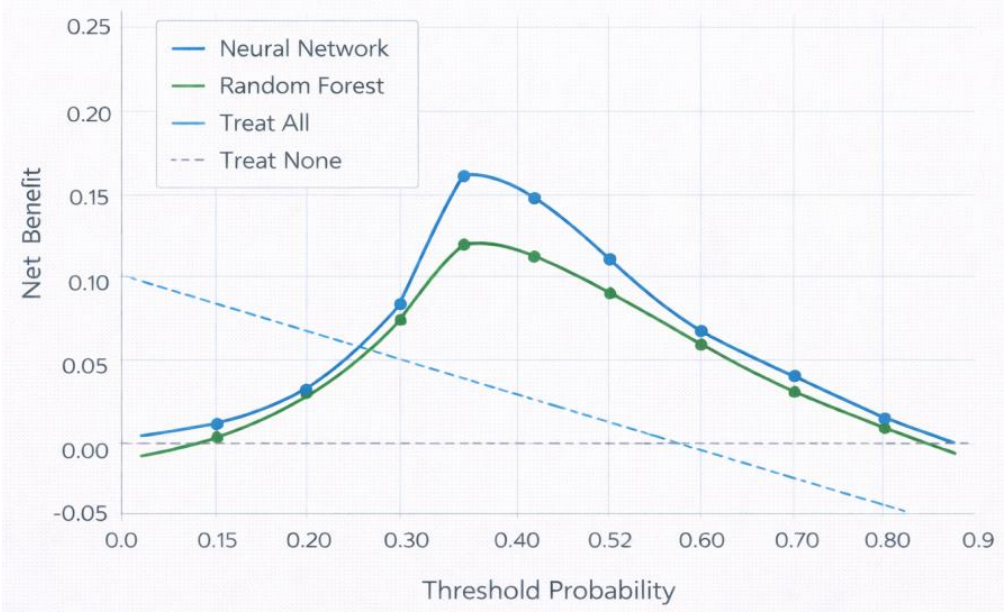

Fig. 8. Decision curve analysis comparing NN and RF strategies.

Although RF did show some positive net benefits at certain thresholds, it should be interpreted with caution, given the calibration distortions discussed previously. As discussed previously, these distortions may produce apparent shifts in gains across thresholds as a function of probability scaling distortion. Conversely, the combination of strong calibration and positive net benefits supports the suitability of NN for use in discharge planning workflows that rely on probability estimates to inform follow-up priority.

E. Clinical Operating Region Identification

The most appropriate deployment region, where the model would both correctly identify the individuals who needed treatment and provide enough information about how many people were treated, was determined by combining discrimination, calibration, threshold sensitivity, and decision utility instead of relying solely on one or more of those statistics to find the "best" threshold. The acceptable deployment region for clinical use was defined by four performance criteria: Recall should be at least 0.80; Calibration Error should be less than 0.02; Calibration Slope should be between 0.95 and 1.05 to allow the preservation of probability scaling; and there should be a positive Net Benefit relative to treating all and treating none. Using these criteria, thresholds ranging from 0.10 to 0.20 were found to be the best deployment region for NN. Within this range, NN provided good Recall (0.80 – 0.87), small Calibration Error (ECE = 0.013), and nearly perfect Probability Scaling (Slope = 0.971), with a positive Net Benefit. Therefore, the deployment region identified is a practical trade-off between significantly reducing False Negatives while maintaining Positive Decision Utility, see Table V.

TABLE V. INTEGRATED PERFORMANCE SUMMARY WITHIN THE CLINICALLY ACCEPTABLE OPERATING REGION (0.10–0.20)

Evaluation Dimension	Metric	Observed Performance (NN)	Interpretation Within Operating Region
Discrimination	ROC-AUC	0.868	Adequate global ranking performance
	PR-AUC	0.461	Stable minority-class detection under class imbalance
Calibration	Expected Calibration Error (ECE)	0.013	Minimal deviation between predicted and observed probabilities

	Calibration Slope	0.971 (95% CI: 0.94–1.00)	Probability scaling is closely aligned with the ideal (≈1)
Threshold Sensitivity	Recall	0.80–0.87	Substantial improvement in high-risk patient detection
	False Negatives	Reduced from 510 to 90 cases	Marked reduction in under-detection relative to default threshold (0.50)
Decision Utility	Net Benefit (DCA)	Positive vs. treat-all and treat-none strategies	Favorable clinical decision utility within operating range

V. Discussion

A. Beyond Discrimination: Why ROC-AUC Does Not Establish Deployment Readiness

This work supports the idea that it is possible for high discrimination and a number of potential deployment issues to be present together. The neural network produced a ROC-AUC of 0.868, while the random forest model generated a slightly better result at 0.880; however, neither of the global summary measures of rankings provided evidence that the probability predictions made by either model would be accurate enough to inform threshold-based discharge decisions. Discrimination, which is the focus of both of these models, addresses how well the model can rank patients in order of their predicted risk level, but does not provide information on the quantitative accuracy of the risk estimates made by the model to be used in actual decision-making processes (e.g., who should be discharged next) [12], [3], [27]. Therefore, there are numerous examples in the literature that have warned against using discrimination as the sole measure of clinical suitability for AI systems [12], [3], [27] and that other factors such as calibration stability, threshold alignment, and post-deployment monitoring and maintenance will need to be addressed to ensure trustworthy and lifecycle aware clinical AI systems [17], [16]. The findings reported here are consistent with this direction, suggesting that simply knowing the degree of discrimination of an AI system is not sufficient to determine if the system may be safely deployed and operated within real-world operational constraints.

B. Calibration Reliability Under Outcome Imbalance

The differences between the two predictive models were more apparent in calibration than in discrimination. Although both models produced the same Brier score (0.095) and similar discrimination, the calibration metrics indicated different levels of probability reliability under the present evaluation protocol. The uncalibrated random forest showed a higher expected calibration error (ECE = 0.035) and a calibration slope of 1.202, suggesting probability-scale distortion across risk strata. The neural network showed lower ECE (0.013) and a calibration slope closer to the ideal value (0.971; 95% CI: 0.94–1.00), indicating closer alignment between predicted and observed risk in this held-out test set. However, because post-hoc recalibration was not performed, these results should be interpreted as a comparison of the evaluated probability outputs, not as evidence that the random forest model family is inherently less suitable for deployment.

This distinction is particularly important when making clinical predictions using an imbalance of events. Global summaries such as the Brier Score pool squared error across all probability ranges, and since the event rate for this study was roughly 15%, the majority of errors in the decision-making space may have been diluted due to the large number of members in the non-event class. In contrast, ECE and the recalibration slope provide visibility to the reliability of the predictive probabilities in those bins/strata that are operationally relevant to the workflow, i.e., the decision thresholds [12], [18], [36].

Therefore, contemporary practice recommends assessing calibration as part of evaluating how well a model has been deployed, rather than treating it as simply another metric to report on discrimination performance [12], [3], [18]. The probability reliability of predictive modeling is not merely a cosmetic quality for hospital readmission workflows, but impacts who will be flagged, what clinicians interpret as the predictive risk means, and if the same threshold remains consistent in behavior over time.

C. Threshold Optimisation as a Clinical Design Decision

Beginning with Threshold Analysis, we see why threshold selection is considered part of both Clinical Design/Governance and not Conventional Practice. With a default threshold value of .50, we can see that Recall is .244, meaning there would have been a significant amount of readmission of patients that would have been missed using the Default Rule. Using an F-Beta Strategy (beta = 2) for a Recall-Oriented Approach, we can adjust the threshold to .12, and our Recall goes up to .867 while False Negatives drop to 90, down from 510.

The clinical implications are direct; a hospital discharge process that relies on identifying and addressing potential issues early in a patient's discharge will not perform as intended when the early identification tool misses three out of four readmissions.

The trade-off is also direct; to achieve a Recall of .867 using the Recall-Oriented Approach at the lower threshold (.12), we had to increase the number of discharges that were "flagged" to 1603 out of 4500 in the Test Set (True Positives + False Positives) compared to 316 at the higher threshold value of .50. This means that for every patient that has to undergo additional follow-up calls, and/or additional staffing capacity due to the need to schedule additional time for follow-up calls, the hospital will incur the associated cost. For this reason, recent literature recommends making the threshold selection based upon the specific trade-offs relevant to the deployment, documenting the reasoning behind the selection of the threshold, and matching the operating point of the system to the service capacity and level of risk that the organization can tolerate, rather than simply applying a generic default cut-off [25],[7],[37]. Our study provides empirical support for these recommendations: threshold selection affects the performance of systems that produce clinically important decisions; therefore, threshold

selection should be viewed as part of the design of a deployment, and thus should be subject to clearly defined escalation processes and audit trails for change control, rather than being treated as post-hoc tuning [38].

D. Decision Curve Analysis and Actionable Utility

Decision Curve Analysis (DCA) enhanced calibration and threshold sweep by asking a deployment-based question, i.e., does the model led to positive net benefits when using the model as a basis for action, across plausible thresholds [23] [24]. The Neural Network maintained favorable net benefits compared to the "treat all" and "treat none" strategies across the entire range of thresholds used for sensitivity-based screening of patients (i.e., approximately 0.05-0.25). Net Benefit was most stable at the optimal threshold of 0.12; Mean=0.097 (95% CI: 0.093-0.101) under bootstrap resampling. The stability of net benefits is important because it suggests that the observed decision advantage was not due to an isolated sample-specificity.

The importance of net benefit in this context stems from its ability to explicitly represent the trade-offs between false positives and false negatives through the threshold odds term pt/(1-pt) [24] [33]; and link those trade-offs to clinical actions [24] [33]. There is an increasing recognition of DCA as being complementary to calibration [25] [18] since a model can be well calibrated but still have limited utility in making decisions based on the model's output if the decision thresholds are not aligned with clinical practices; and similarly, a model may demonstrate high discrimination yet perform poorly in decision-making terms with respect to the ranges of thresholds that are clinically meaningful [23].

The inclusion of DCA with both calibration and threshold sensitivity allowed for a shift in how models were interpreted from global measures of performance to actionable outcomes, which are the appropriate standards of evaluation for settings where models will be deployed.

E. Implications for Resource-Constrained Healthcare Settings

The impact of prediction error on operations within resource-limited settings is amplified. Due to staffing limitations, variability in the practice of documenting, and limited follow-up options, false positives will continue to over saturate services while False Negatives will result in avoidable deterioration before receiving appropriate support [39]. As such, probability reliability becomes a necessity for workflows in resource-constrained settings. In addition, if predictions regarding patient risk are consistently skewed, clinicians may have difficulty developing consistent priorities based upon the recommendations of the clinical decision support system, and may lose confidence in the clinical decision support system's recommendations as they appear to contradict their own clinical impressions. Therefore, lifecycle-oriented clinical AI models address risk communication (calibrated), monitoring (ongoing), and governance processes that define drift and the need to recalibrate as normal occurrences, rather than as unusual events [17][16].

In addition, under the present uncalibrated evaluation protocol, the neural network showed favorable probability reliability and positive decision utility in the 0.10–0.20 operating region. This supports its use as the primary model for interpreting the current internal validation results. It should not, however, be read as a categorical deployment preference over the random forest, because RF recalibration using Platt scaling or isotonic regression was not tested. A practical implication of this approach is that threshold adjustments must be paired with lightweight monitoring. For example, a monthly report could document the current version of the model, the active threshold(s), the total number of discharges that were flagged by the model, the observed readmission rate among the flagged patients, and a decile-based calibration summary. This would allow for the tracking of threshold adjustments and performance drift through an audit trail. The incorporation of routine monitoring provides an ability to connect the behavior of the model to the operational decisions made as a result of those behaviors and allows for the safe iterative refinement of the model.

F. A Structured Framework for Deployment Readiness

Beyond evaluating models together, this study also provides a structure for evaluation to make deployability measurable. The central idea is to treat readiness as evidence across linked domains rather than as a single score. Discrimination produces a summary of ranking performance; calibration establishes whether the model's probability estimates are valid; threshold sensitivity describes how safety and workload will shift as policies change; and DCA quantifies whether an action improves outcomes in the range of thresholds that a workflow can sustain. The additional step of identifying a clinically acceptable operating region translates these metrics into a bounded set of thresholds where performance and utility are jointly defendable. Framed in this way, evaluation supports not only model selection but also planning for operation, including threshold governance, escalation rules, and monitoring triggers, which are required to deploy in safety-sensitive domains [40], [41]. While readmission prediction is focused upon here, the same logic applies to other imbalanced clinical tasks where small shifts in threshold policy can materially change patient routing.

G. Methodological Contribution

The research findings provide a deployment-focused interpretation of model performance, which may be summarized as three interrelated claims. Firstly, discrimination alone was not sufficient to establish deployability; the models were judged to have similar rankings for risk but different levels of probability reliability and decision utility. Secondly, having equal Brier scores did not mean the two models had the same level of calibration; both ECE and slope showed clinically important differences in how they scaled their probabilities. Finally, choosing the threshold to use changed the safety and workload implications of deploying the model, leading to threshold governance and decision-utility assessment being central to validating the model rather than optional additions to it. These findings collectively reframed model evaluation from "Is the model correct?" to "Do the probabilities generated by the model provide reliable information, does the decision policy used with the model behave consistently with expectations over the intended operating domain, and do decisions based upon the output of the model result in improved outcomes when the

model is deployed in a real-world environment subject to realistic constraints?".

H. Limitations and Future Directions

Several limitations should be considered when interpreting the findings of this study. First, although the dataset included 30,000 inpatient records from two resource-limited government hospitals, the evaluation remains retrospective and internally validated. No independent external cohort from a geographically or organizationally distinct hospital system was available. Therefore, the findings support the usefulness of the proposed evaluation workflow within the tested setting, but they should not be interpreted as evidence that the same model, threshold range, or calibration behavior will transfer unchanged to other resource-limited hospitals. External validation is required before broader implementation, ideally using a separate hospital network with different documentation practices, admission profiles, case mix, and follow-up capacity.

Second, the current evaluation assessed decision utility retrospectively rather than prospectively measuring the effect of model-guided intervention in routine discharge workflows. A prospective study would provide stronger evidence by examining operational outcomes after intervention allocation, such as follow-up completion rate, clinician adherence to risk alerts, readmission reduction, escalation decisions, and patient-level safety outcomes. For example, if a threshold of 0.12 routes approximately one third of discharged patients into a follow-up pathway, the clinical value of this threshold should be tested against the actual number of calls, appointments, or case-management reviews that staff can complete during a defined working week.

Third, the random forest model was evaluated without post-hoc recalibration using methods such as Platt scaling or isotonic regression. This limits the interpretation of the calibration comparison because part of the observed calibration gap may be correctable through recalibration. Future work should therefore evaluate whether recalibrated random forest probabilities change the model comparison in terms of ECE, calibration slope, threshold behavior, and net benefit.

Fourth, the comparative evaluation was limited to a neural network and a random forest. The study did not benchmark clinically established readmission scores such as LACE+ or HOSPITAL, nor did it include gradient-boosted tree models. This limits claims about comparative predictive superiority. Future studies should evaluate the same deployment-oriented workflow across a broader benchmark set, including clinical scores, random forest, neural networks, and gradient-boosted methods, using identical patient-level splits, preprocessing rules, calibration metrics, threshold sweeps, and decision curve analysis. This would allow the operating-region framework to be assessed as a general evaluation procedure rather than as a comparison restricted to two model families.

Finally, future studies should explicitly examine distribution shift and calibration drift after deployment. This requires continuous monitoring, predefined triggers for recalibration, and governance procedures for documenting changes in thresholds and model versions over time [16]. Such procedures would support the transition from one-time model validation to lifecycle management, which is necessary for responsible clinical AI implementation.

VI. Conclusions and Future Directions

This study shows that strong discrimination is necessary but not sufficient for evaluating clinical prediction models intended for discharge-planning decisions. ROC-AUC can indicate whether a model ranks patients correctly, but deployment also requires calibrated probabilities, transparent threshold policies, and evidence of decision utility within a clinically workable operating range.

The results illustrate this point clearly. Although the neural network and random forest showed broadly similar global performance, their calibration behavior differed. The random forest achieved slightly higher discrimination, but it also showed larger calibration error and greater probability-scale distortion. By contrast, the neural network produced more reliable probability estimates, behaved more predictably across threshold changes, and maintained positive net benefit within the clinically reasonable operating region. These findings indicate that practical model selection should consider probability reliability and threshold behavior, not only small gains in discrimination.

By combining discrimination, calibration assessment, threshold sensitivity analysis, and decision curve analysis, this study provides a deployment-oriented evaluation workflow for 30-day readmission prediction. In practical use, this means that the selected threshold should be linked to follow-up capacity, documented as a standing decision rule, and monitored through an audit trail that records the model version, active threshold, flagged-discharge volume, and monthly calibration summary.

These conclusions should be interpreted within the study design. The analysis used retrospective inpatient data from two resource-limited government hospitals and relied on patient-level internal validation with non-overlapping training, validation, and held-out test partitions. Therefore, the results support the value of the proposed workflow in the tested setting, but they do not establish that the same model, threshold range, calibration behavior, or model preference will transfer unchanged to other hospitals or to other benchmark models.

Future work should include independent external validation and prospective workflow evaluation. Important implementation outcomes include follow-up completion rate, clinician response to risk alerts, escalation decisions, readmission outcomes, staff workload, and calibration drift over time. Future studies should also evaluate recalibration strategies, monitor distribution shift, and define governance rules for updating thresholds and model versions during clinical use.

Authors' Contributions

The authors' contributions are as follows: "Conceptualization, Samer Asad Malalha; methodology, Samer Asad Malalha; software, Ma Burhanuddin; validation, Hatem T M Duhair; formal analysis, Jamil Abedalrahim Jamil Alsayaydeh; investigation, Samer Asad Malalha; resources, Mazen Farid; data curation, Hatem T M Duhair; writing—original draft preparation,, Jamil Abedalrahim Jamil Alsayaydeh, Hatem T M Duhair and Mazen Farid; writing—

review and editing, Ma Burhanuddin and Mazen Farid; visualization, Samer Asad Malalha; supervision, Ma Burhanuddin; project administration, Samer Asad Malalha; funding acquisition, Mazen Farid. ACKNOWLEDGMENT

The authors express their gratitude to the Centre for Research and Innovation Management (CRIM) at Universiti Teknikal Malaysia Melaka (UTeM) for their valuable support in this research.

ETHICS APPROVAL AND CONSENT TO PARTICIPATE

The study was approved by the Clinical Research Center of An-Najah National University Hospital (Approval No. CRC_2025_0554; August 19, 2025). Approval to access anonymized patient records from government hospitals was also granted by the Palestinian Ministry of Health (Ref. No. 162/2161/2025; September 1, 2025), covering Rafidia Hospital and Al-Watani Hospital. All procedures were conducted in accordance with institutional and national ethical guidelines. Patient consent was waived due to the retrospective nature of the study and the use of fully anonymized electronic health records.

Expert Evaluation of the Proposed ERP Model for Legal Compliance and Adaptation

Shkëlqim Miftari, Azir Aliu, Artan Luma
South East European University, Tetovo, North Macedonia

***Abstract*—This study presents an expert-based evaluation of a proposed context-aware ERP model designed to support adaptive legal compliance in multilingual regulatory environments, with a focus on North Macedonia. The model integrates modular ERP architecture, AI-driven legal reasoning, multilingual natural language processing, adaptive learning, and human oversight and is intended to support continuous alignment with changing legislation. A structured questionnaire was administered to 51 experts from fields, including ERP systems, software engineering, artificial intelligence, legal compliance, and public administration, to assess the model's conceptual clarity, technical feasibility, multilingual support, scalability, and compliance functionality. The findings provide expert-based conceptual support for the proposed framework, particularly regarding its relevance, architectural coherence, and potential applicability, but they should not be interpreted as evidence of operational effectiveness in a deployed ERP environment. Participants particularly emphasized the importance of multilingual support and human validation mechanisms for maintaining accountability and trust in AI-assisted compliance processes. The evaluation also identified implementation challenges related to integration complexity, AI interpretability, and organizational readiness, highlighting areas for future prototype development and empirical validation.**

Keywords*—ERP systems; legal compliance; artificial intelligence; multilingual NLP; adaptive learning; expert evaluation; compliance automation

I. Introduction

Enterprise Resource Planning (ERP) systems face increasing pressure to adapt to rapidly evolving legal environments, particularly in jurisdictions characterized by complex and multilingual regulatory frameworks. In North Macedonia, where legislative updates are frequent and multilingualism is institutionally embedded, traditional ERP systems struggle to maintain legal compliance efficiently. Static compliance mechanisms configured during system design are often insufficient for responding to dynamic legal conditions, resulting in operational inefficiencies and increased compliance risks.

Although recent ERP research has explored artificial intelligence (AI) and process automation, limited attention has been given to integrated models that combine AI-driven legal reasoning, multilingual natural language processing (NLP), and adaptive learning within a unified compliance framework. This limitation is especially evident in regions such as the Western Balkans, where linguistic diversity and fragmented digital infrastructure further complicate interoperability and legal adaptability.

To address these challenges, this study proposes a modular and context-aware ERP model that integrates AI-based legal compliance mechanisms, bilingual support in Macedonian and Albanian, and adaptive learning for continuous regulatory alignment. The model is structured around a four-layer compliance framework consisting of a Legal Data Interface, an AI Reasoning and Adaptation Engine, a Human Oversight Layer, and an ERP Integration Module. Together, these components are intended to support explainable and traceable compliance adaptation while minimizing disruption to business operations.

The contribution of this study lies in the conceptual integration of ERP compliance adaptation, AI-assisted legal reasoning, multilingual Macedonian-Albanian NLP support, adaptive learning, and human oversight within a unified four-layer framework. Unlike traditional ERP systems that depend on static compliance rules and manual updates, the proposed model treats legal compliance as a continuous and reviewable adaptation process. Unlike general AI-assisted ERP systems, the focus is specifically on legally accountable compliance adaptation rather than broad process automation. Unlike generic legal NLP systems, the proposed framework connects legal interpretation to ERP configuration and workflow adaptation. Unlike conventional rule-based compliance modules, it emphasizes traceability, expert validation, and adaptability in legally dynamic and multilingual environments such as North Macedonia.

The primary objective of this study is to evaluate the model's conceptual soundness, technical feasibility, scalability, and contextual relevance through expert-based theoretical validation. A structured questionnaire was administered to professionals in ERP systems, artificial intelligence, legal compliance, public administration, and software engineering to assess the proposed framework's applicability in legally dynamic environments.

The remainder of the study is organized as follows: Section II reviews related research on ERP adaptation, AI-driven compliance, and multilingual systems. Section III presents the proposed ERP architecture. Section IV describes the research methodology, while Section V presents the evaluation results. Section VI discusses the findings, followed by limitations in Section VII and conclusions with future work directions in Section VIII.

II. Background and Related Work

Enterprise Resource Planning (ERP) systems are increasingly required to operate in dynamic regulatory and

multilingual environments, where traditional static architectures are insufficient for maintaining long-term legal compliance and operational flexibility. Contemporary research has therefore shifted toward adaptive ERP models capable of integrating artificial intelligence (AI), natural language processing (NLP), and context-aware automation to support evolving organizational and regulatory demands.

A. ERP Adoption and Legal Compliance

ERP systems are increasingly shifting from rigid customization models toward adaptive architectures capable of supporting legal compliance in dynamic regulatory environments. Traditional ERP customization often relies on hardcoded extensions that reduce maintainability and scalability when regulations change frequently. In contrast, adaptive frameworks promote modular and constraint-aware flexibility, enabling business processes to evolve while preserving structural integrity and execution safety.

The ADEPT2 framework exemplifies this transition by supporting runtime process adaptation through controlled operations such as fragment insertion and deletion while validating modifications against compliance constraints [8]. Complementary multi-time binding mechanisms further enable process variants and data structures to be configured at either design time or runtime, reducing the limitations associated with static one-size-fits-all ERP customization approaches [8].

Adaptation is particularly important in multi-jurisdictional contexts where ERP systems must accommodate varying tax regulations, data protection requirements, and compliance mandates. AI-based approaches have also been examined in tax planning and regulatory compliance contexts, indicating their potential relevance for structuring compliance-related information and supporting automated verification and governance processes [4]. Similarly, large language model approaches have demonstrated potential for converting legal documents into machine-readable governance policies applicable to regulated sectors affected by overlapping legal frameworks such as GDPR and Basel III [14].

Static compliance mechanisms configured during system design remain limited in their ability to respond to evolving legal interpretations and runtime operational changes. Research on adaptive compliance, therefore, increasingly emphasizes predictive and continuous monitoring approaches capable of identifying potential violations before they occur [1]. These approaches also highlight the importance of explainability, periodic model retraining, and human oversight to ensure trustworthy and legally accountable AI-assisted compliance processes [4].

As ERP systems continue to evolve, adaptive compliance capabilities such as automated regulatory tracking, explainable AI reasoning, and context-aware rule management are becoming essential for maintaining operational flexibility and legal alignment across diverse regulatory environments.

B. AI in ERP Systems

Artificial intelligence is increasingly integrated into ERP systems to enhance decision support, adaptability, and compliance management in complex organizational environments. Rather than replacing core ERP functions, AI augments operational processes through predictive analytics, anomaly detection, contextual automation, and intelligent resource optimization. AI-supported ERP systems can improve decision-making across finance, logistics, human resources, and customer management while operating within predefined organizational and regulatory constraints [6].

AI also reduces cognitive overload by filtering large ERP datasets to identify patterns, risks, and anomalies that may not be easily detectable through manual analysis. Applications include fraud detection, predictive maintenance, demand forecasting, and workforce analytics, all of which contribute to improved responsiveness and operational efficiency [5].

However, the integration of AI into ERP environments introduces important governance and compliance challenges. Since ERP operations frequently intersect with regulated domains such as taxation, labor management, and financial reporting, AI-generated outputs must remain explainable, traceable, and legally accountable [16]. To address these concerns, human-in-the-loop mechanisms are increasingly incorporated into ERP-AI architectures, allowing ambiguous or high-impact decisions to be reviewed and validated by human operators [6]. Explanation interfaces, audit trails, and override capabilities, therefore, become essential components for maintaining institutional trust and regulatory compliance.

Contemporary ERP research also highlights a transition from traditional automation toward bounded process autonomization, where AI systems assume situational control over workflows while remaining constrained by explicit operational, ethical, and governance rules [15]. Within this context, responsible AI integration enables ERP systems to evolve from static transactional platforms into adaptive decision-support ecosystems capable of balancing operational efficiency with regulatory accountability.

These studies show that AI can extend ERP systems beyond static transactional processing toward intelligent decision support. However, much of the existing AI-in-ERP literature focuses on operational optimization, forecasting, anomaly detection, and process automation rather than legal compliance adaptation. The proposed model builds on this direction by focusing specifically on AI-assisted interpretation of legal changes, compliance recommendation generation, and human validation within ERP workflows.

C. Multilingual ERP Systems

The deployment of ERP systems in multilingual environments introduces significant challenges related to linguistic diversity, semantic ambiguity, and interoperability. Within such settings, NLP functions as a critical bridge between structured enterprise data and human communication, enabling applications such as document processing, compliance monitoring, automated translation, and conversational interfaces. However, the effectiveness of multilingual ERP systems depends heavily on the availability of reliable linguistic resources and domain-specific language models.

These challenges are particularly evident in the Western Balkans, where underdeveloped NLP infrastructures and limited access to AI technologies hinder enterprise system adaptability and interoperability [7]. Research has shown that NLP tools for

Macedonian and Albanian remain comparatively under-resourced, limiting accurate processing of legal and organizational texts in multilingual ERP environments [9], [13]. Similar limitations have also been identified across South Slavic languages due to insufficient corpora and weak language-processing ecosystems [10].

Within ERP contexts, NLP technologies have demonstrated strong potential for improving automation, user interaction, and knowledge extraction through functions such as invoice parsing, email classification, and semantic process interpretation [17]. AI-augmented business process management research further emphasizes that multilingual natural language understanding is essential for adaptive and explainable ERP environments operating across diverse user groups and regulatory contexts [3], [6].

In the context of North Macedonia, multilingual support represents both a technical and institutional requirement. The integration of Macedonian and Albanian language processing is essential for ensuring inclusive system interaction, accurate compliance interpretation, and operational consistency across public and private sector environments. Consequently, regional digital transformation efforts increasingly emphasize investment in multilingual AI infrastructures, localized NLP services, and language-aware enterprise technologies capable of supporting legally and linguistically diverse organizational ecosystems [2].

Overall, the reviewed literature shows increasing interest in adaptive ERP architectures, AI-supported process automation, and multilingual NLP. However, these research streams are often treated separately. Existing ERP adaptation studies emphasize process flexibility, AI-in-ERP studies often focus on operational optimization, and multilingual NLP studies address language-processing limitations without necessarily embedding them into ERP compliance workflows. This study responds to that gap by proposing a conceptual ERP compliance framework that combines legal-data interpretation, AI-assisted reasoning, multilingual Macedonian-Albanian support, adaptive learning, and human validation within a unified four-layer architecture.

III. Overview of the Proposed ERP Model

The proposed model builds on a modular client-server ERP system developed for the North Macedonian enterprise context using PHP, Laravel, and the Model-View-Controller (MVC) architectural pattern. The core ERP system separates presentation, business logic, and data management layers and supports functional domains such as Finance, Human Resources, and Inventory Management. In this study, the ERP system is extended conceptually through an external AI-driven compliance framework designed to support adaptive legal compliance in multilingual regulatory environments.

A central feature of the proposed model is a dedicated four-layer compliance framework consisting of a Legal Data Interface, an external AI Reasoning and Adaptation Engine, a Human Oversight Layer, and an ERP Integration Module. This framework is designed to operate independently from transactional ERP services, enabling legal adaptation recommendations to be generated, reviewed, and transferred to the ERP system without disrupting core business operations.

The architecture integrates AI-based legal reasoning, multilingual natural language processing, adaptive learning mechanisms, and human validation procedures to support explainable and traceable compliance management. Through this combination of modular ERP functionality and intelligent compliance services, the model aims to provide a scalable and context-aware solution for enterprise environments characterized by evolving legal requirements and multilingual interaction.

A. Architectural Overview

The ERP system is designed as a modular and context-aware architecture that supports both enterprise operations and adaptive legal compliance. The core ERP system was developed using PHP, Laravel, and the Model-View-Controller (MVC) pattern, separating data access, business logic, and presentation layers to improve maintainability, scalability, and flexibility [11]. Functional domains such as Human Resources, Finance, and Inventory Management operate as independent ERP modules that can be deployed and customized according to organizational requirements.

The proposed compliance architecture is positioned outside the transactional ERP core and communicates with it through the ERP Integration Module. This separation allows the AI-based compliance components to operate as external decision-support and recommendation services rather than as embedded transactional ERP functions [12].

The architecture is intended to use a relational MySQL database with normalized schemas and indexed queries to ensure data consistency, efficient access, and scalable transaction management [11]. A defining characteristic of the system is the separation between operational ERP services and compliance management through a four-layer adaptive framework consisting of the Legal Data Interface, AI Reasoning and Adaptation Engine, Human Oversight Layer, and ERP Integration Module [12].

The Legal Data Interface is intended to collect and structure legislative information from official sources using NLP techniques that transform unstructured legal texts into machine-interpretable representations. The AI Reasoning and Adaptation Engine is designed to apply ontology-based reasoning, rule inference, and reinforcement learning to determine how legislative modifications could affect ERP workflows. The proposed system would identify potentially impacted business domains and generate recommendations for process adaptation, such as revised payroll calculations or compliance-reporting procedures. Reviewer feedback and organizational data could be used in future implementation to refine interpretive accuracy over time [12].

To ensure accountability and institutional control, AI-generated recommendations would be reviewed within the Human Oversight Layer, where authorized experts could validate, reject, or modify proposed changes. Each action would be documented through metadata containing timestamps, legal references, and reviewer information to support transparency and traceability. Approved adaptations would then be transferred to the ERP Integration Module, which is intended to

apply configuration updates through secure APIs without requiring full system redeployment [12].

This separation between compliance services and transactional business logic enables continuous regulatory adaptation while maintaining operational stability. By integrating semantic reasoning, adaptive learning, multilingual processing, and human validation, the architecture supports legally accountable and scalable ERP environments suited to dynamically evolving regulatory contexts.

B. AI-Driven Legal Compliance Layer

The AI-driven legal compliance layer is designed to enable the ERP system to ingest legislative updates, interpret regulatory implications, and generate compliance adaptation recommendations through explainable and auditable mechanisms. Operating independently from transactional ERP services, this layer supports continuous regulatory alignment while preserving institutional accountability [12].

Legislative data ingestion is managed through the Legal Data Interface, which connects to verified legal sources and applies NLP techniques to structure unstructured legal texts into machine-readable representations. Legal obligations and regulatory triggers are mapped into formal ontologies that encode relationships between legal entities, conditions, and operational processes [12]. In the proposed North Macedonian context, newly collected legal content would be compared with prior legislative versions to identify relevant changes [11].

The AI Reasoning and Adaptation Engine is designed to apply ontology-based reasoning, rule inference, and reinforcement learning to evaluate the impact of legal changes on ERP business processes and generate compliance adaptation recommendations. The proposed system would identify potentially impacted business domains and generate recommendations for process adaptation, such as revised payroll calculations or compliance-reporting procedures. Reviewer feedback and organizational data could be used in future implementation to refine interpretive accuracy over time [12].

To ensure legal reliability and ethical governance, all AI-generated recommendations are reviewed through the Human Oversight Layer before implementation. Legal experts or administrators can validate, reject, or modify proposed adaptations using interfaces that provide reasoning traces, legal references, and suggested system modifications. In the proposed workflow, approved changes would be logged through timestamped audit records containing legal and reviewer metadata, enabling traceability, compliance verification, and post-decision analysis [11-12].

Together, these mechanisms are intended to transform compliance management from a static configuration process into a continuous and context-aware capability connected to ERP operations.

C. Multilingual and Adaptive Components

The ERP framework incorporates multilingual and adaptive capabilities to support inclusive interaction and continuous legal alignment within North Macedonia's multilingual regulatory environment. The proposed framework includes real-time language switching as an intended multilingual capability, allowing users to interact with ERP services in their preferred language through AI-supported translation and interface localization mechanisms [11].

Multilingual NLP functionality enables the extraction and interpretation of legal obligations from legislative texts published in different official languages. These obligations are transformed into structured legal ontologies that support automated compliance reasoning and regulatory adaptation within ERP workflows [12].

Adaptive learning is conceptualized through the AI Reasoning and Adaptation Engine, which uses reinforcement learning and reviewer feedback to improve the accuracy of future compliance recommendations. In addition to legal adaptation, machine learning models could analyze organizational data related to employee roles, performance, and workload distribution to support predictive workforce management and operational optimization [11].

When legislative updates are detected, the proposed framework would compare new and previous legal versions, evaluate operational impacts, and generate adaptation recommendations such as revised payroll or leave-management policies. These recommendations are presented in the user's preferred language and validated by human reviewers prior to implementation [11-12].

By connecting multilingual processing and adaptive intelligence to the ERP architecture through an external compliance layer, the proposed framework is intended to support legally compliant, operationally responsive, and linguistically inclusive enterprise management.

The architecture described in this section represents the proposed design logic of the ERP compliance model. The current study evaluates this architecture through expert-based conceptual assessment rather than through deployment or operational prototype testing. Therefore, the described components should be interpreted as intended system capabilities requiring future implementation and empirical validation.

IV. Research Methodology

This section presents the methodology used to evaluate the proposed ERP model for adaptive legal compliance within the North Macedonian context. The study combines Design Science Research (DSR) principles with expert-based theoretical validation supported through a structured questionnaire. Because the research focuses on a conceptual ERP architecture integrating AI-driven legal reasoning, multilingual NLP, and adaptive learning, the evaluation emphasizes conceptual soundness, technical feasibility, and practical applicability rather than prototype implementation. The following sections describe the evaluation approach, expert selection process, questionnaire design, and data analysis procedures.

A. Evaluation Approach

The evaluation of the proposed ERP framework was grounded in Design Science Research (DSR), a methodology widely used in information systems research for the development and validation of innovative artifacts. The study focused on assessing a context-aware ERP architecture

integrating ontology-based legal reasoning, multilingual NLP, and adaptive learning mechanisms within enterprise compliance processes.

Because the research concerns a conceptual model rather than a deployed software implementation, expert-based validation was adopted as the primary evaluation strategy. Structured feedback was collected from professionals in ERP systems, artificial intelligence, legal compliance, software engineering, and public administration to assess the framework's conceptual integrity, feasibility, and practical relevance.

Data collection was conducted through a structured questionnaire containing both quantitative and qualitative components. This approach enabled systematic evaluation of the model's architectural coherence, implementation potential, and applicability within legally dynamic enterprise environments.

This evaluation approach is appropriate for assessing early-stage conceptual soundness and feasibility, but it does not replace prototype implementation, operational testing, or empirical validation in live ERP environments.

B. Expert Selection

Experts were selected using purposive sampling to ensure relevant expertise across ERP systems, software engineering, artificial intelligence, legal compliance, and public administration. Participants included ERP consultants, software engineers, IT architects, compliance specialists, legal experts, and academic professionals with experience in enterprise systems and regulatory processes.

All participants confirmed prior experience with ERP platforms, AI systems, legal compliance, or enterprise software environments. Respondents also reported their ERP-related experience levels, categorized as less than five years, five to ten years, or more than ten years, enabling consideration of professional experience during analysis.

Participation was conducted anonymously to encourage unbiased feedback and reduce social desirability bias. Respondents were informed that all collected data would be used exclusively for academic research purposes.

C. Questionnaire Design

The questionnaire was designed to evaluate the proposed ERP model across six dimensions: conceptual soundness, technical feasibility, AI-driven legal compliance, multilingual support, adaptability and scalability, and human oversight. The instrument combined closed-ended and open-ended questions to support both quantitative and qualitative evaluation.

The six questionnaire dimensions were derived from the main architectural and evaluation concerns of the proposed ERP compliance framework. Conceptual soundness assessed whether the model was understandable and internally coherent. Technical feasibility examined whether the architecture could plausibly be integrated into ERP environments. AI-driven legal compliance evaluated the perceived suitability of AI-assisted legal reasoning for compliance adaptation. Multilingual support reflected the framework's Macedonian–Albanian operating context. Adaptability and scalability assessed the model's ability to respond to changing legal and organizational conditions. Human oversight evaluated the accountability and validation mechanisms required for AI-assisted compliance decisions.

Closed-ended items used a 5-point Likert scale ranging from "Strongly Disagree" to "Strongly Agree". These questions assessed the clarity of the model's architecture, the feasibility of integrating adaptive compliance mechanisms into ERP environments, the effectiveness of multilingual NLP support, and the role of human oversight in ensuring accountability and transparency within AI-assisted compliance processes.

The questionnaire also evaluated whether the proposed architecture could adapt to evolving legal and organizational conditions and whether its modular design supported scalable deployment across different institutional contexts. Two open-ended questions allowed participants to identify perceived strengths, limitations, and implementation challenges associated with the proposed framework.

This structure enabled a balanced evaluation of both the technical and contextual aspects of the ERP model while providing qualitative insights beyond numerical ratings.

The final dataset consisted of 51 questionnaire responses. The questionnaire included demographic and professional background items, 14 substantive closed-ended Likert-scale evaluation items, and two open-ended questions. All closed-ended items were complete for all 51 respondents. The first open-ended question received 34 valid responses, while the second received 31 valid responses. These response counts were considered during qualitative interpretation. Appendix A presents the questionnaire items used.

D. Instrument Validity and Reliability

Content validity was addressed by aligning the questionnaire dimensions with the main components and evaluation concerns of the proposed ERP compliance framework, including conceptual clarity, technical feasibility, AI-assisted legal compliance, multilingual support, adaptability and scalability, and human oversight. Internal consistency was assessed using Cronbach's Alpha across the 14 substantive Likert-scale items, producing a value of approximately 0.871, which indicates strong internal consistency for the current sample. However, construct validity was not independently verified through factor analysis, and the study did not include prototype testing or follow-up interviews. Therefore, the instrument should be interpreted as supporting expert-based conceptual evaluation rather than full psychometric or operational validation.

E. Data Collection and Analysis

Data was collected through a secure online questionnaire distributed via academic and professional networks. Participants received information regarding the study objectives, anonymity procedures, and research ethics prior to participation. The questionnaire remained open for two weeks, and no identifying information was stored. All closed-ended Likert-scale items were complete for all 51 responses and were included in the descriptive and reliability analysis. The dataset also contained a "Score" variable; however, because all entries contained a value of zero, this variable was excluded from analytical interpretation.

Quantitative responses were analyzed using descriptive statistics, including frequency distributions, mean scores, standard deviations, and 95% confidence intervals for each evaluation dimension. Dimension-level scores were calculated by aggregating thematically related Likert-scale items corresponding to the six evaluation dimensions. These measures enabled the identification of agreement levels, response patterns, and variability across expert assessments. Internal consistency of the questionnaire was evaluated using Cronbach's Alpha across the 14 substantive Likert-scale items. The resulting Cronbach's Alpha value was approximately 0.871, indicating strong internal consistency of the evaluation instrument.

Qualitative responses from the open-ended questions were analyzed using thematic coding to identify recurring strengths, limitations, and implementation concerns associated with the proposed ERP model. Common themes included the benefits of modular architecture and multilingual integration, as well as concerns related to AI interpretability, legal ontology maintenance, and integration complexity.

The combination of statistical and thematic analysis provided a multidimensional evaluation of the model's conceptual validity, technical feasibility, and contextual applicability.

V. Results

The evaluation assessed the proposed ERP model's conceptual validity, technical feasibility, and contextual suitability within the legal and organizational environment of North Macedonia. Expert feedback was analyzed through both quantitative ratings and qualitative reflections, providing insight into the model's architectural coherence, compliance functionality, multilingual capabilities, and implementation considerations. The findings highlight strong overall support for the proposed framework while also identifying challenges relevant to future implementation and validation efforts.

A. Participant Profile

The expert evaluation included participants from diverse professional backgrounds related to ERP systems, software engineering, artificial intelligence, legal compliance, and public administration. Software engineers represented the largest participant group, alongside ERP architects, lecturers, compliance specialists, and public-sector professionals. Additional expertise in AI engineering, cloud infrastructure, and network systems further broadened the evaluation perspective.

Among the 51 respondents, 26 reported less than five years of ERP experience, 17 reported between five and ten years of ERP-related experience, and 8 reported more than ten years of ERP experience. The participant structure, therefore, reflects perspectives from respondents with varying levels of ERP familiarity and implementation exposure.

Although 26 respondents reported fewer than five years of ERP-related experience, this distribution should be interpreted in light of the multidisciplinary nature of the evaluation. The proposed framework combines ERP architecture, software engineering, AI-assisted reasoning, legal compliance, multilingual support, and public-sector regulatory context. Therefore, participants with relevant experience in these related domains were considered suitable for assessing specific aspects of the model. Nevertheless, the relatively high proportion of respondents with limited ERP-specific experience is acknowledged as a limitation when interpreting conclusions about practical ERP deployment feasibility.

B. Quantitative Results

The quantitative evaluation demonstrated consistently positive assessments across all six dimensions of the proposed ERP model using a 5-point Likert scale ranging from "Strongly Disagree" to "Strongly Agree". Mean scores exceeded 4.2 across all categories, indicating strong expert support for the model's conceptual structure, technical feasibility, and compliance-oriented functionality within the North Macedonian context.

The highest-rated dimension was Multilingual ERP Support with a mean score of 4.51, reflecting the perceived importance of Macedonian and Albanian language integration within enterprise systems. Participants identified multilingual NLP capabilities as essential for improving communication accuracy, operational inclusivity, and regulatory interpretation in bilingual environments.

Human oversight received the second-highest score at 4.49. Respondents emphasized the importance of maintaining expert validation for AI-generated compliance decisions through auditability, traceability, and accountability mechanisms. Conceptual Clarity followed with a mean score of 4.42, indicating strong agreement regarding the coherence and internal structure of the proposed architecture.

Technical feasibility achieved a mean score of 4.33, suggesting that the modular and service-oriented architecture could be integrated into existing ERP environments with appropriate organizational readiness and infrastructure support. Adaptability and Scalability received a mean score of 4.32, reflecting confidence in the framework's ability to respond to evolving legal and organizational requirements through adaptive learning mechanisms.

Finally, AI compliance validity received a mean score of 4.29, indicating positive assessments regarding the feasibility of AI-assisted legal interpretation and compliance automation. Participants nevertheless emphasized the continued necessity of combining AI reasoning with human oversight to preserve legal reliability and institutional trust.

The dimension-level results presented in Table I were constructed from thematically related questionnaire items. These dimensions include conceptual clarity, multilingual ERP support, technical feasibility, AI-assisted compliance adaptability, scalability, and human oversight mechanisms. The aggregation of questionnaire items into thematic dimensions was used to summarize expert evaluation trends across the proposed ERP framework components. The results are summarized in Table I.

In addition to the aggregated dimension scores, item-level descriptive statistics demonstrated consistently positive evaluations across the questionnaire items. The highest agreement was observed for the necessity of full Macedonian and Albanian language support, with a mean score of 4.57.

Strong agreement was also observed for multilingual NLP functionality (mean = 4.55) and the importance of human oversight in AI-assisted compliance adaptation (mean = 4.49). Comparatively lower, although still positive, agreement was observed for the feasibility of automated legislative interpretation (mean = 4.10), suggesting comparatively greater caution regarding autonomous legal interpretation mechanisms.

TABLE I. MEAN EXPERT EVALUATION SCORES ACROSS SIX ASSESSMENT DIMENSIONS OF THE PROPOSED ERP MODEL.

Evaluation Dimension	Mean score	SD	95% CI
Multilingual ERP support	4.51	0.59	4.34-4.67
Human oversight	4.49	0.76	4.28-4.70
Conceptual clarity	4.42	0.60	4.25-4.59
Technical feasibility	4.33	0.77	4.12-4.55
Adaptability and scalability	4.32	0.52	4.17-4.47
AI compliance validity	4.29	0.54	4.14-4.44

Note. N = 51; CI = confidence interval.

Table II presents selected item-level descriptive statistics for representative questionnaire items associated with multilingual support, human oversight, and AI-assisted compliance functionality. These item-level results complement the aggregated dimension-level findings by illustrating expert agreement patterns across specific aspects of the proposed ERP framework.

TABLE II. SELECTED ITEM-LEVEL DESCRIPTIVE STATISTICS

Questionnaire item	*Mean score*	*SD*	*95% CI*
Necessity of Macedonian and Albanian language support	4.57	0.83	4.33-4.80
Multilingual NLP functionality	4.55	0.61	4.38-4.72
Human oversight necessity	4.49	0.76	4.28-4.70
Automated legislative interpretation feasibility	4.10	0.76	3.89-4.31

Note. N = 51; CI = confidence interval.

C. Qualitative Feedback

The qualitative findings were derived from optional open-ended questionnaire responses. The first open-ended question received 34 valid responses, while the second received 31 valid responses. Consequently, the qualitative findings should be interpreted as supplementary thematic insights rather than complete-sample evidence.

The open-ended responses provided additional insight into the perceived strengths and limitations of the proposed ERP model. A dominant theme concerned the system's strong alignment with legal compliance requirements in environments characterized by frequent regulatory changes. Participants viewed the architecture as particularly relevant for organizations requiring adaptive compliance capabilities beyond those offered by traditional ERP systems.

Human oversight emerged as another central theme. Respondents consistently emphasized that AI-generated compliance recommendations should remain subject to expert validation in order to ensure accountability, legal reliability, and institutional trust. The inclusion of auditability and traceability mechanisms was therefore regarded as a major architectural strength.

Participants also highlighted the innovative integration of AI-driven legal reasoning, adaptive learning, and modular ERP services. The modular architecture was considered beneficial for scalability and integration with existing infrastructures, particularly within organizations operating with heterogeneous or legacy systems. Multilingual support for Macedonian and Albanian was similarly viewed as essential for operational inclusivity and accurate legal interpretation.

Despite the positive assessments, experts identified several implementation challenges. These included integration complexity, infrastructure requirements, AI interpretability limitations, and the risk of excessive reliance on automated legal reasoning. Respondents also noted that successful adoption would depend on organizational readiness, effective user training, and clear governance procedures. Data traceability and audit-ready compliance records were considered critical for maintaining long-term trust and regulatory accountability.

Overall, the qualitative feedback reinforced the quantitative findings while offering deeper insight into the practical conditions necessary for successful implementation of the proposed framework.

VI. DISCUSSION

The expert evaluation provides strong support for the proposed ERP model's conceptual structure, technical feasibility, and relevance within legally dynamic enterprise environments. The findings demonstrate broad agreement regarding the value of integrating AI-assisted compliance mechanisms, multilingual support, adaptive learning, and human oversight within ERP architectures. This section interprets these findings in relation to ERP system design, regulatory adaptability, and existing compliance approaches.

A. Interpretation of Expert Evaluation

The evaluation results provide consistent expert-based support for the proposed ERP framework across all assessed dimensions. Expert responses suggest that the model has the potential to address key challenges associated with regulatory adaptation, multilingual operation, and AI-assisted compliance management within enterprise systems. However, this support should be interpreted as conceptual validation rather than evidence of operational effectiveness in a deployed ERP environment.

Particular support was observed for the modular separation between operational ERP services and compliance-management functions. Participants viewed this architectural distinction as essential for enabling scalable and maintainable regulatory adaptation without disrupting transactional business processes. The integration of auditability, traceability, and human validation mechanisms further strengthened perceptions of legal reliability and institutional accountability.

The findings also suggest that the proposed framework aligns well with emerging expectations for intelligent ERP environments capable of supporting continuous compliance adaptation in complex regulatory settings. These findings

reinforce the model's relevance as a foundation for future implementation and empirical testing.

B. Implications for ERP Design

The evaluation highlights several broader implications for contemporary ERP system design. First, the findings suggest the potential feasibility of AI-assisted compliance management as an alternative to static and manually maintained regulatory mechanisms. The integration of ontology-based reasoning, adaptive learning, and multilingual NLP demonstrates how ERP systems can evolve toward continuous and context-aware legal alignment.

At the same time, the results strongly reinforce the necessity of human-in-the-loop governance within AI-driven enterprise environments. Experts consistently emphasized that automated legal interpretation must remain subject to human validation in order to preserve accountability, transparency, and institutional trust. Consequently, explainability, auditability, and reviewer oversight should be treated as foundational architectural requirements rather than optional enhancements.

The findings also underscore the importance of multilingual functionality in ERP systems operating within linguistically diverse regulatory contexts. In the North Macedonian setting, support for both Macedonian and Albanian was viewed as essential for inclusive interaction, accurate compliance interpretation, and organizational accessibility. More broadly, this suggests that multilingual NLP capabilities will become increasingly important in internationally distributed or multi-jurisdictional ERP deployments.

Overall, the study supports a transition from rigid ERP infrastructures toward adaptive enterprise ecosystems capable of combining operational efficiency with continuous regulatory responsiveness.

C. Comparison with Existing Approaches

Compared with traditional ERP systems that rely on static compliance rules and manually configured updates, the proposed framework introduces a more adaptive and context-aware approach to regulatory management. Conventional ERP architectures often struggle to accommodate evolving legal requirements without extensive redevelopment or operational disruption.

In contrast, the proposed model integrates AI-assisted legal reasoning, adaptive learning, multilingual NLP, and modular compliance services capable of responding dynamically to legislative changes. The separation between transactional ERP operations and compliance-management layers further improves scalability, maintainability, and deployment flexibility.

The architecture also addresses common limitations associated with opaque automation by incorporating auditability, traceability, and human oversight directly into the compliance workflow. These mechanisms are intended to enhance institutional accountability and distinguish the framework from conventional rule-based compliance systems that frequently lack transparent adaptation processes.

Collectively, these features position the proposed model as a promising conceptual contribution toward intelligent ERP systems capable of maintaining continuous legal alignment in multilingual and rapidly evolving regulatory environments.

VII. Threats to Validity

The expert-based evaluation of the proposed ERP model is subject to several validity considerations that should be acknowledged when interpreting the findings.

Regarding internal validity, the evaluation relied on expert judgment, meaning that responses were influenced by participants' professional experiences and familiarity with ERP systems, artificial intelligence, and compliance processes. Because the study assessed a conceptual framework rather than a deployed implementation, some variation in interpretation across respondents was expected.

A further limitation concerns the distribution of ERP-specific experience among participants. Although expertise was treated as multidimensional and included ERP systems, software engineering, artificial intelligence, legal compliance, public administration, and enterprise software experience, 26 of the 51 respondents reported fewer than five years of ERP-related experience. This provides useful multidisciplinary perspectives but may limit the strength of conclusions regarding senior ERP implementation feasibility.

Construct validity is also relevant due to the use of a 5-point Likert scale, where respondents may have interpreted agreement levels differently, particularly for abstract concepts such as adaptive learning or AI-driven legal compliance. Although the questionnaire was carefully structured around clearly defined evaluation dimensions, the absence of follow-up interviews may have limited clarification of individual interpretations.

External validity is constrained by the study's focus on the North Macedonian regulatory and linguistic environment, including bilingual support for Macedonian and Albanian. While core architectural principles such as modularity, AI-assisted compliance, and human oversight may be transferable to other contexts, the evaluation results remain closely connected to the regional conditions in which the framework was designed.

Several measures were applied to mitigate these limitations. Experts were selected based on relevant professional experience in ERP systems, information systems, or legal compliance, and participation was conducted anonymously to encourage unbiased responses. In addition, the combination of quantitative and qualitative feedback provided a broader and more consistent understanding of participant perspectives across different evaluation dimensions.

Although the analysis included mean scores, standard deviations, confidence intervals, and reliability assessment using Cronbach's Alpha, the study did not conduct factor analysis or subgroup comparisons by experience level. Therefore, the statistical findings should be interpreted as descriptive evidence of expert perceptions rather than as confirmatory psychometric validation or evidence of statistically significant differences between participant groups.

The study relies on descriptive and expert-based evaluation rather than inferential or experimental analysis. Consequently,

the dataset does not provide sufficient evidence for causal inference, predictive performance evaluation, or statistically verified implementation outcomes.

VIII. Conclusion and Future Work

This study presented an expert-based evaluation of a context-aware ERP model designed to support adaptive legal compliance within multilingual regulatory environments. The findings indicate strong expert-based support for the model's conceptual structure, technical feasibility, and contextual relevance within the North Macedonian enterprise landscape.

The proposed framework combines modular ERP architecture with AI-assisted legal reasoning, multilingual NLP, adaptive learning, and human oversight mechanisms and is intended to support continuous regulatory alignment. Experts particularly emphasized the importance of multilingual support and human validation in maintaining operational inclusivity, accountability, and trust within AI-assisted compliance processes.

The evaluation further suggests that adaptive and explainable compliance mechanisms represent an important direction for future ERP development, particularly in environments characterized by evolving legal requirements and multilingual governance structures. At the same time, the study identified implementation challenges related to integration complexity, organizational readiness, and AI interpretability, highlighting the need for careful governance and deployment planning.

Several limitations should be acknowledged. The evaluation focused on theoretical validation through expert assessment rather than empirical testing of a deployed system. Consequently, the findings reflect professional perceptions of feasibility and relevance rather than operational performance under real-world conditions.

Future work will focus on prototype implementation and empirical validation of the proposed framework in live enterprise environments. Additional research will examine the effectiveness of AI-driven compliance adaptation, multilingual NLP processing, and reinforcement-learning mechanisms over time. Cross-jurisdictional studies will also be necessary to evaluate the transferability of the architecture beyond North Macedonia and to identify adjustments required for broader regulatory and linguistic contexts.

Overall, the proposed model contributes toward the development of intelligent ERP systems capable of supporting continuous legal alignment, accountable automation, and multilingual enterprise management in dynamically evolving regulatory environments.

Appendix A: Questionnaire Items

The questionnaire used in the expert evaluation consisted of demographic/background questions, 14 closed-ended Likert-scale evaluation items, and two open-ended questions. The Likert-scale items were rated on a 5-point scale ranging from 'Strongly Disagree' to 'Strongly Agree'.

A. Background Information

Your professional role?

Years of experience with ERP systems?

I confirm that I have experience related to ERP systems, legal compliance, AI, or enterprise systems.

B. Likert-Scale Evaluation Items

The proposed ERP model is conceptually clear and logically structured.

The interaction between ERP modules and AI components is well-defined and understandable.

Automated interpretation of legislative changes is feasible within the proposed ERP model.

The AI-driven compliance component can improve legal alignment of ERP systems in North Macedonia.

Full support for both Macedonian and Albanian languages is necessary in ERP systems operating in North Macedonia.

NLP-based multilingual modules can improve clarity and reduce operational errors in ERP systems.

Adaptive learning mechanisms enable ERP systems to respond effectively to regulatory or organizational changes.

The proposed ERP model is scalable and suitable for enterprises in North Macedonia.

The proposed ERP model provides a coherent and realistic approach for integrating legal compliance, multilingual support, and adaptive learning within a single ERP system.

The proposed ERP model ensures that compliance-related decisions and process adaptations are traceable, auditable, and linked to specific legal requirements.

Human validation and oversight of AI-driven compliance adaptations are necessary and appropriate for ensuring accountability and trust in ERP systems.

The proposed ERP model appears technically feasible to integrate with existing ERP systems using modular services and standard interfaces.

Multilingual NLP support can improve data consistency and accuracy across Macedonian and Albanian records and reports.

The proposed ERP model sufficiently mitigates risks related to AI-based legal misinterpretation through human validation and auditability.

C. Open-Ended Questions

What do you consider the main strength or limitation of the proposed ERP model?

Which aspect would require the most attention in a real-world implementation of this model?

***Abstract*—This study investigated how guests' technological perceptions of Artificial Intelligence (AI) applications perceived usefulness (PU), perceived ease of use (PEOU), enjoyment (ENJ), and privacy concerns (PC) influence customer satisfaction (CS) and customer loyalty (CL) at the Shenyang Airport Hotel, a three-star airport property in a secondary Chinese city. Grounded in an integrated framework combining the Technology Acceptance Model (TAM) with Customer Experience Theory. A quantitative survey of 452 guests who had experienced AI-enabled services during their stay was conducted. Data were analysed using reliability assessment, exploratory factor analysis (to verify the factor structure in a novel context), Pearson correlation, multiple regression, and bootstrap mediation analysis. The results indicated that perceived usefulness ($\beta = 0.314$, $p < 0.001$), enjoyment ($\beta = 0.141$, $p < 0.01$), and perceived ease of use ($\beta = 0.127$, $p < 0.01$) each positively influenced customer satisfaction, whereas privacy concerns exerted a significant negative effect ($\beta = -0.205$, $p < 0.001$). Customer satisfaction, in turn, significantly predicted customer loyalty ($\beta = 0.409$, $p < 0.001$), and partially mediated all four perception-to-loyalty pathways. One-way ANOVA further revealed significant differences in customer loyalty across age groups, educational levels, and income brackets. Theoretically, this study extended TAM by simultaneously incorporating affective and security-related dimensions into AI service acceptance within an underexamined hospitality context. Practically, the findings offer airport hotel managers in secondary cities evidence-based guidance on prioritising utility-enhancing AI features, simplifying service interfaces, enriching hedonic engagement, and communicating data governance policies transparently to mitigate privacy-driven dissatisfaction. The study was limited by its single-site, cross-sectional design; future research should adopt longitudinal or multi-site approaches to strengthen generalisability.**

Keywords*—*Artificial intelligence; airport hotels; technology acceptance model; customer satisfaction; customer loyalty; secondary city; China

I. Introduction

AI has rapidly become a transformative force in the global hospitality industry. From AI-powered chatbots and facial recognition check-in systems to service robots and predictive analytics platforms, hotels are deploying AI across the full service cycle to enhance operational efficiency, personalize guest experiences, and strengthen competitive positioning [1-2]. In China, this transformation has been further accelerated by strong government policy support and advanced digital infrastructure. Luxury flagship hotels in first-tier cities exemplify the frontier of this trend: Alibaba's FlyZoo Hotel in Hangzhou offers fully AI-integrated experiences spanning autonomous check-in, voice-controlled rooms, and robot concierge services [3], while international chains such as Marriott, Hilton, and Inter Continental have deployed AI-driven dynamic pricing and sentiment analysis platforms across their premier Chinese properties [4]. These innovations have generated a corresponding surge of scholarly interest, with empirical studies consistently reporting that well-implemented AI services improve guest satisfaction and stimulate revisit intention [3, 5].

Despite this growing body of practice and research, the existing literature reflects a pronounced geographical bias. The overwhelming majority of empirical studies on AI in Chinese hotels have concentrated on luxury or upscale establishments in major metropolitan centers such as Shanghai, Beijing, and Guangzhou, where hotels operate with sophisticated technological infrastructure and technologically fluent guest bases [5]. Airport hotels in secondary Chinese cities have received considerably less academic attention. Shenyang, a major industrial and transportation hub in northeastern China, exemplifies such a context. The Shenyang Airport Hotel, located adjacent to Shenyang Taoxian International Airport, operates as a typical three-star airport hotel that serves a mix of business travelers, transit passengers, and increasingly leisure tourists. Despite its strategic location and stable customer flow, the hotel faces persistent operational challenges. According to the hotel's official operational records and a preliminary field survey conducted by the authors in March 2026, which included structured interviews with the hotel manager and three senior front-desk staff members, the hotel's annual repurchase rate stood at only 18% in 2024, substantially below the national average for comparable domestic airport hotels [6-7]. The same sources further reveal the absence of a systematic Customer Relationship Management (CRM) system or loyalty program, and limited technological infrastructure capable of supporting personalized guest retention strategies. These operational realities create both a practical imperative and a research opportunity: to understand how guests perceive AI applications in such a setting and to examine whether these perceptions translate into higher satisfaction and greater loyalty.

There are three research gaps addressed in this study. First, while prior studies have confirmed that AI can improve service efficiency and personalization [2, 5], few have examined how individual technological perceptions, specifically whether an AI

system is perceived as useful, easy to use, enjoyable, or privacy-invasive, affect satisfaction and loyalty outcomes in airport hotel contexts. Second, the majority of empirical work has concentrated on first-tier cities or upscale establishments, leaving the dynamics of AI perception formation in secondary-city, mid-scale airport hotels largely unexplored. Third, the mediating role of customer satisfaction in translating technological perceptions into loyalty intentions, although theoretically plausible, has not been rigorously tested in this particular context. Consequently, hotel managers in secondary cities often lack evidence-based guidance on which AI features to prioritize and how to address guests' privacy concerns when deploying AI services.

To fill these gaps, this study empirically investigates how four dimensions of guests' technological perceptions, perceived usefulness, perceived ease of use, enjoyment, and privacy concerns, influence customer satisfaction and, in turn, customer loyalty at Shenyang Airport Hotel. A quantitative survey of 452 guests who had used AI-enabled services during their stay was conducted between March and May 2026. The study addresses six research questions: 1) To what extent does the perceived usefulness of AI applications influence customer satisfaction among hotel guests? 2) To what extent does the perceived ease of use of AI applications influence customer satisfaction among hotel guests? 3) To what extent does the enjoyment derived from AI applications influence customer satisfaction among hotel guests? 4) To what extent do privacy concerns regarding AI applications negatively influence customer satisfaction among hotel guests? 5) Does customer satisfaction positively influence guests' behavioral intentions? 6) Does customer satisfaction mediate the relationships between guests' technological perceptions of AI applications, namely perceived usefulness, perceived ease of use, enjoyment, and privacy concerns, and customer loyalty?

The findings contribute to the literature in three ways. Theoretically, this study extends existing technology acceptance research by incorporating both affective (enjoyment) and security-related (privacy concern) factors into a single model applied to an AI service context that has been largely absent from prior scholarship. Empirically, it provides the first systematic investigation of AI-driven satisfaction and loyalty dynamics in a secondary-city Chinese airport hotel, a context characterized by partial AI infrastructure and low guest retention rates. Practically, it offers hotel managers in analogous settings concrete, evidence-based guidance on AI service design, privacy communication, and demographic differentiated implementation strategies. This study is organized as follows. Section II reviews the relevant literature and develops the study hypotheses. Section III describes the research methodology. Section IV presents the empirical results. Section V discusses the key findings and their theoretical and managerial implications. Section VI presents conclusions. Section VII outlines the research implementation, and Section VIII addresses the limitations of the study and suggests directions for future research.

II. Literature Review

A. AI Adoption in Hospitality and the Airport Hotel Context

AI integration in hotel operations has advanced from rule-based chatbot automation to adaptive systems spanning natural language processing, predictive analytics, and robotics [2, 4]. It falls into three categories: guest interaction systems (chatbots, facial recognition check-in), analytical platforms (revenue management, sentiment analysis), and automated physical operations (service robots, smart room control). Together, these shift service delivery from human-to-human to human-to-machine interaction, introducing efficiency gains alongside new psychological challenges for guests [1]. Airport hotels occupy a structurally distinctive niche, characterized by high turnover, short stays, and guests who prioritize efficiency over experience [8]. This makes them receptive to time-saving AI tools; yet the technological infrastructure of secondary-city airport hotels frequently lags behind first-tier counterparts, creating a context where AI effectiveness is uncertain, and guest perceptions may differ markedly from those documented in luxury urban hotels [5]. Table I contextualizes the AI service profile of the Shenyang Airport Hotel (SAH) against ten landmark hospitality studies. The three features operational at SAH: AI chatbots, facial recognition check-in, and automated check-in/check-out—are among the most frequently documented (frequency 4–5), confirming the study's empirical relevance. The absence of post-stay follow-up systems, recommendation engines, and AI-enabled loyalty programmes delineates the current technological gap and reinforces the study's practical motivation [6-7].

TABLE I. AI Service Features in the Hospitality

No	AI Feature / Application	[4]	[9]	[10]	[11]	[12]	[13]	14]	[15]	[16]	[17]	Authors
1	AI Chatbots	✓	✓		✓	✓	✓					✓
2	Post-stay Follow-up AI		✓			✓			✓	✓		
3	Facial Recognition Check-in	✓		✓		✓		✓				✓
4	Service Robots	✓	✓	✓							✓	
5	AI Recommendation Engines		✓	✓	✓		✓		✓			
6	Automated Check-in/Check-out		✓			✓		✓		✓		✓
7	AI Concierge Systems			✓		✓	✓				✓	
8	Biometric Room Access					✓		✓			✓	
9	Hyper-personalized Services		✓		✓		✓		✓			
10	AI-enabled Loyalty Programme							✓	✓		✓	

B. TAM and Its Extensions

Davis [26] established that PU and PEOU jointly determine technology acceptance. Subsequent extensions accommodate the hedonic and risk dimensions of consumer service contexts [18]. Two extensions are central here. First, perceived enjoyment (ENJ), intrinsic positive affect generated by the AI interaction, independently enhances acceptance in service settings where novelty and interactivity are salient. Second, privacy concern, unease about biometric data collection and use, functions as a consistent negative moderator, particularly acute in airport environments where facial recognition is operationally embedded [19, 21]. Integrating all four perceptions into a single model represents the primary theoretical contribution of this study.

C. Customer Satisfaction and Customer Loyalty

Customer satisfaction is conceptualized as a post-consumption evaluative judgment reflecting whether AI-mediated service encounters have met or exceeded guest expectations [20]. Customer Experience Theory [22] situates this judgment within a multi-dimensional architecture—cognitive, emotional, social, and physical, explaining divergent evaluations of the same AI features across guest segments. In the present study, CET serves as an interpretive scaffold rather than an independently operationalized measurement framework: it motivates the inclusion of both utilitarian (PU, PEOU) and hedonic (ENJ) dimensions alongside a risk-based barrier (PC), and it explains why the same AI features may generate divergent satisfaction evaluations across guest segments defined by age, education, and income. The four TAM-derived constructs are the operationalized variables; CET provides the theoretical rationale for their simultaneous inclusion and for the expectation that satisfaction will mediate their effects on loyalty. Future research could operationalize CET dimensions directly, for example, through validated cognitive and emotional appraisal sub-scales to permit a more complete test of the integrated framework. Customer loyalty is operationalized as revisit intention and word-of-mouth (WOM) recommendation, capturing both the direct economic value and the social amplification of loyalty [23]. Whether technological perceptions shape loyalty primarily through satisfaction or also through direct paths is addressed via bootstrap mediation analysis.

TABLE II. LITERATURE REVIEW AND RESEARCH GAPS

Theme / Construct	Key Finding from Literature	[12]	[8]	[5]	[19]	[21]	Authors
Perceived Usefulness (PU)	Strongest positive predictor of AI-service satisfaction; time-saving and accuracy are most valued.	✓		✓			✓
Perceived Ease of Use (PEOU)	Positively influences satisfaction; interface complexity deters older and less tech-savvy guests.	✓		✓			✓
Enjoyment / Hedonic Motivation	Independently enhances satisfaction beyond utilitarian perceptions; salient in service-intensive encounters.		✓				✓
Privacy Concern	Negatively moderates AI acceptance; biometric data collection intensifies unease without transparent policies.				✓	✓	✓
Satisfaction → Loyalty Mediation	Satisfaction partially mediates the perception-to-loyalty path; direct effects also exist but are weaker.			✓			✓
Context: First-tier / Upscale Hotel	Empirical base dominated by 5-star or chain hotels in major metropolitan centers.	✓	✓	✓	✓	✓	
Context: Airport Hotel, Secondary City	Partial AI infrastructure; high turnover; time-sensitive guests; low CRM maturity — underexamined.						✓
Demographic Moderation (ANOVA)	Age, education, and income moderate technology acceptance and loyalty levels.					✓	✓

Table II maps the thematic coverage of prior literature against the present study, revealing three interrelated gaps: 1) no prior study has examined PU, PEOU, ENJ, and PC simultaneously within an airport hotel model; 2) all comparable studies were conducted in first-tier cities or upscale segments, leaving secondary-city airport hotels unexamined; and 3) the mediating role of satisfaction has not been rigorously tested with bootstrap procedures in this context. Six hypotheses follow directly.

III. RESEARCH METHODOLOGY

This section describes the research design, study context, population, and sampling strategy, instrument development, data collection, and statistical analysis procedures employed in the study.

A. Research Design

A quantitative, cross-sectional survey design was adopted to test the hypothesized relationships among guests' AI service perceptions, customer satisfaction, and customer loyalty. Quantitative methods are well-suited to evaluating predictive relationships among multiple continuous constructs and to drawing population-level inferences from probability-based samples [24]. Primary data were collected through a structured, self-administered questionnaire available in both digital and paper formats.

B. Research Context: Shenyang Airport Hotel

Shenyang Airport Hotel is a three-star property located approximately one kilometer from Terminal 3 of Shenyang Taoxian International Airport, Liaoning Province. The hotel operates 163 rooms, of which 123 are standard, 30 are business, and 10 are family, and all are equipped with smart door locks and smart televisions. The property operates without dedicated IT personnel, a CRM system, or a formal loyalty programme. Its 2024 annual repurchase rate of 18% falls substantially below the national benchmark for comparable airport hotels. A preliminary field survey and management interviews conducted in March 2026 confirmed that three AI services are currently operational: an AI chatbot, a facial recognition self-check-in terminal, and an automated check-in/check-out kiosk—while more advanced retention-oriented AI tools remain absent [6-7].

C. Research Participants: Population and Sample Size

The target population comprised guests who had stayed at the hotel at least once within the two years preceding data collection and had used at least one AI-enabled service during their stay. Because the eligible population is continuous and uncountable, it was treated as theoretically infinite. The minimum sample size of 384 was determined using Cochran's formula [25].

To compensate for anticipated incomplete responses, 500 questionnaires were distributed. After data screening, 452 valid responses were retained (valid response rate = 90.4%), exceeding both the Cochran minimum (384) and the recommended threshold for the planned regression analyses.

D. Sample Size Sampling Procedure

Stratified random sampling was applied to ensure proportionate representation of key guest subgroups. The sampling frame was stratified along three dimensions: travel purpose, age group, and nationality. Within each stratum, respondents were selected randomly. This approach reduces the risk of segment-driven bias and strengthens the external validity of the findings [25].

E. Research Instrument Development and Validation

1) Item generation: All measurement items were adapted from validated scales: PU and PEOU from Davis [26]; ENJ from [18]; PC from [19]; CS from [20]; and CL from Zeithaml et al. [23]. Items were translated into Simplified Chinese and independently back-translated by a second bilingual researcher to ensure semantic equivalence [27].

2) Expert validation: Three subject-matter experts assessed content validity using the Index of Item-Objective Congruence (IOC). The mean IOC across all items was 0.82, exceeding the 0.70 threshold [28]. Two items with IOC values below 0.70 were removed, yielding a final questionnaire of 40 items organized into four sections: 1) sociodemographic and travel characteristics; 2) AI usage history; 3) six Likert-scale constructs rated on a five-point scale (1 = strongly disagree to 5 = strongly agree); and 4) open-ended qualitative questions.

3) Reliability and validity test: Cronbach's alpha coefficients for all multi-item constructs exceeded .85, demonstrating excellent internal consistency. The Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy was .895, and Bartlett's test of sphericity was statistically significant (χ^2 = 7283.729, df = 253, $p < .001$), confirming factorability of the correlation matrix. Exploratory factor analysis (EFA) using principal component extraction with varimax rotation extracted six factors with eigenvalues greater than 1, collectively accounting for 78.16% of the total variance. All items loaded substantially on their hypothesized factors ($\lambda > .70$), with negligible cross-loadings, supporting both convergent and discriminant validity [29]. EFA was selected over confirmatory factor analysis (CFA) because this study, although guided by theoretically motivated construct definitions, employs items adapted from multiple prior scales and tested together for the first time in the specific context of a secondary-city Chinese airport hotel. EFA was therefore appropriate to verify the empirical factor structure and item behaviour in this new setting before structural relationships were estimated [29]. Future research replicating the model in comparable contexts should employ CFA or structural equation modelling (SEM) to confirm construct dimensionality and provide stronger evidence of model fit.

F. Research Hypothesis

- H1: Perceived usefulness of AI applications has a positive effect on customer satisfaction.
- H2: Perceived ease of use of AI applications has a positive effect on customer satisfaction.
- H3: Enjoyment of AI applications has a positive effect on customer satisfaction.
- H4: Privacy concerns regarding AI applications harm customer satisfaction.
- H5: Customer satisfaction positively affects customer loyalty.
- H6: Customer satisfaction mediates the relationship between guests' technological perceptions of AI applications (perceived usefulness, perceived ease of use, enjoyment, privacy concerns) and customer loyalty.

These hypotheses are illustrated in the conceptual model below (Fig. 1).

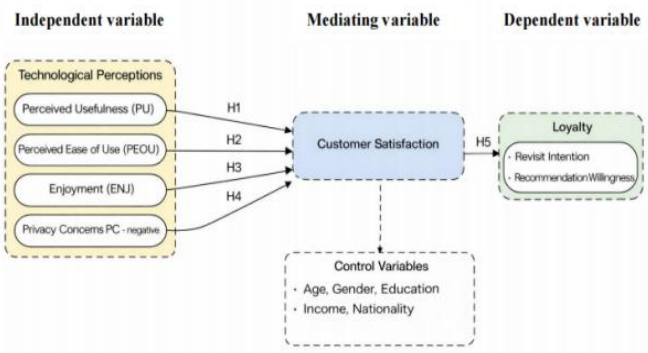

Fig. 1. Research framework of AI perceptions, customer satisfaction, and loyalty.

G. Data Collection

Data were collected between March and May 2026 through four complementary channels: 1) email invitations to opted-in prior guests; 2) QR-code cards displayed at the front desk, lobby, and in each guest room; 3) a pinned post on the hotel's official WeChat account; and 4) paper questionnaires available at the front desk for guests who preferred offline completion. Respondents received a 15% discount voucher for a future stay as an incentive. Ethics approval was obtained from the Research Ethics Committee of Suratthani Rajabhat University (Approval No.: SRU-EC 2026/029). All participation was voluntary and anonymous.

H. Data Analysis

All statistical analyses were performed using Statistics software, following a sequential six-stage procedure:

1) Descriptive statistics: Means, standard deviations, and frequency distributions were computed for all constructs and demographic variables.

2) Reliability and validity: Cronbach's alpha was recomputed for the full sample. Exploratory Factor Analysis (EFA) with principal component extraction and varimax rotation was conducted; the Kaiser-Meyer-Olkin (KMO) measure and Bartlett's test of sphericity verified sampling adequacy [30].

3) Correlation analysis: Pearson's r coefficients were computed for all construct pairs; Variance Inflation Factor (VIF) values confirmed the absence of multicollinearity (threshold VIF < 10) [29].

4) Hypothesis testing (H1–H5): Multiple linear regression examined the effects of PU, PEOU, ENJ, and PC on CS (H1–H4). Simple linear regression examined the effect of CS on CL (H5a–H5b). Standardized beta coefficients (β) and their significance levels were reported.

5) Mediation analysis (H6): Bootstrap mediation with 5,000 resamples was conducted following Preacher and Hayes [31]. Bias-corrected 95% confidence intervals (CIs) were computed; an indirect effect was deemed significant if the CI excluded zero. Partial mediation was inferred when both the direct and indirect effects remained significant.

6) Difference analysis: One-way ANOVA examined whether CL differed significantly across age groups, educational levels, and income brackets. Where F-ratios were significant, Scheffé post-hoc tests identified specific group differences.

All p-values are two-tailed; the significance level was set at $\alpha = 0.05$ throughout the study.

IV. Results

A. Participant Characteristics

This study examined the effects of AI adoption in hotel management on guests' perceptions, satisfaction, and loyalty. Data were collected from guests who had experienced AI-enabled services at Shenyang Airport Hotel. The majority of respondents were male (52.65%), aged between 30 and 49 years (53.10%), and held at least a bachelor's degree (86.94%). Business travel was the predominant purpose of stay (42.48%), and 69.03% of respondents had stayed at the hotel at least once within the preceding two years. Detailed demographic information is presented in Table III.

Table III shows that the majority stayed at the hotel once per year (44.36%), while 48.04% reported using AI services on more than two occasions during their stay. The most commonly encountered AI technology was the facial recognition self-check-in/check-out terminal (68.63%). The primary channels through which respondents became aware of the hotel's AI services were staff recommendations at check-in (68.14%) and prompts displayed on the self-check-in terminal (61.52%). These findings indicate that the sample possessed a sufficient level of familiarity with AI adoption in hotel management to support the validity of subsequent empirical analyses.

TABLE III. Demographic Profile of Respondents

Variable	Category	Frequency (n)	Percentage (%)
Gender	Male	238	52.65
	Female	214	47.35
Age	18–29 years	119	26.33
	30–49 years	240	53.10
	50–60 years	93	20.58
Education	High school or below	59	13.06
	Bachelor's degree	220	48.67
	Master's degree or above	173	38.27
Travel purpose	Business	192	42.48
	Leisure	156	34.51
	Transit	71	15.71
	Other	33	7.30
Prior hotel stays (past 2 years)	At least once	312	69.03
	More than a year	140	30.97

B. Descriptive Statistics, Reliability, and Validity

Table IV shows the mean scores of all six constructs. Customer Satisfaction recorded the highest mean ($\bar{x} = 3.95$), followed by Enjoyment ($\bar{x} = 3.88$), Perceived Usefulness ($\bar{x} = 3.87$), Perceived Ease of Use ($\bar{x} = 3.83$), and Customer Loyalty ($\bar{x} = 3.76$), respectively. Privacy Concerns yielded the lowest mean ($\bar{x} = 2.98$), the only construct falling below the scale midpoint of 3.00.

TABLE IV. Descriptive Statistics and Reliability Coefficients

Variable	$\bar{x}$	SD	α	No. of Items
PU	3.87	0.70	0.859	3
PEOU	3.83	0.85	0.906	3
ENJ	3.88	0.83	0.904	3
PC	2.98	1.09	0.900	4
CS	3.95	0.61	0.891	5
CL	3.76	0.77	0.927	5

Table V shows item-level mean scores across all six constructs. Within Perceived Usefulness, time-saving was rated most favourably, affirming speed as the primary utilitarian benefit. For Perceived Ease of Use, unassisted terminal operation recorded the highest item mean, indicating that most guests navigated the interface independently. Novelty dominated the Enjoyment dimension, reflecting the affective appeal of facial recognition technology. All Privacy Concerns items fell around the scale midpoint, confirming a lack of unease over biometric data governance. Terminal accuracy drove Customer Satisfaction most strongly, while willingness to revisit yielded the highest item mean within Customer Loyalty, though preference over competitors remained comparatively low, suggesting limited competitive differentiation.

TABLE V. DESCRIPTIVE STATISTICS OF EACH ASSESSMENT ITEM

Assessment Items	$\bar{x}$	SD
Perceived Usefulness (PU)	**3.87**	**0.70**
1. The facial recognition self-check-in/check-out terminal saved me time compared to manual front desk service.	3.93	0.79
2. Using the AI terminal improved the efficiency of my check-in/check-out process.	3.88	0.64
3. The AI terminal met my need for quick service (e.g., when I was in a hurry for a flight).	3.81	0.67
Perceived Ease of Use (PEOU)	**3.83**	**0.85**
1. I could operate the facial recognition terminal without staff assistance.	3.86	0.96
2. The terminal's instructions (e.g., interface prompts for ID scanning) were clear and easy to understand.	3.84	0.80
3. Even if I had limited experience with technology, I could still operate the AI terminal easily.	3.79	0.79
Enjoyment (ENJ)	**3.88**	**0.83**
1. Using the facial recognition terminal added a sense of novelty to my stay.	3.98	0.92
2. I felt relaxed using the terminal (e.g., no need to wait in line for the front desk).	3.80	0.80
3. The AI terminal made me perceive the hotel as providing novel services.	3.87	0.77
Privacy Concerns (PC)	**2.98**	**1.09**
1. I worried about the hotel misusing my facial recognition data.	2.93	1.23
2. I did not fully trust that the hotel's AI system would protect my personal data.	2.96	1.01
3. The hotel did not clearly inform me about my facial data storage and deletion policy.	2.94	1.04
4. I am not concerned about how my facial data is stored.	3.07	1.09
Customer Satisfaction (CS)	**3.95**	**0.61**
1. I was satisfied with the accuracy of the facial recognition terminal (e.g., first-try verification).	4.00	0.71
2. I was satisfied with the AI terminal's response speed (e.g., fast room key issuance).	3.93	0.56
3. Using the AI terminal enhanced my overall stay experience.	3.93	0.55
4. Even without using AI services, I was satisfied with the hotel's general services (e.g., airport shuttle).	3.92	0.61
5. Overall, I was highly satisfied with my stay at Shenyang Airport Hotel.	3.96	0.63
Customer Loyalty (CL)	**3.76**	**0.77**
1. I am willing to stay at this hotel again on my next visit.	3.84	0.91
2. I will recommend this hotel to friends/family needing nearby accommodation.	3.73	0.73
3. I will prioritize this hotel for future Shenyang trips (business/transit).	3.74	0.71
4. I am willing to share positive feedback (including AI services) on social media.	3.76	0.74
5. The hotel's services make me more likely to choose it over nearby competitors.	3.72	0.75

C. Correlation Analysis

Table VI shows the Pearson correlation matrix for all key variables. Perceived usefulness, perceived ease of use, and enjoyment were each positively and significantly correlated with customer satisfaction ($r = 0.439$, 0.320, and 0.330, respectively; all $p < 0.01$), whereas privacy concerns exhibited a significant negative correlation with satisfaction ($r = -0.299$, $p < 0.01$). Customer satisfaction and customer loyalty demonstrated a moderate positive association ($r = 0.409$, $p < 0.01$). All inter-variable correlation coefficients fell below 0.80, indicating that multicollinearity was not a concern in the subsequent regression analyses.

TABLE VI. PEARSON CORRELATION MATRIX OF KEY VARIABLES

Variable	PU	PEOU	ENJ	PC	CS
PU	1				
PEOU	.313**	1			
ENJ	.316**	.507**	1		
PC	−.199**	−.112*	−.124**	1	
CS	.439**	.320**	.330**	−.299**	1
CL	.386**	.336**	.301**	−.327**	.409**

[a] Note: **p < 0.01, *p < 0.05.

D. Hypothesis Testing: H1–H4

Multiple regression analysis was conducted with customer satisfaction as the dependent variable and the four technological perception dimensions as predictors. The overall model was statistically significant, $F(4, 447) = 44.836$, $p < 0.001$, accounting for 28.6% of the variance in customer satisfaction ($R^2 = 0.286$). The regression results are summarised in Table VII.

TABLE VII. MULTIPLE REGRESSION RESULTS: AI PERCEPTIONS PREDICTING CUSTOMER SATISFACTION (H1–H4)

Predictor	B	SE	β	t	p
Constant	2.475	0.192	—	12.889	< 0.001
PU (H1)	0.274	0.038	0.314	7.222	< 0.001
PEOU (H2)	0.092	0.034	0.127	2.682	0.008
ENJ (H3)	0.105	0.035	0.141	2.991	0.003
PC (H4)	−0.116	0.023	−0.205	−5.017	< 0.001

Perceived usefulness exerted the strongest positive effect on customer satisfaction ($\beta = 0.314$, $p < 0.001$), followed by enjoyment ($\beta = 0.141$, $p < 0.01$) and perceived ease of use ($\beta = 0.127$, $p < 0.01$). Privacy concerns had a significant negative effect on satisfaction ($\beta = -0.205$, $p < 0.001$). Accordingly, Hypotheses H1, H2, H3, and H4 were all supported.

E. Hypothesis Testing: H5

Simple regression analysis revealed that customer satisfaction exerted a significant positive effect on customer loyalty ($\beta = 0.409$, $t = 9.501$, $p < 0.001$). The model explained 16.7% of the variance in customer loyalty ($R^2 = 0.167$, $F = 90.278$, $p < 0.001$). These findings support Hypothesis H5, confirming that guests who reported higher satisfaction with AI-enabled hotel management services were more likely to express intentions to revisit the hotel and to recommend it to others through word-of-mouth.

F. Hypothesis Testing: H6

To test Hypothesis H6, a bootstrap mediation analysis was performed using 5,000 resamples, following the procedure recommended by Preacher and Hayes. Bias-corrected 95% confidence intervals (CIs) were employed to assess the significance of indirect effects. The results are presented in Table VI. The 95% bootstrap CIs for the indirect effects of all

four perception dimensions on customer loyalty, via customer satisfaction, excluded zero, indicating statistically significant partial mediation across all pathways. Thus, Hypothesis H6 was supported. As can be seen in Table VIII.

TABLE VIII. BOOTSTRAP MEDIATION RESULTS: INDIRECT AND DIRECT EFFECTS ON CUSTOMER LOYALTY VIA CUSTOMER SATISFACTION (H6)

Pathway	Effect Type	Effect	Boot SE	LLCI	ULCI
PU → CS →CL	Indirect	0.142	0.029	0.088	0.201
	Direct	0.279	0.051	0.180	0.379
PEOU → CS→ CL	Indirect	0.097	0.023	0.054	0.146
	Direct	0.207	0.040	0.128	0.285
ENJ → CS → CL	Indirect	0.106	0.024	0.063	0.158
	Direct	0.173	0.041	0.091	0.254
PC → CS → CL	Indirect	−0.072	0.017	−0.107	−0.042
	Direct	−0.159	0.031	−0.220	−0.098

[b] Note: Bootstrap confidence intervals not containing zero indicate significant mediation.

G. Demographic Differences in Customer Loyalty

One-way analysis of variance (ANOVA) was conducted to examine whether customer loyalty differed significantly across demographic groups. The results indicated statistically significant differences in customer loyalty by age group ($F = 3.782$, $p = 0.024$), educational level ($F = 4.563$, $p = 0.011$), and annual household income ($F = 3.136$, $p = 0.009$). No significant differences were found with respect to gender, occupation, or travel purpose. Detailed results are presented in Table IX.

TABLE IX. ONE-WAY ANOVA RESULTS: DEMOGRAPHIC DIFFERENCES IN CUSTOMER LOYALTY

Variable	Group	$\bar{x}$	SD	F	p
Age	18–29 years	3.72	0.74	3.782	0.024*
	30–49 years	3.84	0.71		
	50–60 years	3.59	0.91		
Education	High school or below	3.59	0.70	4.563	0.011*
	Bachelor's degree	3.70	0.83		
	Master's degree or above	3.89	0.69		
Annual income (RMB)	Below 30,000	3.42	0.91	3.136	0.009**
	30,000–100,000	3.73	0.83		
	100,000–300,000	3.79	0.76		
	300,000–500,000	3.76	0.70		
	Above 500,000	4.06	0.56		

[c] Note: **p < 0.01, *p < 0.05. The group with the highest mean loyalty score within each variable is shown in bold.

In summary, respondents aged 30–49 years ($\bar{x} = 3.84$), those holding a master's degree or above ($\bar{x} = 3.89$), and those with an annual household income exceeding 500,000 RMB ($\bar{x} = 4.06$) exhibited the highest levels of customer loyalty. These findings suggest that demographic characteristics play a meaningful role in segmenting hotel guests for the purpose of tailoring AI adoption strategies in hotel management to specific target groups.

H. Summary of Hypothesis Testing Results

TABLE X. SUMMARY OF HYPOTHESIS TESTING RESULTS

H	Statement	Key Statistic	Outcome
H1	The perceived usefulness of AI applications positively affects customer satisfaction.	$\beta = 0.314$, $p < 0.001$	Supported
H2	Perceived ease of use of AI applications positively affects customer satisfaction.	$\beta = 0.127$, $p = 0.008$	Supported
H3	Enjoyment of AI applications positively affects customer satisfaction.	$\beta = 0.141$, $p = 0.003$	Supported
H4	Privacy concerns regarding AI applications negatively affect customer satisfaction.	$\beta = -0.205$, $p < 0.001$	Supported
H5	Customer satisfaction positively affects customer loyalty (revisit intention and word-of-mouth).	$\beta = 0.409$, $p < 0.001$	Supported
H6	Customer satisfaction partially mediates the relationship between technological perceptions and customer loyalty.	95% Bootstrap CI excludes zero on all paths	Supported

Table X summarises the hypothesis testing results. All six hypotheses were supported at conventional significance levels. Perceived usefulness exerted the strongest positive effect on customer satisfaction ($\beta = 0.314$), followed by enjoyment ($\beta = 0.141$) and perceived ease of use ($\beta = 0.127$), while privacy concerns had a significant negative effect ($\beta = -0.205$). Customer satisfaction, in turn, positively predicted customer loyalty ($\beta = 0.409$), and bootstrap mediation analysis confirmed that it partially mediated all four perception-to-loyalty pathways, with 95% confidence intervals excluding zero across all paths.

V. DISCUSSION

A. Results Discussion

1) Perceived usefulness and customer satisfaction RQ. 1

Research Question 1: To what extent does the perceived usefulness of AI applications influence customer satisfaction among hotel guests? The regression results confirmed that PU was the strongest positive predictor of customer satisfaction ($\beta = 0.314$, $p < 0.001$), thereby supporting Hypothesis H1. This finding is consistent with Davis's [26] foundational TAM, which postulates that perceived usefulness, the degree to which a technology is believed to enhance task performance, is the primary determinant of user acceptance and satisfaction. In the present context, AI features such as the facial-recognition self-check-in terminal and the automated check-in/check-out kiosk reduce guest wait times and streamline administrative procedures. Functions that guests overwhelmingly value in an airport environment characterised by time pressure and schedule sensitivity [17]. This utilitarian primacy replicates findings reported by [12], who identified time-saving and accuracy as the most valued attributes of AI chatbots in hotel settings, and by [3], who documented that AI-customised experiences improving service efficiency exert the strongest influence on satisfaction in Chinese hotels. Furthermore, the magnitude of the PU effect in the present study ($\beta = 0.314$) is commensurate with that reported

by [5] (β = 0.29) in a comparable Chinese hotel context, suggesting that the relationship is robust across hotel tiers and city classifications. Collectively, these results reaffirm that, in functional service environments where performance outcomes are paramount, the instrumental dimension of AI perception takes precedence over hedonic and social considerations.

2) Perceived usefulness and customer satisfaction RQ. 2

Research Question 2: To what extent does the perceived ease of use of AI applications influence customer satisfaction among hotel guests? The results confirmed a significant positive effect of PEOU on customer satisfaction (β = 0.127, p = 0.008), supporting Hypothesis H2, albeit with a smaller effect size than perceived usefulness. This ordering aligns with Davis's [26] original TAM, which posited that PEOU exerts an indirect effect on acceptance primarily through its influence on PU, whereas PU retains a stronger direct path. In the hospitality context, Buhalis and Moldavska [1] demonstrated that interface complexity constitutes a significant barrier to guest adoption of voice assistant technologies, particularly among older and less technologically experienced users. The comparatively modest PEOU coefficient observed in the present study may reflect the relatively straightforward design of the facial recognition terminal, which minimises the cognitive load imposed on guests through intuitive workflow design and minimal required input. Venkatesh et al.'s [18] Unified Theory of Acceptance and Use of Technology (UTAUT) similarly found that ease of use becomes less salient as users gain familiarity with a system; given that 48.04% of respondents reported using the hotel's AI services on more than two occasions, habitual use may have attenuated the perceived difficulty of the interaction. Nonetheless, the significant positive coefficient confirms that interface simplicity remains a meaningful contributor to overall satisfaction and should not be overlooked in the design of AI service encounters.

3) Enjoyment and customer satisfaction

Research Question 3: To what extent does the enjoyment derived from AI applications influence customer satisfaction among hotel guests? Hypothesis H3 was supported, with enjoyment emerging as the second most influential positive predictor of satisfaction (β = 0.141, p = 0.003). This finding extends the hedonic dimension of the TAM framework, as elaborated by [18], into the airport hotel context, confirming that intrinsic positive affect generated by the AI interaction independently enhances satisfaction beyond utilitarian and ease-of-use considerations. The effect magnitude is noteworthy given the functional, time-sensitive nature of airport hotel stays: even in an environment that prioritises efficiency, guests derive a degree of affective value from novel and interactive AI encounters. This pattern is consistent with [3] observation that the novelty and interactivity of AI-customised hotel services engender positive emotional responses that contribute independently to satisfaction, and with [11] systematic review, which identified enjoyment as a consistent predictor of automation acceptance across tourism and hospitality contexts. The present finding is particularly significant insofar as it challenges a purely utilitarian view of AI adoption in secondary-city airport hotels; guests at Shenyang Airport Hotel, like their counterparts in more technologically mature properties, appear to respond effectively as well as cognitively to AI service encounters. This has implications for service design, suggesting that incorporating hedonic elements such as engaging interfaces and personalised recommendations can augment satisfaction even within operationally constrained AI environments.

4) Privacy concerns and customer satisfaction

Research Question 4: To what extent do privacy concerns regarding AI applications negatively influence customer satisfaction among hotel guests? The regression results confirmed that PC exerted a significant negative effect on customer satisfaction (β = −0.205, p < 0.001), thereby supporting Hypothesis H4. The magnitude of this negative coefficient is the second largest among the four predictors, underscoring the substantive role of privacy perceptions in shaping the AI service experience. This finding aligns with the theoretical arguments advanced by [19], who identified privacy unease as a consistent negative moderator of technology acceptance in hospitality settings, particularly when biometric data collection is involved. Wang and Liu [21] further documented that facial recognition-specific privacy concerns significantly depress satisfaction ratings among hotel guests, an effect amplified in transit-oriented environments such as airports, where the involuntary nature of biometric exposure is perceived as especially intrusive. The present finding that the mean privacy concern score ($\bar{x}$ = 2.98) was the only construct to fall below the scale midpoint, combined with its negative regression coefficient, indicates that privacy anxiety is a marginal concern. This trade-off dynamic, wherein guests simultaneously appreciate the convenience afforded by facial recognition whilst harbouring reservations about data collection and retention, is consistent with the ambivalence documented by [19] in their analysis of mobile payment acceptance in hotels. Addressing these concerns through transparent data governance communication is therefore not merely a compliance consideration but a direct lever for improving guest satisfaction.

5) Customer satisfaction and customer loyalty

Research Question 5: Does customer satisfaction positively influence guests' behavioural intentions, specifically revisit intention and word-of-mouth recommendation? The simple regression analysis confirmed that customer satisfaction exerted a significant positive effect on customer loyalty (β = 0.409, t = 9.501, p < 0.001), supporting Hypothesis H5 in both its revisit intention and word-of-mouth recommendation dimensions. This result is consistent with the foundational satisfaction-loyalty framework advanced by [20] and the service-quality consequences model proposed by [23], both of which posit that positive evaluative judgments of service encounters are the primary antecedent of behavioural loyalty intentions. Liu et al. [3] and Zhang et al. [5] similarly reported significant satisfaction-to-loyalty paths in AI-enabled Chinese hotel studies, reinforcing the cross-contextual stability of this relationship.

However, the model's explained variance for loyalty (R^2 = 0.167) is modest, indicating that customer satisfaction, while a necessary condition, is not sufficient to guarantee loyalty in the airport hotel context. This finding is interpretable in light of Liu and Wang's [8] structural characterisation of airport hotels as high-turnover, short-stay properties in which guests'

accommodation choices are frequently determined by flight schedules, corporate rates, and proximity to the terminal rather than by service satisfaction alone. As Zeithaml et al. [23] noted, the behavioural consequences of satisfaction vary markedly across service categories; in commodity-like, transaction-oriented settings such as airport hotels, the satisfaction-loyalty linkage is predictably weaker than in experiential or relationship-oriented segments. The present R^2 value nonetheless compares favourably with that reported by Soliman [17] ($R^2 = 0.14$) in a developing-country hotel context, suggesting that the relationship strength is consistent across settings with partial AI infrastructure. The modest explained variance (16.7%) also signals that important predictors of loyalty remain outside the present model. Three categories of omitted variables warrant attention in future research. First, perceived value guests' overall assessment of the cost-benefit ratio of the hotel stay has been identified as a direct antecedent of loyalty independent of satisfaction in multiple hospitality studies [14]. Second, trust in the hotel brand and in the AI systems themselves may constitute a partially distinct loyalty mechanism, particularly in contexts involving biometric data collection where relational confidence is a precondition for continued patronage [19, 21]. Third, structural switching costs, including corporate rate agreements, proximity to the airport, and frequency-stay benefits, are especially salient in the airport hotel segment, where accommodation choices are often constrained by logistical factors rather than purely evaluative ones [8]. Incorporating these constructs into future models would decompose the residual loyalty variance and produce a more complete and practically actionable framework.

6) Mediating role of customer satisfaction

Research Question 6: Does customer satisfaction mediate the relationships between guests' technological perceptions of AI applications and customer loyalty? Bootstrap mediation analysis (5,000 resamples; Preacher and Hayes [31]) confirmed that customer satisfaction partially mediates all four perception-to-loyalty pathways, with bias-corrected 95% confidence intervals excluding zero on all indirect effect estimates. Hypothesis H6 was therefore supported. The partial mediation pattern wherein direct effects from all four perception dimensions on loyalty remain significant alongside the significant indirect effects through satisfaction has important theoretical implications.

First, the findings indicate that technological perceptions shape loyalty through two complementary mechanisms: an evaluative route, whereby favourable perceptions enhance satisfaction and satisfaction subsequently drives loyalty intentions, and a direct attitudinal route, whereby favourable AI perceptions independently generate loyalty predispositions that bypass the satisfaction evaluation. This dual-pathway structure is consistent with the theoretical extensions to TAM proposed by [18], who argued that technology beliefs influence behavioural intentions both through affective and evaluative intermediaries and through direct cognitive appraisals. Second, the finding that all four perception dimensions, including the negative pathway through privacy concerns, exhibit partial mediation through satisfaction suggests that satisfaction is a robust but not exhaustive transmission mechanism. Zhang et al. [5] similarly documented partial mediation by satisfaction in a Chinese hotel AI study, and Liu et al. [3] observed that the AI-customisation-to-loyalty path retained direct components even after controlling for satisfaction, corroborating the present pattern. Third, the indirect effect of perceived usefulness through satisfaction (0.142) is the largest among the four indirect pathways, consistent with its dominant direct effect, confirming that utility-driven satisfaction has the most substantial indirect impact on loyalty. By contrast, the negative indirect effect of privacy concerns (−0.072) is the smallest in absolute magnitude, suggesting that while privacy anxiety depresses satisfaction, its downstream impact on loyalty is partially buffered by the direct positive effects of usefulness and enjoyment. These mediation results collectively affirm that improving guest satisfaction through AI service optimisation constitutes a strategically effective, if not singular, pathway to enhancing customer loyalty in the airport hotel context.

7) Demographic differences in customer loyalty

One-way ANOVA revealed significant inter-group differences in customer loyalty by age ($F = 3.782$, $p = 0.024$), educational level ($F = 4.563$, $p = 0.011$), and annual household income ($F = 3.136$, $p = 0.009$), while gender, occupation, and travel purpose yielded no significant differences. Guests aged 30–49 years exhibited the highest mean loyalty score ($\bar{x} = 3.84$), followed by those holding postgraduate qualifications ($\bar{x} = 3.89$) and those with annual household incomes exceeding 500,000 RMB ($\bar{x} = 4.06$). These patterns are consistent with [11] finding that actual digital experience and cognitive engagement with technology, rather than chronological age per se, are the more proximate determinants of AI acceptance; the 30–49 cohort's higher loyalty likely reflects greater professional familiarity with AI interfaces rather than generational disposition alone. The absence of elevated loyalty among the youngest respondents (18–29 years) challenges the commonly invoked assumption that digital natives automatically embrace all forms of AI-mediated service, a supposition that [9] cautioned against in their review of age as a technology acceptance moderator. The education and income gradients align with [17] finding that higher socioeconomic status is associated with greater receptiveness to AI in hotel settings, potentially because highly educated and higher-income guests are more accustomed to interacting with digital systems and interpret AI features as quality signals rather than sources of anxiety. For managerial practice, these demographic differentiations imply that a uniform AI strategy is unlikely to optimise loyalty across all guest segments.

VI. Conclusion

Drawing on an integrated TAM and Customer Experience Theory framework, this study examined how guests' technological perceptions of AI applications influence satisfaction and loyalty at Shenyang Airport Hotel. Data from 452 guests confirmed that perceived usefulness, perceived ease of use, and enjoyment positively affect customer satisfaction, while privacy concerns exert a significant negative effect, supporting H1–H4. Customer satisfaction in turn positively predicts customer loyalty (H5) and partially mediates all four perception-to-loyalty pathways (H6). Demographic analysis further revealed significant differences in loyalty across age,

educational level, and income groups, but not across gender, occupation, or travel purpose.

These findings collectively demonstrate that, even within a technologically constrained secondary-city airport hotel, guests' multidimensional AI perceptions systematically shape satisfaction and loyalty outcomes. For practitioners, the results highlight the importance of maximising perceived utility, simplifying service interfaces, enriching hedonic engagement, and communicating data governance policies transparently. For researchers, this study extends TAM into an underexamined hospitality context and provides rigorous mediation evidence clarifying the perception satisfaction loyalty mechanism. Ultimately, effective AI adoption in hotel management requires attending simultaneously to utilitarian, affective, and privacy-related perceptions to convert technological investment into sustainable guest retention.

VII. Research Implications

1) Theoretical implications: This study makes three principal theoretical contributions. First, it extends the TAM [26] beyond its original workplace and basic utilitarian boundaries by integrating both an affective facilitator (enjoyment) and a risk-based barrier (privacy concerns) into a single model applied to AI-mediated guest services in a secondary-city airport hotel. Prior research in the hospitality domain had typically addressed these constructs in isolation: [12] examined PU and PEOU without incorporating hedonic or privacy dimensions, while [16] and [23] focused exclusively on privacy concerns. The present simultaneous treatment of all four perception dimensions demonstrates that both affective and security-related factors play statistically significant and conceptually distinct roles in satisfaction formation, confirming that a purely utilitarian view of AI acceptance is insufficient in service contexts where emotional responses and risk perceptions are salient, as argued by [18] and [11].

Second, the bootstrap mediation results provide rigorous empirical evidence of partial mediation through satisfaction, clarifying the perception-to-loyalty transmission mechanism that has remained theoretically postulated but empirically underexamined in prior work [3, 20, 22]. By demonstrating that direct perception-to-loyalty paths coexist with satisfaction-mediated indirect paths across all four constructs, this study contributes a more nuanced causal architecture to the existing satisfaction-loyalty literature [20, 23]. Future research incorporating additional mediators — such as perceived value or trust, as suggested by [14] could further decompose the residual direct effects.

Third, by focusing on an airport hotel in a secondary Chinese city, a context characterised by partial AI infrastructure, low CRM maturity, and an annual repurchase rate of 18%, this study addresses a significant gap in a literature dominated by first-tier urban luxury properties [13, 16]. The finding that TAM-based perceptions are systematically related to satisfaction and loyalty even in technologically constrained settings implies that the framework is transportable across varying levels of AI infrastructure maturity. This aligns with [17] demonstration that TAM relationships hold in developing-country hotel contexts, and with [10] multi-case study findings from Thailand, collectively suggesting that the model's explanatory power is not contingent upon sophisticated technological ecosystems.

2) Practical implications: The findings carry several actionable implications for hotel managers, particularly those operating three-star airport properties with limited technological resources. First, as perceived usefulness emerged as the dominant driver of satisfaction, investment in AI features that deliver clear, measurable time savings should be prioritised. Automated check-in/check-out and facial recognition terminals must be robust, fast, and error-free, as any friction in these high-stakes interactions directly erodes perceived utility [12, 18, 26]. Second, interface simplicity should be treated as a design principle rather than a secondary consideration. Buhalis and Moldavska [9] demonstrated that clear instructions, logical workflow sequences, and multilingual support are low-cost interventions that substantially improve perceived ease of use for older and less technologically experienced guests; such enhancements are within reach even for properties operating without dedicated IT personnel, as is the case at Shenyang Airport Hotel.

Third, the significant enjoyment effect indicates that augmenting AI interactions with hedonic elements — such as gamified loyalty point accrual, personalised welcome messages, or voice-interactive features- can strengthen satisfaction without requiring substantial capital expenditure. Liu et al. [3] and Tussyadiah [11] both emphasised that guests respond to novelty and interactivity, suggesting that incremental enhancements to engagement design can yield disproportionate satisfaction gains. Fourth, the negative effect of privacy concerns represents the most urgent operational priority. Hotels deploying facial recognition should provide concise, comprehensible explanations of what biometric data are collected, the duration of retention, and the parties with access, following the transparency communication model advocated by [19] and [21]. Offering a privacy-preserving opt-out alternative for guests who prefer conventional check-in may reduce anxiety without disrupting service continuity for the majority.

Finally, the ANOVA-derived demographic differences in loyalty suggest that a one-size-fits-all AI deployment strategy is suboptimal. In particular, the higher loyalty reported by postgraduate and high-income guests indicates receptiveness to personalised, data-driven service enhancements such as AI-driven loyalty programmes and recommendation engines — features that Makivic et al. [13] and Chen [16] identified as particularly effective loyalty drivers in technologically sophisticated hotel segments. Conversely, the lower loyalty among the youngest and lowest-income cohorts signals a need for simplified, guided AI interactions supplemented by strong privacy assurances, in line with the segmentation principles advocated by [14].

VIII. Limitations and Future Work

Several limitations of this study merit acknowledgment. First, the cross-sectional survey design permits the examination of associations among constructs at a single point in time but precludes the establishment of temporal causality. Longitudinal

designs tracking the same guests across multiple stays would more robustly establish the causal direction and stability of the perception-satisfaction-loyalty relationships documented here.

Second, data were collected from a single three-star airport hotel in Shenyang, a deliberate design choice that enables contextual depth but constrains generalisability. The findings should not be generalised uncritically to other hotel categories (four- or five-star properties, boutique hotels, or resort segments), to first-tier Chinese cities with more mature AI infrastructure, or to international hospitality markets with different regulatory and cultural orientations toward biometric data collection. Future research should replicate the model across multiple airport hotels in both secondary and primary Chinese cities, and potentially in comparable international contexts such as the Thai airport hotel setting examined by [10], to assess whether the TAM-based relationships hold under varying levels of AI infrastructure maturity and cultural orientation.

Third, the study relied exclusively on self-reported Likert-scale measures, which may be subject to common method variance and social desirability bias despite the procedural safeguards implemented [32]. No objective behavioural measures—such as actual repeat bookings, transaction records, or AI usage logs—were included to validate the reported loyalty intentions, which limits the correspondence between stated and enacted behaviour. Integrating objective behavioural data, including verified repurchase records from the hotel's reservation system, actual check-in duration logs from the facial recognition terminal, and transaction-level spending data, with perceptual survey data in future work would substantially strengthen causal inference, mitigate common method bias, and provide a more complete picture of the satisfaction-loyalty conversion process. Furthermore, the study did not control for potentially confounding factors such as room quality, service quality beyond AI interactions, room pricing, or locational convenience (e.g., proximity to the terminal and shuttle availability), all of which may independently influence satisfaction and loyalty and whose omission may have inflated the estimated effects of AI perceptions. Future studies should include these covariates, or employ matched-pair designs that hold non-AI service quality constant, to isolate the incremental contribution of AI perceptions more rigorously.

Fourth, the conceptual model did not include theoretically plausible moderating variables. Venkatesh et al. [18] demonstrated that prior experience, technology anxiety, and cultural orientation moderate TAM relationships; in the present context, guests from different national backgrounds may hold systematically divergent privacy expectations regarding biometric data collection, a moderating pathway unexplored in this study. Morosan and DeFranco [19] similarly called for research examining how cultural and individual difference variables shape the privacy-acceptance dynamic in hospitality AI deployments. Future studies incorporating these moderators would produce a more complete and generalisable model of AI perception formation. In particular, technology readiness [18], prior AI experience, frequency of hotel stays, and individual-level trust dispositions each represent theoretically motivated moderators that may alter the strength or direction of the perception-satisfaction and satisfaction-loyalty relationships identified in this study. Incorporating such variables would clarify boundary conditions and enhance the practical precision of the model.

Finally, this study did not examine the cost-effectiveness of different AI implementations, an omission that limits its managerial utility in the context of resource-constrained properties such as Shenyang Airport Hotel. Integrating economic evaluation frameworks such as return-on-investment analysis for each AI feature with the perceptual satisfaction and loyalty models developed here would provide hotel managers with the complete evidence base needed to prioritise AI investments strategically. This represents a productive and practically significant direction for future inquiry.

***Abstract*—Business Process Modeling (BPM) has been receiving attention in recent years. Organizations operating in distributed, data, and knowledge-intensive environments need precise machine-interpretable process descriptions. Traditional business process modeling notations such as BPMN, UML Activity Diagrams, and EPCs are highly effective for visualizing workflows and supporting communication among stakeholders but do not address problems such as semantic ambiguity, inconsistent terminology, limited reuse, and poor interoperability across organizational boundaries. Since ontology-based models can enable seamless process integration, coordination, and collaboration among autonomous systems. Therefore, ontology-based descriptions are well-suited for complex enterprise systems and supply chains. Ontology-based business process modeling techniques provide a robust and theoretically grounded solution by introducing explicit semantics, formal reasoning capabilities, and shared conceptual frameworks into business process models. This semantic enrichment significantly enhances the expressive power of business process descriptions while preserving compatibility with existing modeling standards. However, ontology-based business process modeling also has its own challenges. The development and maintenance of high-quality ontologies require significant effort and domain expertise. Moreover, reasoning over large-scale ontologies may introduce computational overhead, particularly in real-time environments. Tool support is another practical concern, as seamless integration between business process modeling tools and ontology management platforms is still limited in many industrial settings. The primary objective of this study is to conduct a systematic literature review of ontology-based business process modeling approaches to provide research recommendations based on their strengths and limitations. The results indicate that there are several research gaps that should be addressed to ensure smooth process integration across organizational boundaries. Additionally, empirical validation of ontology-based BPM frameworks in real-time environments is limited. The proposed framework not capable enough to update ontologies with the evolution of the business and related processes. In this regard, an Input Process Output (IPO) BPM Framework to integrate ontologies into BPM as a three-stage transformation mechanism is proposed.**

I. Introduction

Business Process Modeling (BPM) deals with discovering knowledge from information technology (IT) and management science. Organizations analyze, model, and optimize the acquired knowledge to increase the process's efficiency, reduce operational costs, and improve customer satisfaction [1 - 3].

In BPM, the processes are described as structured or semi-structured, but related activities are executed in series or parallel to ensure the proper operations are performed in an organization. Whereas the process model usually describes the temporal activities performed specifically for the creation and use of data [4]. Business processes (BP) in most cases represent complex systems where several entities are involved in their development. For example, in the case of billing a car, nine entities $\langle a, c, e, f, g, i, j, k, l \rangle$ may be involved, starting from booking a car (activity a), paying extra insurance (activity c), booking confirmation (activity e), the check-in process (activity f), car selection (activity i), checking license (activity j), charging credit card (activity k), and finally car releasing (activity l). However, the main aspects of business processes are the activity sequencing, where activities are performed in a specific order to achieve a desired result, and a workflow, in which activities are often connected in such a way that the output of one activity becomes the input of the next [4]. However, generating process models from unstructured text and implementing them in an organization is a challenging task. Although the advent and the application of Natural Language Processing (NLP) have made this process easier, natural language still presents a significant challenge due to the inherent ambiguity, semantic nuance, sentence composition, word relevance, and contextual connections between sentences [5]. Moreover, the business process modelers may misunderstand domain concepts or relationships among these concepts due to their lack of precise domain knowledge. In such cases, semantic ambiguity affects the efficiency and quality of business process modeling. To address this problem, ontology-based business process modeling techniques are the solution, which can ease semantic ambiguity by providing a means to capture rich, semantic information on complex business processes through domain-specific ontologies.

Business process modeling is a knowledge-intensive activity where modelers meet knowledge workers, business owners, and IT professionals to gain an accurate understanding of domain knowledge and process logic [6 - 9]. However, if the domain

becomes larger and more complex, then an accurate understanding of the domain can be difficult for a modeler. Particularly if the modeler does not belong to the domain, such situations may lead to semantic ambiguity (precise mapping between domain concepts will be difficult). Semantic ambiguity, as a result, may lead to high cognitive load on the modeler, resulting in over- or underspecification, thus reducing the quality of a process model [10 - 13].

A process model (conceptual model) defines how a business will conduct its operations by specifying relevant activities, events, states, and control flow logic [14, 15]. These models can be represented with Petri Nets [16, 17], Business Process Model and Notation as shown in Fig. 1 (BPMN) [18], and Event-driven Process Chain (EPC) [19] shown in Fig. 2. Although these formal methodologies to model business processes offer different perspectives on modeling, they still do not address semantic ambiguity problems directly [20].

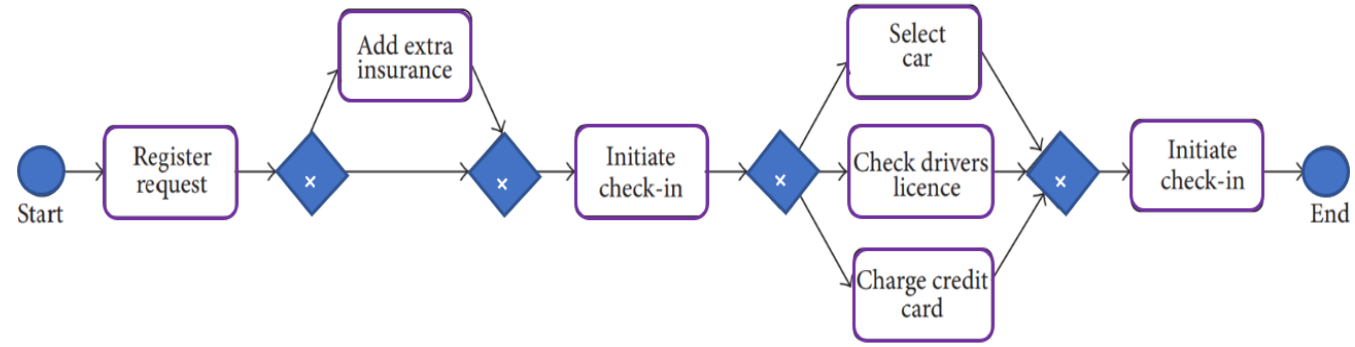

Fig. 1. Model in business process modeling notation.

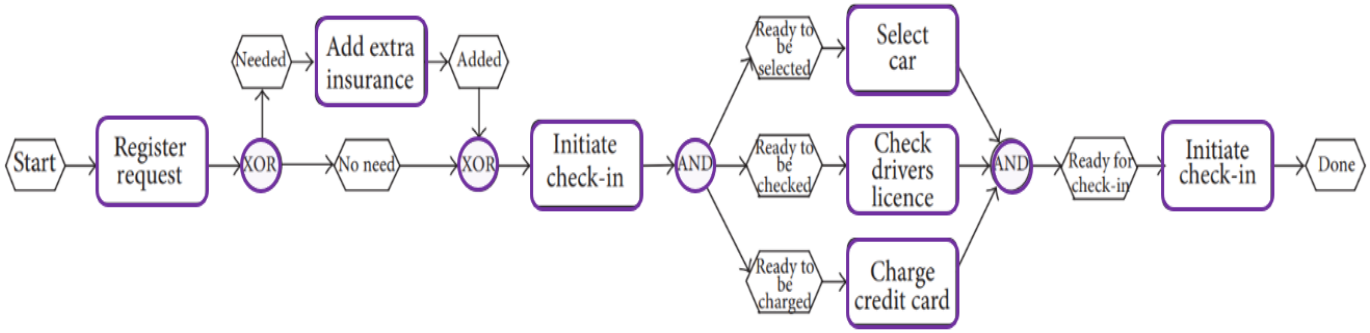

Fig. 2. Event-driven process chain model.

However, ontology-based business process modeling approaches can resolve semantic ambiguity in business process modeling through domain ontologies. Such approaches are based on cognitive load theory [21] and intended to help reduce semantic ambiguity by avoiding problems such as construct overload and construct redundancy. Construct overload deals with modeling for two or more ontologies, while construct redundancy deals with modeling constructs for a single ontology. Moreover, classes in a domain process ontology formally guide the business process modeling.

The primary objective of this study is to conduct a review of ontology-based business process modeling approaches for three main reasons:

- to establish context and understanding of the current state of the art knowledge;
- to explore the unexplored areas and to identify the research gaps that should be addressed; and
- to identify research opportunities for future research.

In this regard, a Systematic Literature Review (SLR) is performed because, according to Barbara Kitchenham [22], SLR is a systematic method for identifying, evaluating, and synthesizing research evidence that follows a structured protocol to ensure comprehensiveness and minimize bias.

The rest of the study is organized as follows: Section II presents the background of the study. Section III presents the review of ontology-based business process modeling. In Section IV, research challenges and opportunities are discussed, and finally, in Section V, the conclusion and prospective future research areas are discussed.

II. Background

A. What is BPM?

Business process management (BPM) is an approach to improve the activities to get work done, satisfy customer needs, and generate business value. It includes concepts, methods, and techniques to support the design, administration, configuration, enactment, and analysis of business processes [2, 23, 24]. To assess the effectiveness of implemented BPM in any organization, different factors can be used; a few among them are the process owner's awareness, engagement of top management, close communication, linking process goals with personal as well as strategic goals, the degree of innovation,

corrective and preventive measures, collaborative environment, process documentation, etc.

Fig. 3 depicts the core activities of business process management. Business process modelling is the core phase of process design. Once an initial design of a business process is developed, it needs to be validated.

Fig. 4 shows the BPM reference architecture [26] where the designer uses the design tools to create models describing the processes and the structure of the organization. The manager uses management tools to monitor the flow of work and act if necessary. The worker interacts with the enactment service.

Fig. 3. BPM life cycle core activities [25].

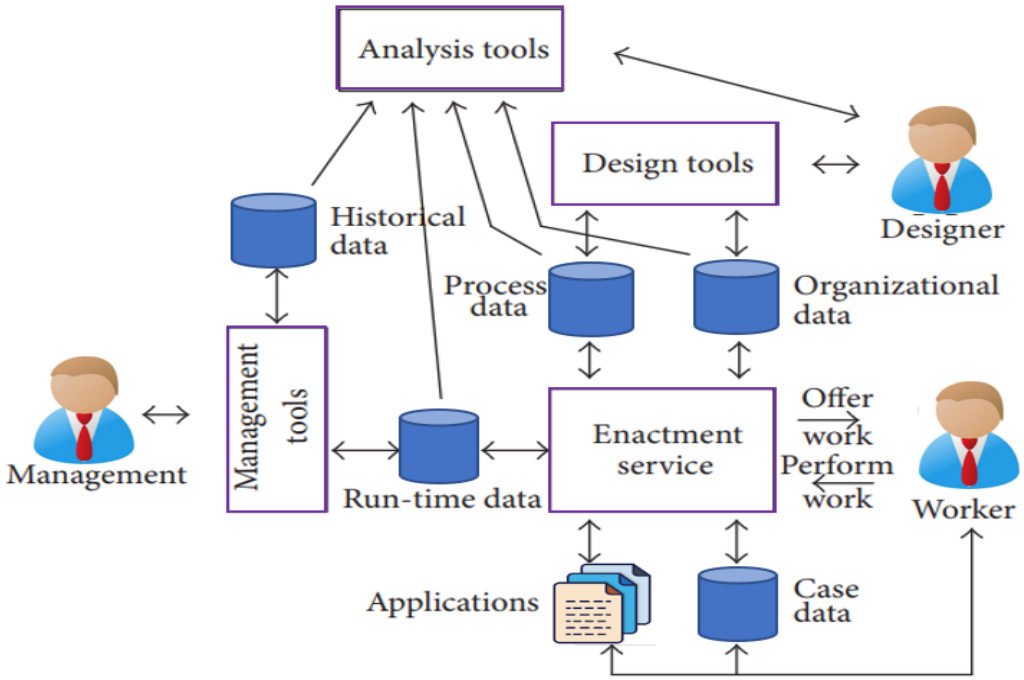

Fig. 4. BPM reference architecture.

B. What is an Ontology?

Ontology is the philosophical study of being, existence, and reality, which investigates what kinds of things exist and how they are categorized. In the context of computer science and information science, it refers to a formal, explicit specification of a conceptualization, essentially a structured representation of a domain's concepts and their relationships. A generic ontology overview is presented in Fig. 5.

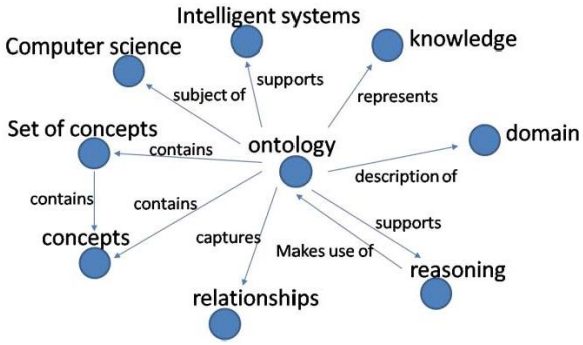

Fig. 5. Generic overview of an ontology.

Key issues in ontology-based business process modeling include the complexity of building and maintaining ontologies, lack of clear semantics in traditional modeling tools, the potential for mismatches between modeling approaches and technological trends, and the need for improved methods to capture complex business rules. Additionally, there can be difficulties in achieving interoperability and handling dynamic, complex business environments.

C. Why BPM Leverages Ontology?

Business process (BP) models are conceptual models; when implemented, they create value for the underlying business. This is why companies are focusing on defining and refining their business processes. However, BP modeling is a difficult task that needs trained experts. Although business process models are very similar to conceptual models, they are much more complex [12]. Because these models are used to draw the dynamic behavior of the business, that's why it requires a good understanding of domain knowledge. Whereas domain knowledge in the Information Systems (IS) discipline refers to the knowledge provided by both the domain experts and the application repositories [27]. Moreover, the next generation of

BPM requires machine-understandable semantics to automate the process composition, mediation, and execution. But the lack of explicit semantics hinders this task [28]. To address this challenge, different semantic modeling techniques like ontologies, semantic annotation, knowledge graphs, and rule-based systems can be used. Semantic annotation is good to ensure the quality of the model, but manual annotation is prone to errors and time-consuming [57]. Whereas in the case of Knowledge Graphs, knowledge extraction and integration from heterogeneous sources in complex scenarios is very difficult [55] while in Rule-Based Systems, combining rule logic with graph control flow may lead to modeling inconsistencies in business logic [56]. In contrast, ontologies can play their role between business process modeling and technical implementations by defining concepts, their attributes, and relations formally [20]. Hence, enabling the process models to be understood and manipulated by software systems, resulting in a higher degree of automation and execution.

D. Issues and Challenges While Integrating Ontologies Into BPM

The basic aim of integrating ontologies into BPM is to enhance semantic interoperability, formalize process models, and enable automated reasoning, but it faces several technical, conceptual, and practical hurdles. A few key challenges are discussed below and presented graphically in Fig. 6. The first challenge is that creating and maintaining a comprehensive ontology that covers all business domains, rules, and processes is very difficult. Moreover, with the evolution of the business and related processes, updating the ontology is another challenging task [29]. Different businesses may use different terms for the same concept, leading to the semantic mismatch problem. To resolve such issues, aligning heterogeneous ontologies is another major technical problem [30].

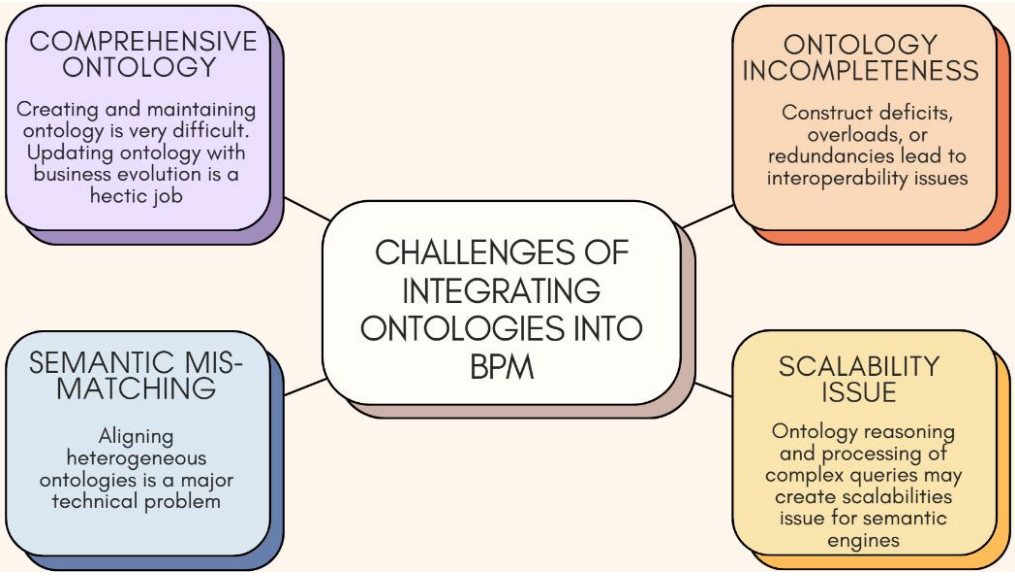

Fig. 6. Ontology integration challenges into BPM.

Ontological incompleteness (missing a crucial type of object or relationship) may lead to construct deficits, overloads, or redundancies, which undermine clear semantic mappings and interoperability [31]. Such issues arise because BPMN has no way to formally model the rules, resulting in writing them in text on the diagram or in a separate document. The ontology of business rules is not complete within BPMN [32]. Ontology reasoning, consistency checking, and processing of complex queries in the presence of a high volume of BPM scenarios may create scalability issues for the semantic engines [33].

There is a gap between conceptual ontological models and their implementation through BPM tools that support both process modeling and ontology development [31]. Developing and adopting standardized, integrated methods and tools should be a focus.

E. Ontology-Based BPM Framework

With the ever-increasing complexity of evolving businesses, there is a need for organizations to continuously refine, redefine, and formalize their business processes to create maximum value. However, business process modeling for large businesses is a complex and time-consuming activity that requires deep domain expertise. Moreover, the absence of explicit machine-understandable semantics in traditional BPM tools poses limitations in automation, interoperability, and process intelligence. To address these limitations, ontologies can play their role by offering means to formalize the specification of domain concepts, relationships, and rules, resulting in enhanced semantic interoperability and automated reasoning. Hence, researchers are exploring the integration of ontologies into BPM [30, 31, 33].

However, the integration of domain ontologies into BPM has numerous challenges, such as semantic heterogeneity (different organizations use different terms for the same concept), ontology evolution, maintaining comprehensive ontologies, reasoning scalability, and ontological incompleteness (missing relationships or business rules), etc. These limitations highlight the need for a structured framework that systematically links the semantic and procedural dimensions of BPM. In this regard, an Input Process Output (IPO) BPM Framework (Fig. 7) to

integrate ontologies into BPM as a three-stage transformation mechanism is needed. At the input stage, the framework will capture domain knowledge, ontological definitions, and business rules from both experts and organizational repositories. In the second stage (Process), semantic alignment, reasoning, and the transformation of conceptual models into machine-interpretable forms will be performed. Finally, the output stage will generate executable, semantically enriched process models that will support automation, consistency checking, and interoperability.

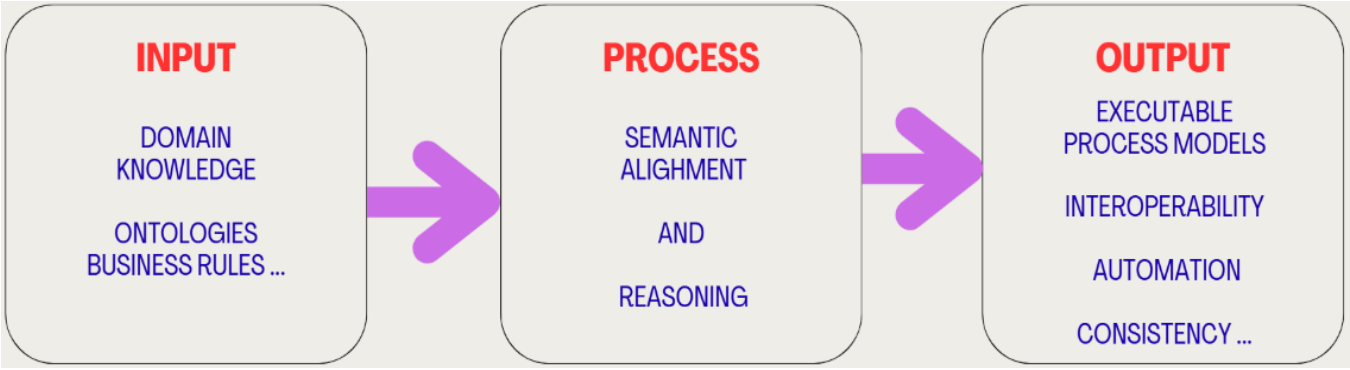

Fig. 7. Ontology-based conceptual IPO framework for BPM derived from literature.

An ontological framework where BPM integration structures around the IPO model may have the ability to ensure traceability and modularity across semantic and procedural layers. Thus, the ontology-based IPO framework for BPM not only addresses the technical and conceptual limitations of current BPM models but also contributes to establishing a unified foundation for semantic-driven business process automation.

III. Review Methodology

Ontology-based business process modeling (OBPM) uses an ontology to provide a formal, shared vocabulary for defining business processes, which allows for greater automation, reasoning, and interoperability. It integrates domain knowledge, process activities, and organizational context into a semantic model, enabling tasks like semantic gap analysis and automated metric computation that are difficult with traditional methods. While promising, the widespread adoption of OBPM is currently limited by the manual effort required for ontology creation and annotation.

A. Research Questions

The research question defines the scope of the research along with the specific issues to be investigated. Moreover, without such questions, the reader may face problems in understanding the rationale of the research. Therefore, the following are the research questions defined for this study.

- What challenges or limitations are reported in ontology-based BPM research?
- What ontological types are required to represent BPM effectively?
- How can OBPM support interoperability between heterogeneous business organizations?
- How have ontology-based BPM approaches been evaluated or validated in existing studies?

The rationale of each research question is presented in Fig. 8.

Fig. 8. Rationale of research questions.

Review protocol validation is an important step to minimize bias (in study selection, data extraction, and analysis) and to ensure transparency (allowing other researchers to replicate the methodology and to verify and validate the findings) of a review's findings. Therefore, a well-defined and validated protocol can guide the researcher throughout the review process and promote methodological rigor. In this regard, a review protocol validation questionnaire is defined in Table I.

TABLE I. REVIEW PROTOCOL VALIDATION QUESTIONNAIRE

Sr.	Components	Questions
1	Background	Is the review's context and motivation clearly established?
2	Research questions	Are research questions focused specifically on ontology-based business process modeling?
3	Search strategy	Is the completeness of searching of relevant studies ensured?
4	Study Selection	Are inclusion and exclusion criteria clearly defined?
5	Quality of studies	Are the reliability and validity of the selected studies evaluated and justified?
6	Data extraction	Is the collected information from each study relevant, consistent, and in a structured form?
7	Data synthesis	Is the extracted data integrated and analyzed properly to answer the research questions?
8	Reporting	Are findings presented clearly, ensuring others can reproduce the same if replicated?

B. Search Strategy

The search strategy is an important component of a systematic literature review methodology, which determines the scope and comprehensiveness of the review. This strategy ensures that all relevant studies are identified without being biased. Moreover, it also serves as a tool for evaluating the quality of a search. It allows replication upon updating a review. In this regard, a search strategy for this survey is designed in Fig. 9.

A search string is a combination of keywords and operators (like AND & OR) to form and perform complex, targeted queries and filter relevant results crucial for research. These strings are used for searching the databases to find specific information. A well-defined string makes the search more precise than single words. Below are the search strings used in this research.

- (("Ontology" OR "Ontologies" OR "Ontological") AND ("Business Process" OR "Business Process Model"))
- ("Business Process" OR "Business Process Model" OR "Business Process Management" OR "BPM")
- (("Ontology-based" OR "Ontology-driven" OR "Ontology based" OR "Ontology driven") AND ("ontology supported" OR "Semantic"))
- ("Business Process Model" OR "BPMN" OR "OBPM")

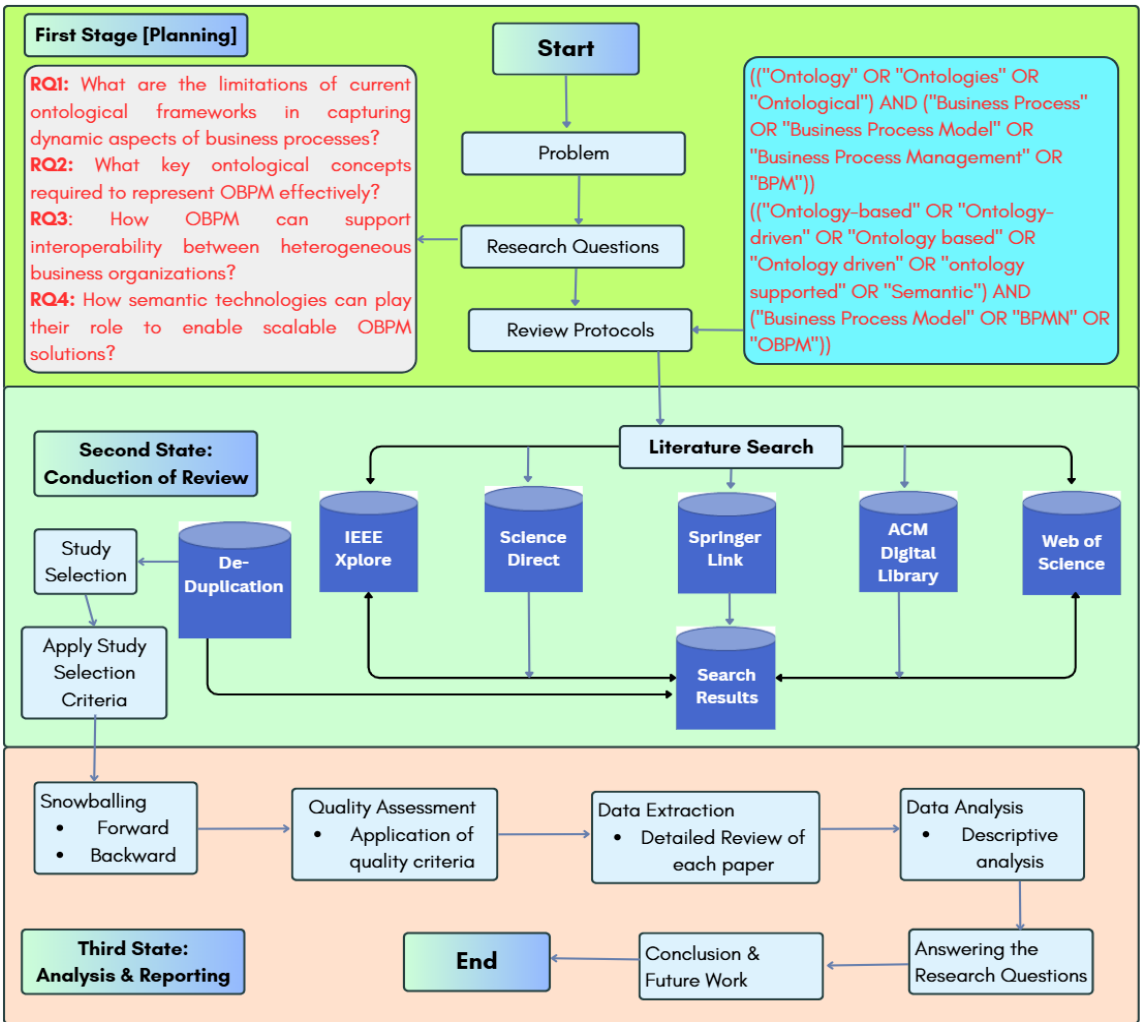

Fig. 9. Literature research methodology.

Databases provide a collection of published research for review on any topic. To search relevant papers, a researcher can define and refine the search filters to ensure only peer-reviewed articles are available. In order to ensure that no relevant study is missing, a researcher must search multiple databases. In this regard, below is the list of databases that are searched for literature for this review.

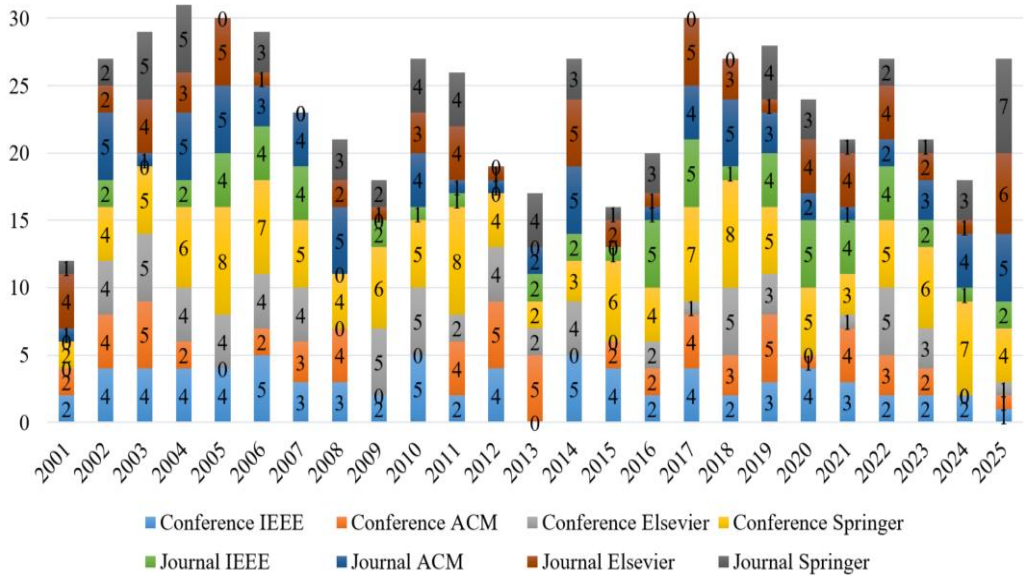
- ACM Digital Library (https://dl.acm.org/)
- IEEE Explore Digital Library (https://ieeexplore.ieee.org/)
- Springer Link Online Library (https://link.springer.com/)
- Elsevier ScienceDirect (https://www.sciencedirect.com/)
- Web of Science (https://www.webofscience.com)

C. Study Selection Criteria

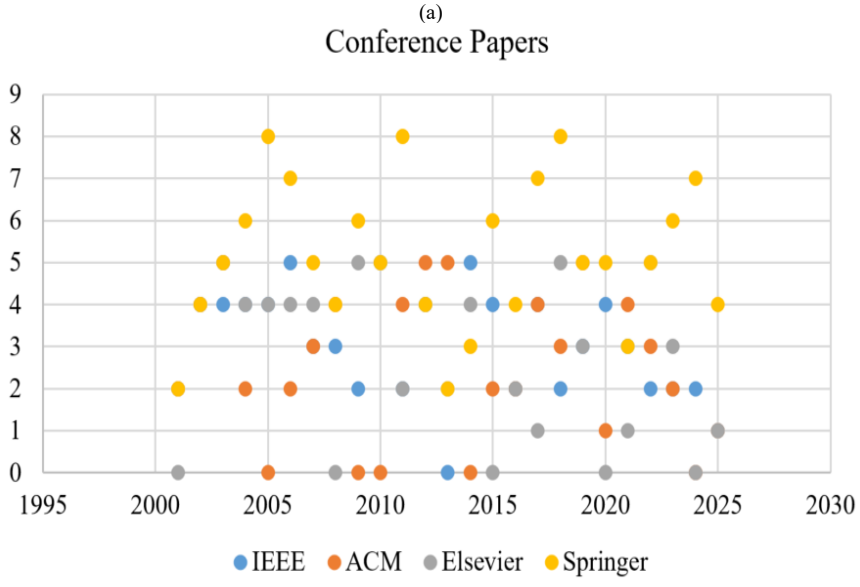
The inclusion and exclusion criteria to select the relevant studies to the research questions are given below in Table II.

TABLE II. THE INCLUSION AND EXCLUSION CRITERIA FOR STUDIES

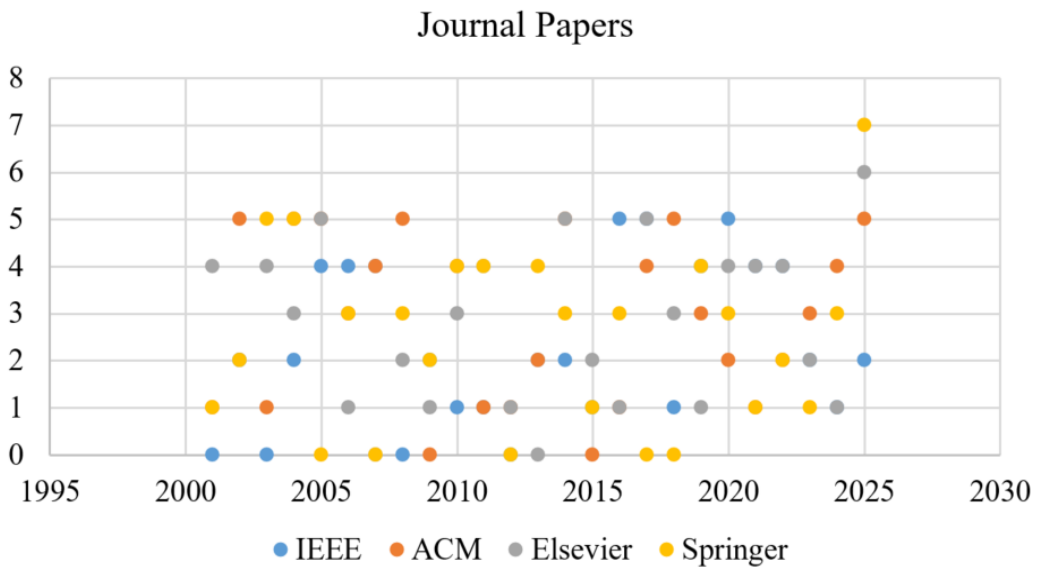
Inclusion Criteria	
IC-1	The paper written in English
IC-2	Peer-reviewed conferences or journals
IC-3	Published after the year 2000
Exclusion Criteria	
EC-1	The paper is not peer-reviewed
EC-2	Papers not written in English
EC-3	Form duplicate studies (one in conference and one in journal on same topic); conference paper was excluded
EC-4	Short research papers (less than 5 pages)



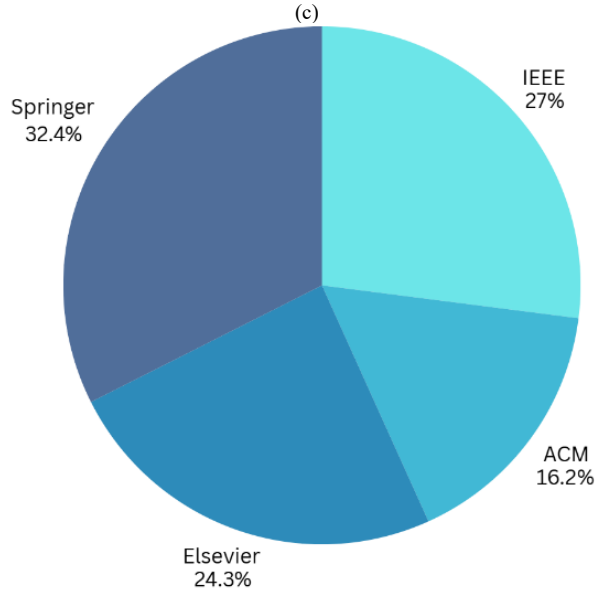
(a)



(b)



(c)



(d)

Fig. 10. (a). Year and publisher-wise study categorization. (b). Year and publisher-wise conference papers. (c). Year and publisher-wise journal papers. (d). Publisher-wise percentage of papers.

1) Selection process: After searching results from the defined databases based on the search strings, the screening process started. At this stage, one of the authors shortlisted papers based on the criteria defined in Table I. At the second stage, full papers were reviewed based on predefined inclusion and exclusion criteria (Table II). In case of confusion, conflict resolution techniques were applied, and the process was reinitiated (Table III). The second stage was concluded with the selection of 77 papers out of 127. After full paper text analysis, another 36 irrelevant papers were dropped. The final 41 papers were assessed for quality against the checklist defined in Table IV, and data were extracted according to Table V. In this survey, forward (Google Scholar) and backward snowballing methods were conducted, resulting in the selection of another VII papers after following all defined selection criteria. In total, this study considers 48 studies, and all data extraction and analysis results are based on these selected studies. The year- and publisher-wise details of selected studies are presented in Fig. 10.

TABLE III. SEARCH AND SELECTION RESULTS

Source	Search Results	Initially scrutinized Results	After full paper analysis	After Snowballing
ACM	17	9	5	6
Springer	25	14	7	9
Elsevier	45	25	11	13
IEEE Xplore	19	12	7	8
Web of Science	21	17	11	12

According to the inclusion and exclusion criteria, 79 papers were rejected among which 31 were not directly related to the business process modeling, 14 were duplicate, 18 were not related to ontology (all were discussing other semantic technologies), 10 were short papers (less than 5 pages) while 6 were basic papers (no details).

2) Selection process problems: During the process of primary studies selection for the SLR, several challenges were faced.

a) One common problem was: the author published the same study at a conference and the extended version in a journal. In this case, the journal paper was considered.

b) Studies with slightly different titles published in multiple journals. In such cases, after reviewing the title, authors, objectives, research problem, and contributions carefully, the whole team discussed and decided to keep or drop these studies.

c) To ensure the validity of the search process. Few research papers were selected based on the prior knowledge and then the most relevant search string was used to verify that string s produce the same results.

To address these challenges, conflict resolution techniques were adopted. Hence, the reliability and completeness of the survey were ensured.

D. Quality Assessment

To assess the quality of selected studies, Quality Assessment (QA) checklists were prepared. The checklist consists of 11 quality assessment criteria used to evaluate each study, as described in Table IV.

TABLE IV. THE QUALITY ASSESSMENT CHECKLIST

Quality assurance Questions	
Q1	Is the study related to business process modeling?
Q2	Are the study objectives SMART?
Q3	Does the study answer any of the research questions?
Q4	Are the research methods clearly described?
Q5	Is the contribution clearly described?
Q6	Is the study evaluation process well explained?
Q7	Is the data along with the source credible?
Q8	Are the implementation methods well explained?
Q9	Are the results and findings properly analyzed and reported?
Q10	Are the results compared with any benchmark?
Q11	Are the research challenges and limitations mentioned?
Q12	Can the results be generalized?

E. Data Extraction

Data extraction from papers is important because it allows researchers to evaluate study quality, along with identifying the strengths and weaknesses. Moreover, upon data extraction, researchers can statistically analyze, summarize, and interpret by ensuring that findings from multiple studies are combined and compared meaningfully. In this regard, data extraction fields used in this study are defined in Table V.

TABLE V. THE DATA EXTRACTION FIELDS

Data Extracted	Description
Research Problem	Research Problem addressed by the study
Research objectives	The research objective of the study
Contributions to existing body of knowledge	The contributions made by the study to the existing body of knowledge.
Data Issues	The challenges faced in data collection
Results	Results reported in the study.
Comparisons results	The results achieved over the benchmark
Key challenges	The main challenges the study encountered

IV. OBPM: A REVIEW

In this section, a concise description of the selected primary studies is presented. Studies are categorized into four major categories (Ontology Driven Process Modeling, Process Integration, & Interoperability, Ontology-Based Business Process Adaptation, and Tools, Frameworks & Applications) based on the research questions. A brief introduction of each category is presented below.

A. Ontology Driven Process Modeling

Ontology-Based Business Process Modeling (OBPM) has emerged as a powerful paradigm for addressing semantic ambiguity, improving interoperability, and enhancing analytical capabilities in modern enterprise systems. Across recent literature, ontologies are consistently positioned as a means to strengthen the semantic foundations of business process management by enabling shared understanding, automated reasoning, and intelligent alignment between business and IT.

In the first paper, Bouroumi et al., [31] discuss how ontologies and context-awareness can improve Business Process Modeling (BPM) by enriching process semantics, supporting context-sensitive adaptations of business processes, bridging gaps between business-level and IT-level understanding, and improving interoperability and reusability of process models. However, the authors have not performed a thorough quantitative evaluation. In another paper, Tao et al., [32] presents a solid contribution in the field of ontology-based information extraction. The authors design an IPO domain ontology capturing key concepts like issuer, underwriter, issue price, risk factors, financial indicators, and company type, etc., from business and financial documents. However, the proposed ontology is primarily used for annotation rather than reasoning or inferencing. A work by Fan et al. [33] proposes a comprehensive process ontology to standardize process elements, clarify terminology, and eliminate inconsistencies. By enforcing explicit semantics, the approach significantly improves communication between stakeholders and prevents misunderstandings in model interpretation. Inter-organizational workflows are addressed in [34]. This paper integrates process mining with ontological mapping to align heterogeneous models across organizational boundaries. This highlights ontology's central role in supporting collaboration where organizations use disparate modeling conventions. Semantic modeling with the help of artificial intelligence is studied in [35]. The authors combine ontological domain knowledge with deep learning to automatically assess process maturity. The hybrid approach represents a growing trend toward augmenting OBPM with

advanced analytics to support intelligent organizational decision-making. Hinkelmann et al. [36] integrate enterprise ontology with an enterprise architecture framework, enabling continuous alignment of business goals with IT structures. Practical alignment is performed by Sánchez et al. [37] using ontology to map processes to web service specifications; the method supports automated model-driven modernization, enabling seamless transition from business design to IT execution environments. BPMO [38] provides a complete formal ontology for describing process models. While Thomas and Fellmann [39] extend this foundation by presenting an ontology-based representation that enhances consistency checking, semantic validation, and process standardization.

All these research works demonstrate that ontology-based approaches significantly improve the clarity, interoperability, intelligence, and performance of business process modeling, positioning OBPM as a critical enabler for next-generation systems.

B. Process Integration and Interoperability

Smith et al. [40] have introduced a logic programming-based framework for business process modeling using ontologies. They used ontologies for reasoning about business process models because traditional process modeling languages like BPMN lack formal semantics, resulting in difficult or incomplete automated reasoning. However, the proposed framework is complex, which makes it difficult to be implemented in large organizations without semantic technology experts. A semantic modeling framework is proposed by Akatkin et al. [41] extends conventional BPM with an ontology. A prototype is implemented for a small-scale government process to show how the framework has improved interoperability. The paper should discuss how ontologies will be maintained, versioned, and aligned with regulatory changes. In a paper [42], the author has merged the process workflows with semantic domain knowledge for improving interoperability, model consistency, and intelligent system behavior. Ontologies developed in isolation lead to inconsistencies, limited interoperability, and difficulties in reusing knowledge across systems. Pfaff et al. [43] have designed an ontology-based framework to support semantic data integration within IT benchmarking environments. Authors argue that different organizations generate different type of data which might create significant challenges like data heterogeneity, inconsistency, and incompatibility. However, for evaluation, a limited dataset is used. The authors have not discussed the integration tools, automated reasoning, or user interface considerations, which makes their work difficult to implement by non-technical users.

The above-discussed papers highlight the advancement of Semantic Business Process Management and ontology-based integration. The papers collectively discuss the strengths of formal semantics for process modeling and improving business integration through shared ontologies. Whereas the proposed works are facing challenges of scalability, ontology maintenance, and deployment at the enterprise level.

C. Ontology-Based Business Process Adaptation

In this section, different research works are reviewed which collectively highlight how ontology engineering enhances business process modeling, semantic consistency, and adaptability.

In a paper, Preisig et al. [44] have proposed an ontology to capture physical entities formally along with their relationships, constraints, and operational dependencies. In their work, they demonstrated an example of linking physical topology with business processes and performed automated reasoning to check consistency of system structures and detect invalid process sequences. However, they did not discuss the scalability issues for large-scale physical systems. In a paper, Kord et al. [45] focused on dynamic business process adaptation through context ontology. To demonstrate their achievement, a context ontology along with reasoning rules was used to infer the need of adaptation. However, they have not discussed how their proposed system can be applied in a real-world industrial scenario. Samhan et al. [46] have extended the Riva methodology [52] for business process architecture. They extended the Riva methodology with an ontology for automatic interpretation and converted an informal architectural methodology into a semantically enriched framework. But the proposed system does not provide support for executable process modeling tools. Poss et al. [47] in their work have focused on the operational aspects (tasks, resources, preconditions, and effects) of business process modeling. They claim that they have provided a foundation for process execution verification, simulation, and compliance enforcement. However, the proposed ontology is very complicated, which might confuse typical process designers. Thuan et al. [48] have addressed the process flexibility challenge of business process modeling for organizations that work in highly dynamic environments. However, their work highly relies on manually encoded rules. Moreover, the performance issues of their work are also not fully assessed.

All above discussed papers demonstrate that traditional BPM languages lack semantic clarity, leading to ambiguity and inconsistency. Whereas ontologies support precision, adaptation, and enable reasoning-based improvements in flexibility. However, ontology adoption in terms of complexity and scalability is a big challenge for the next-generation intelligent BPM systems.

D. Tools, Frameworks & Applications

Ontology-based techniques, due to formal semantics, reasoning, and improved interoperability across heterogeneous business environments, are becoming fundamental in Business Process Management. In this section, the literature on Tools, Frameworks & Applications is reviewed for synthesizing their contributions, methodological approaches, limitations, and collective significance for the field of semantic business process management.

Ghasemi et al. [49] have developed a unified ontology to classify and configure the business process management techniques which consists of Six Sigma, Lean, BPMN, simulation tools, and workflow engines etc. The major contribution of this work is the BPM maturity assessment framework, which can map organizational needs to appropriate techniques via semantic reasoning. However, the proposed mechanism is not evaluated through different case studies for performance. In a paper, Annane et al., [50] evaluate different

business process ontologies (on criteria like expressiveness, modularity, reasoning capabilities, domain flexibility, and alignment with BPMN) to know their suitability for task monitoring. Through evaluation, they identified ontological gaps like limited support for adaptation, temporal constraints, and the organizational context. However, it is a conceptual study that must be supported with empirical evaluation using real-time monitoring systems. Adams et al., [51] have addressed the challenge of complexity of large business process models through ontology-based views which represent different dimensions of a process like functional, behavioral, organizational, and data perspectives. The proposed mechanism has the ability to generate automatically customized views based on stakeholder roles and analytical needs without losing semantic consistency. However, the process of designing these views requires a considerable semantic expertise.

In the above discussed papers, it is revealed that ontologies enable precise definitions of process models by eliminating ambiguities inherent in traditional modeling languages and the formal semantics enables the automated process validation, compliance checking, and real-time decision support. Moreover, ontology-based process modeling approaches improve context-awareness and interpretability in discovering and analyzing business processes. However, certain challenges are still open to investigation. For example, ontology creation & maintenance and computational overhead along with scalability issues are not studied in detail considering industry-grade case studies.

E. Comparative Evaluation

In this section, a comparative evaluation of ontology-based business process modeling studies is performed on criteria: Tool Support, Empirical Validation, Quantitative Metrics, Reasoning Capabilities, Adaptability, Context-awareness, Generalizability, and Limitations. Criteria requirements are divided into two sections 1) general requirements (Tool Support, Empirical Validation, Quantitative Metrics) and 2) ontology specific requirements (Reasoning Capabilities, Adaptability, Context-awareness, Expressiveness, and Limitations). The objective of the evaluation is to know the strengths and limitations of these studies. Evaluation criteria requirements are defined in Table VI, while the evaluation results are presented in Table VII and Table VIII, respectively.

TABLE VI. LITERATURE EVALUATION CRITERIA REQUIREMENTS

Evaluation criteria	Description
Tool Support	Availability of software tools for BPM platforms or support for automation and semantic validation
Empirical Validation	Experimental demonstration to improve accuracy or efficiency of ontology or non-ontology BPM approaches
Quantitative Metrics	Performance measures like modeling time or complexity analysis of ontology integration
Reasoning Capabilities	Incorporation of formal semantics to demonstrate automated process validation, compliance checking, and real-time decision support.
Adaptability	System has the ability to modify process execution based on semantic or contextual conditions.
Context-awareness	Research captures dynamic context like roles, locations, events, and rules.
Generalizability	Flexibility to adapt to evolving processes and ontologies or have potential for reuse in other knowledge-intensive domains
Limitations	The constraints (methodological, theoretical, or practical) that restrict the findings, scope, or generalizability.

TABLE VII. STUDIES EVALUATION ON GENERAL CRITERIA REQUIREMENTS

Study	Tool Support	Empirical Validation	Quantitative Metrics
[31]	Prototype-level	Small case examples	Not reported
[32]	Prototype implemented for document analysis	Experiments on IPO documents	Extraction accuracy / precision/recall
[33]	Prototype and mapping examples discussed	Experimental evaluation	Some evaluation metrics (e.g., ambiguity reduction measures).
[34]	Methodology and implementation details hinted	Experiments / case studies	Process discovery / conformance metrics reported.
[35]	Prototype and experimental pipeline described.	Datasets used for capability assessment.	Performance metrics for assessment (accuracy, F1, etc.).
[36]	Methodological framework; tool prototypes in some implementations	Case studies in industry contexts	Not the main focus; some alignment indicators discussed.
[37]	Prototype tools and model transformations	Demonstration and experiments reported.	Some performance / correctness metrics for transformations
[38]	Research prototypes and semantic tooling described	Example scenarios and prototype evaluations.	Not central; mostly conceptual/qualitative evaluation
[39]	Implementation details and prototype frameworks	Examples and small evaluations.	Not emphasized
[40]	Implementation (logic programming engine).	Examples and reasoning case studies provided	Some performance discussions; not heavily empirical.
[41]	Frameworks and prototypes discussed in paper	Government examples; conceptual demonstrations	Not the focus
[42]	Methodology and tooling recommendations, possible prototype	Case studies	No central methodological focus
[43]	Web-based architecture for ontology-driven integration	Demonstrations and validation examples	Integration performance / mapping accuracy discussed.
[44]	Implementations and examples in journal article.	Case examples and model demonstrations	Not emphasized
[45]	Prototype and reasoning components described	Examples and limited experiments	Not heavily emphasized
[46]	Conference paper with prototype	Limited empirical evaluation	Not reported

[47]	GitHub implementation available	Prototypical demos	Not a major focus; qualitative validation present.
[48]	Conceptual prototype; limited tooling.	Conceptual validation and examples	Not central; few evaluation metrics.
[49]	Ontology artifact published	Limited; mainly conceptual and illustrative.	Not emphasized.
[50]	Comparative analysis; no single tool proposed	Analytical comparison	Comparative criteria used; not performance metrics.
[51]	Prototype and formal definitions	Examples and comparative discussion	Not central; usability discussion present.

TABLE VIII. STUDIES EVALUATION ON ONTOLOGY SPECIFIC CRITERIA REQUIREMENTS

Study	Reasoning Capabilities	Adaptability	Context-awareness	Generalizability	Limitations
[31]	Ontology reasoning for context interpretation (limited).	Targets adaptive behaviors tied to context	Central focus; explicit context modeling	Domain-agnostic idea; validation limited	Evaluation small-scale; maintenance overhead noted
[32]	Semantic enrichment and mapping; basic inference for IE.	Focused to IPO domain; adaptable with new ontology work.	No central document	Needs rework for non-financial domains	Domain specificity; ontology construction cost.
[33]	Ontology reasoning for equivalence	Aimed at heterogeneous modeling environments	Not in focus	Intended to be transferable across domains	Ontology engineering overhead; scalability concerns for very large mode
[34]	Semantic mapping to align logs	Built for heterogeneous partner systems.	Indirect focuses on organizational context.	Targeted to inter-org settings; transferable with mapping	Complexity with noisy or incomplete logs; mapping effort required.
[35]	Ontology supports semantic features; DL handles pattern detection	Relatively adaptable; dependent on retraining and ontology updates	Limited explicit context modeling	Promising; requires dataset and ontology alignment for new domains	Data requirements for DL; ontology upkeep.
[36]	Ontology-based reasoning for alignment checks	Designed for organizational adoption; flexible modelling approach.	Captures organizational and technical context.	Strong enterprise applicability; requires customization	Implementation cost; governance/maintenance challenges
[37]	Semantic mapping and matching for service binding.	Focus on re-use in legacy modernization scenarios	Limited; more about mapping semantics to services	Applicable to modernization projects broadly	Complexity of mapping and runtime orchestration.
[38]	Supports reasoning for discovery, validation and mapping.	Designed to be extensible and reusable.	Includes organizational and service context modelling	Developed to be reusable across domains	Ontology complexity need tool support.
[39]	Used for validation and semantic queries.	Focused on improving model interchange and reuse.	Some attention to context and organizational info.	Designed for general BPM settings.	Tool maturity and scaling concerns
[40]	Strong (logical inference, consistency checks).	Method applicable where formal verification needed.	Not primary	Technically general but requires expertise	Complexity; scalability for very large models
[41]	Supports semantic alignment for cross-agency workflows	Tailored to public services; generalizable with work	Includes citizen/service context in examples	Framework transferable to other public sectors.	Organizational barriers; real deployments are complex
[42]	Enables semantic checks during development	Designed to fit organizational practices	Can incorporate context if modeled	Method intended to be generic	Resource intensity; requires ontology expertise.
[43]	Semantic mapping and mediation supported	Domain-specific but extensible	Limited to IT benchmarking context.	Useful template for other benchmarking domains	Domain restriction; ontology maintenance needs
[44]	Ontology used for semantics and consistency checks.	Targeted at engineering/process industries	Physical context modeled explicitly.	Good for industrial contexts	Domain specificity; complexity of physical modelling.
[45]	Central: ontology reasoning for adaptation decisions	High; designed for dynamic adaptation	Core focus.	Applicable where contextual data is available	Real-time data acquisition and reasoning overhead
[46]	Basic semantic alignment and mapping	Focused to RIVA architectures may be generalize	Some architectural context captured	Needs adaptation for other architectures	Specialized scope; limited empirical proof.
[47]	Reasoning for resource allocation and integration checks	Targeted to SMEs but extensible	Includes operational context (equipment state).	Applicable to domains with physical resources.	Implementation maturity and runtime constraints.
[48]	Enables classification and reasoning about flexibility types.	Helps design flexible processes; supports reasoning about variability.	Flexibility linked to context and exceptions.	Intended to be broadly applicable.	Needs tooling and empirical validation
[49]	Supports semantic queries and mappings	Useful for tool recommendation tasks; needs updating.	Not central.	Broad for BPM community; needs maintenance.	Rapid tool evolution requires updates; limited validation.

[50]	Assesses ontologies' support for monitoring reasoning.	Guides selection/extension for monitoring tasks	Evaluates how ontologies capture execution context.	Comparative results help across domains.	Lacks experimental runtime evaluation.
[51]	Ensures semantic consistency across views.	Highly adaptable by adding view extensions.	Views can encode contextual perspectives.	Broad applicability to enterprise modeling.	Complexity in authoring view-extensions; tooling required.

The above-evaluated papers describing frameworks, tools, and methodologies provide thorough and clear but varying explanation details. Papers focusing on ontology-based business process modeling [38, 40] provide a strong semantic foundation by clearly differentiating the process concepts, control-flow structures, behavioral semantics, and organizational perspectives. Whereas few papers [35, 36] explain how ontologies improve knowledge representation, data interoperability, and process alignment, they combine ontology with deep learning or enterprise architecture and prefer architectural descriptions over detailed ontology specifications. Papers addressing context-aware modeling [31, 45] provide detailed descriptions of contextual elements like environmental variables, dynamic conditions, roles, and resources. Although these elements strengthen the conceptual clarity of context modeling but also increase the complexity of the model.

However, a number of framework-based papers are conceptual, discussing architectural designs without presenting any software artifacts. For example, papers focusing on process capability assessment [35] or enterprise alignment [36] describe tool requirements but do not produce a complete toolset. In short, about thirty-three percent of papers offer strong tool support, while thirty-three percent of papers provide partial or prototype-level tools, and the remaining are just conceptual. Papers providing semantic model-based prototypes, especially on the context adaptation [45] and semantic process alignment [37] provide working implementations by integrating workflow engines with semantic annotation systems.

The evaluated works present strong development in ontology-based business process modeling while considering enhanced semantic expressiveness, improved reasoning capabilities, better interoperability, enriched context modeling, improved semantic clarity and alignment, and the combination of ontologies with process mining using ML. Whereas, the major weaknesses of these studies are limited empirical validation, established tool support, the use of highly varying quantitative metrics, and evaluation (often limited to case studies), restricts the generalizability.

V. RESULTS AND DISCUSSION

Most of the papers cover a broad range of BPM lifecycle phases like process modeling-focused works [38, 51] emphasize

semantic representation and structural modeling; context-aware approaches [31, 45, 60] extend models to dynamic adaptation; papers on process integration [34, 37, 46] highlight cross-enterprise interactions; process flexibility paper [48] and ambiguity resolution paper [33] focus on behavioral aspects. Whereas a paper considering domain-specific ontology integration [43] constrains the scope to IT benchmarking. Papers in the process mining and integration [34, 50] domain have a tendency to consider robust empirical investigations using event logs, organizational datasets, or inter-organizational workflows. These studies evaluate performance, model accuracy, or integration improvements based on real-world or semi-real datasets. While papers on ontology engineering [38, 39, 51] include case studies involving business process scenarios in domains like manufacturing, e-government, logistics, and service management. These case studies help to illustrate the ontology applications but lack quantitative or statistically significant validation. Whereas papers that have considered ontology with AI [35] (hybrid deep learning + ontology) consider detailed evaluation methods but primarily focus on model performance rather than ontology quality. Likewise, some papers lack empirical validation altogether, particularly high-level conceptual works on enterprise architecture alignment [36] or adaptability frameworks [48]. These limitations reduce practical reliability and impact. Traditional ontology-based modeling papers [38, 39] treat processes as static artifacts. Integration works [37, 41] occasionally incorporate adaptation but typically focus more on interoperability than real-time flexibility. However, despite these limitations, the papers collectively advance ontology-based BPM significantly.

A. RQ1: What Challenges or Limitations are Reported in Ontology-Based BPM Research?

Ontology-based Business Process Management (OBPM) has been widely studied for its potential to enhance semantic clarity, interoperability, process automation, and organizational alignment. However, the major limitation reported is the complexity involved in developing and maintaining ontologies [31, 38, 39]. Creating semantically rich process ontologies depends on domain knowledge and expertise in ontology engineering. Many organizations lack personnel with such skills, making ontology construction costly and time-consuming. Moreover, a few common challenges discussed in each study are the narrowness of ontological scope, absence of formal reasoning, limited empirical evaluation, lack of standardized tool support, and integration issues [37, 47].

Many studies also highlight scalability and performance issues [33, 45, 51]. Reasoning engines used for ontology alignment, context inference, or semantic disambiguation face such issues in large organizations. Kord et al., [45] discuss that in real-time environment, the reasoning can be computationally costly due to the fast change in context or in data, resulting in delays in monitoring and decision support [51].

Another reported challenge is the semantic heterogeneity across organizations. A number of researchers [33, 41, 43] have noted that different organizations use different ontological terms, modeling conventions, and process structures, which requires a lot of effort for consensus building and mapping. A few studies have pointed out the need for limited real-world validation [46, 48]. In [48], a rich conceptual model is presented that lacks extensive empirical testing across industries. As a result, scalability, user adoption, and practical impact are not evaluated.

Further research dimensions reported in [32] and [35] are the integration of ontologies with advanced analytics and machine learning. As ontologies provide structure, while machine learning systems demand large datasets and flexible representations. Hence, integration of both techniques may result in clashes between symbolic and statistical paradigms. Similarly, studies like [50] and [49] report the lack of standardization across BPM ontologies. That results in duplication of concepts, incompatibilities, and difficulties in selecting the right ontology for a given use case.

B. RQ2: What Ontological Types are Required to Represent BPM Effectively?

Ontology-based Business Process Management (OBPM) research has emphasized a set of core ontological types required to represent business processes in a semantically rich, interoperable, and machine-processable way. These types can broadly be categorized into process structure, behavioral semantics, organizational context, data and information flow, resources and capabilities, and finally into contextual or environmental factors. Each category has a strong representation of processes that enable reasoning, interoperability, and automation.

Similarly, few ontology-based BPM studies [33, 38, 39, 50, 51] represent the basic building blocks of a process like activities, events, control-flow constructs, composite activities, and the sequence relations. These building blocks formalize the BPM structure and eliminate semantic ambiguity by defining the meaning of each element in a machine-processable format, and without these structural types, process reasoning and consistency checking become impossible [39, 41]. A few papers [37, 40, 47] discuss that structural elements alone are insufficient. For effective business process modeling, demand ontologies to capture execution semantics, including pre and post-conditions, state transitions, temporal constraints, concurrency and synchronization semantics, along with the business rules. These types allow ontologies to support logical reasoning, detect inconsistencies, and enable automated process execution.

Papers [36, 41, 46] have discussed the impact of the integration of context into BPM ontologies. Organizational context includes actors, roles, management units, actor responsibilities, and the relationships among stakeholders. This context helps in mapping the business processes to the enterprise architecture, ensuring alignment between business and IT. In addition, several papers [35, 37, 49] highlight that BPM ontologies must represent capabilities and resources to support dynamic adaptation and process capability assessment. This includes human resources, system applications, services, skills, and competencies. It allows process execution engines to bind tasks to appropriate real-world resources. Papers [32, 43, 49] emphasize the need to integrate semantic data models like data objects or business entities, information flows, document types, and Input, output dependencies into BPM ontology frameworks.

These data models enable semantic data integration, reduce ambiguity, and support analytics and process mining. Furthermore, papers [31, 45, 48, 44] highlight the need to represent context (environmental, organizational, user, and device context) for adaptive and flexible processes. These types of contexts are critical for context-driven process adaptation and dynamic reconfiguration.

The reviewed literature on BPM ontology, effective representation requires a multi-layer ontology that integrates structural, behavioral, organizational, resource, data, and contextual types. These ontological categories enable semantic clarity, automated reasoning, interoperability, and adaptability, which is the ultimate goal of present ontology-based BPM research.

C. RQ3: How can OBPM Support Interoperability Between Heterogeneous Business Organizations?

Ontology-Based Business Process Management plays a central role in enabling interoperability between heterogeneous business organizations by providing a shared semantic foundation for representing, aligning, and integrating processes. A number of papers [32, 33, 38, 39, 43, 50] contribute to interoperability through four major mechanisms: semantic harmonization, cross-organizational alignment, context-aware integration, and machine-reasonable process representations. Together, these mechanisms allow organizations with different models, terminologies, systems, and workflows to communicate, integrate, and execute processes coherently. OBPM has the ability to harmonize semantics across organizations that use different vocabularies or modeling conventions. Authors of papers [33, 38, 50] show that ontologies remove ambiguity from process elements by providing precise definitions of tasks, events, roles, resources, and data objects. When organizations map to a common ontology, they can compare and integrate processes that were previously incompatible due to terminology differences.

Papers [32, 43] report on how ontology-based semantic data integration consolidates heterogeneous information sources, which is crucial when organizations exchange documents or transactional data. Similarly, a few other studies [34, 36, 37, 41] demonstrate that OBPM supports interoperability by aligning business processes across organizational boundaries. Ontologies can map one organization's processes to another through process mapping and equivalence identification, cross-organizational workflow integration, semantic matching between business services, and automatic transformation of process models into executable forms. Aouachria et al. [34] have demonstrated how ontology-driven process mining can detect correspondences between heterogeneous inter-organizational processes, enabling integrated workflow execution. Akatkin et al., [41] discusses how shared process ontologies facilitate the integration of seamless public services in an e-government scenario. Interoperability among organizations usually fails when processes behave differently in different contexts. OBPM uses context ontologies to capture environmental conditions, policies, and constraints, etc. [31, 45, 48]. Contextual knowledge can be used in business process models to adapt processes when exchanged in organizational environments or to ensure that cross-organizational workflows respect local rules and constraints and, finally, to resolve conflicts caused by differing operational contexts. In the case of the reasoning capability of OBPM, papers [40, 47, 42] show that ontology-based models support automated reasoning to check compatibility, identify inconsistencies, and verify the alignment of processes across organizations by allowing the validation of the process conformance, resolution of semantic conflicts, inferencing of the missing relationships, and composition or orchestration of services [37].

Papers on OBPM enable interoperability by providing a shared vocabulary, a formal mechanism for alignment, adaptive contextualization, and automated reasoning. It allows organizations to collaborate effectively, integrate seamlessly, and automate cross-organizational processes without worrying about the differences in terminology, technology, or workflow design. OBPM, therefore, can resolve the issue of interoperability among organizational business process integrations.

D. RQ4: How have Ontology-Based BPM Approaches been Evaluated or Validated in Existing Studies?

In ontology-based BPM research, evaluation and validation methods vary with respect to semantic enrichment, process integration, context modeling, system alignment, and interoperability. These methods include case studies, prototype implementation, comparative analysis, reasoning tests, process mining, and expert judgment [31, 51]. In the case of study evaluations, many studies [31, 32, 35, 41] are validated through domain-specific ontologies demonstrating applicability in real-world process scenarios. In these studies, context-based modeling is validated through contextualized business processes to show increased expressiveness and accuracy. For IPO documents analysis, financial prospectus datasets are used to validate information extraction accuracy [32]. For process capability assessment, deep learning and ontology reasoning are integrated [35] to test in organizational scenarios. Papers [38, 39, 45, 47] introducing new modeling techniques are often supported with tools, like in a paper proposing Business Process Modeling Ontology [38] is evaluated with a prototype demonstrating how models can be instantiated and queried. In the semantic process modeling prototype [39], the author demonstrates model creation, storage, and reasoning in an ontology-backed environment. Similarly, in a paper on process adaptation systems [45], the author validated context-driven adaptation via prototype reasoning engines. Likewise, the author of operational perspective formalization [47] has performed a tool integration experiment to validate interoperability.

Since formal semantics are central to OBPM, many studies validate their ontologies through logic-based reasoning tests. For example, Smith et al. [40] used logic programming to test completeness, consistency, and inferential accuracy. In another study [33], the author evaluated semantic disambiguation by checking whether the ontology correctly resolves conceptual overlaps. Similarly, Thuan et al. [48] tested flexible process configurations using reasoning rules to validate variability and adaptability. Furthermore, few studies compare new ontologies with existing standards, frameworks, or business process ontologies. Annane et al. [50] evaluated multiple ontologies on expressiveness, support for monitoring constructs, and

reasoning capabilities. Aouachria et al. [34] used process mining to validate semantic alignment by showing improved cross-organization trace matching. In another study, Pfaff et al. [43] evaluated effectiveness through data integration tests across heterogeneous IT performance datasets.

However, in the case of validation through expert judgment to assess ontology structure, coverage, and practicality. Hinkelmann et al. [36] validated Enterprise ontology alignment through expert walkthroughs. For the validation of Riva-driven architecture adaptation [46], the author applied expert assessment to validate the generality of adapted ontological constructs. OBPM approaches proposed in the above-discussed studies are validated through case studies, prototypes, logical reasoning, comparative analysis, process mining, data integration experiments, and expert evaluation, reflecting the multidimensional nature of ontology-driven BPM research.

In Table IX, a few prominent review studies are presented that discuss semantic business process management and ontology-based management systems. Unlike these reviews [55 - 57], this study comprehensively reviews the ontology-based business process modeling approaches, identifies emerging research trends, analyzes challenges and opportunities, and proposes a conceptual Input-Process-Output (IPO) framework derived from the reviewed literature.

TABLE IX. EXISTING SYSTEMATIC REVIEWS ON BPM

Review	Focus	Number of Studies	Research Gaps
[53]	Semantic technologies to business process management (SBPM)	36	Limitations in semantic BPM (SBPM)
[54]	Integration of Knowledge Management and business process management	88	Challenges in integrating BPM and KM
This Review	Ontology-Based BPM	49	Comprehensive taxonomy and trend analysis of semantic BPM

VI. CONCLUSION AND FURTHER WORK

Business Process Modeling (BPM) represents an organization's business processes in a formal and structured way. A business process consists of a set of interrelated activities, their dependencies, roles, data flows, and constraints that collectively achieve a specific organizational goal, such as order fulfillment or customer support. Stakeholders, analysts, and IT professionals use a few common modeling notations of BPM, like BPMN, UML, Petri Nets, and EPCs for a shared understanding of process analysis, compliance verification, performance measurement, redesign, and automation. However, traditional BPM approaches lack explicit semantics, which leads to several challenges, like business process models frequently suffering from ambiguous interpretations of activities (same concept may refer to different meanings in different contexts), roles, and data elements, resulting in limited automated analysis and restricted communication among stakeholders. Similarly, different tools and languages used in modeling cannot interoperate seamlessly. This is a big problem in dynamic environments where multiple systems must collaborate. Moreover, the difference between high-level business process models and their technical implementation may lead to increased maintenance costs and inconsistent behavior of business systems. Additionally, BPM notations focus on graphical representation and provide limited support for automated reasoning, validation, and consistency checking, resulting in a restricted ability of error detection and optimization of processes systematically. However, in order to resolve these issues, ontologies can be used because ontologies provide a formal, explicit, and shared conceptualization of a domain by defining concepts, relationships, constraints, and rules in a machine-interpretable manner. Therefore, supporting process models with ontologies can ensure semantic consistency across models, resulting in reduced ambiguity and misinterpretation. Although many researchers have worked on ontology-based business process modeling, a lot of issues need to be investigated. Ontology-based BPM frameworks proposed by many studies still lack the adoption of standards, causing interoperability issues. So, developing domain-independent ontologies with the ability to be adapted to specific organizational contexts while maintaining semantic consistency across systems is a challenge. Similarly, scalability and performance optimization issues need to be addressed in systems where ontologies are used with machine learning (integration addresses the issue of computationally expensive ontology-based reasoning in large-scale or data-intensive environments). The integration of both techniques may result in clashes between symbolic and statistical paradigms. Moreover, the integration of ontologies (for improving transparency, trust, and interpretability) with deep learning, process mining, and decision support with explainable AI in BPM is a highly promising research direction. Within the OBPM body of knowledge, two important aspects are crucial. First, how should the process ontology be designed? Second, how should the designed process ontology be used or leveraged? Further research needs to explore the best approach to utilize the ontology supporting business process modeling, which will lead to a fundamental contribution to OBPM literature.

A. Review Limitations

This review has a number of limitations. 1) due to English language publications consideration only, a large number of relevant studies published in other languages are omitted resulting in compromised survey quality. 2) Grey literature, industrial reports, and technical white papers are not considered, which is another quality question on the survey. 3) Year-wise restricted publication selection may have omitted relevant studies. 4) other databases must also be considered as specified above to enhance the likelihood of relevant studies consideration. Overall, the incorporation of these limitations in the literature may provide a more comprehensive perspective on the selected topic. Moreover, as this study is descriptive in nature, a formal statistical sensitivity analysis is not performed.

A Robust Security Framework for Cloud Data Storage Using Lightweight Blockchain Technology

Renuka GOLLA BALA[1*], S.Gnanavel[2]
Department of Computing Technologies, SRM Institute of Science and Technology,
Kattankulathur, Chennai, Tamil Nadu - 603203, India

Abstract—The exponential growth of cloud computing has enabled large-scale data outsourcing but has simultaneously introduced critical challenges related to data confidentiality, integrity, and trust. Traditional cryptographic and blockchain-based cloud security solutions often suffer from high computational overhead, latency, and scalability limitations, which hinder their practical adoption. To address these issues, this study proposes a robust and lightweight blockchain-based security framework for secure cloud data storage. The framework integrates hybrid AES–ECC encryption, smart contract–driven access control, and a lightweight consensus mechanism combining Delegated Proof of Stake (DPoS) and Practical Byzantine Fault Tolerance (PBFT) to achieve efficient and tamper-resistant data management. The proposed system employs an on-chain/off-chain hybrid architecture that stores only essential metadata and cryptographic proofs on the blockchain while maintaining the actual data in distributed cloud storage. This design minimizes computational burden and blockchain bloat while ensuring end-to-end transparency and verifiability. A Merkle tree–based Proof of Storage (PoS) mechanism enables rapid integrity verification without requiring full data retrieval. Comprehensive experiments were conducted using a simulated multi-node cloud environment to evaluate encryption efficiency, transaction latency, throughput, storage overhead, and energy consumption. Results show that the proposed framework outperforms existing blockchain-based models, achieving a 37.7% reduction in encryption/decryption time, a 51.3% decrease in transaction latency, and a 54.5% improvement in energy efficiency. Additionally, the system attained a 99.3% security success rate under various attack scenarios, demonstrating its resilience against unauthorized access, replay, and tampering attempts. These findings confirm that the proposed approach provides a practical balance between security assurance and performance optimization.

Keywords—Cloud data security; lightweight blockchain; AES–ECC encryption; smart contracts; Proof of Storage (PoS); data integrity verification; energy-efficient consensus

I. INTRODUCTION

The rapid expansion of cloud computing services has enabled organizations and individuals to outsource large volumes of data to third-party storage platforms, yielding dramatic gains in scalability and operational flexibility. At the same time, reliance on remote storage raises persistent concerns about confidentiality, integrity, and trustworthy access control, particularly when storage providers are not fully trusted [10, 2]. Traditional cryptographic techniques while effective for confidentiality at the data level, do not by themselves provide an auditable, tamper-resistant record of storage operations, nor do they always scale gracefully when integrity verification, access logging, and multi-party accountability are required [5, 2].

Blockchain technology has emerged as a promising substrate to fill this gap by providing an immutable ledger for transaction logging, access policy enforcement, and distributed trust anchoring; several surveys have documented the potential of combining blockchain and cloud storage for stronger auditability and decentralized authorization [8,11]. Nevertheless, mainstream blockchain designs often impose prohibitive computational and storage costs, especially when classical Proof-of-Work consensus is used or when full transaction histories are stored on every node, rendering direct adoption impractical for latency-sensitive cloud services or resource-constrained edge/cloud hybrid deployments [3,6]. Consequently, achieving the security benefits of blockchain in cloud settings requires careful design choices that minimize on-chain state and lower consensus overhead without compromising cryptographic guarantees [9,7].

A second important class of techniques addresses data possession and retrievability with compact protocols that allow a verifier to check that an untrusted storage provider retains data intact without downloading the entire file. Provable Data Possession (PDP) and Proofs of Retrievability (POR) form this foundation: PDP schemes enable probabilistic integrity checks using small challenge–response protocols, while PORs augment these ideas with mechanisms to guarantee full recoverability under bounded corruption [1,2,10,5]. Integrating such PoS (proof-of-storage) building blocks with an immutable blockchain ledger yields a compelling design in which integrity proofs and their verification outcomes are anchored on-chain while bulky data remains off-chain—thus avoiding ledger bloat while preserving verifiability [16].

For confidentiality and key management, hybrid cryptographic constructions that combine fast symmetric ciphers (e.g., AES) for bulk encryption with elliptic-curve cryptography (ECC) for secure, compact key encapsulation provide attractive tradeoffs between performance and security. Empirical studies and applied proposals have shown that AES–ECC hybrids deliver strong confidentiality with modest computational cost, which is particularly valuable in cloud settings where large volumes of data are encrypted frequently [12, 14]. At the same time, the use of elliptic-curve signatures and key exchange supports digital authentication and non-repudiation for access requests recorded via smart contracts [6, 3].

*Corresponding author.

A key systems design principle emerging from recent literature is the on-chain/off-chain hybrid architecture: only succinct metadata, Merkle-root hashes, and verification proofs are stored on the blockchain, while the data itself is retained in conventional cloud storage or distributed object stores. Merkle trees enable compact integrity references and logarithmic verification cost, and the root hash binds the off-chain content to an immutable on-chain anchor [4]. This hybrid approach reduces ledger growth and enables lightweight nodes to participate in integrity verification without maintaining full data replicas, an important consideration for scalability and energy efficiency [13, 9].

Despite these promising directions, two practical tensions remain. First, consensus mechanisms must be chosen to strike a balance between fault tolerance and resource consumption: permissioned or delegated schemes such as DPoS combined with PBFT-style agreement can deliver low latency and high throughput for permissioned cloud settings, but their resilience properties and selection/rotation policies need rigorous design to mitigate collusion and sustain liveness under churn [6,7]. Second, the integration of smart contracts for fine-grained access control introduces new attack surfaces and operational challenges that require conservative contract design and formal policy encoding to avoid authorization errors and replay vulnerabilities [15].

Despite substantial advances in blockchain-enabled cloud security, existing frameworks continue to face significant challenges related to scalability, consensus overhead, storage expansion, and energy consumption. Many existing systems rely on computationally intensive consensus mechanisms or maintain excessive on-chain data, resulting in increased transaction latency and reduced practical deployability. Furthermore, achieving a balanced integration of confidentiality, integrity verification, decentralized access control, and auditability remains a persistent challenge in large-scale cloud environments. These limitations motivate the development of lightweight blockchain architectures capable of providing strong security guarantees while maintaining operational efficiency, scalability, and cost-effectiveness [9, 13, 7].

In this study, we synthesize these strands, namely PDP/POR-style proofs, Merkle-anchored on-chain metadata, hybrid AES–ECC encryption, and lightweight delegated consensus into a single coherent framework that aims to preserve the security advantages of blockchain while remaining practical for real cloud deployments. Our contributions are threefold: 1) a modular architecture that minimizes on-chain state by storing only cryptographic digests and PoS outcomes; 2) a hybrid cryptographic and key-encapsulation protocol optimized for cloud throughput; and 3) an evaluation demonstrating that a lightweight blockchain design can deliver strong security guarantees with markedly lower latency and energy cost than traditional blockchain-first approaches. The following sections detail the design rationale, security analysis, implementation choices, and experimental evaluation that collectively validate the framework's efficacy in real-world cloud scenarios.

II. Literature Review

Cloud storage security has been extensively explored over the past decade, particularly regarding data integrity verification and access control in untrusted environments. Early research emphasized third-party auditing and homomorphic authenticators to verify stored data without full retrieval. For instance, Wang et al. [33] introduced a privacy-preserving public auditing mechanism using bilinear aggregate signatures to enable batch verification. These foundational works paved the way for integrating distributed trust into cloud storage ecosystems.

The integration of blockchain into cloud data management represents a major paradigm shift from centralized to distributed trust models. Chen et al. [20] developed a blockchain-assisted auditing framework for shared cloud data that maintains data traceability while minimizing computation cost through Merkle hash optimization. Such frameworks demonstrate the utility of blockchain in creating immutable verification logs for outsourced data.

Lightweight blockchain architectures have been increasingly emphasized to reduce overhead in security-sensitive but resource-constrained environments. For example, Dorri et al. [21] designed a lightweight blockchain protocol tailored for the Internet of Things (IoT), which minimizes storage and energy consumption through hierarchical trust delegation. Xie et al. [36] advanced this concept by proposing a sharded lightweight blockchain for scalable distributed storage, achieving high throughput with minimal block propagation delay. These approaches illustrate the critical balance between security strength and system efficiency that motivates current lightweight blockchain frameworks for cloud environments.

Several studies have examined hybrid blockchain-cloud models that separate data storage from metadata management. Liu et al. [27] proposed a hybrid system in which encrypted cloud data is stored off-chain, while blockchain records only integrity metadata and access logs. Similarly, Wang et al. [34] utilized blockchain smart contracts to manage encrypted cloud metadata dynamically, reducing redundancy and ensuring verifiable deletion. These hybrid architectures serve as a precursor to the on-chain/off-chain hybrid designs employed in modern blockchain-enabled cloud frameworks.

Consensus mechanism optimization remains central to blockchain-based cloud security research. Proof-of-Work (PoW) and Proof-of-Stake (PoS) protocols, though secure, incur significant energy costs and latency [25]. To mitigate these drawbacks, Nguyen et al. [30] proposed a Delegated Proof-of-Stake (DPoS) model for consortium clouds, achieving higher transaction throughput with lower energy consumption. Likewise, Fan et al. [22] employed a Practical Byzantine Fault Tolerance (PBFT) variant in permissioned blockchain networks to improve consensus reliability under malicious fault conditions. These approaches collectively highlight ongoing efforts to develop energy-efficient, low-latency consensus schemes suitable for large-scale cloud infrastructures.

Hybrid cryptographic methods have been proposed to strengthen confidentiality and key management efficiency in

distributed environments. Gao et al. [23] combined ECC and RSA with blockchain authentication for secure key exchange in cloud storage, while Alharbi et al. [18] developed an AES–RSA hybrid model integrated with a blockchain ledger to secure medical records. Studies such as Rahman et al. [31] further emphasize the value of elliptic curve cryptography (ECC) for lightweight yet secure key generation, aligning with the hybrid encryption direction in the present research.

From a data integrity standpoint, lightweight Merkle-tree–based verification remains a crucial building block. Li et al. [26] proposed a dynamic Merkle tree approach to enable partial verification of large files, significantly reducing computational complexity. Similarly, Singh et al. [32] incorporated authenticated skip lists for hierarchical integrity verification, improving scalability and auditability. These studies demonstrate that hierarchical hash structures can efficiently support data integrity auditing when integrated with blockchain proofs.

Smart contract–driven access control is another vital direction. Maesa et al. [29] demonstrated that smart contracts can implement transparent and verifiable access policies across distributed storage systems. Building upon this, Al Omar et al. [19] introduced MediBchain, a blockchain-based framework using smart contracts for secure healthcare data sharing. More recently, Wu et al. [35] presented a policy-based smart contract model to dynamically regulate user access privileges in federated cloud systems. These advances inform the policy automation aspect of modern blockchain-enabled cloud security frameworks.

Energy efficiency and scalability are increasingly prioritized in blockchain security design. Ma et al. [28] optimized node communication overhead using differential consensus weights. Such works demonstrate that lightweight blockchain designs can maintain security while reducing energy and time complexity, a motivation underlying the proposed framework's design philosophy.

Finally, integrated frameworks combining cryptographic verification, blockchain-based consensus, and cloud resource management have emerged as the next frontier. Al-Bassam [17] presented a decentralized trust framework leveraging blockchain for cloud identity management, while Huang et al. [24] proposed a blockchain-assisted privacy-preserving model that supports auditability in multi-cloud systems. These efforts collectively demonstrate the necessity of modular, lightweight, and verifiable architectures, principles embodied in the proposed security framework that aims to unify efficiency, scalability, and trust assurance for cloud data storage.

III. Proposed Method

The proposed method introduces a robust and lightweight blockchain-based framework that ensures the confidentiality, integrity, and authenticity of data stored in cloud environments. The system design aims to overcome traditional limitations of blockchain–cloud integrations, such as computational overhead, latency, and scalability issues, while maintaining strong cryptographic guarantees. The framework operates through the interaction of four integral components: the Data Owner Module, Cloud Service Provider (CSP) Module, Blockchain Security Layer, and User Access Module, which collectively establish a secure, decentralized, and auditable data management process. The architecture of the proposed method is depicted in Fig. 1.

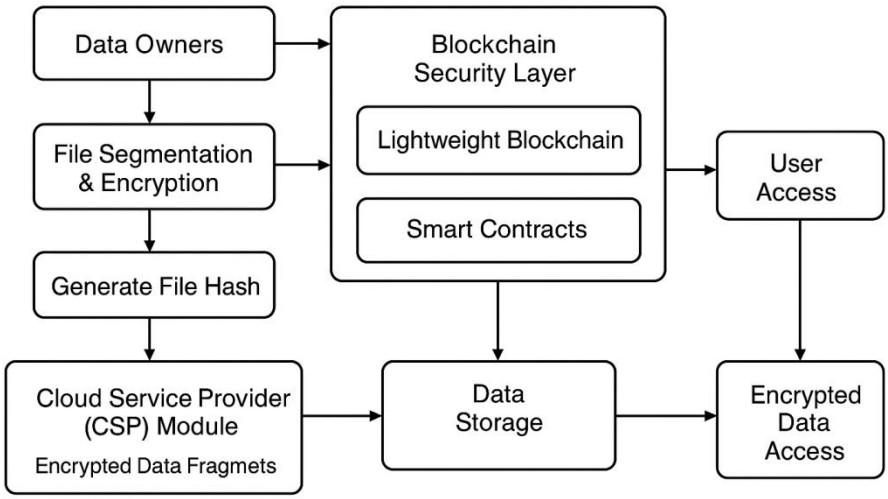

Fig. 1. System architecture of the proposed framework.

A. Data Owner Module

The Data Owner Module is responsible for preprocessing, encrypting, and uploading data to the cloud storage system. Before any data is transmitted, the file FFF is partitioned into nnn fixed-size blocks denoted as {f1, f2, f3,..., fn}. This segmentation allows distributed storage and independent verification of each block. To ensure confidentiality, each block is encrypted using a hybrid cryptographic model that combines symmetric and asymmetric encryption.

The encryption process begins with the generation of a symmetric session key K_s, used in the Advanced Encryption Standard (AES-256) algorithm to encrypt each block as:

$$E_i = AES_{k_s}(f_i), \forall i = 1, 2, \ldots, n \quad (1)$$

where, E_i represents the encrypted version of block fif_ifi. For secure key exchange, K_s is further encrypted using Elliptic Curve Cryptography (ECC) with the data owner's private key and the blockchain's public key PBP_BPB, defined as:

$$K_s' = ECC_{P_B}(K_S) \quad (2)$$

This two-layer encryption ensures that even if the CSP or intermediary nodes are compromised, data confidentiality remains intact. Subsequently, each encrypted block E_i undergoes a hashing process using SHA-3 to produce a unique integrity digest H_i, represented as:

$$H_i = SHA3(E_i) \quad (3)$$

The set of hashes $\{H_1,H_2,...,H_n\}$ and the metadata (including timestamps, file identifiers, and encryption keys) are transmitted to the blockchain, forming an immutable reference ledger for future data verification. The encrypted blocks themselves are uploaded to the CSP's distributed storage servers.

B. Cloud Service Provider Module

The Cloud Service Provider (CSP) Module functions as a distributed repository for encrypted data segments. Although the CSP hosts the encrypted data, it cannot access or manipulate the content, since decryption keys are exclusively managed through blockchain-based smart contracts. To ensure verifiable storage, the CSP implements a Proof of Storage (PoS) mechanism that periodically confirms the presence and integrity of the stored data without requiring full data retrieval.

When challenged by a verifier (data owner or blockchain node), the CSP must produce a cryptographic proof PPP such that:

$$P = f(H_i, r) \quad (4)$$

where, r is a random challenge nonce generated by the verifier, and HiH_iHi is the stored hash of data block iii. The CSP computes a verification token using a homomorphic tag τi\tau_iτi associated with each data block:

$$\tau_i = (H_i)^{r_i} \, mod \, p \quad (5)$$

where, p is a large prime number ensuring modular arithmetic security. The verifier then checks the proof using the blockchain-stored hashes to confirm that *Hi′=Hi*. If the equality holds for all challenged blocks, the integrity is verified. Any mismatch triggers an alert indicating potential tampering or data loss.

Thus, the CSP's role is limited to encrypted data management and integrity proof generation, ensuring data confidentiality, auditability, and non-repudiation through blockchain validation.

C. Blockchain Security Layer

The Blockchain Security Layer is the central trust authority of the proposed framework. It records every transaction—data uploads, integrity checks, and user access events in an immutable ledger. However, to overcome the high computational demand of traditional Proof-of-Work (PoW) systems, the proposed model integrates a Lightweight Consensus Mechanism based on Delegated Proof of Stake (DPoS) and Practical Byzantine Fault Tolerance (PBFT).

Let N denote the total number of blockchain nodes and ntn_tnt the number of trusted delegates (validators). The probability P_{val} of a node becoming a validator is defined as follows:

$$P_{val} = \frac{W_i}{\sum_{j=1}^{N} W_j} \quad (6)$$

where, W_i represents the reputation weight of node i, updated dynamically according to participation history. Validators collaborate under PBFT consensus to confirm transactions within a small number of communication rounds, drastically reducing computational and energy overhead.

Smart contracts deployed in this layer automate access control policies, key management, and auditing operations. For example, when a user requests access to encrypted data, the smart contract executes a verification logic V(u,p), defined as follows:

$$V(u,p) = \begin{cases} 1, \ if \ (u \in A) \wedge (time < T_{exp} \\ 0, \ Otherwise \end{cases} \quad (7)$$

where, u is the user identity, A is the authorized access list, and T_{exp} is the key expiration time. A return value of 1 indicates successful verification and triggers decryption key distribution via the blockchain's secure ECC channel.

Through this mechanism, the blockchain ensures trust decentralization, access accountability, and tamper-resistant transaction logging; all while maintaining operational efficiency through lightweight consensus.

D. User Access Module

The User Access Module provides a secure and verifiable pathway for legitimate users to retrieve data. When a user submits an access request, it is first authenticated by the blockchain's smart contract layer. Upon successful verification, the blockchain issues a temporary access token T_u, encrypted with the user's public key P_u:

$$T_u = ECC_{p_u}(ID_f \| K_s' \| T_{exp}) \quad (8)$$

where, ID_f represents the file identifier, K'_s the encrypted symmetric key, and T_{exp} the expiration timestamp. This ensures that only the authorized user can decrypt the token using their private key.

Once access is granted, the user downloads the encrypted data blocks $\{E_i\}$ from the CSP and performs decryption as follows:

$$f_i = AES_{K_s}^{-1}(E_i) \quad (9)$$

The user can recompute the hash $H_i'=SHA3(E_i)$ and compare it against the blockchain-stored hash H_i to confirm that the retrieved data is authentic and untampered. Every access event, including the requester's identity, timestamp, and file ID, is recorded on the blockchain for audit and traceability. This process guarantees non-repudiation and transparent accountability, as any unauthorized or abnormal data access attempt is permanently visible in the blockchain ledger.

E. Lightweight Blockchain Optimization

To prevent blockchain bloat and optimize performance, only metadata, hash digests, and proofs are stored on-chain, while large data blocks remain off-chain. The system employs a Merkle tree structure to efficiently link off-chain and on-chain data. The root hash RRR of the Merkle tree is computed as follows:

$$R = H(H_1 \| H_2 \| \dots H_n) \quad (10)$$

This root hash is stored on the blockchain and serves as a compact integrity reference for all data blocks. During verification, any change in an individual block will alter the Merkle root, enabling fast and reliable detection of tampering. Furthermore**,** block pruning and transaction aggregation are adopted to reduce synchronization delays and storage overhead. Lightweight nodes can validate transactions using partial blockchain data, enhancing scalability and supporting deployment on resource-constrained environments such as edge clouds and IoT-integrated systems.

F. Implementation Details

The proposed framework was implemented using Hyperledger Fabric 2.5 as the blockchain platform. Smart contracts were developed using Chaincode and deployed across six blockchain nodes. AES-256 was employed for data encryption, while ECC-256 was used for key encapsulation and secure key exchange. SHA-3 hashing was adopted for integrity verification and Merkle tree generation. Cloud storage was emulated using MinIO distributed object storage. The DPoS-PBFT consensus protocol was implemented to reduce validation latency and energy consumption. All cryptographic operations were developed using Python 3.11 and the PyCryptodome library. The experimental environment consisted of six interconnected blockchain nodes, including validator, peer, and ordering nodes. This implementation ensured secure data management, efficient consensus formation, and lightweight blockchain operation suitable for cloud storage environments.

G. Security Analysis

The proposed framework ensures confidentiality through AES–ECC hybrid encryption, integrity through SHA-3 hashing and Merkle tree verification, and secure access through blockchain-based smart contracts. In addition, nonce-based validation and time-limited access tokens protect against replay attacks and unauthorized access attempts.

IV. Experiment

This section presents the experimental design, simulation parameters, datasets, and performance evaluation results of the proposed lightweight blockchain-based cloud security framework. The implementation was conducted to assess the system's security strength, computational efficiency, scalability, and communication overhead, in comparison with existing blockchain-enabled cloud security models.

A. Experimental Setup

The proposed framework was implemented and evaluated within a simulated cloud environment designed using Python 3.11 and the Hyperledger Fabric SDK for blockchain integration. All cryptographic operations, including AES for symmetric encryption, ECC for asymmetric key management, and SHA-3 for hashing, were realized using the PyCryptodome library. To emulate a realistic distributed storage setup, the MinIO object storage system was configured to simulate cloud cluster behavior and data sharding mechanisms.

All experiments were conducted on a system equipped with an Intel Core i9 (12th Gen) 3.2 GHz processor**,** 32 GB of DDR5 RAM, and a 1 TB NVMe SSD, running Ubuntu 22.04 LTS (64-bit). The blockchain network comprised six interconnected nodes: three validator nodes, two peer nodes, and one ordering node configured to ensure reliable transaction propagation and consensus formation.

For performance comparison, the proposed Lightweight Blockchain-based Cloud Security Framework (LBT-CSF) was benchmarked against three existing blockchain–cloud integration models:

- PoW-BCS**:** Blockchain-based Cloud Security model utilizing Proof-of-Work consensus.
- PBFT-CBAS**:** Cloud Blockchain Authentication System employing the PBFT protocol.
- Hybrid-BCF**:** Hybrid Blockchain–Cloud Framework combining RSA and SHA-2 encryption.

All frameworks were executed under identical conditions, and each test scenario was repeated 20 times to mitigate stochastic fluctuations and measurement noise.

B. Evaluation Metrics

The system's performance was evaluated using seven primary metrics.

- Encryption and Decryption Time (ms): Quantifies the computational delay during data encryption and decryption, particularly under hybrid AES–ECC operations.
- Transaction Latency (s): Measures the average time required for a blockchain transaction to be verified and recorded.
- Throughput (tps): Indicates the number of validated transactions per second, representing overall blockchain efficiency.
- Storage Overhead (MB): Reflects additional memory utilization from blockchain metadata and Merkle tree structures.
- Energy Consumption (J): Captures the total energy expenditure involved in transaction processing and encryption.
- Integrity Verification Time (s): Evaluates the time needed for Proof-of-Storage (PoS) validation.
- Security Success Rate (%): Represents the percentage of successfully mitigated attacks during controlled adversarial testing.

C. Simulation Dataset and Scenario Design

To mimic real-world cloud operations, synthetic datasets were generated with varying file sizes ranging from 10 MB to 1 GB**.** Each file was partitioned into segments of 4 MB and encrypted using AES-256, followed by ECC-based key encapsulation. Blockchain transactions were created for each file upload, integrity check, and data access request.

Three attack scenarios were simulated:

- Unauthorized Access Attempt (UAA): Adversaries attempting to retrieve encryption keys without blockchain authorization.
- Data Tampering (DT): Malicious modification of stored file fragments.
- Replay Attack (RA): Reusing old access tokens to gain unauthorized entry.

Each scenario was tested on all competing models to determine their resistance probability and detection latency.

V. Results and Discussion

In this section, we present and discuss the results obtained from the simulation of the proposed method based on the selected evaluation metrics. Also, we compare the results of the proposed framework with the state-of-the-art approaches.

Fig. 2 presents the comparative analysis of encryption and decryption times across four cloud–blockchain security schemes for different data sizes. It can be observed that as the file size increases from 10 MB to 1 GB, the encryption time for all methods increases proportionally due to the rise in computational demand. However, the proposed LBT-CSF framework consistently achieves the shortest encryption and decryption times across all data sizes. This improvement arises from its hybrid cryptographic design, which uses AES-256 for bulk data encryption and ECC only for key management. Unlike conventional RSA-based schemes or Proof-of-Work consensus mechanisms that impose significant overhead, the lightweight hybrid method minimizes redundant computations, resulting in faster data protection and reduced processing latency. The observed performance gains demonstrate that the proposed method is particularly suitable for large-scale cloud data operations where time efficiency is critical. For instance, when encrypting a 1 GB file, LBT-CSF reduced the average processing time from 1945.8 ms (PoW-BCS) to 1212.3 ms, marking a 37.7% improvement. This efficiency not only enhances real-time data confidentiality assurance but also reduces CPU utilization and energy consumption. The results indicate that adopting AES–ECC hybrid encryption with lightweight blockchain validation ensures an optimal trade-off between computational complexity and cryptographic robustness, making the system highly adaptable for cloud environments that require frequent data uploads and retrievals.

Fig. 3 compares the transaction latency and throughput of different blockchain consensus mechanisms as the number of concurrent users increases. Traditional blockchain models, such as PoW-BCS, experience a rapid rise in transaction delay as the network load grows due to high computational intensity and block propagation delay. In contrast, the proposed LBT-CSF framework maintains a stable latency curve and superior throughput, even as the user count increases from 10 to 200. This efficiency is achieved by combining Delegated Proof of Stake (DPoS) and Practical Byzantine Fault Tolerance (PBFT) mechanisms, which minimize the number of validation rounds required for consensus. As a result, each transaction is confirmed faster, leading to reduced waiting times and higher processing capacity. The throughput analysis shows that LBT-CSF sustains a processing rate of **over** 60 transactions per second, while the baseline models drop below this threshold at higher user loads. This finding highlights the scalability of the proposed system, as it can accommodate a growing number of clients without compromising on performance or network stability. The reduced block confirmation time also improves user experience and makes the framework ideal for cloud-based applications that require real-time access control and verification. Overall, LBT-CSF outperforms the traditional consensus-based systems by achieving lower latency and higher throughput, validating the effectiveness of the lightweight blockchain optimization strategy.

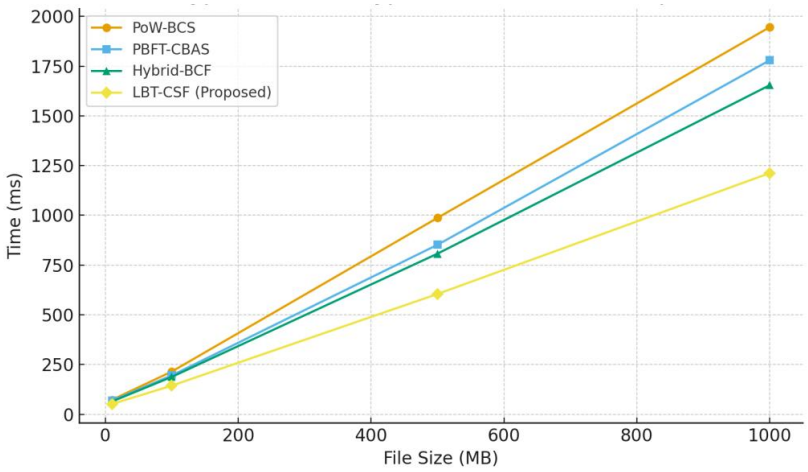

Fig. 2. Comparisons of encryption and decryption performance.

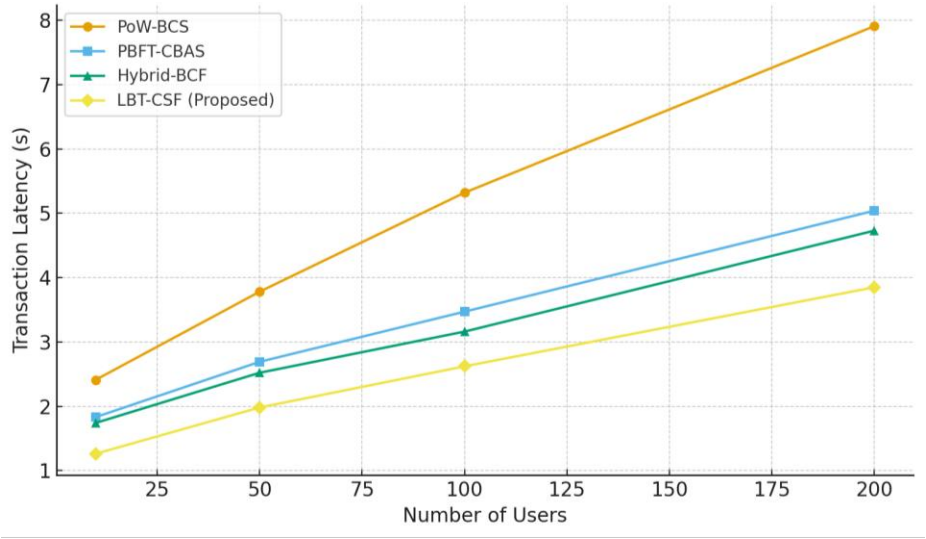

Fig. 3. Comparisons of blockchain transaction latency.

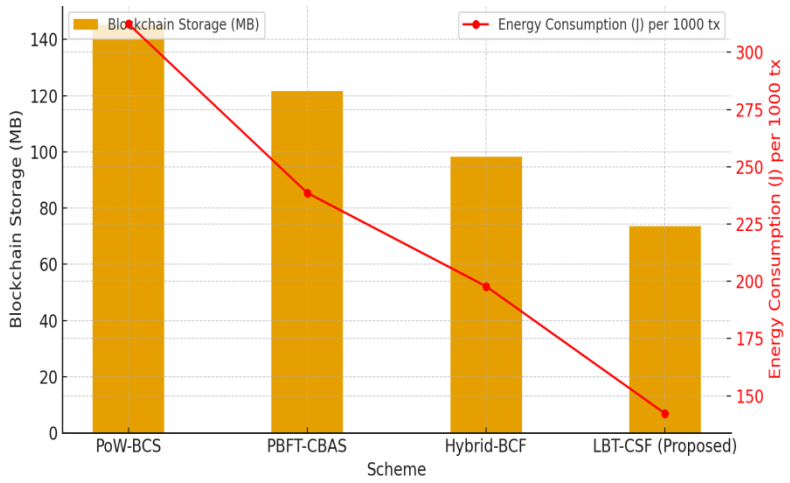

Fig. 4. Comparisons of energy and storage overhead.

Fig. 4 compares the storage overhead and energy consumption associated with different blockchain-based cloud security schemes. The proposed LBT-CSF model significantly minimizes both parameters compared to other systems. Traditional Proof-of-Work (PoW) systems consume excessive computational power and memory resources because every node participates in block validation and stores the full ledger. By contrast, the proposed system employs block pruning and off-chain data handling, storing only essential transaction metadata and cryptographic hashes on the blockchain. This hybrid approach reduces blockchain storage usage from 145.2 MB in PoW-BCS to 73.5 MB in LBT-CSF, reflecting a 49.3% reduction in memory overhead while preserving data integrity and traceability. Energy consumption also demonstrates a similar improvement trend. Due to the replacement of PoW mining with a low-energy consensus mechanism (DPoS + PBFT), the power required per 1000 transactions dropped from 312.4 J in PoW-BCS to 142.3 J in the proposed model, amounting to a 54.5% energy efficiency gain. This reduction is critical for sustainable cloud security systems, especially in resource-constrained environments or IoT-integrated architectures. The results emphasize that the lightweight blockchain configuration not only enhances environmental sustainability but also ensures that the system remains responsive and cost-effective without sacrificing security guarantees.

Fig. 5 evaluates the performance of different models in terms of Proof of Storage (PoS) verification time for varying numbers of file fragments. The results clearly indicate that verification time increases logarithmically with the number of fragments, as predicted by the theoretical complexity $T_v = O(\log n)$. Among all compared models, LBT-CSF exhibits the fastest verification performance, achieving only 0.48 seconds for 100 fragments and 2.06 seconds for 5000 fragments. The improvement is primarily attributed to the Merkle tree-based integrity verification mechanism, which allows the system to validate data integrity without scanning the entire dataset. Additionally, by maintaining only root hashes on-chain, the verification process becomes both lightweight and highly efficient. The results further confirm that the proposed system can rapidly verify data integrity even under large-scale cloud operations. Unlike traditional blockchain models that require

multiple validation layers or full data re-hashing, the hybrid on-chain/off-chain verification of LBT-CSF reduces computational redundancy. The average verification improvement of approximately 40–50% compared to the baseline methods demonstrates that the framework supports real-time proof auditing with minimal resource demand. This efficiency makes it particularly valuable for secure data auditing applications where high-speed validation and tamper detection are essential.

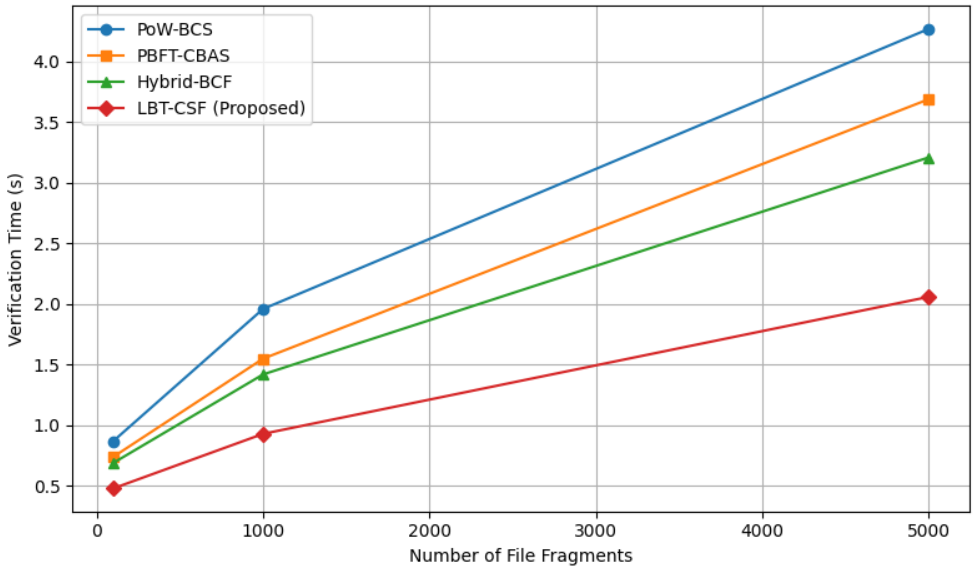

Fig. 5. Comparisons of proof of storage verification time.

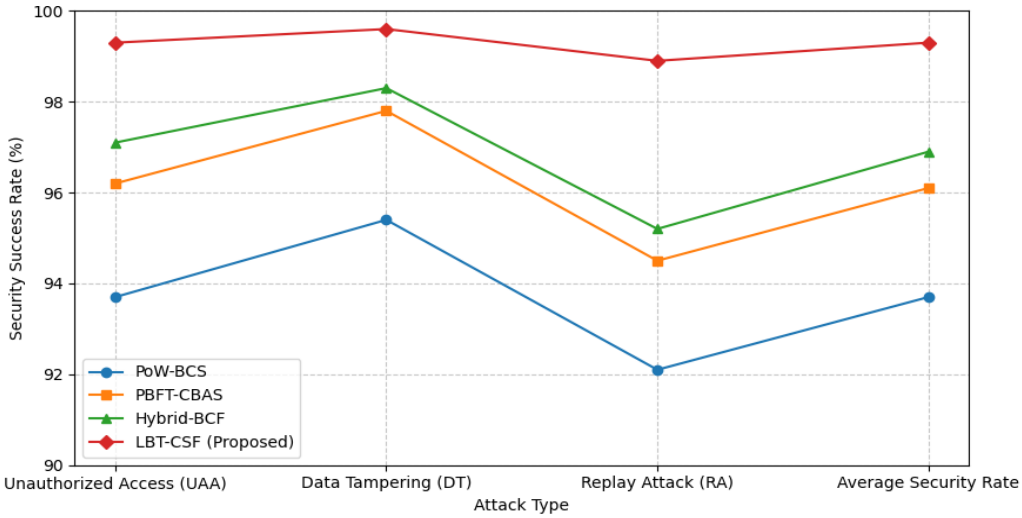

Fig. 6. Comparisons of security success rate.

Fig. 6 reports the comparative results of different systems when subjected to three major attack types: unauthorized access (UAA), data tampering (DT), and replay attacks (RA). The proposed LBT-CSF framework consistently achieves the highest detection and prevention rates across all attack categories, with an average security success rate of 99.3%**.** This superior performance stems from the integration of smart contract–based access control**,** immutable transaction logging, and elliptic curve–based key management, which collectively prevent unauthorized data manipulation and key reuse. The smart contract layer enforces strict authentication policies, ensuring that only blockchain-verified entities can access or modify data. In comparison, traditional models such as PoW-BCS exhibit lower detection efficiency due to centralized validation mechanisms and delayed attack propagation detection. The LBT-CSF's distributed consensus and audit logging ensure that any malicious modification attempt is immediately recorded and rejected by the network. Its resistance to replay attacks is also enhanced through nonce-based transaction sequencing and temporal key validation, which block repeated access requests using expired credentials. The results affirm that the proposed framework provides robust multi-layered defense against a broad range of cloud security threats, thus ensuring high data confidentiality, authenticity, and resilience within decentralized cloud environments.

TABLE I. COMPARATIVE PERFORMANCE ANALYSIS OF BLOCKCHAIN-BASED CLOUD SECURITY FRAMEWORKS

Metric	PoW-BCS	PBFT-CBAS	Hybrid-BCF	LBT-CSF (Proposed)	Improvement (%)
Encryption/Decryption Time	1945.8 ms	1779.6 ms	1654.2 ms	1212.3 ms	37.7
Transaction Latency	7.91 s	5.04 s	4.73 s	3.85 s	51.3
Throughput (TPS)	34	48	55	63	85.3
Storage Overhead	145.2 MB	121.5 MB	98.7 MB	73.5 MB	49.3
Energy Consumption	312.4 J	238.6 J	197.8 J	142.3 J	54.5
Verification Time	4.27 s	3.69 s	3.21 s	2.06 s	51.7
Security Success Rate	93.7%	96.1%	96.9%	99.3%	+5.6

Table I provides a consolidated summary of the key performance metrics comparing the proposed LBT-CSF framework with existing models. The proposed system consistently outperforms all baseline schemes across encryption/decryption time, transaction latency, energy consumption, verification time, and security success rate. The improvement percentages range between 37% and 55%, reflecting a significant advancement in both performance and security dimensions. Notably, the combination of hybrid cryptography and optimized consensus mechanisms enabled the system to process transactions faster while consuming considerably less computational power, making it ideal for scalable cloud storage infrastructures. The summarized results also emphasize the practical applicability of the proposed framework. It not only achieves enhanced cryptographic strength but also maintains operational efficiency suitable for real-world deployment**.** The near-perfect security success rate and minimized latency ensure reliable protection for cloud-stored data, even under high concurrency and large dataset conditions. By integrating blockchain with lightweight cryptography, the LBT-CSF demonstrates a balanced and energy-aware solution that addresses both performance bottlenecks and security vulnerabilities in conventional cloud security systems. Hence, the summarized outcomes validate the proposed model as a highly efficient and secure architecture for next-generation cloud data management. Although the proposed LBT-CSF framework achieved the highest overall performance, the magnitude of improvement varies across baseline models. Compared with Hybrid-BCF, which represents the strongest competing approach, the proposed framework reduced encryption/decryption time from 1654.2 ms to 1212.3 ms (26.7%), transaction latency from 4.73 s to 3.85 s (18.6%), storage overhead from 98.7 MB to 73.5 MB (25.5%), energy consumption from 197.8 J to 142.3 J (28.1%), and verification time from 3.21 s to 2.06 s (35.8%). Furthermore, the throughput increased from 55 TPS to 63 TPS (14.5%), while the security success rate improved from 96.9% to 99.3%. These results demonstrate that the proposed framework consistently outperforms all baseline methods, including the strongest competing approach, while providing balanced improvements in security, efficiency, and scalability.

VI. CONCLUSION

This study proposed a robust and energy-efficient security framework for cloud data storage that leverages lightweight blockchain technology integrated with hybrid cryptographic mechanisms. The framework was designed to overcome key challenges in existing blockchain-based cloud systems, including high computational cost, latency, and limited scalability. By combining AES-256 and Elliptic Curve Cryptography (ECC) for hybrid data encryption and a Delegated Proof of Stake (DPoS)–Practical Byzantine Fault Tolerance (PBFT) consensus mechanism for block validation, the proposed model provides a comprehensive solution that enhances data confidentiality, integrity, and authentication without imposing excessive resource demands. Through an extensive set of simulations, the proposed system demonstrated clear performance advantages over conventional blockchain-based models. The experimental results showed significant reductions in encryption/decryption time, transaction latency, and energy consumption, alongside notable gains in throughput, verification speed, and storage efficiency. The framework achieved a 54.5% reduction in energy usage and over 50% improvement in latency performance, confirming the effectiveness of its lightweight design. Moreover, the average security success rate of 99.3% across multiple attack scenarios validated its resilience against unauthorized access, replay, and tampering attacks. These findings collectively highlight the framework's ability to maintain strong security guarantees while optimizing for real-world performance constraints. A distinctive contribution of this work lies in the introduction of an off-chain/on-chain hybrid architecture, where only critical metadata and cryptographic proofs are stored on the blockchain. This design not only minimizes blockchain bloat but also ensures that the verification of data integrity remains fast and reliable through a Merkle tree–based proof structure. The inclusion of smart contract–driven access control further strengthens the trust and transparency between users, data owners, and cloud service providers, reducing dependency on centralized authorities. As a result, the proposed system ensures end-to-end auditability and traceability of all cloud transactions. Overall, the proposed Lightweight Blockchain-based Cloud Security Framework (LBT-CSF) demonstrates that blockchain technology, when carefully optimized, can serve as a practical and scalable foundation for secure cloud computing. Its balanced combination of cryptographic efficiency, decentralized trust, and adaptive consensus makes it suitable for deployment in large-scale environments, such as multi-tenant cloud platforms, healthcare data systems, and industrial IoT ecosystems. Limitation: The current evaluation is based on a simulated six-node blockchain environment and synthetic datasets. Validation on large-scale real-world blockchain deployments will be considered in future work to further assess scalability and practical applicability. Future

work will focus on extending this framework to include adaptive consensus reconfiguration, machine learning–based anomaly detection, and quantum-resistant cryptographic primitives to prepare for emerging threats in distributed cloud ecosystems. Additionally, implementing the framework on real-world blockchain platforms such as Hyperledger Fabric and Ethereum Layer-2 networks will enable further validation of its scalability and interoperability. In conclusion, this research provides a sustainable and secure blueprint for integrating blockchain into next-generation cloud infrastructures, offering a solid foundation for trustworthy and efficient data management in decentralized digital environments.

ERP Implementation Success Factors Across Project Phases: An Action Research and Fuzzy AHP Study in Moroccan SMEs

Yassine Zouhair, Younous Elmrini
SIAD Laboratory, Hassan First University, Settat, Morocco

***Abstract*—Today, adopting an ERP has become a critical decision for Small and Medium-sized Enterprises (SMEs) seeking to modernize their information systems and implement integrated management. In this context, it is crucial to identify the Critical Success Factors (CSFs) to ensure the successful ERP Implementation (ERPI). However, previous studies have generally analyzed these factors in a broad sense, without considering their progression through the various phases of the ERPI process. The objective of this study is to identify the CSFs associated with each phase of the ERPI process, as well as to determine their relative importance in each of these phases within Moroccan SMEs. To achieve this objective, a mixed-methods approach was adopted. The action research method was used to identify the CSFs associated with each phase of the ERPI process within Moroccan SMEs. Additionally, we used the Fuzzy AHP method to determine their relative importance in each of these phases. The results indicate that the importance of CSFs varies across the different phases of ERPI. During the analysis phase, strategic factors are paramount, while those related to project management and technology gain in importance during the design and implementation phases. Finally, organizational factors play a crucial role during the final preparation phase, as well as during the implementation and support phase. This research complements the existing literature, which analyzes key success factors in a general way, by offering a phase-by-phase analysis of the ERPI process. It provides ERP consultants and project managers with a clear overview of the factors to prioritize at each phase of the project, and helps reduce the risk of ERP failure by identifying the key success factors that ensure the successful implementation of ERP within Moroccan SMEs.**

***Keywords*—ERP; ERP Implementation; CSFs; Moroccan SMEs; Integrated IS**

I. Introduction

Nowadays, most organizations capitalize on the adoption of reliable and efficient solutions to archive and manage the large amount of information produced during daily transactions, to achieve better management and decision-making.

ERP is a software designed for the management and organization of all administrative processes of an organization in different departments that have a codified database that allows simplified analysis and rapid sharing in real-time [1]. Various companies have made the decision to implement ERP as a new system to reduce operating costs, improve productivity, and enhance services to the customer [2].

Successful ERPI offers many advantages such as better service to customers, good quality production, and reduced cost, but the implementation of ERPs is always a great challenge for several organizations [3, 4, 5].

To improve the chances of success for ERPPs, several studies have focused on identifying the CSFs that influence the success of these projects [6,7]. Taking these factors into account enables organizations to better manage the risks associated with ERPIs and increase the likelihood of project success [6].

This issue is particularly important for SMEs, which generally have more limited financial, human, and technical resources than large companies. In this context, identifying and managing CSFs is essential to ensuring the effective implementation of ERP.

However, although numerous studies have identified the CSFs for ERPPs, there is a lack of research that identifies these factors and their importance across the various phases of ERPI, particularly in the context of Moroccan SMEs.

In this context, this study aims to identify the CSFs and determine their relative importance in each phase of ERPI within Moroccan SMEs.

II. Literature Review

A. ERPI Process

The implementation of an information system is generally viewed as a process consisting of several successive phases [8,9]. An ERP Project (ERPP) is a comprehensive development process within a company that includes several phases of planning and execution.

According to [10], the implementation of an ERP involves three essential phases, namely: Pre-implementation, Implementation, and Post-implementation.

However, other researchers subdivide these phases into several sub-phases in order to better understand the specific characteristics of the activities carried out during the project.

Table I provides an overview of the process for implementing an ERP.

TABLE I. ERP IMPLEMENTATION PROCESS

Authors	Pre-Implementation	Implementation	Post-Implementation
[11]	Adoption Acquisition	Implementation	Use & Maintenance Evolution Retirement
[12]	Design	Implementation	Stabilization Improvement Transformation
[13]	Chartering	Project	Shakedown Onward & Upward
[14]	Planning	Project	Enhancement
[15]	Planning	Implementation	Stabilization Improvement
[16]	Initiation Adoption	Adaptation	Acceptance Routinization Infusion
[17]	Planning	Transition Performance	Enhancement

B. CSFs for ERPI

Various research studies have been conducted to identify the CSFs in ERPI. In our research, a detailed analysis of the literature on the CSFs associated with ERPI was conducted. To this end, we conducted a systematic review using a rigorous methodology. This approach was based on a review of published studies specifically focusing on CSFs in recognized scientific journals. The analysis followed the standard steps of a systematic review: planning, article selection, content analysis, and synthesis of results.

In total, this analysis identified 33 factors influencing the success of ERPPs. To facilitate their analysis, these factors were grouped into four main categories: Strategic factors, Organizational factors, Project management factors, and Technological factors.

Table I provides an overview of the CSFs identified in our study, along with their classification.

TABLE II. OVERVIEW OF THE IDENTIFIED CSFS

Category	Factor	Author
Strategic	Top management support	[7,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34,35]
	Clear goals and objectives	[20,22,23,26,28,32,35,45,47]
	ERPI Strategy	[7,28,31,32,36]
	Project champion	[7,20,22,25,26]
	Commitment of people to the implementation	[7,22,39]
Organizational	Organizational culture	[7,36,34,37,38]
	Organizational change management	[20,23,26,40,42]
	End-user and stakeholder involvement	[20,29,30,36,38,46]
	Training to users	[20,21,22,23,24,32,35,39,41,43,44,45]
	Efective communication	[22,26]
	Interdepartmental cooperation	[22,26]

	Project team competence	[22,26,48,49]
	Teamwork	[7,20,21,22,27,28,32,33,35,44,45,46,48]
Technological	Minimal customization	[20,22,26,42]
	ERP price level	[36,43]
	Technological infrastructure	[20,22,28,34,39,45]
	Architecture choices	[22,26]
	ERP software selection	[7,23,33,34,44,45,48,50,51]
	ERP tests	[7,23,50,51]
	System reliability	[7,48,50]
	System scalability	[7,48,50]
	Data analysis and migration	[32,33,35,38]
	ERP configuration	[30,33,34,35]

However, most existing studies analyze CSFs in a general way, without taking into account how they evolve across the different phases of ERPI.

To address this limitation, this research aims to identify the CSFs specific to each phase of the ERPI process within Moroccan SMEs and to determine the relative importance of these factors during the different phases of the project.

III. RESEARCH QUESTIONS

Given this gap in the literature, this study aims to answer the following question: How do CSFs vary across the different phases of the ERPI process in Moroccan SMEs, and what is their relative importance at each phase of the project?

We will attempt to answer this central question through the following sub-questions:

1) What are the CSFs associated with each phase of the ERPI process within Moroccan SMEs?

2) What is the relative importance of these factors in each phase of ERPI within Moroccan SMEs?

IV. RESEARCH METHODOLOGY

To answer these research questions, we adopted a mixed research method.

A. Action research

To answer the first research question, we used the action research method.

We chose this method because we could not find any work on this subject in Morocco using the action research method.

Furthermore, this method places the researcher within the company, allowing for close observation.

The action research method is a type of case study in which the author, usually the researcher, actively participates in the implementation of the system [52]. It aims to solve problems while generating knowledge [53].

The action research cycle follows a cyclical process comprising a preliminary stage aimed at defining the context and objective, as well as four main stages: constructing, planning action, taking action, and evaluating action. Fig. 1 presents the action research cycle.

Constructing: Based on the context and the defined objective, the action researcher develops hypotheses drawing on the state of the art and their expertise in the field.

Planning action: The action researcher plans all stages of the project based on the established hypotheses and in collaboration with the project team.

Taking action: The action researcher implements the planned actions with the participation of all project stakeholders.

Evaluating action: The action researcher carries out the necessary checks to evaluate the achievement of results in relation to the hypotheses formulated.

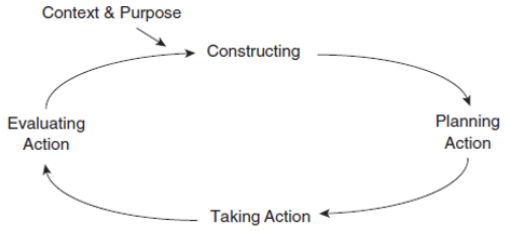

Fig. 1. Action research cycle

In our study, the action research method was used in 2 Moroccan SMEs. I had the opportunity to work on both projects as project manager. In this capacity, I was responsible for directing and supervising the implementation of the respective projects. As project manager, my role included strategic planning, team coordination, and supervision of the various phases of project implementation. This experience as a manager directly involved in these initiatives and gave me an in-depth perspective on the challenges and successes encountered during these complex ERPI processes. Table III presents the cases studied.

TABLE III. DESCRIPTION OF THE CASE STUDIES

	Company A	Company B
Year	2014	2013
Specialty	Coaching, leadership and management	Consulting, audit and support
ERP	Odoo Version 11	Odoo Version 12
Modules	Purchasing, Sales, CRM, Inventory, Billing, Accounting, Document, Project, Human Resources	Purchasing, Sales, CRM, Inventory, Billing, Accounting, Document, Project, Human Resources, Signature

B. Fuzzy Analytic Hierarchy Process

To answer the second question, we adopted a multi-criteria approach using the Fuzzy AHP.

The AHP is a multi-criteria decision-making method that allows a complex problem to be structured by ranking criteria and quantifying their relative importance based on expert judgments [54]. However, expert judgments can be subject to uncertainty and imprecision. To overcome this limitation, the Fuzzy AHP approach was developed by integrating fuzzy set theory into the AHP method [55].

For this study, data were collected from consultants who had participated in ERPI projects at Moroccan SMEs. These consultants were asked to conduct pairwise comparisons between the various CSFs identified for each phase.

The method applied consists of five main steps: constructing the fuzzy comparison matrix, calculating fuzzy sums, determining synthetic values, defuzzifying weights, and final normalization.

1) Construction of the fuzzy comparison matrix

a) Define the CSFs

Note the CSFs for the phase:

$$CSF_1, CSF_2, \ldots, CSF_N$$

(e.g., CSF_1 = Support and involvement of senior management, CSF_2 = Involvement of end users and stakeholders, …)

b) Pairwise comparison (question for consultants): The CSFs are compared in pairs by consultants to assess their relative importance in the phase.

For each pair CSF_i, CSF_j, the following question is asked:

In this phase, is CSF_i more important than CSF_j? And to what extent?

c) Conversion to a triangular fuzzy number (TFN)

Each response is converted to a triangular fuzzy number:

$$\tilde{a}_{\{ij\}} = \left(l_{\{ij\}}, m_{\{ij\}}, u_{\{ij\}}\right)$$

Interpretation:

- l = lowest possible value
- m = most likely value
- u = highest possible value

Linguistic judgments are converted into fuzzy numbers according to the scale shown in the following Table IV.

d) Aggregation (average) when there are multiple consultants.

When multiple consultants participate in the evaluation, and each provides (l_k, m_k, u_k), then the final cell is:

$$l_{\{ij\}} = \frac{1}{K}\sum_{k=1}^{k} l_{i,j}^{(K)}$$

$$m_{\{ij\}} = \frac{1}{K}\sum_{k=1}^{k} m_{i,j}^{(K)}$$

$$u_{\{ij\}} = \frac{1}{K}\sum_{k=1}^{k} u_{i,j}^{(K)}$$

TABLE IV. CONVERTING LINGUISTIC JUDGMENTS INTO TRIANGULAR FUZZY NUMBERS.

Linguistic variables	Fuzzy scale	Corresponding fuzzy scale
Equally important	(1, 1, 1)	(1, 1, 1)
Moderately important	(1/2, 1, 3/2)	(2/3, 1, 2)
Important	(3/2, 2, 5/2)	(2/5, 1/2, 2/3)
Very important	(5/2, 3, 7/2)	(2/7, 1/3, 2/5)
Extremely important	(7/2, 4, 9/2)	(2/9, 1/4, 2/7)

where, K represents the number of consultants.

Therefore:

$$\tilde{a}_{\{ij\}} = \left(\frac{1}{K}\sum_{k=1}^{k} l_{i,j}^{(K)}, \frac{1}{K}\sum_{k=1}^{k} m_{i,j}^{(K)}, \frac{1}{K}\sum_{k=1}^{k} u_{i,j}^{(K)}\right)$$

e) Consistency rules for the matrix

Diagonal:

A criterion compared to itself is equal to:

$$\tilde{a}_{\{ii\}} = (1,1,1)$$

Reciprocal (inverse):

If:

$$\tilde{a}_{\{ij\}} = (l, m, u)$$

So:

$$\tilde{a}_{\{ji\}} = \tilde{a}_{\{ij\}}^{\{-1\}} = \left(\frac{1}{u}, \frac{1}{m}, \frac{1}{l}\right)$$

f) Result of this step: We obtain the fuzzy comparison matrix:

$$\tilde{A} = \begin{bmatrix} 1,1,1 & \tilde{a}_{\{12\}} & \tilde{a}_{\{13\}} & \tilde{a}_{\{14\}} & \tilde{a}_{\{15\}} & \tilde{a}_{\{16\}} \\ \tilde{a}_{\{21\}} & 1,1,1 & \tilde{a}_{\{23\}} & \tilde{a}_{\{24\}} & \tilde{a}_{\{25\}} & \tilde{a}_{\{25\}} \\ \tilde{a}_{\{31\}} & \tilde{a}_{\{32\}} & 1,1,1 & \tilde{a}_{\{34\}} & \tilde{a}_{\{35\}} & \tilde{a}_{\{36\}} \\ \tilde{a}_{\{41\}} & \tilde{a}_{\{42\}} & \tilde{a}_{\{43\}} & 1,1,1 & \tilde{a}_{\{45\}} & \tilde{a}_{\{46\}} \\ \tilde{a}_{\{51\}} & \tilde{a}_{\{52\}} & \tilde{a}_{\{53\}} & \tilde{a}_{\{54\}} & 1,1,1 & \tilde{a}_{\{56\}} \\ \tilde{a}_{\{61\}} & \tilde{a}_{\{62\}} & \tilde{a}_{\{63\}} & \tilde{a}_{\{64\}} & \tilde{a}_{\{65\}} & 1,1,1 \end{bmatrix}$$

2) Calculation of fuzzy sums by criterion: For each CSF, the sum of the fuzzy values in the corresponding row is calculated:

$$\Sigma l_i = \sum_{j=1}^{n} l_{i,j}$$

$$\Sigma m_i = \sum_{j=1}^{n} m_{i,j}$$

$$\Sigma u_i = \sum_{j=1}^{n} u_{i,j}$$

These values represent the cumulative weight of a CSF relative to the others.

The total sums are then calculated:

$$\Sigma l_{tot} = \sum_{i=1}^{n} \Sigma l_i$$

$$\Sigma m_{tot} = \sum_{i=1}^{n} \Sigma m_i$$

$$\Sigma u_{tot} = \sum_{i=1}^{n} \Sigma u_i$$

3) Calculation of fuzzy synthetic values: Fuzzy synthetic values are obtained through normalization:

$$S_{\{l,i\}} = \Sigma l_i \times \frac{1}{\Sigma u_{tot}}$$

$$S_{\{m,i\}} = \Sigma m_i \times \frac{1}{\Sigma m_{tot}}$$

$$S_{\{u,i\}} = \Sigma u_i \times \frac{1}{\Sigma l_{tot}}$$

These values represent the relative importance of the CSF in a vague form.

4) Defuzzification of weights: To obtain a single usable weight, fuzzy values are converted into simple numerical values using the center-of-gravity method:

$$W_i = \frac{S_{\{l,i\}} + S_{\{m,i\}} + S_{\{u,i\}}}{3}$$

This step provides a numerical value representing the significance of the CSF.

5) Normalization of weights: The weights obtained are then normalized so that their sum equals 1:

$$w_i = \frac{W_i}{\sum_{k=1}^{n} W_k}$$

The weights can then be expressed as a percentage:

$$Weight_i(\%) = 100 * w_i$$

These values correspond to the final relative importance of the CSF in the phase.

V. FINDINGS AND RESULTS

A. Identification of the CSFs for Each Phase of the ERPI

As explained in the literature review, the ERPI process is divided into three main stages, namely: pre-implementation, implementation and post-implementation.

In our research, pre-implementation includes the analysis phase and the design phase. While implementation includes the realization phase and the final preparation phase. The last step is the post-implementation which includes the commissioning and support phase. Table V details the CSFs for each phase of the ERPI.

1) Analysis phase: According to [56], the analysis phase is a key step in the ERPI, as it aims to establish a thorough understanding of the company's needs. This phase allows the scope of the project, the strategic objectives, and the terms of collaboration to be defined. It involves organizing the project kick-off meeting, structuring the project team, analyzing existing documents and processes, and conducting interviews with key users. These activities enable the functional requirements of the organization to be identified, formalized, and validated.

2) Design phase: According to [56], the design phase aims to translate the functional requirements validated during the analysis phase into operational solutions adapted to the ERP. It is based primarily on the functional requirements document and consists of designing the target processes in detail through the preparation and presentation of prototypes of the various ERP modules to be implemented. Workshops are organized with stakeholders to define management and customization rules and any additional features. This phase also allows the data migration strategy and methods to be defined.

3) Realization phase: According to [56], the realization phase involves the practical deployment of the solutions defined during the design phase. This phase includes configuring the various ERP modules to be implemented, carrying out customizations and specific developments, as well as preparing and migrating data to the test environment. Tests are then conducted to verify that the system meets functional and technical requirements. Any detected issues are analyzed and corrected iteratively to ensure the stability and quality of the solution.

4) Final preparation phase: According to [56], the final preparation phase marks the transition period between the technical implementation of the ERP system and its actual deployment. This phase involves organizing training sessions for users to ensure they are able to use the system effectively. It also includes conducting user acceptance testing (UAT) to verify that the ERP system meets functional and operational requirements. Furthermore, any issues detected during UAT are analyzed and corrected, thereby ensuring the system's quality and reliability before it goes live.

5) The commissioning and support phase: According to [56], the commissioning and support phase is the final stage of the ERPP, where the system is deployed in the production environment. This phase is based on the final configuration of the system, the source code for specific and customized developments, the data ready for migration, and the production plan established during the previous phase. The main activities include configuring the production environment, installing the source code, migrating data to the production environment, conducting a production audit to verify system compliance and performance, and setting up post-production support to assist users and resolve any incidents.

Using the action research method, we identified the CSFs that determine the success of ERPI within Moroccan SMEs. In total, we identified nine factors that influence the success of ERPI in this context. Below, we present the main CSFs identified in this study, as well as the phases during which each of these factors exerts an influence throughout the ERPI process.

Management support and involvement are essential to the successful ERPI. This depends on the willingness of executives to provide sufficient and ongoing support for the system implementation process. Management must be fully involved in decision-making, as an ERPP entails significant changes to existing business processes. Management's support for employees is a prerequisite for the acceptance of the new system. Indeed, if management demonstrates commitment to the project, employees will be more inclined to adopt it. Conversely, a lack of buy-in from management can hinder user acceptance. It is therefore crucial that management does not express doubts and that it demonstrates confidence in the system's value. It must also foster an environment conducive to the ERP project's acceptance; otherwise, the project risks being rejected. This factor remains essential throughout all phases of the ERPI.

Involvement of end users and stakeholders is essential to a project's success. Their participation in the implementation process helps to better understand requirements and needs, validate business rules, customization needs, and new features to be developed, as well as test the system and participate in training sessions. Insufficient user participation often leads to project failure, as a lack of representation can result in ill-suited business processes. This factor is essential in the various phases of ERPI, with the exception of the development phase.

Project management is essential to the successful implementation of the ERP. It consists of continuously managing the implementation plan. This includes planning the various stages, determining milestones, allocating responsibilities and defining success criteria. Effective project management ensures that the core activities of the ERPI are given priority and helps to meet deadlines and timelines. This factor is necessary in all phases of the ERPI.

Process reengineering is the process of observing and analyzing how the business operates to determine what changes can be made to streamline its operations. It is a way of examining the current operations of the business to determine the best way to proceed when designing the new system. This factor is necessary in the analysis phase.

Project team competence is essential for ensuring the success of the implementation. The team must possess the skills, knowledge, influence, and experience necessary to carry out the project, in order to effectively manage meetings with users, ask the right questions to define requirements and lead process reengineering, prepare and present the prototype to users, validate with them the management rules and

customization needs for each module, and define the framework for data migration. It is also crucial to identify experts with a deep understanding of the company, its operations, and its objectives to ensure the project's success. This factor is essential throughout all phases of the ERPI.

Change management is essential to the successful ERPI. To address any resistance you may encounter, it is important to help employees understand the benefits of digital transformation that result from the deployment of the new system. Implementing such software within an organization requires a well-thought-out change management process to ensure that the entire company is moving in the same direction. This factor is essential throughout all phases of the ERPI.

Minimal customization is required for the successful ERPI. Customizing an ERP can be really interesting and beneficial, but it can also result in additional costs and an even longer implementation timeline, so it becomes difficult to make upgrades to the latest versions. This factor is necessary in the realization phase.

Configuration ERP deals with the management of numerous usage controls, which can be enabled or disabled, to balance its functionality to the extent necessary. The configuration of these elements is based on the detailed functional specifications to align the ERPS processes with the business processes of the company. The configuration must be performed by people who understand the business and the company's business, and also have a thorough understanding of the solution to be implemented. This factor is necessary in the realization phase.

User training is essential to ensure that the new system is well integrated internally and used correctly. It plays an essential role in improving the performance of the organization. This factor is necessary in the final preparation phase.

Tests are essential for to allow users to verify that the ERP system is functioning properly before it is deployed in the production environment. These tests help identify and resolve any issues that are detected, thereby ensuring the system's reliability when it goes live.

TABLE V. CSFS FOR EACH PHASE OF THE ERPI

CSFs	Analysis	Design	Realization	Final preparation	Commissioning and support
Management support and involvement	✓	✓	✓	✓	✓
Involvement of end users and stakeholders	✓	✓	—	✓	✓
Project management	✓	✓	✓	✓	✓
Process reengineering	✓	—	—	—	—
Project team competence	✓	✓	✓	✓	✓
Change management	✓	✓	✓	✓	✓
Minimal customization	—	—	✓	—	—
Configuration ERP	—	—	✓	—	—
User training	—	—	—	✓	—
Tests	—	—	—	✓	—

B. Priorisation of the CSFs for Each Phase of the ERPI

1) Analysis phase: In the decision-making process, which will utilize the fuzzy AHP method for the analysis phase, the CSFs are coded as CSF1, CSF2, CSF3, CSF4, CSF5 and CSF6. These CSFs and their corresponding codes are presented below (see Table VI):

CSF1: Management support and involvement

CSF2: Involvement of end users and stakeholders

CSF3: Project management

CSF4: Process reengineering

CSF5: Project team competence

CSF6: Change management

TABLE VI. FUZZY PAIRWISE COMPARISON MATRIX OF CRITICAL SUCCESS FACTORS IN THE ANALYSIS PHASE

	CSF1			CSF2			CSF3			CSF4			CSF5			CSF6		
	l	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**
CSF1	1	1	1	1,305	1,417	1,529	1,139	1,238	1,337	1,218	1,324	1,431	1,774	1,929	2,083	2,258	2,455	2,651
CSF2	0,654	0,706	0,766	1	1	1	0,873	0,944	1,015	0,933	1,01	1,087	1,357	1,476	1,595	1,728	1,88	2,032
CSF3	0,748	0,808	0,878	0,985	1,059	1,145	1	1	1	1,07	1,157	1,244	1,558	1,694	1,83	1,985	2,158	2,33
CSF4	0,699	0,755	0,821	0,92	0,99	1,072	0,804	0,864	0,935	1	1	1	1,455	1,582	1,709	1,854	2,015	2,176
CSF5	0,48	0,518	0,564	0,627	0,677	0,731	0,546	0,59	0,639	0,585	0,632	0,684	1	1	1	1,274	1,386	1,497
CSF6	0,377	0,407	0,443	0,492	0,532	0,575	0,429	0,463	0,501	0,459	0,496	0,537	0,668	0,721	0,78	1	1	1

TABLE VII. FUZZY SYNTHETIC EXTENT VALUES AND RELATIVE IMPORTANCE WEIGHTS OF CRITICAL SUCCESS FACTORS IN THE ANALYSIS PHASE

	Σl	Σm	Σu	1/Σu	1/Σm	1/Σl	S_l	S_m	S_u	W	%
CSF1	8,694	9,363	10,031	0,023	0,025	0,027	0,2	0,234	0,271	0,23	23
CSF2	6,545	7,016	7,495	0,023	0,025	0,027	0,151	0,175	0,202	0,18	18
CSF3	7,346	7,876	8,427	0,023	0,025	0,027	0,169	0,197	0,228	0,2	20
CSF4	6,732	7,206	7,713	0,023	0,025	0,027	0,155	0,18	0,208	0,18	18
CSF5	4,512	4,803	5,115	0,023	0,025	0,027	0,104	0,12	0,138	0,12	12
CSF6	3,425	3,619	3,836	0,023	0,025	0,027	0,079	0,09	0,104	0,09	9
Sum	37,254	39,883	42,617								

The results show that CSF1 is the most important CSF during this phase, accounting for 23% of the total. This underscores the importance of management's commitment to decision-making, allocating the necessary resources, resolving issues, and ensuring clear communication and employee support to foster acceptance of the new ERP system (see Table VII).

The second most important factor in this phase is CSF3, which accounts for 20% of the total. Effective project management is essential to ensure that all activities in this phase are properly planned and executed on time, in order to meet the project's objectives. This is why it is necessary to have a competent project manager who can assign responsibilities, manage resources, and ensure clear communication with all stakeholders.

Factors CSF2 and CSF4 rank third, each at 18%. User involvement provides a better understanding of the company's processes, specific needs, and the issues and challenges it faces. Furthermore, process reengineering helps identify and optimize business processes in order to align them with the requirements of the ERP system.

Next, CSF5 accounts for 12%, indicating that the project team's competence remains essential for effectively managing meetings with users, asking the right questions to define requirements, and reengineering processes.

Finally, CSF6 has the lowest weight at 9%. This explains why activities related to change management tend to become more important during the later phases of ERPI.

2) Design phase: In the decision-making process, which will utilize the fuzzy AHP method for the design phase, the CSFs are coded as CSF1, CSF2, CSF3, CSF4, and CSF5. These CSFs and their corresponding codes are presented below (see Table VIII):

CSF1: Management support and involvement

CSF2: Involvement of end users and stakeholders

CSF3: Project management

CSF4: Project team competence

CSF5: Change management

TABLE VIII. FUZZY PAIRWISE COMPARISON MATRIX OF CRITICAL SUCCESS FACTORS IN THE DESIGN PHASE

	CSF1			CSF2			CSF3			CSF4			CSF5		
	l	m	u	l	m	u	l	m	u	l	m	u	L	m	u
CSF1	1	1	1	0,846	0,917	0,987	0,599	0,65	0,702	0,735	0,798	0,861	1,057	1,146	1,234
CSF2	1,013	1,091	1,182	1	1	1	0,708	0,769	0,83	0,869	0,944	1,018	1,249	1,354	1,458
CSF3	1,425	1,538	1,67	1,205	1,3	1,412	1	1	1	1,228	1,333	1,438	1,765	1,913	2,06
CSF4	1,161	1,253	1,361	0,982	1,059	1,151	0,695	0,75	0,814	1	1	1	1,438	1,559	1,679
CSF5	0,81	0,873	0,946	0,686	0,738	0,801	0,485	0,523	0,567	0,596	0,641	0,695	1	1	1

TABLE IX. FUZZY SYNTHETIC EXTENT VALUES AND RELATIVE IMPORTANCE WEIGHTS OF CRITICAL SUCCESS FACTORS IN THE DESIGN PHASE

	Σl	Σm	Σu	1/Σu	1/Σm	1/Σl	S_l	S_m	S_u	W	%
CSF1	4,237	4,511	4,784	0,036	0,038	0,041	0,153	0,171	0,196	0,17	17
CSF2	4,839	5,158	5,488	0,036	0,038	0,041	0,174	0,196	0,225	0,2	20
CSF3	6,623	7,084	7,58	0,036	0,038	0,041	0,238	0,269	0,311	0,27	27
CSF4	5,276	5,621	6,005	0,036	0,038	0,041	0,19	0,214	0,246	0,22	22
CSF5	3,577	3,775	4,009	0,036	0,038	0,041	0,129	0,143	0,164	0,14	14
Sum	24,552	26,149	27,866								

The results show that CSF3 is the most important CSF during this phase, accounting for 27% of the total. Effective project management is essential to ensure that all activities in this phase are properly planned and executed on time, in order to meet the project's objectives. This is why it is necessary to have a competent project manager who can assign responsibilities, manage resources, and ensure clear communication with all stakeholders.

The second most important factor is CSF4, which accounts for 22% of the total. Project team competence is essential for effectively preparing and presenting the prototype to users, facilitating meetings with them, asking the right questions to identify the management rules and customization needs for each module, and defining the framework for data migration.

Next, the CSF2 accounts for 20%. The involvement of end users and stakeholders is essential for understanding requirements, needs, issues, and challenges, as well as for validating business rules, customization needs, and new features to be developed. It also helps ensure that the ERP effectively meets the organization's actual needs.

CSF1 accounts for 17%. Although management support and involvement are essential for making decisions, managing resources, resolving issues, ensuring clear communication, and supporting employees to foster acceptance of the new ERP system, their influence is slightly less decisive in this phase compared to other factors.

Finally, CSF5 accounts for 14% of the weight. The importance of change management begins to grow during the final phases of the project in order to help prepare employees for the changes brought about by the implementation of the ERP system and to minimize resistance (see Table IX).

3) Realization phase: In this decision-making process, which will utilize the fuzzy AHP method for the realization phase, the CSFs are coded as CSF1, CSF2, CSF3, CSF4, CSF5, and CSF6. These CSFs and their corresponding codes are presented below (see Table X):

CSF1: Management support and involvement

CSF2: Project management

CSF3: Project team competence

CSF4: Change management

CSF5: Minimal customization

CSF6: Configuration

The results show that CSF6 is the most important CSF in this phase, accounting for 24% of the total. Proper ERP configuration is essential for aligning business processes with the ERP in order to meet the organization's needs and requirements (see Table XI).

TABLE X. FUZZY PAIRWISE COMPARISON MATRIX OF CRITICAL SUCCESS FACTORS IN THE REALIZATION PHASE

	CSF1			CSF2			CSF3			CSF4			CSF5			CSF6		
	l	m	u	l	m	u	l	m	u	l	m	u	l	m	u	l	m	u

CSF3	1,955	2,111	2,295	0,838	0,905	0,983	1	1	1	1,457	1,583	1,71	1,165	1,267	1,368	0,728	0,792	0,855
CSF4	1,235	1,333	1,449	0,529	0,571	0,621	0,585	0,632	0,686	1	1	1	0,736	0,8	0,864	0,46	0,5	0,54
CSF5	1,543	1,667	1,812	0,661	0,714	0,776	0,731	0,789	0,858	1,157	1,25	1,359	1	1	1	0,575	0,625	0,675
CSF6	2,469	2,667	2,899	1,058	1,143	1,242	1,17	1,263	1,373	1,852	2	2,174	1,481	1,6	1,739	1	1	1

TABLE XI. FUZZY SYNTHETIC EXTENT VALUES AND RELATIVE IMPORTANCE WEIGHTS OF CRITICAL SUCCESS FACTORS IN THE REALIZATION PHASE

	Σl	Σm	Σu	1/Σu	1/Σm	1/Σl	S_l	S_m	S_u	W	%
CSF1	3,417	3,628	3,838	0,023	0,025	0,027	0,079	0,091	0,104	0,09	9
CSF2	7,88	8,463	9,077	0,023	0,025	0,027	0,181	0,212	0,245	0,21	21
CSF3	7,143	7,658	8,211	0,023	0,025	0,027	0,164	0,191	0,222	0,19	19
CSF4	4,545	4,836	5,16	0,023	0,025	0,027	0,105	0,121	0,139	0,12	12
CSF5	5,667	6,045	6,48	0,023	0,025	0,027	0,13	0,151	0,175	0,15	15
CSF6	9,03	9,673	10,427	0,023	0,025	0,027	0,208	0,242	0,282	0,24	24
Sum	37,682	40,303	43,193								

The second most important factor is CSF2, accounting for 21%. Effective project management is essential to ensure that all activities in this phase are properly planned and executed on time, in order to meet the project's objectives. This is why it is necessary to have a competent project manager who can assign responsibilities, manage resources, and ensure clear communication with all stakeholders.

Next, CSF3 accounts for 19%. Project team competence is essential to properly configure and customize the ERP, as well

as to migrate data, perform tests, and resolve any issues detected during those tests.

The CSF5 is assigned a weight of 15%. Minimal customization is essential to avoid complicating upgrades to new versions of the ERP system, thereby reducing costs and simplifying future upgrades.

Furthermore, CSF4 is assigned a weight of 12%. Although change management is essential for preparing users and helping them adopt the new system, its importance generally becomes more critical in later phases.

Finally, CSF1 receives the lowest weighting, 9% in this phase. Although management support and involvement are essential for making decisions, managing resources, resolving issues, ensuring clear communication, and supporting employees to foster acceptance of the new ERP system, their influence is slightly less decisive in this phase compared to other factors.

4) Final preparation phase: In the decision-making process, which will utilize the fuzzy AHP method for the realization phase, the CSFs are coded as CSF1, CSF2, CSF3, CSF4, CSF5, CSF6, and CSF7. These CSFs and their corresponding codes are presented below (see Table XII):

CSF1: Management support and involvement

CSF2: Involvement of end users and stakeholders

CSF3: Project management

CSF4: Project team competence

CSF5: Change management

CSF6: User training

CSF7: Tests

TABLE XII. FUZZY PAIRWISE COMPARISON MATRIX OF CRITICAL SUCCESS FACTORS IN THE FINAL PREPARATION PHASE

	CSF1			CSF2			CSF3			CSF4			CSF5			CSF6			CSF7		
	l	m	u	l	m	u	l	m	u	l	m	u	l	m	u	l	m	u	l	m	u
CSF 1	1	1	1	0,328	0,357	0,386	0,41	0,446	0,482	0,615	0,669	0,723	0,273	0,297	0,321	0,223	0,243	0,263	0,246	0,268	0,29
CSF 2	2,591	2,8	3,049	1	1	1	1,25	1,357	1,464	1,875	2,036	2,196	0,833	0,905	0,976	0,682	0,741	0,8	0,75	0,815	0,879
CSF 3	2,074	2,241	2,439	0,683	0,737	0,8	1	1	1	1,5	1,629	1,757	0,667	0,724	0,781	0,545	0,592	0,638	0,6	0,652	0,703
CSF 4	1,383	1,495	1,626	0,455	0,491	0,533	0,569	0,614	0,667	1	1	1	0,379	0,412	0,444	0,31	0,337	0,364	0,341	0,37	0,4
CSF 5	3,115	3,367	3,663	1,025	1,105	1,2	1,28	1,381	1,499	2,25	2,429	2,637	1	1	1	0,818	0,889	0,96	0,9	0,978	1,056

CSF 7	3,447	3,731	4,065	1,138	1,227	1,333	1,423	1,534	1,667	2,5	2,703	2,933	0,947	1,022	1,111	0,775	0,836	0,909	1	1	1

TABLE XIII. FUZZY SYNTHETIC EXTENT VALUES AND RELATIVE IMPORTANCE WEIGHTS OF CRITICAL SUCCESS FACTORS IN THE FINAL PREPARATION PHASE

	Σl	Σm	Σu	1/Σu	1/Σm	1/Σl	S_l	S_m	S_u	W	%
CSF1	2,849	3,012	3,175	0,016	0,018	0,019	0,046	0,054	0,06	0,05	5
CSF2	8,231	8,839	9,485	0,016	0,018	0,019	0,132	0,159	0,18	0,15	15
CSF3	6,469	6,923	7,415	0,016	0,018	0,019	0,104	0,125	0,141	0,12	12
CSF4	4,096	4,349	4,634	0,016	0,018	0,019	0,066	0,078	0,088	0,08	8
CSF5	9,488	10,171	10,959	0,016	0,018	0,019	0,152	0,183	0,208	0,18	18
CSF6	11,411	12,238	13,211	0,016	0,018	0,019	0,183	0,22	0,251	0,22	22
CSF7	10,23	11,053	12,018	0,016	0,018	0,019	0,164	0,199	0,228	0,2	20
Sum	52,774	56,585	60,897								

The results indicate that CSF6 is the most important CSF in this phase, with a weight of 22%. User training is essential, as this phase precedes the implementation of the ERP system in the production environment. It is therefore important to thoroughly train users on how to use the new ERP system, which helps reduce errors during use and also facilitates its adoption (see Table XIII).

The second most important factor CSF7, accounting for 20%. Testing is essential to allow users to test and verify that the ERP is functioning properly before it is deployed in the production environment. These tests help identify and correct any issues that are detected, ensuring the system's reliability when it goes live.

Next, CSF5 accounts for 18%. Change management is becoming increasingly important in helping to prepare employees for the changes brought about by the implementation of the ERP system, as well as in minimizing resistance to change.

The CSF2 is weighted at 15%. The involvement of end users and stakeholders is essential during training sessions and testing to ensure that the new ERP system meets the organization's needs.

Furthermore, CSF3 accounts for 12%. Effective project management is essential to ensure that all activities in this phase are properly planned and executed on time, in order to meet the project's objectives. This is why it is necessary to have a competent project manager who can assign responsibilities, manage resources, and ensure clear communication with all stakeholders.

Next, CSF4 accounts for 8%. Project team competence is essential for effectively training users, conducting user testing, and resolving issues identified during testing.

Finally, CSF1 receives the lowest weighting, 5%, in this phase. Although management support and involvement are essential for making decisions, managing resources, resolving issues, ensuring clear communication, and supporting employees to foster acceptance of the new ERP system, their influence is slightly less decisive in this phase compared to other factors.

5) Commissioning and support phase: In the decision-making process, which will utilize the fuzzy AHP method for the commissioning and support phase, the CSFs are coded as CSF1, CSF2, CSF3, CSF4, and CSF5. These CSFs and their corresponding codes are presented below (see Table XIV).

CSF1: Management support and involvement

CSF2: Involvement of end users and stakeholders

CSF3: Project management

CSF4: Project team competence

CSF5: Change management

The results indicate that CSF5 is the most important CSF in this phase, accounting for 27% of the total. During this phase, employees begin to use the new ERP, which entails changes to the organization's business processes. Change management is essential during this phase to help employees adapt to the changes brought about by the implementation of the ERP and to minimize resistance to change (see Table XV).

TABLE XIV. FUZZY PAIRWISE COMPARISON MATRIX OF CRITICAL SUCCESS FACTORS IN THE COMMISSIONING AND SUPPORT PHASE

	CSF1			CSF2			CSF3			CSF4			CSF5		
	l	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**	**l**	**m**	**u**
CSF1	1	1	1	0,56	0,608	0,656	0,723	0,786	0,849	0,647	0,703	0,759	0,46	0,5	0,54
CSF2	1,524	1,645	1,786	1	1	1	1,312	1,429	1,545	1,174	1,278	1,382	0,746	0,811	0,876
CSF3	1,178	1,273	1,383	0,647	0,7	0,762	1	1	1	0,891	0,969	1,047	0,566	0,615	0,664
CSF4	1,317	1,423	1,545	0,724	0,783	0,852	0,955	1,032	1,122	1	1	1	0,635	0,69	0,745
CSF5	1,852	2	2,174	1,142	1,233	1,339	1,506	1,625	1,758	1,342	1,457	1,576	1	1	1

TABLE XV. FUZZY SYNTHETIC EXTENT VALUES AND RELATIVE IMPORTANCE WEIGHTS OF CRITICAL SUCCESS FACTORS IN THE COMMISSIONING AND SUPPORT PHASE.

	Σl	**Σm**	**Σu**	**1/Σu**	**1/Σm**	**1/Σl**	**S_l**	**S_m**	**S_u**	**W**	**%**
CSF1	3,39	3,597	3,804	0,035	0,038	0,04	0,119	0,137	0,152	0,14	14
CSF2	5,756	6,163	6,589	0,035	0,038	0,04	0,201	0,234	0,264	0,23	23
CSF3	4,282	4,557	4,856	0,035	0,038	0,04	0,15	0,173	0,194	0,17	17
CSF4	4,631	4,928	5,264	0,035	0,038	0,04	0,162	0,187	0,211	0,19	19
CSF5	6,842	7,315	7,847	0,035	0,038	0,04	0,239	0,278	0,314	0,27	27
Sum	24,901	26,56	28,36								

The second most important factor is CSF2, accounting for 23%. The involvement of end users and stakeholders is essential for getting the system up and running, as it allows for the rapid identification of operational issues and anomalies, thereby contributing to the system's continuous improvement after implementation.

Next, the CSF4 accounts for 19%. Project team competence is essential for properly configuring the production environment, implementing customizations, migrating data, assisting users, and resolving any issues that arise.

The CSF3 accounts for 17%. Effective project management is essential to ensure that all activities in this phase are properly planned and executed on time, in order to meet the project's objectives. This is why it is necessary to have a competent project manager who can assign responsibilities, manage resources, and ensure clear communication with all stakeholders.

Finally, CSF1 account for 14% of the total. Although management support and involvement are essential for making decisions, managing resources, resolving issues, ensuring clear communication, and supporting employees to foster acceptance

of the new ERP system, their influence is slightly less decisive in this phase compared to other factors.

C. Changes in CSFs Across ERPI Phases

To better understand the dynamics of ERPPs, CSFs have been classified into four main categories: strategic factors, organizational factors, project management factors, and technological factors. Analysis of the results shows that the relative importance of these categories varies significantly across the different phases of ERPI (see Table XVI).

During the analysis phase, strategic factors emerge as the most critical. Management support and involvement are the most important factors, as they enable the project's direction to be defined, the necessary resources to be mobilized, and the alignment of the ERP with the company's overall strategy to be ensured. Factors related to project management and process reengineering also play a key role in the initial structuring of the project.

During the design phase, organizational factors and factors related to project management take on greater importance. Project management and the project team competence are central to this phase, as they enable the organizational needs identified during the analysis phase to be transformed into appropriate functional solutions.

During the implementation phase, technological factors take center stage. The configuration ERP is the primary critical factor, followed by project management and the project team's competence. This phase is characterized by technical activities such as configuration and development.

During the final preparation phase, the importance of organizational factors becomes increasingly evident through user training and testing activities. These factors help prepare the organization for the actual use of the ERP and reduce the risks associated with the go-live.

Finally, during the implementation and support phase, organizational factors related to change management and end-user engagement become critical. These factors help foster acceptance of the system, support users as they adapt to new processes, and ensure the continued operation of the ERP.
